sSOLIS, respectively. In all cases, the corrected air mass *m* (considering diffraction and altitude effects) and the solar zenith angle are calculated for the mid-point of each hour. The parametrization in (Kasten y Young, 1989) is used for the corrected air mass. A brief description of each of these models is provided here for completeness.

ESRA model: This model (Rigollier et al. 2000) estimates the direct and diffuse irradiance over an horizontal plane, and then adds them to obtain GHI. The Linke Turbidity for an air mass equal to 2 is its single parameter. In its hourly version, the beam component is given by

$$I_{bh}^{ESRA} = I_0 f_n \cos\theta_z e^{-0.8662 m \delta_R T_L} \quad (1)$$

where I_0 = 1367 Wh/m² is the hourly solar constant, $f_n = (r_0/r)^2$ is the orbital eccentricity factor parametrized in (Spencer 1971), and δ_R is the Rayleigh optical thickness (Kasten, 1996). The solar zenith angle, θ_z, is calculated at the midpoint of each hour from location and time information, in the usual form. Further corrections regarding altitude effects according to (Remund, 2003) are not implemented, since all the locations considered are in altitudes over the sea level below 140 meters, and these effects are negligible. The numerical factor *0.8662* in eq. (1) has an historical origin, associated to changes in the parametrization of δ_R. In early work, the Rayleigh optical thickness parametrization did not include absortion by permanent gases in the atmosphere and these effects appeared incorrectly as an increased effective turbidity (Inechien y Perez, 2002; Mavromatakis y Franghiadakis, 2007). In later work (Louche et al., 1986; Grenier et al., 1994; Kasten, 1996) the parametrization of δ_R was modified to include these effects and consequently, the turbidity T_L(m) was adjusted, since the product $\delta_R(m)\cdot T_L(m)$ is independent of air mass. The ratio of Linke Turbidity (new/old) at *m=2* gives rise to the *0.8662* factor in eq. (1) (Kasten, 1996). The Linke Turbidity coefficient takes into account the effects due to water vapor and aerosols and it is frequently interpreted as the number of clear, dry atmospheres which would produce the same effect on solar radiation as the actual atmosphere.

Diffuse irradiation on a horizontal plane is estimated as the product of the extraterrestrial irradiation times a diffuse transmitance factor on a vertical path (T_z) multiplied by a difuse angular modificator F_d,

$$I_{dh}^{ESRA} = I_0 f_n T_z(T_L) F_d(\theta_z, T_L) \quad . \quad (2)$$

The T_z and F_d expressions proposed in (Rigollier, 2000) are used here. Localization of this part of the model can be done with diffuse irradiation data. However, under clear sky conditions the diffuse fraction in the region of interest is about 10% (Abal et al. 2017), so small deviations due to the diffuse parametrization are expected to have little impact on model performance. The sum of eq. (1) and eq. (2) then provide the global irradiation on a horizontal surface.

KIP model: A second clear-sky model based on Linke Turbidity is described in (Kasten, 1984). Inechien and Perez observed a solar zenith angle and altitude dependence in its performance and introduced a correction (Inechien and Perez, 2002) which implies the inclusion of two altitude-dependent parameters a_1 and a_2 and the parametrization of global horizontal irradiation as ,

$$I_h^{KIP} = a_1 I_0 f_n \cos\theta_z e^{-a_2 m [f_{h1} + f_{h2}(T_L - 1)]} \quad . \quad (3)$$

Here $f_{h1} = \exp(-h/8000)$ and $f_{h2} = \exp(-h/1250)$ are coefficients that depend on the site altitude above sea level (*h)* in meters. The KIP model introduces a_1 and a_2 as linear functions of the altitude (Inechien and Perez, 2002) so that at sea level *(h=0)* a version of Kasten's original model is obtained. However in this formulation T_L is the main parameter used to describe the atmosphere.

sSOLIS Model: This simplified version of the SOLIS model, adequate for real-time use, has been proposed by (Inechien, 2008). The original SOLIS model is a spectrally resolved physical model based on radiative transfer model (RTM) calculations. The empirical equation is adopted as a good approximation for GHI,

$$I_h^{sSOLIS} = I_0' f_n \cos\theta_z e^{-\frac{\tau_g}{\cos^g \theta_z}} \quad (4)$$

Similar expression are used for beam and diffuse irradiance. I_0' is an enhanced extraterrestrial irradiance. In the original SOLIS model (Mueller, 2004) the optical depth τ_g and the parameter g are calculated from a RTM for different sun elevation angles, which limits the real-time applicability of this model. To solve this problem, Ineichen fitted analytical expressions for the parameters involved. Explicit expressions for I_o', τ_g and g as functions of aod700, water vapor *(w)* and atmospheric pressure *(p)* are provided in (Inechien 2008). According to this author, the simplification implies a negligible bias and standard deviation of 3 W/m^2 when compared with the results of the original RTM calculation.

2.2 Amospheric data

Three atmospheric variables (T_L, aod700 and w) are used as input for the models described above. For the region of interest in this work ground-based measurements are not available for any of them. However, as the are expected to vary slowly, yearly cicles of daily information based on satellite and ancialliary ground data can be used. In the following, this metodology is explained in further detail.

Linke Turbidity

As mentioned before, T_L includes in an effective way information on water vapor content and aerosols in the atmosphere. T_L can be estimated either from (i) watervapor and aerosol optical thickness at different wavelengths (Remund et al., 2003), (ii) from ground-based clear-sky DNI mesurements and eq. (1) or (iii) from clear-sky GHI measurements and eqs. (1) and (2) (Diabaté et al., 2003; Raichijk, 2009). When clear-sky DNI is avialable, (ii) is the preferred method (Pedros et al., 1999; Raichijk and Fasulo, 2010; Remund et al., 2003). For the region of interest in this work, this is not the case and it is necessary to resort to methods based on GHI data. The alternative of using parametric models to estimate the diffuse fraction from GHI and then use method (ii) mentioned above to obtain T_L from DNI has been used by (Cucumo et al., 2000) but the high uncertainty introduced by the DNI estimation procedure (Abal, 2017) render this method unreliable.

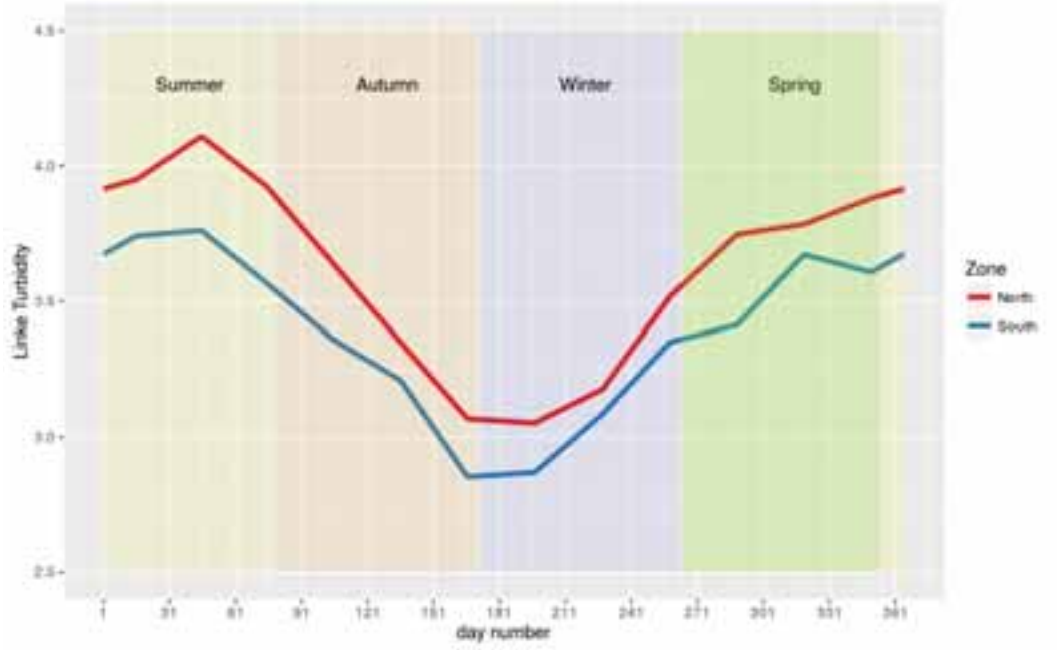

Fig. 1: Early cycle for Linke's Turbidity Parameter for Northern and Southern regions of Uruguay

In this work, we use the method (iii), to estimate daily T_L at several locations in the region of interest. T_L is determined in order to get the best fit of the ESRA model against clear-sky GHI ground data for ten different locations in the region that includes Uruguay and neighboring areas (Laguarda and Abal,

2016). Clear sky hourly data were selected from the 2010-2015 period using the procedure described in (Remund et al., 2003). Then, the monthly-averaged T_L was chosen in order to minimize a statistical indicator Kolmogorov Smirnoff Index (KSI), defined in Appendix A. The monthly values of T_L and their uncertainty was determined using a standard 10-fold cross validation technique. The data set used to obtain the T_L cycles is independent of the data used in this work for the evaluation of the clear sky models. This method was validated against the DNI-based method for a few locations where DNI measurements were available, for details we refer to (Laguarda and Abal, 2016). A daily T_L cycle is constructed by linear interpolation of the monthly mean values. Since the observed spatial dependence of this cycle is weak, just three daily-interpolated cycles (for the northern (N), center (C) and southern (S) parts of the country) adequately describe average atmospheric conditions at all sites. The T_L cycles used in this work (Northern and Southern regions) are shown in Fig. 1.

Aerosol Optical Depth and Water Vapor

The sSOLIS model describes the atmosphere using only aod700 and water vapor density as required information. Since there are no AeroNet or similar specialized measuring sites for these magnitudes in Uruguay, MODIS daily satellite estimates for water vapor column, Angstrom exponent and aod550 for 15 years (2/2002 to 12/2016) were used to estimate yearly cycles of the atmospheric variables. The Angstrom relation is used to obtain aod700 from aod550,

$$\tau_{700} = \tau_{550} \left(\frac{700}{550} \right)^{\alpha} \tag{5}$$

where α is the Angstrom exponent. Yearly cycles of average water vapor and aod700 were generated to be used as input for the sSOLIS model. The long term Aqua-MODIS satellite time series (area-averaged) data was used. The data is downloaded from the NASA site https://giovanni.gsfc.nasa.gov/giovanni/, and belongs to the level 3 series (highest quality available).

Specifically, daily information of Aerosol Angstrom coefficient (α), aod550, and precipitable water vapor column (w) from 2002 to 2015 were used for each site of interest. Using eq. (5), a series for aod700 series was obtained for each site. The final smoothed aod700 and *w* yearly cycles are obtained by averaging the series for each day of the year, and then taking a 25-day moving average and excluding data that exceeds 2 times the standard deviation for each day. The resulting smoothed cycles and the 15-year average cycles for w and aod700 at a given site are shown in Figs. 2 and 3, respectively.

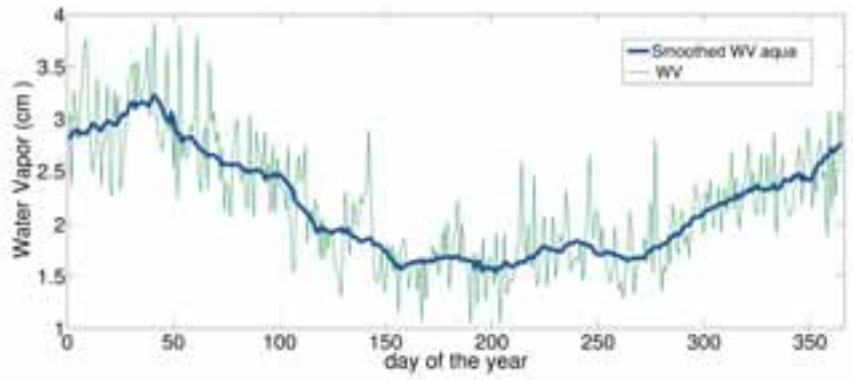

Fig. 2: Water vapor column cycle (in cm) from Aqua MODIS for the LE site, averaged by a 25-day moving window. The thin line shows the 15-year average cycle without smoothing.

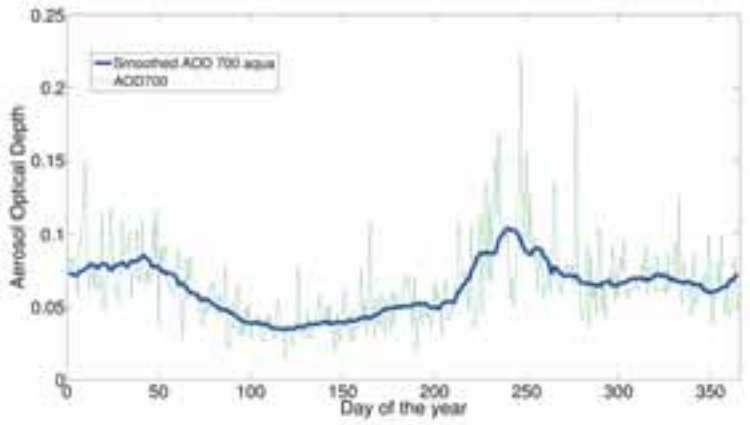

Fig. 3: Aerosol Optical Depth (dimensionless) yearly cycle from Aqua MODIS for the LE, averaged by a 25-day moving window. The thin line shows the 15-year average aod700 without smooting.

2.3 Ground solar irradiance data

The hourly irradiance predicted by these three models are compared with more than two years (January 2015 – March 2017) of GHI ground data from five sites from the continuous solar irradiance monitoring network run by our laboratory (see Table 1 and Fig. 4) GHI is registered each minute with first class or better pyranometers which are calibrated every two years at our laboratory against a Kipp & Zonen CMP22 secondary standard. This calibration is traceable to the PMOD World Radiation Center primary standard and to the World Radiometric Reference. All sites are in rural or semi-rural areas at low altitudes (less than 140 meters above the sea level) in a temperate climate.

Table 1: Details for the ground stations. The clear sky hours correspond to the data filtered and selected in the period january 2015 - March 2017 in all locations.

Site Code	Zone code	Latitude South degrees	Longitude West degrees	Altitude (m. a. s. l.)	Valid daytime hours	Clear Sky hours
LB	S	34.67	56.34	37	8985	3105
AR	N	30.40	56.51	136	9832	3218
LE	N	31.27	57.89	50	6147	1958
TT	S	33.28	54.17	35	6854	1840
RC	S	34.49	54.31	20	8676	2496
Total	-	-	-	-	40494	12617

Clear-sky filtering procedure

The ground data is filtered for basic quality control and integrated to obtain 40494 (daytime) valid hourly records. In order to obtain data associated to clear sky conditions, the algorithm in (Remund et al. 2003) is used to select 12617 (mostly) clear-sky hours. This algorithm is based in apply five consecutive filters to GHI hourly data.

1. DNI > 200 W/m^2. If DNI simultaneous information isn't available, it is estimated using Erbs correlation (Erbs et al., 1982). This procedure is only approximate, but it is sufficient to discriminate low direct radiation hours.
2. The hourly modified clearness index k_t' (Perez et al., 1990), Ec. (6), must be bigger than 0.7 (Molineaux and Delaunay, 1995).

$$k_t' = \frac{k_t}{0.1 + 1.031\, e^{-\frac{1.4m}{9.4+0.9m}}} \qquad (6)$$

where $k_t = I_h / I_0$ is the usual clearness index, and m is the air mass.

3. The daily clearness index ($K_t = H_h / H_0$) must be over 0.4.
4. For a given day if the clear sky hours are less than the 40% of the valid hours, then the whole day is discarded.
5. Data with solar altitude below 10 degrees is discarded.

After this set of five filters is applied, a set of clear sky hours is obtained for each site. The last column of Table 1 shows the number of hours for each site. These data was used as indicated in Section 2.2 to obtain monthly averaged T_L values for each site. Since site-to-site variability is low, data was grouped in three regions (North, Middle and South) and monthly T_L cycles for each region were obtained. These average cycles were interpolated linearly to obtain daily data and avoid abrupt changes across consecutive months.

Fig. 4: The area of interest in this paper includes the whole Uruguayan territory (located in the southeastern of South America). The blue dots show the sites that recorded the ground GHI data used in this work.

In (Laguarda and Abal, 2016) the ESRA model with these T_L cycles was compared to hourly clear sky data from 8 sites and the relative Root Mean Square Deviation (RMSD) was between 4.1 % and 5.1 % for all sites. These results show that clear-sky GHI can be estimated in this region by the ESRA model with uncertainty under 5 % using the mean T_L cycle determined for a broad region from long-term data. Marginal

improvements (under 1 %) can be obtained by using specific T_L cycles for each site.

3. Model performance

Three indicators used to evaluate model performance are Mean Bias Deviation (MBD), Root Mean Square Deviation (RMSD) and the Kolmogorov-Smirnov Integral (KSI). They measure bias, spread and distance between statistical distributions, respectively. Their definitions are standard and can be found in Appendix A. Table 2 lists these indicators for each clear-sky model and site. All models have small negative bias (indicating a tendency to underestimate GHI). Typical RMSD value range between 4 % and 7 %, depending on site and model.

Table 2: Relative performance indicators (in % of mean GHI) for each model and site.

Site	Mean	ESRA			KIP			sSOLIS		
Code	**Wh/m2**	**MBD**	**RMSD**	**KSI**	**MBD**	**RMSD**	**KSI**	**MBD**	**RMSD**	**KSI**
LB	615	0.0	4.3	1.1	-4.4	6.1	4.4	-2.3	6.0	2.7
AR	629	-0.6	4.3	1.1	-5.0	6.5	5.0	-2.1	5.5	2.1
LE	662	-0.3	3.8	0.9	-4.5	5.9	4.5	-3.4	5.9	3.4
TT	589	-0.8	4.8	1.0	-5.2	7.0	5.2	-2.0	6.2	2.4
RC	616	-1.0	4.7	1.2	-5.3	7.0	5.3	-2.3	6.2	2.8
ALL	**622**	**-0.5**	**4.4**	**1.1**	**-4.9**	**6.5**	**4.9**	**-2.4**	**6.0**	**2.7**

A simple global indicator C can be constructed for each model by averaging the absolute bias with RMSD and KSI (Gueymard 2014, Abal et al, 2017). This indicator, shown in Table 3, suggests that ESRA is the best model, followed by sSOLIS.

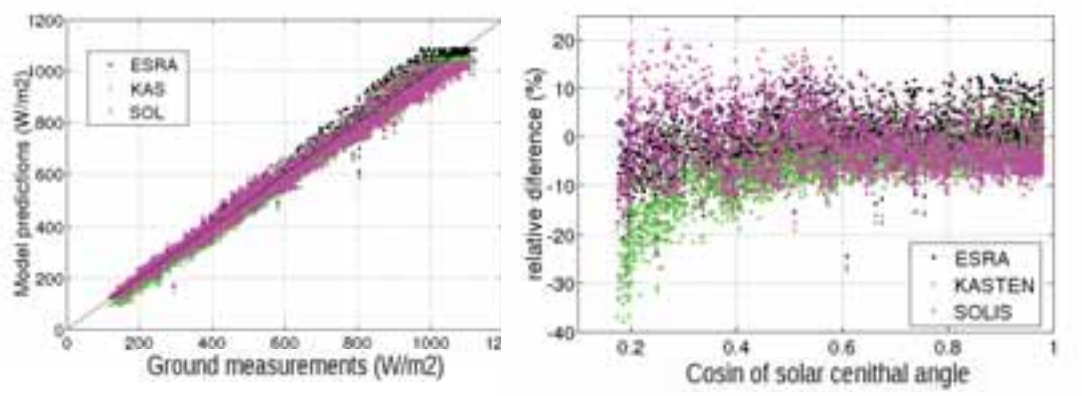
Tab. 3: Global indicator for each model

Model	C = (|MBD|+RMSD+KSI)/3
ESRA	2.0
KIP	5.4
sSOLIS	3.7

Fig. 5 shows detailed results for the LE site. The Left panel compares model prediction with grouind measurments. The small negative bias (underestimation) is associated to high irradiance (> 700 W/m^2) conditions. The right panel shows relative differences vs cosine of zenith angle. For low cosine values (low solar altitude) the biases increase as expected. The KIP model has a particularly large bias under this conditions. Fig. 6 shows the absolute difference between the ESRA model prediction and the ground truth vs Irradiation value. GHI values where classified into 11 bins, and average and standard deviation for each bin was calculated. This shows that bias is under 25 W/m^2 in all cases. For this model, negative biases come mainly from low irradiance (< 400 W/m^2) values. Since we are considering clear-sky data, these values are associated to low solar altitudes for which measurements are most uncertain.
Part of the observed deviations may be due to error in measurement or to errors in the automated clear-sky algorithm classification (i.e. mostly clear hours classified as cloudy or partly cloudy hours classified as

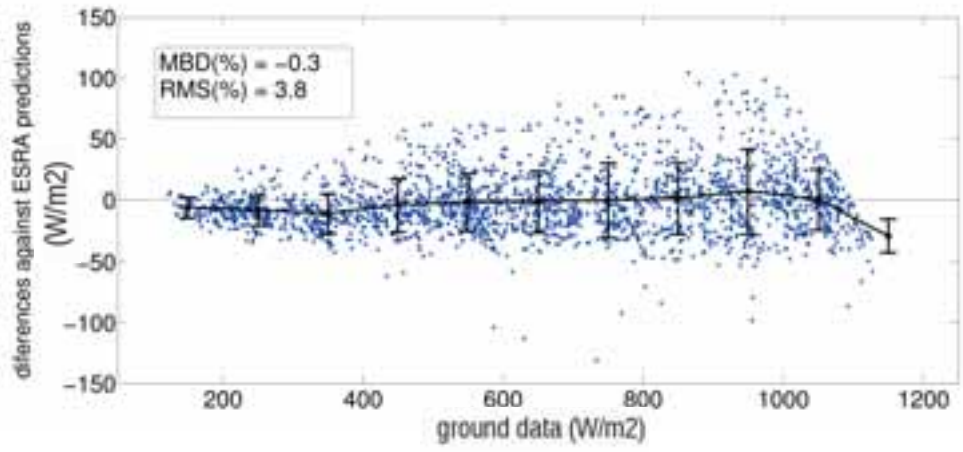
clear). This can only be assessed by a manual selection of the clear sky hours, a daunting task for the amount of data considered in this work.

Fig. 5: LB site. (left) Model predictions of clear sky GHI vs ground measurements and (right) relative difference between predictions and measurements vs cosine of the solar zenith angle z.



These results are similar to those found in the literature for these models. In (Ineichen, 2006) data from 16 sites in the Northern Hemisphere (with latitudes ranging between 30 and 48 degrees) was used to compare the performance of eight clear-sky models. Among them, the SOLIS model (the simplified model was not introduced until 2008), the ESRA and the KIP models. The SOLIS model was found to be one of the best among the models considered. Another comprehensive comparison was performed in (Gueymard, 2012) using high quality data from five sites in the Northern Hemisphere (latitudes between 19.5 and 40 degrees).

Fig. 6: Differences between ground data and ESRA model Predictions in LE station. Means are showed in black for different regions. The black bars represent the standard deviation in each region.



Tab. 4: A comparison of indicators for the selected models

Model	Indicator	(Gueymard, 2012)	(Ineichen, 2006)	This work
ESRA	MBD (%)	3.1	4.0	-0.5
	RMSD (%)	4.5	6.0	4.4
KIP	MBD (%)	not tested	-0.2	-4.9
	RMSD (%)	not tested	4.6	6.5
sSOLIS	MBD (%)	-1.6	(*) 1.8	-2.4
	RMSD (%)	2.8	(*) 4.9	6.0
Mean GHI(W/m^2)		675.6	547.0	622.0

(*) indicators are for the original SOLIS model.

In this comprehensive comparison, 18 clear-sky models where considered (the KIP model was not among them). The ESRA and simplified SOLIS where included and in fact, the sSOLIS was found to be the second best model, after the REST2 model.

It is not always possible to compare results from different authors, but in these cases, enough information is given so that results for all sites can be reduced to the same form and their averages are compared in Table 4. The relative RMSD indicators are similar in the three studies, ranging between 3% and 6% of the mean. As noted in (Ineichen, 2006) since there are no large differences in performance, the best clear sky model for a given region and application should be chosen with consideration to implementation simplicity and with regard to the quality and availability of its input data. For instance, in this study ESRA outperforms the sSOLIS model, which was found to be the second best among 18 other models in (Gueymard 2012). However, this study used the best available data for water vapor and aod, while in our implementation we have used daily averages based on satellite retrievals, which is available for this region. So, model rankings should not be read as ranking models according to their accuracy, but rather as ranking local model implementations (which include the quality of their input data).

4. Summary and conclusions

Three simple clear sky models (ESRA, Simplified SOLIS (sSOLIS) and Kasten (KIP)), are considered and evaluated using data for the region of Uruguay and neighboring areas (southeastern South America). These models have been selected taking into account the availability of the required input information for this area. Two of them use Linke Turbidity as their single parameter and sSOLIS uses water vapor density and Aerosol Optical Depth at 700 nm. This information was obtained from the MODIS satelite database on a daily basis and averaged over 15 years. The average Linke Turbidity was obtained from a large set of clear-sky GHI data for 10 sites on the region of interest by minimization of the KSI index.

The models are evaluated against an independent data set (i.e. not used to determine the TL cycles) from five sites in the region of interest. Clear sky conditions are automatically selected based on a set of criteria suggested by Remund, in which the Perez modified clearness index plays an important role. Results show that all models have RMSD between 4.3 % and 7 % of the mean value of GHI. Mean Bias is mostly negative for all models and sites, reaching -5.3%.

Our first conclusion is that our implementation of the ESRA model has the best indicators over all sites considered in this work. A combined indicator selects this model as the best alternative to estimate clear-sky GHI in this region. Clear-sky GHI can be estimated with bias under 1% and Root Mean Square Deviations under 5 % of the mean. In absolute terms, averaged over sites, the bias is MBD = -3 W/m^2 and the RMSD = 27 W/m^2. These indicators can be improved if T_L information for specific sites is used in the ESRA model.

However, the implementation based on the average cycle has indicators that are low enough to allow the use of the ESRA model in automated quality-check procedures for the ground GHI data. Furthermore, it is an adequate starting point for a physically motivated all sky irradiation model in which information about cloudiness is obtained from satellite images.

A second conclusion is that, since there are no drastic variations in performance, the selection of a clear sky model should take into account its ease of implementation and the quality and availability of its input data.

6. Appendix: Statistical indicators

There are several concordance indicators between measurements $\hat{Y}_i$, and n estimates Y_i of a variable. In this section RMSD, MBD, and KSI are defined.
The root mean square deviation (RMSD), and de Mean Bias Deviation (MBD) are defined as

$$RMSD=\sqrt{\frac{1}{n}\sum_{i=1}^{n}(\hat{Y}_i-Y_i)^2}$$

$$MBD=\frac{1}{n}\sum_{i=1}^{n}\hat{Y}_i-Y_i$$

For a variable z, the the Kolmogorov-Smirnov Integral indicator (KSI) is defined as

$$KSI=\int_{z_{min}}^{z_{max}} D(z)\,dz \quad ,$$

where

$$D(z)=\left|F_{\hat{Y}}(z)-F_Y(z)\right|$$

Here F_Y ($F_{\hat{Y}}$) is the empirical cumulative distribution function (CDF) for the variable Y ($\hat{Y}$), were Y and $\hat{Y}$ the measuements and model estimated data vectors of GHI, z is variable in the range of GHI. In this case, KSI (same units as GHI, W/m^2) is a measurements of the absolute difference between the CDFs.

Each statistical indicator can be expresed in a dimentionless way as

$$rMBD=\frac{RMBD}{mean(\hat{Y})}$$

and similar relations for the other indicators.

Abstract

This paper introduces a concept for global tilted irradiance (GTI) subordinate standard spectra to supplement the current standard spectra used in solar photovoltaic applications, as defined in ASTM G173 and IEC60904. The proposed subordinate standard spectra correspond to atmospheric conditions and tilt angles that depart significantly from the main standard spectrum, and can be used to more accurately represent various local conditions. For the definition of subordinate standard spectra cases with an elevation of 1.5 km above sea level the question arises whether the air mass should be calculated including a pressure correction or not. This study focuses on the impact of air mass used in standard spectra, and uses data from 29 locations to examine which air mass is most appropriate for GTI and direct normal irradiance (DNI) spectra. Overall, it is found that the pressure corrected air mass of 1.5 is most appropriate for DNI spectra. For GTI a non-pressure-corrected air mass of 1.5 was found to be more appropriate. The suitability of this selection for a given site is best for mid latitudes (~35°) and elevations below 1 km. It also depends on the vertical distributions of aerosols and water vapor.

Keywords: solar spectra, efficiency rating, spectral response, standardization, air mass

1. Introduction

Standard solar irradiance spectra are required to compare and specify key parameters of solar technologies, such as the efficiency of photovoltaic (PV) cells. In particular, the recent IEC standard 60904-3 prescribes a Direct Normal Irradiance (DNI) spectrum and a Global Tilted Irradiance (GTI) spectrum for a 37° tilted sun-facing surface, both defined for a clear-sky condition with air mass 1.5 (AM1.5) and low aerosol content. The IEC spectra are identical to the ASTM G173 spectra when scaled by a factor of 0.99708. These reference spectra are widely used for rating purposes when different products, such as PV cells, have to be compared under Standard Test Conditions (STC), as discussed by, e.g., Gueymard et al. (2002). To maintain comparability of results, it is important that a single standard spectrum for either GTI or DNI be used for the purpose. The present authors are also working towards replacing the current (but outdated) ISO 9845 spectra by the IEC spectra just mentioned within the ongoing update of the ISO standard.

The unique importance of the IEC (or ASTM) spectra is not at all called into question in this work. However, these reference spectra may differ strongly from realistic average spectra at sites with different atmospheric

doi:10.18086/swc.2017.21.06 Available at http://proceedings.ises.org

conditions or for tilt angles that are different from 37°. For such cases, it is useful to compare products using both the standard spectra and additional subordinate reference spectra that correspond better to specific local atmospheric conditions and sun-receiver geometries than the standard spectra. In particular, it should be noted that the current standards only represent sea-level conditions. High-elevation sites tend to have higher solar resource, which attracts many solar energy projects. In the case of small installations, for instance, such a rough comparison can be helpful as a simple product pre-selection tool when sophisticated performance evaluation is not feasible. For larger installations requiring more sophisticated evaluations, this kind of comparison may reduce the effort by decreasing the number of initial product candidates.

The impacts of the incident spectrum on the performance of different PV cell technologies have been studied using both measured and modeled solar spectra (Fernandez et al., 2014; Nofuentes et al., 2017; Dirnberger et al., 2015; Polo et al., 2017). These publications show the importance of atmospheric conditions on the magnitude and shape of incident spectra and underline the need for specific methods to evaluate spectral effects in yield analyses. One way to improve the state-of-the-art in PV modeling is to provide subordinate standard spectra that cover situations beyond what the ASTM G173/IEC 60904-3 standards are meant to address.

Section 2 below briefly presents suggestions for subordinate standard spectra corresponding to eight sets of atmospheric conditions and a range of tilt angles that are currently considered within the ISO working group. High-elevation locations (1.5 km above sea level) are included as well. Section 3 discusses the proper definition of air mass in the case of elevated sites. To this end, the cumulative annual direct normal and global tilted irradiations are analyzed as a function of air mass, based on irradiance measurements at 29 sites. Furthermore, the average solar spectra for two elevated sites are analyzed to establish which definition of air mass to use. Finally, a conclusion and an outlook are presented.

2. Proposed subordinate standard spectra

Subordinate GTI spectra are proposed for nine atmospheric conditions defined in terms of aerosol optical depth at 500 nm (AOD500), precipitable water vapor (PW), and elevation, as given in Table 1. The suggested tilt angles are from 0° to 90° in increments of 5°. To limit the number of subordinate spectra other parameters such as the azimuth orientation of the surface are not varied. Exemplary spectra for a tilt angle of 20° are shown in Fig. 1. As in the existing standards, AM1.5 is used. Why this specific air-mass value was selected originally is discussed elsewhere (Ross and Gonzalez, 1980; Gueymard et al., 2002). To be clear, the air mass indicates the *relative* (non-pressure corrected) air mass value M_{npc}. A discussion on various definitions of air mass appears in the next section. Additionally, DNI spectra for the same atmospheric conditions are also investigated, but are not shown graphically since they are not recommended as subordinate standard spectra. However, the air mass selection for DNI spectra is specifically discussed in what follows.

Tab. 1: Suggested conditions for the GTI subordinate standard spectra, below those used in (IEC, 2016). All cases use the aerosol type "rural" and the albedo "light sandy soil" except for DustyMedHum, for which "Desert_Max" and "dune sand" are used. The abbreviations used to describe the atmosphere are defined in (Gueymard, 2005).

Short name	Description	Elev. (km)	AOD@ 500nm	PW (cm)	Representative Atmosphere
IEC 60904	Reference (IEC 60904-3)	0	0.084	1.416	USSA
SemClmedHum	Semi-clean, medium humidity, sea level	0	0.27	1.416	USSA
SemClHum	Semi-clean, humid, sea level	0	0.27	4.115	TRL
HazMedHum	Hazy, medium humidity, sea level	0	0.54	1.416	USSA
DustyMedHum	Dusty, medium humidity, sea level	0	0.54	1.416	STS
HazHum	Hazy, humid, sea level	0	0.54	4.115	TRL
ClDryHi	Clean, dry, high elevation	1.5	0.084	0.708	MLW
SemClDryHi	Semi-clean, dry, high elevation	1.5	0.27	0.708	MLW
HazDryHi	Hazy, dry, high elevation	1.5	0.54	0.708	STW

Some aspects of the existing IEC/G173 standard spectra that can be considered outdated are modified here for creation of the proposed subordinate spectra. The first of these aspects is related to circumsolar radiation. DNI is defined in terms of the viewing geometry of a pyrheliometer following the WMO recommendations for a slope angle of 1° and an opening angle of 2.5° (WMO, 2014). In IEC/G173 this opening angle was slightly larger (2.9°).Second, the newer SMARTS version 2.9.5 (Gueymard, 2001, 2005) is used here to construct the proposed subordinate spectra as opposed to v2.9.2 that was used for the current standards. Third, the solar constant of 1361.2 W/m² (Gueymard, 2012) replaces the outdated historical value of 1367 W/m² (see justification in Kopp and Lean, 2011). The extraterrestrial spectrum (ETR) selected within SMARTS is still "Gueymard, synthetic" (as was used in the current standards) but multiplied by 1361.2/1367. Spectral changes resulting from all of the above relative to G173 are minor, as shown in Fig. 2.

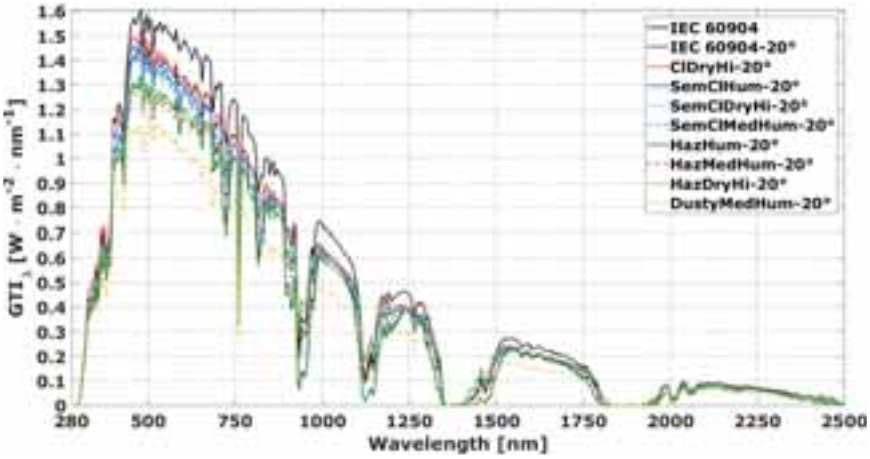

Fig. 1: Proposed subordinate standard spectra for GTI on a surface tilted 20° toward the equator.

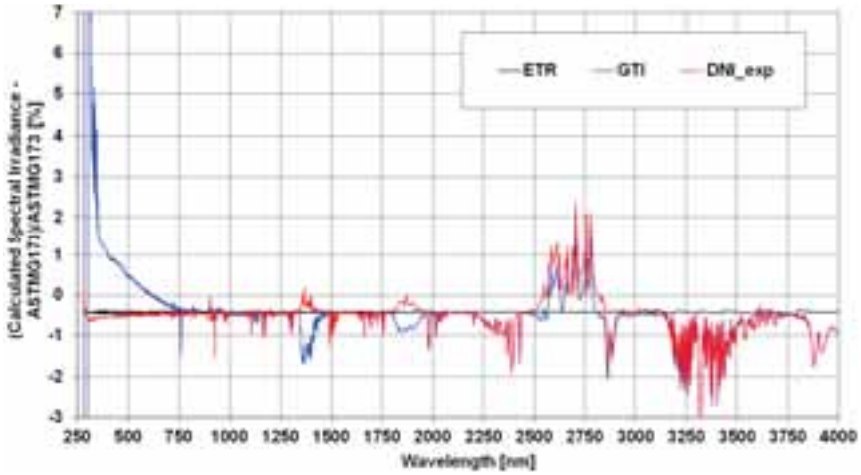

Fig. 2: Effect of changed circumsolar radiation settings, solar constant and SMARTS version, relative to the corresponding DNI and GTI spectra promulgated in G173 (red and blue line). The change of the extraterrestrial spectrum is shown in black.

The responsivity of a PV cell relative to an incident broadband solar irradiance, is obtained by multiplying its spectral responsivity, R_λ, with the solar irradiance spectrum, E_λ, according to

$$R_S = \frac{\sum_{j=1}^{N} R_\lambda(\lambda_j) \cdot E_\lambda(\lambda_j) \cdot \Delta\lambda_j}{\sum_{j=1}^{N} E_\lambda(\lambda_j) \cdot \Delta\lambda_j} \qquad \text{(eq. 1)}$$

where λ_j is the *j*th wavelength in the series 1–*N*. The relative deviation between the R_S value for a test spectrum and that for a reference spectrum is the spectral mismatch δ_{RS}. It can refer to a spectral gain or a spectral loss.

In a related study (Jessen et al., 2018), the proposed subordinate GTI spectra are compared to each other in terms of irradiance and PV device efficiency, using the spectral responsivities of exemplary solar cells from Winter et al. (2009), with or without concentration. The results show that the proposed subordinate spectra generate significant spectral mismatches compared to the IEC spectra (up to 6.5 %, for PV cells at a 37° tilt). Such mismatches indicate potential accuracy improvements that become possible by applying the subordinate standard spectra rather than the IEC spectra for a quick estimation of the *average* device efficiency.

To apply the subordinate standard spectra, manufacturers of solar devices could include PV module efficiencies for the different subordinate spectra in their data sheets. Alternatively, the spectral mismatches between using the IEC/G173 spectra and the subordinate spectra could be stated. A potential customer could then identify the potential change in efficiency based on a site's average AOD500, PW, elevation, and tilt angle. Consideration of all combinations of the aforementioned parameters with a tilt angle step of 5° would result in 171 efficiency values for PV panels, which could be conveniently presented by plotting the efficiency as a function of tilt angle. In case the manufacturer provides the spectral response rather than these values, a potential customer could independently calculate the specific mismatch between results based on either the IEC/G173 spectrum or the relevant subordinate spectrum, and thus estimate the changes in efficiency. Another advantage of these subordinate spectra is that they can assist in characterizing the durability of PV, CPV and CSP materials ex-

posed to natural weathering at a site.

A simple procedure to select subordinate standard spectra based on a site's average AOD500, PW, elevation and tilt angle was tested by Jessen, et al, (2018) at five exemplary sites [Tamanrasset, Sede Boker and Boulder (Baseline Surface Radiation Network, BSRN, König-Langlo et al., 2013), Plataforma Solar de Almería (PSA, Wilbert et al., 2013, Pozo et al., 2011), and Masdar (Kalapatapu et al., 2012)]. Two of these test sites, Tamanrasset and Boulder, are also used in this study. In Fig. 3, the average AOD500 and PW values for the annual data sets that were evaluated at these sites are shown next to the available AOD500 and PW values from the nine suggested atmospheric conditions. At all five test sites, complete time series of spectra (including both clear and cloudy periods) are determined using a combination of the SMARTS model and SEDES2 cloud modifiers (Nann and Riordan, 1991), with inputs based on site-specific sun-photometer and shortwave irradiance measurements. From all these all-sky spectra a site-specific annual-average spectrum is derived as a reference for the applicability test. In these reference spectra the impact of clouds is introduced through the use of SEDES2 in order to obtain realistic average spectra including the effect of clouds. For the subordinate standard spectra we propose only clear-sky spectra because clear sky conditions contribute stronger to the yield than most cloudy conditions and for simplicity. The resulting site-specific spectral mismatch values for the subordinate standard spectra and the IEC spectrum with respect to the site's average spectrum were derived. The subordinate spectrum with the most similar conditions to the site average results in a much lower spectral mismatch than the G173 spectrum (Jessen et al., 2018). Therefore, the proposed GTI spectra are applicable to the five test cases. Tests with other sites, for example with higher PW are of interest. For CSP and CPV applications, however, the suggested atmospheric conditions are found insufficient, due to the strong effects of AOD and Ångström exponent on DNI (Jessen et al., 2018). Hence, it is not intuitively possible to pick the most appropriate DNI spectrum from the subordinate spectra. Many more sets of atmospheric conditions would be required to allow the intuitive selection of a representative spectrum for the five test sites, let alone any other site. Hence, only GTI spectra with tilt variation are suggested for implementation in future standards.

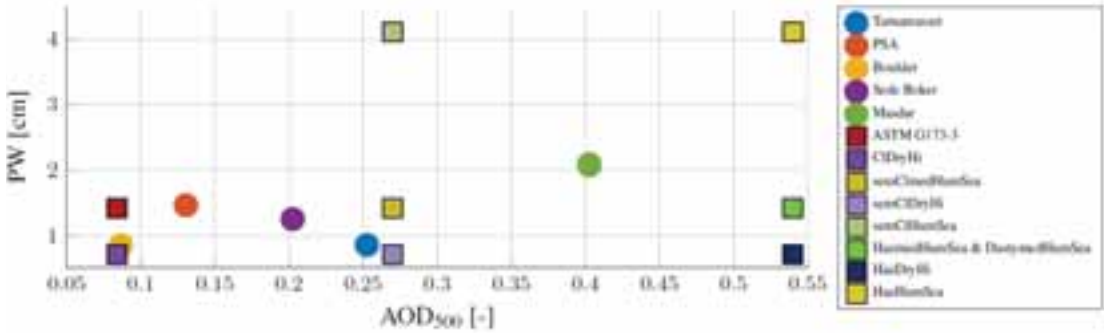

Fig. 3: AOD500 and PW for subordinate standard spectra (squares) and their averages for the sites (circles) that are used to test the intuitive selection of an appropriate reference spectrum. Matching colors mark the specific reference spectrum that would be selected based on a site's AOD500, PW and elevation.

3. Selection of air mass for the subordinate standard spectra

Besides the three AOD500 and three PW categories, an additional site elevation category of 1.5 km is suggested in Table 1 to extend the applicability of subordinate standard spectra. Introduction of high-elevation subordinate spectra raise the question of whether a pressure-corrected (absolute) or non-corrected (relative) definition of air mass is preferable. Note first that "air mass" itself is an ambiguous term. The *relative air mass* is a quantity that would be better called "optical mass for air molecules", since it corresponds to the geometric path length of the sun rays traversing the atmosphere relative to the vertical path length, and is a function only of the sun's zenith angle, Z. This quantity takes atmospheric refraction and Earth sphericity into account, and is thus more appropriate than the conventional $1/\cos Z$ factor used in the plane-parallel approximation that is typical in radiative transfer. Optical masses for aerosols, water vapor or ozone differ from the optical air mass because their concentrations have different vertical profiles. SMARTS, for instance, uses 15 different optical masses, corresponding to as many atmospheric species (or groups of species), because they have different vertical profiles. In contrast, the *absolute air mass* is pressure-corrected to reflect the actual slant "optical mass of air molecules" at higher elevations. At the top of atmosphere, this absolute mass becomes 0, and is conventionally noted AM0. The optical depth due to Rayleigh scattering by air molecules decreases with elevation as a direct function of pressure, whereas optical depths of aerosols and water vapor have a different dependence on pressure, which is moreover highly variable over space and time. All this makes the use of air mass and pressure suscep-

tible to misinterpretation and confusion.

The choice of air mass has a direct impact on the resulting spectrum and needs to be considered carefully. If a high-elevation subordinate standard DNI spectra had to be defined with a pressure-corrected (PC) air mass, M_{pc}, of 1.5, the SMARTS input value for the *air mass* would need to be adjusted accordingly, since the SMARTS input must be a non-pressure corrected (NPC) value. The needed air mass input value for M_{pc} = 1.5 is M_{npc} ≈1.8, considering the ratio between the ambient pressure at 1500 m elevation (≈840 hPa) and 1013.25 hPa. The choice of input value leads to noticeably different solar zenith angles of 48.236° (for M_{npc} = 1.5) and 56.267° (for M_{npc} = 1.8). SMARTS does not actually consider any pressure correction for its optical masses. Instead, the optical depths related to Rayleigh scattering and uniformly-mixed gases are scaled by the pressure ratio. All other optical depths, including those for aerosols and water vapor, are independent from site pressure, because they are defined as column quantities between the surface (at any elevation) and the top of atmosphere. Hence, site elevation and pressure are already accounted for in the inputs for PW and AOD. Changing the relative air mass M_{npc} from 1.5 to 1.8, the pressure from 1013.25 hPa to 840 hPa, and the input elevation from 0 to 1500 m, while maintaining the same AOD input value, results in a noticeable change in the DNI spectrum, so this distinction is important.

In what follows, the air mass effect is investigated by two methods. First, the cumulative relative fraction of annual irradiation is calculated as a function of air mass to determine a characteristic air mass. Based on this, specific air mass values are recommended for the determination of DNI and GTI spectra. Then, for further analysis, the spectral mismatch is evaluated for a number of spectra derived with different air mass options.

3.1 Cumulative relative fraction of annual irradiation as a function of air mass

An appropriate air mass needs to be selected for each subordinate standard spectrum. To that effect, the distribution of annual irradiation over many sites is analyzed as a function of air mass. In the late 1970s, the NASA-recommended terrestrial PV measurement procedures already stipulated an air mass value of 1.5 for reference measurements. This AM1.5 "optimal" value was confirmed in interrelated studies (Gonzalez and Ross, 1980; Ross, 1980; Ross and Gonzalez, 1980) as most representative for performance evaluation of PV concentrators using DNI, but not for fixed-tilt flat-plate PV, based on conditions pertaining only to the continental United States. This was later confirmed by Emery et al. (2002) for DNI, still under U.S. conditions only. These results provide an argument for working with a pressure-corrected M_{pc} =1.5 for standard spectra in the case of DNI. The "pressure-corrected" adjective is emphasized. Assuming equivalence between a spectrum obtained for M_{npc} =1.5 at sea level and another one for M_{npc} =1.8 (or M_{pc} =1.5) at 1500 m would imply that the effects of AOD and PW on DNI decrease the same way as those of air molecules when elevation increases. Based on the discussion above, this might not be the general rule. Hence, further scrutiny will have to be given to this important topic, since it conditions the desirable generalization to any world location.

To determine the appropriate air mass for the subordinate standard spectra, the method used by Emery et al. (2002) is applied to a total of 29 sites from BSRN and enerMENA (Schüler et al., 2016) at latitudes from 30°S to 52°N, including five sites close to the equator (between 16°N and 16°S). Both DNI and GTI are investigated. Since GTI measurements are rare, the model from Skartveit and Olseth (1986) is used to estimate GTI on tilted surfaces oriented towards the equator and with tilt angles equal to each site's latitude. The model uses the measured DNI and GHI along with inputs including solar position, tilt angle, and surface albedo. The latter is set to 0.3 for all sites, which roughly corresponds to the albedo option "light sand" used in G173. Eighteen of the sites are below 750 m elevation while eleven are at higher elevations. With regard to the proposed subordinate standard spectra, a site above 750 m would be considered a high-elevation site.

Figure 4 presents the cumulative relative fraction of annual global tilted irradiation, H_{tilt}, in relation to two alternate definitions of air mass for sites below 750 m elevation. On the left side of Fig. 4, the Y-axis corresponds to the fraction of the annual global tilted irradiation that is received for pressure corrected air masses below the PC air mass given on the X-axis. The right hand side of Fig. 4 uses the NPC air mass. Interestingly, the intersection of some curves with the Y-axis corresponds to a cumulative H_{tilt} strictly positive (and up to 0.18) for the PC air mass. This is because PC air masses below 1 occur for elevated sites due to the pressure correction. On the other hand, some curves cross the X-axis at air masses greater than 1. These curves belong to sites far away from the equator (e.g., Regina, Canada) where the zenith angle is much larger than 0° even at solar noon in summer, so that the air mass never reaches values close to 1. Similarly to Fig. 4, Fig. 5 shows the cumulative H_{tilt} as a function of air mass for sites above 750 m. The difference between the two air-mass cases is much more pronounced here, since the pressure correction is more intense. As in Fig. 4, the PC curves are shifted

towards the left relative to the NPC curves.

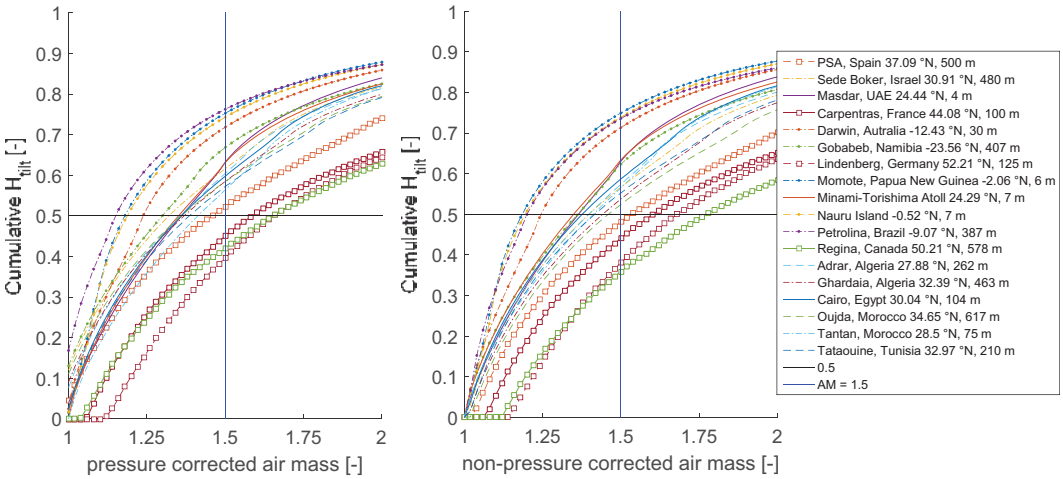

Fig. 4: Cumulative H_{tilt} over the air mass for sites below 750 m above mean sea level. Left: with pressure correction, right: without pressure correction. Sites less than 16° from the equator are marked with dots; sites at latitudes above 37° by squares.

To evaluate the effects of pressure correction and latitude in more detail, the results above are analyzed in terms of the threshold air mass, M_{half}, below which half of a site's total irradiation is received. M_{half} is indicated in Figs. 4 and 5 as the intersection of a site's curve and the horizontal line corresponding to a value of 0.5 on the Y-axis. Four different M_{half} values are derived for each site using PC and NPC air mass for GTI and using PC and NPC air mass for DNI. All M_{half} values for GTI are shown in Fig. 6 as a function of elevation (X-axis) and latitude (color bar). For both definitions of air mass, strong scatter is obvious. It is clear that an air mass value of 1.5 (or of any other fixed value) cannot accurately represent M_{half} at all investigated sites, irrespective of pressure correction. This shows a serious limitation of the approach considered in earlier studies (e.g., Emery et al., 2002), as well as the intrinsic limitation of reference spectra (standard or subordinate) that refer to a single air mass. However, for the simplification implied by the construction of the proposed subordinate spectra, this limitation must be acknowledged and accepted. Its effect, in terms of spectral mismatch, will be evaluated later after selecting single air mass values.

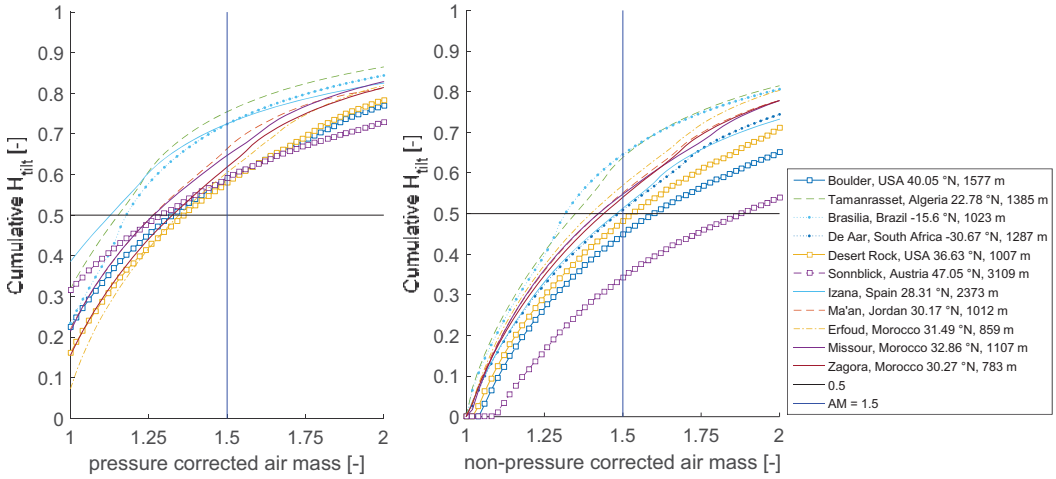

Fig. 5: Cumulative H_{tilt} as a function of the air mass for sites at elevations above 750 m. Left: with pressure correction, right: without pressure correction. Sites less than 16° from the equator are marked with dots; sites at latitudes above 37° by squares.

The spread of M_{half} values found for any small elevation range is related to latitude. Due to the higher solar elevation angles, proximity to the equator is associated with a smaller M_{half} value than higher latitudes. In the PC case, it is found that M_{half} decreases with elevation, so that in general lower M_{half} values are obtained. The elevation dependence is less pronounced in the case of the NPC air mass, whereas the latitude dependence is slightly higher. The latter finding could be expected, since the pressure correction reduces air mass, and hence also the latitude-dependent spread. At more than 3100 m, Sonnblick stands out for the NPC air mass case with a M_{half} value close to 1.9. This is mainly due to latitude (47.05°N). In the PC case, this particular site is much closer to 1.5 since M_{half} is now 1.3. This suggests that the deviations caused by high elevation and high latitude partly compensate each other. For the second highest site, Izaña (2373 m), M_{half} is close to 1.5 in the NPC case,

and ≈1.1 in the PC case, i.e., at the opposite extreme. This also shows that there is strong variability among sites, which cannot be explained by elevation or latitude alone. Typically, commercial PV plants are located below 3000 m due to the unavailability of higher sites, low population density, or other reasons. Therefore, the Sonnblick results are considered marginal, and removed from further analysis.

As stated before, the PC results show a noticeable elevation dependence. Moreover, M_{half} is then always below 1.5. This indicates that the selection of M_{pc} = 1.5 would not be ideal to construct GTI reference spectra, as was also stated early on (Gonzalez and Ross, 1980; Ross, 1980; Ross and Gonzalez, 1980). Using an NPC air mass of 1.5 is not ideal either. Nevertheless, a rather symmetrical spread around M_{npc} = 1.5 and a lower elevation dependence are found. Furthermore, use of the NPC air mass of 1.5 results in the same zenith angle for sea level and any elevation, which is advantageous for application of the spectra. Therefore, an NPC air mass of 1.5 is used for high-elevation subordinate GTI reference spectra in what follows. This result underlines that, in the case of GTI, the appropriate PC air mass is lower for sites with higher elevation.

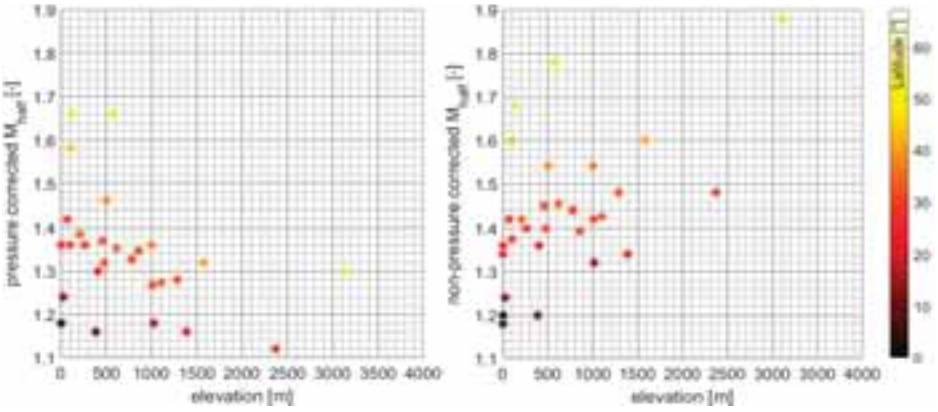

Fig. 6: M_{half} found for 29 sites for latitude-tilt GTI as a function of elevation and latitude (color bar). In the left plot two points are overlapping at elevation close to 0 m and M_{half} =1.18. This is also the case at elevation close to 0 and M_{half} =1.36.

Similar calculations are performed for DNI. Figure 7 presents the cumulative relative fraction of annual H_{b} as a function of air mass for sites below 750 m elevation. The differences between the plots for both air mass definitions are small, due to the low elevation of the sites. For the high-elevation sites in Fig. 8, the differences resulting from using pressure corrected or NPC air mass are clearly visible, due to the low atmospheric pressure at high elevation. The M_{half} values for DNI are shown in Fig. 9.

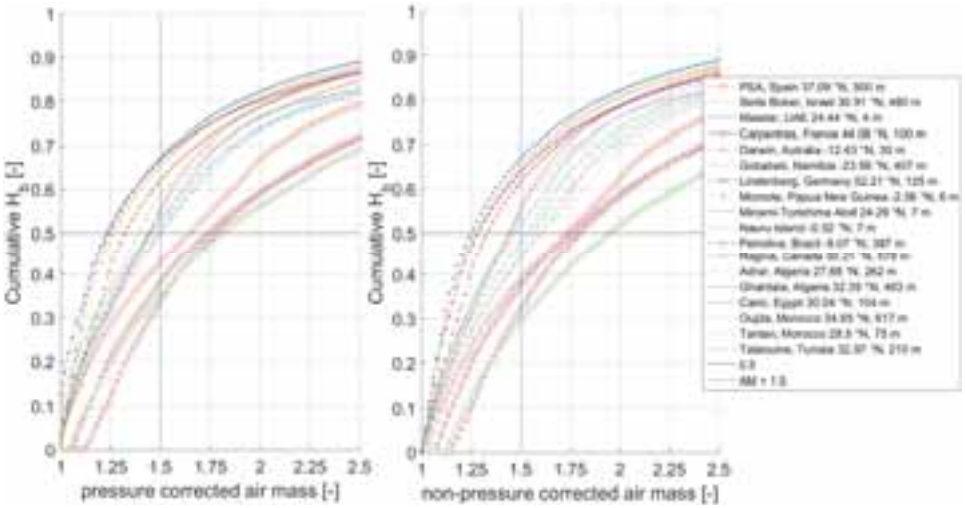

Fig. 7: Cumulative H_b over the air mass for sites below 750 m above mean sea level. Left: with pressure correction, right: without pressure correction. Sites less than 16° from the equator are marked with dots, sites with 37° or more by squares.

In addition to the sites discussed above for GTI, other sites analyzed by Emery et al. (2002) are presented. The latitude dependence is found similar to the case of GTI, albeit even more pronounced. Again, it is clear that the selection of a specific air mass value is not easy, or independent from the pressure-correction issue. Moreover, the highest sites (Sonnblick and Izaña) behave similarly for DNI and GTI. For the NPC air mass, Sonnblick has an M_{half} of 2.25, whereas M_{half} is only 1.52 for the PC case. In both cases, the 1.5 value is approximately midway between what is obtained for sites at high latitudes and sites near the equator, which supports the choice of

that value in the IEC/G173 standard spectrum. However, the elevation dependence of the PC cases is less pronounced for DNI than for GTI. The reverse is true in the NPC cases. The PC results also exhibit a smaller spread of M_{half} than those pertaining to the NPC air mass. This suggests a weak advantage of using the PC air mass definition for DNI. Hence, for DNI, these results are in relative agreement with previous studies (Emery et al., 2002; Gonzalez and Ross, 1980). Consequently, the application of a pressure-corrected air mass of 1.5 is selected here to evaluate the impact of using DNI spectra in spectral mismatch studies. Still, it is stressed that the approach described above and the resulting selection are not entirely satisfying in the case of DNI. Selection of a PC air mass of 1.5 means that higher zenith angles are representative at higher sites, a surprising result possibly explained in terms of Rayleigh transmittance as a function of site elevation. When the sun is at the zenith, the Rayleigh transmittances at 0-m and 1.5-km elevation are nearly identical. For a zenith angle of 80° the Rayleigh transmittance is noticeably lower at sea level due to the exponential behavior of transmittance (0.72 at sea level compared to 0.76 at 1.5 km for a Rayleigh OD of 0.05). Therefore, it could be true that lower air masses contribute more to H_b at higher elevations which means that greater zenith angles are more appropriate at higher elevations. However, both AOD and PW actually decrease with elevation in most cases. A typical scale height for them is 2.1 km, with large spatio-temporal variability, whereas that scale height is fixed at 8.43 km for both Rayleigh scattering and pressure. Therefore, the NPC air mass of 1.5 should also be considered for the DNI spectra. Since it is found problematic and potentially misleading to define subordinate DNI spectra (Jessen et al., 2018), the selection of the correct air mass is of low relevance in that case.

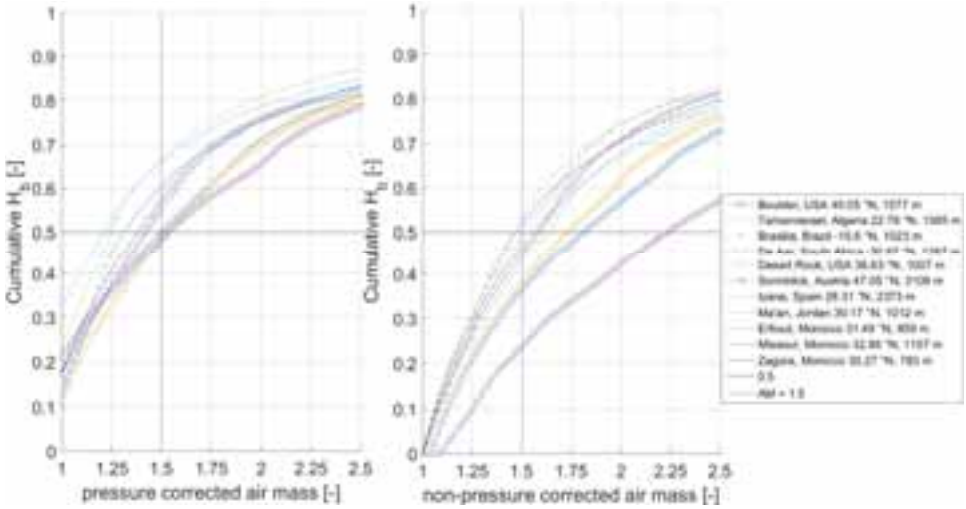

Fig. 8: Cumulative DNI over the air mass for sites at elevations above 750 m above mean sea level. Left: with pressure correction, right: without pressure correction. Sites less than 16° from the equator are marked with dots, sites with 37° or more by squares.

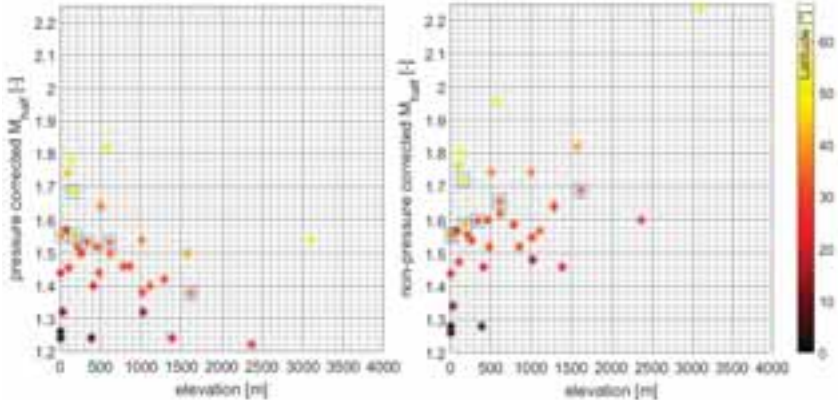

Fig. 9: M_{half} found for 36 sites for DNI as a function of the elevation and the latitude (color bar). Open blue squares mark additional sites from (Emery et al., 2002) (Albuquerque: 35.0853°N, 1619 m; Daggett: 34.8640°N, 610 m; Phoenix: 33.4484°N, 331 m; Tampa: 27.9506°N, 15 m; Sacramento: 38.5816°N, 9 m; Buffalo: 42.8864°N, 183 m; Seattle: 47.6062°N, 158 m).

3.2 Evaluation of air mass selection in terms of spectral mismatches

In order to test the two selections of the PC air mass of 1.5 for DNI and the NPC air mass of 1.5 for GTI, the effect of test spectra on the spectral mismatch is evaluated with different air masses. Two of the five aforementioned sites above 1-km elevation (Tamanrasset and Boulder) are useful to test the air mass specification. For this evaluation, the spectral mismatch values obtained with seven different spectra are compared for each site

and component (DNI or GTI). The reference spectrum in each case is the average spectrum for the site and component (see section 2). The spectral mismatch is calculated for these spectra:

1. ASTM G173/IEC 60904-3
2. The test spectrum for the atmospheric conditions in Tab. 1 that best match the average atmospheric conditions at the site, but for PC air mass M_{pc}=1.5
3. The test spectrum for the atmospheric conditions in Tab. 1that best matches the average atmospheric conditions at the site for NPC air mass M_{npc}=1.5
4. An ad-hoc spectrum specially developed for the site's average AOD, PW, elevation, and the M_{half} value for PC air mass $M_{half.pc}$ that is found for this specific site
5. An ad-hoc spectrum specially developed for the site's average AOD, PW, elevation, and the M_{half} value for NPC air mass $M_{half.npc}$ that is found for this specific site
6. An ad-hoc spectrum specially developed for the site's average AOD, PW, elevation, and M_{pc} = 1.5
7. An ad-hoc spectrum specially developed for the site's average AOD, PW, elevation, and M_{npc} = 1.5.

Moreover, for GTI the tilt angle is adjusted to the site's latitude in cases 4 to 7 just described. In cases 2 to 3 the closest available tilt angle (in 5° steps from 0 to 90°) is selected. For DNI, additionally, the two Ångström exponents for wavelength intervals below and above 0.5 µm are site-adapted in cases 4–7. Table 2 provides the values of M_{half} with and without pressure correction for GTI and DNI.

Tab. 2: M_{half} derived for Tamanrasset and Boulder from Fig. 5 and 8 with and without pressure correction for DNI and GTI.

Site	Component	$M_{half.pc}$, corresponding M_{npc} and standard conditions	$M_{half.npc}$
Boulder	GTI	1.325, corresponding to M_{npc} = 1.6 for ClDryHi	1.6
	DNI	1.5, corresponding M_{npc} = 1.81 for ClDryHi	1.82
Tamanrasset	GTI	1.15, corresponding to M_{npc} = 1.38 for SemClDryHi	1.35
	DNI	1.245, corresponding to M_{npc} = 1.5 for SemClDryHi	1.455

Figure 10 shows the seven DNI spectral mismatches for four CPV cell types under the seven DNI spectra at Tamanrasset. The different spectra are shown on the Y-axis, and mismatches for different PV cell types are shown by the marker type. The markers are connected to each other to increase readability. When using the base case of G173/IEC, deviations up to 4% are found. SemClDryHi behaves even worse than G173 in that case, so that if no pressure correction is applied even higher mismatch values are found. These deviations are mainly caused by Tamanrasset's average Ångström exponent that deviates strongly from that of SemClDryHi. Adjusting all atmospheric inputs to the site's averages reduces the mismatches noticeably for M_{npc} = 1.5, as well as the site's $M_{half,npc}$ and $M_{half,pc}$ (since all three cases result in the same input air mass). The spectrum for these site averages and M_{pc} = 1.5 results in the lowest spectral mismatch. This is surprising because the M_{half} values indicate that M_{npc} = 1.5 is more appropriate. The low spectral mismatches in this case are apparently caused by a compensation of errors. The average site spectrum also contains cloud effects and variations of the atmospheric properties that cannot be considered accurately when dealing with just a single spectrum. The approach using M_{half} is also only an approximation, as mentioned above.

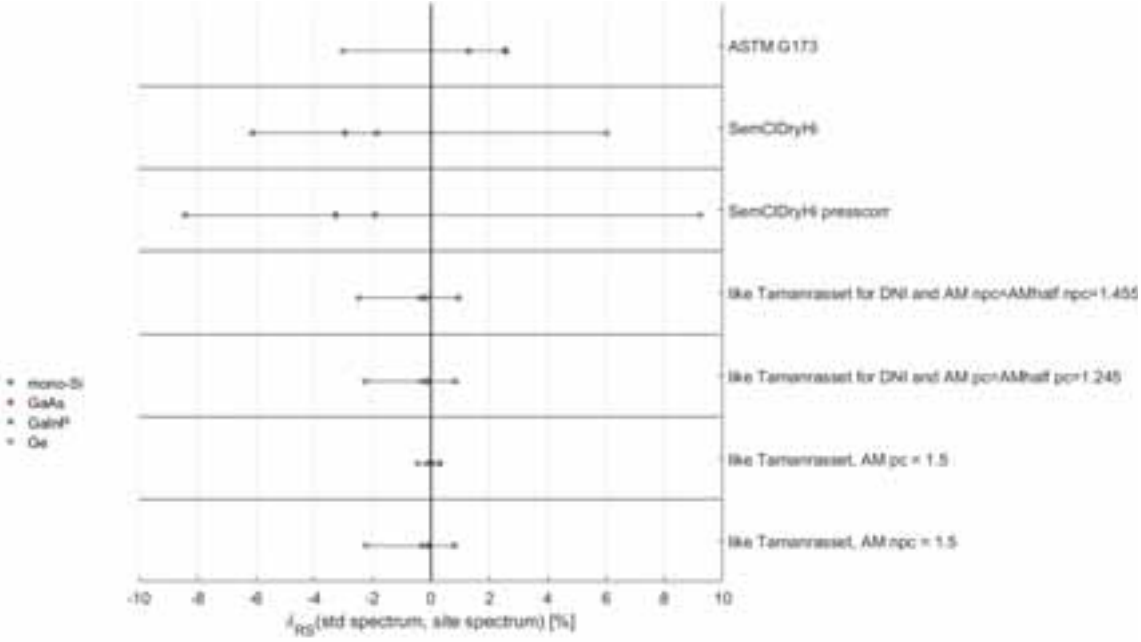

Fig. 10: ***Spectral mismatches for different spectra and CPV cell types for DNI at Tamanrasset.***

The results for Tamanrasset and DNI are summarized in Tab. 3 next to the other three cases, which are also shown in Figs. 11–13. The observations that do not correspond to expectations are marked in bold and underlined letters. The cases with more positive results than expected can be explained by the fact that several approximations and sources of error are included in the approach, and that different errors can compensate each other. The unexpected cases leading to worse results than G173 are marked with a minus sign. They are only found for DNI at Tamanrasset and have been explained above. Overall, it is found that the concept of using M_{half} is helpful, even though other air masses than those selected from M_{half} may perform better. This is interpreted as an effect of mutually compensating errors, too. The results confirm the expectation from section 3.1 that, for GTI, the NPC air mass of 1.5 can be used.

The results from Tab. 3 and Figs. 10 and 12 also show the aforementioned issues in the case of DNI. For Tamanrasset the Ångström exponent is found highly relevant. It can be concluded from this example that, due to the impact and variability of the Ångström exponent, a large number of subordinate DNI standard spectra would be needed to allow the selection of a subordinate spectrum that would be more representative than G173. Since this appears impractical, no subordinate standard spectrum is recommended here for DNI.

For DNI at Boulder, the actual Ångström exponent is similar to that characterizing all 7 test spectra. If site averages of the Ångström exponents, AOD and PW are used, the PC air mass of 1.5 delivers better results than the NPC value of 1.5, as expected. Even if the site averages for all significant inputs are used, greater deviations are found in comparison to GTI due to the high sensitivity of the DNI spectrum to air mass and atmospheric conditions, again as expected.

Tab. 3: Results of the evaluation of spectral mismatch based on air-mass selection. The + sign means improvement compared to G173/IEC, and the – sign means greater spectral errors than G173/IEC. Brackets refer to lower tendency than a sign without brackets, and various signs refer to higher differences. The * symbol means that a low spectral mismatch is found due to mutual compensation of errors. Cases with deviations from the expected behavior are underlined.

Spectrum	Tamanrasset DNI	Tamanrasset GTI	Boulder DNI	Boulder GTI
1. IEC/G173	-4 – 3 %	0.5% - 4.5 %	-7.5 % - 7 %	2 -5 %
2. test M_{pc}=1.5	**-**	+, for a-Si1 worse than G173	**(+)**	((+))
3. test M_{npc}=1.5	**-**	**++, ***	((+))	**++, ***

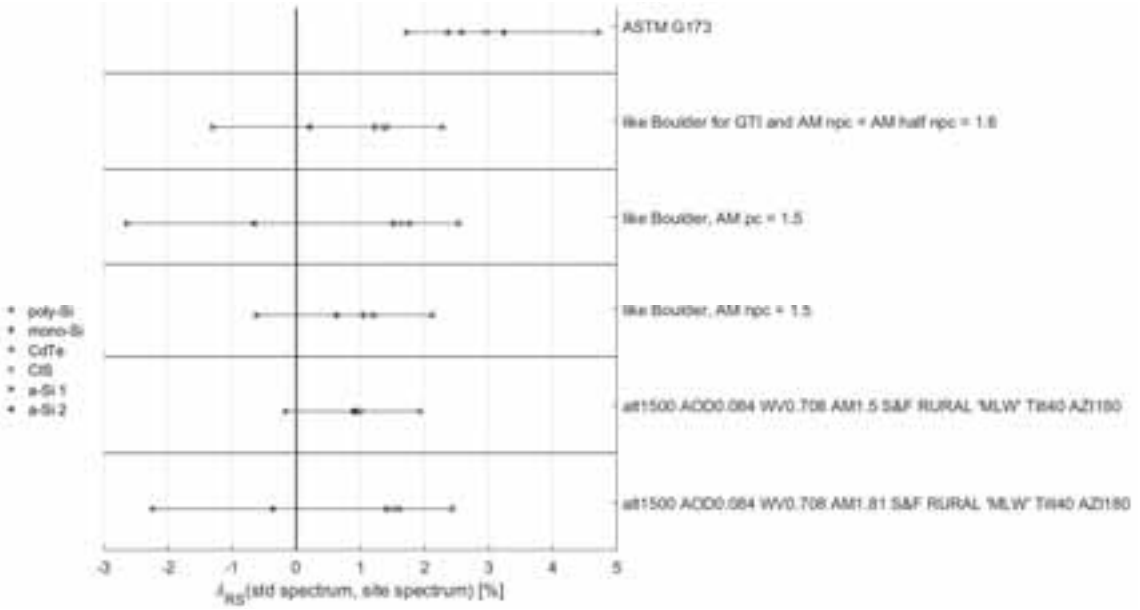

Fig. 13: ***Spectral mismatches for different spectra and PV cell types for GTI and Boulder. The lower two spectra refer to ClDryHi for the tilt angle 40° with and without pressure correction.***

4. Conclusion and outlook

The impact of different climatic conditions on the solar spectrum at the surface, and its consequences for solar energy system performance, reveals that the IEC/G173 standard spectra are far from representing the wide range of locally occurring conditions. Subordinate standard spectra are proposed here for solar energy applications utilizing GTI. They are meant to supplement the main standard spectra as defined in IEC/G173. These subordinate spectra represent atmospheric conditions and sun-receiver geometries that result in incident spectra departing significantly from the existing standard spectra. Some of the subordinate spectra correspond to site elevations of 1.5 km, since such higher-elevation sites are of interest in many solar energy applications. To apply the subordinate spectra, manufacturers could include PV module efficiencies for the different subordinate spectra in their data sheets. A potential customer could then identify the efficiency for the most appropriate subordinate spectra that is found using simple climate parameters, the site's elevation and the tilt angle.

The selection of the correct air mass to use in subordinate spectra is based on an analysis of the cumulative DNI and GTI for different air-mass ranges at 29 sites. A clear latitude dependence of the most appropriate air mass

for each site is found, so that using an air mass of 1.5 must be considered a crude approximation in any case. Overall, it is found that the pressure-corrected air mass value of 1.5 is more appropriate for DNI spectra, but not for GTI, thus confirming earlier studies. A non-pressure-corrected air mass of 1.5 is found more appropriate for GTI. Even though a pressure-corrected air mass is deemed preferable for DNI, the justification is weak. Physical explanations rather suggest that the pressure correction is actually not appropriate in that case. This is not an issue here, however, as we only recommend GTI subordinate spectra, but not DNI spectra. Indeed, it is found that there are no ideal subordinate spectra for DNI. Many subordinate DNI spectra for a large range of atmospheric conditions would be required to reduce the spectral mismatch compared to IEC/G173. It would thus be difficult to select the most appropriate spectrum, which is not practical. Hence, it is recommended not to include any subordinate DNI spectrum in the forthcoming ISO 9845 update.

The finding that a non-pressure corrected air mass of 1.5 is appropriate for GTI was confirmed by evaluating the spectral mismatch obtained for several PV cell types at the high-elevation sites of Boulder and Tamanrasset, using different test spectra. Hence, subordinate GTI spectra with the proposed atmospheric conditions, tilt angles, and non-pressure corrected air mass of 1.5, are recommended for inclusion in the update of ISO 9845, as an addition to the existing IEC or ASTM standard spectra. Comments on the proposed spectra are welcome and can be considered in the ISO and ASTM committees.

We thank the investigators and their support teams for the maintenance of the AERONET, enerMENA and BSRN stations used in this work. We thank the Actris and AERONET staff for their support with the operation, calibration and evaluation of PSA's and Masdar's sun photometer. This work was partly funded by the Helmholtz Association within the DESERGY Project. The financial support provided to the University of Antofagasta by the Chilean Economic Development Agency, CORFO, contract no. 17PTECES-75830 and the contract no.: 17BPE3-83761, and CONICYT/FONDAP/15110019 SERC-Chile is acknowledged.

Survey Research on Integrating Renewable Energy into the Mining Industry

Kateryna Zharan[1], Jan C. Bongaerts[2]

[1 and 2]TU Bergakademie Freiberg, 09599 Freiberg (Germany)

Abstract

Mining operations are energy intensive. The share of energy costs in total share is often reported to be in the range of 30 %. Saving energy costs is therefore an economical key element of any mine operator. With the improving reliability and security of renewable energy (RE) sources, and the requirements to reduce carbon dioxide emissions, perspectives for using RE in mining operations emerge. In fact, these aspects are stimulating the mining companies to search for ways to substitute fossil energy with RE. Survey research is novel on this topic. Hereby, this paper estimates the data of a survey conducted among mining and renewable energy experts. Towards the data estimation, this study applies the following methods. Here, first, to develop the survey we summarized and reviewed the findings from the previous literature review. Secondly, using these literature review three hypotheses have been developed. Thirdly, to compare outcomes of the survey with literature review the evaluating frequencies method has been developed and applied. Consequently, the results gather the expert's knowledge and opinions on incentives for mining operators to turn to RE, barriers and challenges to be expected, environmental effects, appropriate business models and the overall impact of RE on mining operations. In addition, the outcomes of the survey allow for identifying the factors that favor and disfavor decision-making on the use of RE in mining operations.

Keywords: Carbon dioxide emissions, mining industry, photovoltaic, renewable energy, survey research, wind generation.

Introduction

The mining industry still strong depends on conventional energy sources providing for its continuous and stable operations. In addition, energy costs accounts for 30 % of all operating costs in mining operations (Slavin 2017). RE technologies do not require such fossil fuels and have become mature and reliable, in particular for wind and solar power applications. Hence, they become attractive to mining operations, especially in hybrid systems. In this way, combining these sources like solar and wind with backup units provides more reliable, economic load supply and environment-friendly compared to a single source (Talaria, et al. 2017). Usually the cost reduction potential from implementation of the hybrid-energy system in mining operations is in the range of 25%–30%, and sometimes well above (Solar projects, energy efficiency and load shifting for an optimized energy management in the mining industry 2015). They also allow for lower carbon dioxide emissions giving mine operators a possibility to contribute to national and global climate policy agreements. For instance, the Kioto Protocol (United Nations Framework Convention on Climate Change 1997), the Fifth Carbon Budget (Committee on Climate Change 2015), and the Paris Agreement (UNFCCC 2015).

Because of such policies, the installed renewable electricity generation capacity and the rate of diffusion of RE technologies has increased rapidly (Bergek and Mignon 2017). Tab. 1 contains an overview of installed RE capacity in mining operations in particular.

Tab. 1: Installed capacity of renewables powering the mining industry

RE source	Installed capacity, MW
Wind	552
Solar PV	352
Solar thermal	39
Total	943

The energy and mining global ranking report (World Congress 2016) demonstrates the installed capacity of renewables powering the mining industry, which was 943 MW in total until 2016. It breaks down to 552 MW of wind power, 39 MW of solar thermal, and 352 MW of solar photovoltaic (PV). This integration could be

doi:10.18086/swc.2017.21.07 Available at http://proceedings.ises.org

possible because storage technologies become more accessible together with micro-grid integration. Moreover, hybrid energy solutions ensure to have a reliable energy system for mining processing.

Given several pilot projects of RE in mining in the countries such as Australia, Canada, and South Africa (Zharan and Bongaerts 2016) there is no comprehensive approach towards establishing RE into the mining industry as a global priority. This has inspired the authors of this paper to conduct a 31 question survey among experts in mining and in RE technologies about the implementation of RE into the mining industry. The survey captures the experts' assessment of economic, technological, social, and environmental aspects of a replacement of fossil fuel technologies with RE technologies. Furthermore, this survey defines the key factors leading to appropriate decision-making frameworks for energy managers and policy-makers.

The research objectives of this paper are to carry out the Literature Review (LR) in order to develop three hypotheses (H1, H2, H3), to compare the survey results with these hypotheses, to draw conclusions on using RE into the mining industry. Reaching these objectives will provide energy managers, decision-makers, and policy-makers with the expert's perception about implementing RE into the mining processing. That identifies vulnerable and strong priorities towards RE penetration. Therefore, the main purpose of this paper is to recognize the motives leading the experts to use RE for mining operations. Those motives could influence on investment choices (Lillemo, et al. 2013).

To our knowledge, there is no survey completed within this topic. Therefore, this study has a novelty and scientific relevance. Additionally, there is a lack of literature so far with focus on RE penetration into the mining industry.

Methodology

2. 1. Structure of the paper

This paper consists of four sections, and one appendix. Section 1 comprises the relevance of this topic, purpose of this paper, research objectives, and literature review. Section 2 includes the chosen methods developed to reach the purpose of this paper.

In Section 3, the evaluation of the survey's results has been accomplished in two steps. The Step 1 covers the demographic information of experts. Step 2 compares of the frequencies with the LR and demonstrates the Standard errors of the survey data. Section 4 contains the conclusions of this study.

This study has been written in a following order: (i) the survey has been developed based on the literature review. (ii) We choose stratified sampling method as our sampling technique to identify the RE and mining experts who can contribute to the study. (iii) All questions and the response items completed by the experts have been coded. (iv) Three hypotheses have been developed using the Literature Review (LR) method. (v) To evaluate the survey results we used the mean, and standard deviation (Std) criteria, maximum response item, percentage, evaluating frequencies method and standard errors analysis. (vi) Comparative analysis of three hypotheses with the survey results has been established. (vii) We drew the conclusions about the key findings of this study.

2.2. Survey administration

This survey was integrated between November 2016 and January 2017 within RE and mining experts all over the world via personal interview using the conference's platform 6th Solar Integration Workshop, and 15th Wind Integration Workshop in Vienna, Austria, and via email correspondence.

2.3. Research questionnaire and method

We assume that all questions are specific related only to the mining industry. This questionnaire contains two parts. In Part 1, we asked RE and mining experts about perspectives and relevance of the topic, necessity, incentives, barriers, government's support mechanisms, effects with respect to the integration of RE into the mining industry, as well as a significance of the environmental issues for industrial processing. In Part 2, we collected the experts personal information such as gender, age, level of education, working field, and working experience in the field. Tab. 2 shows the codes and scale each of the statements of the survey using the closed ended method of collecting information.

Tab. 2: Codes and scale of the survey

Statement	Code	Scale
1	Q1	two-point scale
2	Q2	three-point scale
3	Q3	five-point scale
4.1 - 6.5; 8 - 9.5	Q4-Q18; Q25 - Q30	six-point scale
7.1 - 7.6	Q19 - Q24	five-point scale
10	Q31	two-point scale

To evaluate the survey results first, the LR method has been chosen to develop three hypotheses. These hypothesis are shown in Appendix A, Tab. A.11. Main goal of this method is to provide complete summery of literature related to the survey questions. Second, three hypotheses have been assessing using the evaluating hypotheses method developed by the authors of this paper. The results of the survey are compared with three hypotheses in order to indicate whether they are true or false.

2.4. Evaluating frequencies method

The interpretations of evaluating frequencies method are as follows:

$$\begin{cases} c \leq a + b \geq d + \mathrm{e} \\ \mathrm{a} + \mathrm{b} \geq 0.33. \end{cases} \quad \text{(eq. 1)}$$

Eq. 1: the frequency of "a and b" is at least 33% and, overall, the ratings of "very important" plus "important" are more frequent than the ratings of "neutral" and of "less important" plus "not important", respectively.

$$\begin{cases} a + b \leq c \geq d + e \\ \mathrm{c} \geq 0.33 \end{cases} \quad \text{(eq. 2)}$$

Eq. 2: the frequency of "c" is at least 33% and, overall, the ratings of "neutral" are more frequent than the ratings of "very important" plus "important" and of "less important" plus "not important", respectively.

$$\begin{cases} c \leq d + \mathrm{e} \geq a + b \\ \mathrm{d} + \mathrm{e} \geq 0.33 \end{cases} \quad \text{(eq. 3)}$$

Eq. 3: the frequency of "d and e" is at least 33% and, overall, the ratings of "less important" plus "not important" are more frequent than the ratings of "neutral" and of "very important" plus "important", respectively.

$$\mathrm{f} \geq \mathrm{B} \; \forall \; \mathrm{f} \in [(\mathrm{a} + \mathrm{b}), \mathrm{c}, (\mathrm{d} + \mathrm{e})] \quad \text{(eq. 4)}$$

Eq. 4: the frequencies of "a and b", of "c" and of "d and e", respectively are all three larger than 33% (B).

Appendix A (Tab. A.11) demonstrates the LR. Based on the LR it assumes, that the Hypothesis 1 (H1) corresponds to the Eq. 1 and carries out for the Q3, Q4, Q5, Q7, Q8, Q9, Q11, Q12, Q15, Q16, Q18, Q19, Q22, Q24, Q25, Q26, Q27, Q28, Q29, Q30 questions. The Hypothesis 2 (H2) corresponds to the Eq. 2 and carries out for the Q6, Q14, Q20 questions. Finally, the Hypothesis 3 (H3) corresponds to the Eq. 3 and obtains for the Q10, Q13, Q17, Q21, Q23 questions.

Results

3.1 Demographic information of experts

This survey sample contained 30 observations, so called a sample size. We take this sample size as the representative sample. All the participants were male. Participants decided themselves either they are experts in the RE or mining industry, and educational institution or not. All experts had an education background starting from bachelor – a university education level. Tab. 3 shows the data of working experience and education level of the survey's participants..

Tab. 3: Working experience and educational level

Work experience in the field	Frequency	Percent	Education level	Frequency	Percent
1-5 years	7	25%	Bachelor	5	17%
5-10 years	9	32%	Master	14	47%
more than 10 years	12	43%	PhD	11	37%
Total	28	100%		30	100%

Furthermore, the surveyed sample contains engineers from either industrial companies or consulting, and researchers from educational institutions. The majority of experts 52 % are involved in the renewable energy industry.

The age of majority of experts 50 % is between 30 and 40 year. Tab. 4 shows the age and working field of the experts.

Tab. 4: Age and working field

Age	Frequency	Percent	Working field	Frequency	Percent
25 – 30 years	5	17%	mining industry	1	4%
30 – 40 years	15	50%	mining + renewable	1	4%
40 – 50 years	6	20%	renewable industry	13	48%
50 – 65 years	3	10%	renewable + education	2	7%
more than 65 years	1	3%	educational institution	10	37%
Total	30	100%		27	100%

The experts represented in this survey research are from 14 countries such as Germany – 9, Denmark – 3, Canada – 3, Finland – 3, Sweden – 2, Australia – 2, USA – 1, Austria – 1, New Zealand – 1, Mexico – 1, Ukraine – 1, France – 1, United Kingdom – 1, Chile – 1.

Tab. 5 shows the description of the survey sample..

Tab. 5: Description of the survey sample

Variables	Measurement	Mean	Std
Gender	Female/Male	1,00	0,00
Age	Six-point scale	3,33	0,96
Education level	Four-point scale	3,20	0,69
Working field	Five-point scale	2,35	0,55
Working experience in the field	Four-point scale	3,18	0,79
Sample size		30	
Response rate	Percent	96,67	

3.2 Comparing of the frequencies with the LR

In this survey research, answers of the experts were categorized in the sense that frequencies of their scale ratings were constructed. For example, if twenty percent of respondents give a rating of “very important” as answers to a specific question, that frequency is 20%.

Characterization refers to the frequency just described, e.g. characterization “a” would be 20 % as explained in Section 2.4. After, these frequencies have been compared with the hypotheses represented in Appendix A. The

results of this survey conforming the frequencies for the Eq.1, Eq.2, and Eq.3 have been shown in the Tab. 6, Tab. 7, and Tab. 8 correspondingly.

Tab. 6: Survey results corresponding to Eq.1

Code	Majority of responces	Number	Frequency	Eq.1
Q3	important	11	39%	64%
Q4	very important	12	40%	70%
Q5	very important	11	37%	70%
Q7	important	11	37%	53%
Q9	very important	11	37%	60%
Q10	important	9	30%	57%
Q12	neutral	8	27%	47%
Q14	important	11	39%	54%
Q15	very important	8	29%	50%
	neutral	8	29%	
Q16	very important	8	29%	57%
	important	8	29%	
	neutral	8	29%	
Q18	important	7	25%	46%
Q19	very important	18	60%	77%
Q20	important	8	27%	43%
Q21	neutral	10	33%	43%
Q22	important	18	60%	73%
Q24	very important	8	28%	48%
Q25	important	13	50%	92%
Q26	important	15	54%	75%
Q27	important	10	36%	50%
Q28	very important	11	39%	68%
Q29	important	7	25%	46%
	neutral	7	25%	
Q30	important	10	36%	68%

According to Table 6, not all results reported by the majority of responses correspond to the Eq. 1. For instance, for the Q21 the majority of experts gave the answer “neutral”, however, based on the evaluating frequency method the result of the Q21 corresponds to the Eq. 1. In this paper, we take the frequency evaluation as the main result to take a decision.

Tab. 7 shows the survey results corresponding to Eq.2.

Tab. 7: The survey results corresponding to Eq.2

Code	Majority of responces	Number	Frequency	Eq.2
Q8	neutral	12	40%	40%
Q17	neutral	11	39%	39%

Tab. 8 demonstrates the survey results corresponding to Eq.3.

Tab. 8: The survey results corresponding to Eq.3

Code	Majority of responces	Number	Frequency	Eq.3
Q6	neutral	8	27%	40%
Q11	less important	9	30%	40%
Q13	important	8	28%	45%
	less important	8	28%	
Q23	less important	10	34%	59%

According to the survey results, the hypotheses 1 (H1) is accepted for the Q3, Q4, Q5, Q7, Q9, Q12, Q14, Q15, Q16, Q18, Q19, Q22, Q24, Q25, Q26, Q27, Q28, Q29, Q30 and is rejected for the Q8, Q11 questions. To explain more precisely, government support mechanism has a "neutral" value, and connection mining to the grid has a "less important" value for experts. The H2 is rejected completely. There are not answers with the "neutral" value for experts. Eventually, the H3 is accepted for the Q13 and Q23 questions and rejected for the Q10, Q17, Q21 questions. In addition, it is confirmed that a lack of business models and development of domestic renewable energy market have "less important" value for experts.

According to the survey results, there are however, the questions which do not account the H1, H2, H3 but they have been identified by surveying. Such as, Q14, Q20, Q21 for the H1 and Q8, Q18 for the H2. For these questions, we accept that the response items are inconsistent and thereby require more detailed study integrating the second round of the survey.

Tab. 9: Comparative analysis of three hypotheses with the survey results

Hypothesis 1			Hypothesis 2			Hypothesis 3		
Important			Neutral			Less important		
LR	Results	Survey	LR	Results	Survey	LR	Results	Survey

Identifying of standard error (SE), which refers to standard deviation of different sample statistics, establishes a data accuracy. The standard errors of each question of the survey is shown in Tab. 10. According to the survey results, the SE of the data is between 0.09 and 0.28.

Tab. 10: Standard errors of the survey data

Code	SE	Code	SE	Code	SE	Code	SE
Q1	0.09	Q9	0.25	Q17	0.26	Q25	0.14
Q2	0.13	Q10	0.22	Q18	0.28	Q26	0.20
Q3	0.17	Q11	0.24	Q19	0.23	Q27	0.23

Conclusions

Summing up the survey research, the results are following:

- Using the LR three hypotheses have been developed.
- Demographic information of experts has been evaluated.
- *Evaluating hypotheses method* has been developed by authors to compare these hypotheses with the survey results.
- Standard errors of the survey data are between 0.09 and 0.28.

The results of this survey show that the integration of RE into the mining industry has perspectives and relevance for 24 experts (80%), with 2 experts (7%) opposing this idea and 4 experts (13%) remaining without an opinion. Decreasing costs of RE generation, off-grid location of a mine, and increasing prices of fossil energy are the main factors towards RE penetration. Volatility of RE technologies and costs of RE generation are the main barriers. Subsidies, establishing a policy, and a carbon tax might be the most efficient government support mechanisms. Reduction in fuel and electricity costs, including transportation costs, predictable energy costs; lower risk from volatile and rising diesel prices; and decreasing carbon emissions are seen as the key effects from RE implementation. All environmental issues such as low-carbon supply chain, recycling programs, using of RE, integrated waste management, and sustainable development are important for industrial companies.

In contrast, a lack of business models and the development of domestic renewable energy market are not important factors towards integrating RE into the mining industry

Tab. A.12. Sample of the questionnaire

Code No.	Number	Question
Q1	1	Have you ever heard about implementation of renewable energy (RE) into the mining industry?
Q2	2	In your opinion, do RE have perspectives and relevance to be considered as an energy source for the mining industry?
Q3	3	How can you evaluate an integration of RE into the mining industry?
	4	The following are incentives to integrate of RE into the mining industry. Please, grade them using the scale from 1 to 5. You can use one number several times
Q4	4.1	Decreasing costs of RE generation
Q5	4.2	Off-grid location of a mine
Q6	4.3	Reliability and security of RE sources
Q7	4.4	Increasing prices of fossil energy
Q8	4.5	Government support
	5	The following are barriers in matter of RE integration into the mining industry
Q9	5.1	Volatility of RE sources
Q10	5.2	High investments in RE technologies
Q11	5.3	Connection of a mine to the grid
Q12	5.4	Costs of RE generation
Q13	5.5	Lack of business models
	6	The following are government's support mechanisms in order to integrate of RE into the mining industry
Q14	6.1	Tax breaks
Q15	6.2	Subsidies
Q16	6.3	Establishing a policy
Q17	6.4	Feed-in tariff
Q18	6.5	Carbon tax
	7	Please, evaluate the following effects from RE integration into the mining industry using the scale from 1 to 5
Q19	7.1	Reduction in fuel and electricity costs, including transportation costs
Q20	7.2	Reduction risk of power loss from supply disruptions
Q21	7.3	Predictable energy costs
Q22	7.4	Lower risk from volatile and rising diesel prices
Q23	7.5	Development of domestic renewable energy market
Q24	7.6	Decreasing of carbon emissions
Q25	8	How important is for your company (institution) making the industrial processing more environmental friendly?
	9	Evaluate, please, the following environmental issues for industrial processing using the scale from 1 to 5
Q26	9.1	Low-carbon supply chain
Q27	9.2	Recycling programs

Q28	9.3	Using of RE
Q29	9.4	Integrated waste management
Q30	9.5	Sustainable development
Q31	10	Have you ever been involved in a project for implementation of RE into the mining industry?

Resource Forecasting

The local climate impact of photovoltaic solar farms ——Results from a field observation campaign in gobi desert

Xiaoqing Gao, Liwei Yang, Xuhong Hou and Xiaoying Hui

Key Laboratory of Land Surface Process and Climate Change in Cold and Arid Regions, Northwest Institute of Eco-Environment and Resources, CAS, Lanzhou, Gansu (China)

Abstract

Large-scale solar power farms are rapidly increasing in size and number across the world. However, the surface heat balance is altered when a photovoltaic (PV) power plant is deployed. Modifications to the surface albedo through the deployment of photovoltaic arrays have the potential to change radiative forcing, surface temperatures and local weather patterns. In this work, the field observation data from a large solar farm and a region without PV array in Golmud are used to study the impact of large solar farms in desert areas on the local climate. The results show the mean daily albedo in the solar farm is 0.19, while it is 0.26 in the region without PV. The annual mean net radiation in the solar farm is evidently higher than that of the region without PV. The annual range of soil temperatures at depths of 5–180 cm in the solar farm is bigger than that in the region without PV. The soil temperatures at different depths in winter in the solar farm are clearly lower than those in the region without PV. The 2-m daytime air temperature in the two sites is essentially the same during winter, while during the other seasons, the daytime air temperature in the PV farm is higher than that in the region without PV, with the maximum difference appearing in summer. The nighttime air temperatures at the height of 2 m during the four seasons in the solar farm are higher than those in the region without PV.

Keywords: meteorological observation, photovoltaic farm, desert areas, local climatic effect

1. Introduction

Renewable energy is considered an important solution for mitigating global warming, energy crisis and environmental pollution. The predominant renewable energy sources include wind, solar, biomass, hydropower and geothermal. Photovoltaic solar power systems have drawn tremendous attention from government sectors, researchers and the industry over the past several decades (Gagnon et al., 2002; Liu et al., 2015).

Large-scale solar power plants are rapidly increasing in size and number in China, as well as in other parts of the world. Photovoltaic (PV) power plants in desert regions have a promising future in China, considering the intense radiation received in large areas in China. However, the surface heat balance is altered when a photovoltaic power plant is operating. Modifications to the surface albedo through the deployment of photovoltaic arrays have the potential to change radiative forcing, surface temperatures and local weather patterns. Nemet (2009) investigated the net radiative forcing from the widespread installation of photovoltaics on the earth's surface. However, Nemet did not consider local microclimates, nor have his analytical results been verified with any field data. Genchi et al. (2002) estimated the impact of large-scale installation of PV systems in Tokyo on the urban heat island effect. The simulation results showed that it would be negligible. Tian et al. (2007) analyzed the effect of the PV module on the microclimate of the urban canopy layer, with the simulation results showing that the urban canopy air temperature alters little and the increase in the PV conversion efficiency can reduce the urban canopy air temperature. Taha (2013) evaluated the potential atmospheric effects of PV deployment in urban areas and the simulation results showed a 1–2 ℃ decrease in peak urban temperatures at six locations across California. Turney and Fthenakis (2011) identified 32 categories of impacts from the installation and operation of large-scale solar power plants. They found the impacts were either beneficial or neutral, except the local climate effect, for which they concluded that research and observations were needed.

The potential effects of the deployment of PV panels on climate have been discussed in previous studies. However, most of these studies focus on urban areas and use simulation methods. In this work, the impact of solar farms on the local meteorology in desert areas is assessed with observational data. It is believed that the results from this research can provide basic data support for the simulation of the local climate effect of a photovoltaic power station.

doi:10.18086/swc.2017.22.01 Available at http://proceedings.ises.org

Moreover, it may be useful for guiding the development and appropriate utilization of solar energy.

2. Materials and methods

2.1. Study area and field experiment description

The observation data is taken from Golmud (36°21′55′′N; 95°06′48′′E; a.s. 2868 m), Qinghai Province. After Tibet, the solar radiation in Golmud is the highest in China. Located at the south edge of the Qaidam Basin, the solar farm covers an area of 2.37 square kilometers, measuring 2296 meters from east to west and 1271 meters from north to south. The type of landform is Gobi Desert, with a continental plateau climate. The dominant wind direction in Golmud is the westerly wind.

Photovoltaic arrays are fixed. The azimuth of a PV array is south, with a tilt angle of 36°, a height of 2.5 m, and a spacing between each PV row in the solar farm of 6 m. The solar conversion efficiency of the solar panels is 15%. There are two observation points in this test; one is in the photovoltaic power station (site A), located at 36˚20.128' N, 95˚13.372' E at an altitude of 2927 m. The underlying surface is the Gobi. Detailed measurements taken at a height of 10 m were wind speed, wind direction, air temperature, humidity and solar radiation, while measurements taken at a height of 2 m were wind speed, wind direction, air temperature and humidity. The measurement taken at a height of 1.5 m was solar radiation. Soil temperatures at 5, 10, 20, 40, 80, and 180 cm were recorded in the solar farm. The other measurement point was outside the photovoltaic power station (site B), to be used as a reference point indicating ambient conditions. It was to the southwest of site A, located at 36˚19.975' N and 95˚12.985' E, at an altitude of 2933 m, with the underlying surface being Gobi with sparse vegetation. Detailed measurements taken at a height of 3 m were wind speed and wind direction, while measurements taken at a height of 2 m were air temperature and humidity. The measurement taken at a height of 1.5 m was solar radiation. Soil temperatures at 5, 10, 20, 40, 80, and 180 cm were recorded in the region without a PV array. The two observation sites were 645 meters apart. The characteristics of the sensors can be found in Table 1. Figure 1 shows an illustration of the solar farm and the locations where the field measurements were taken.

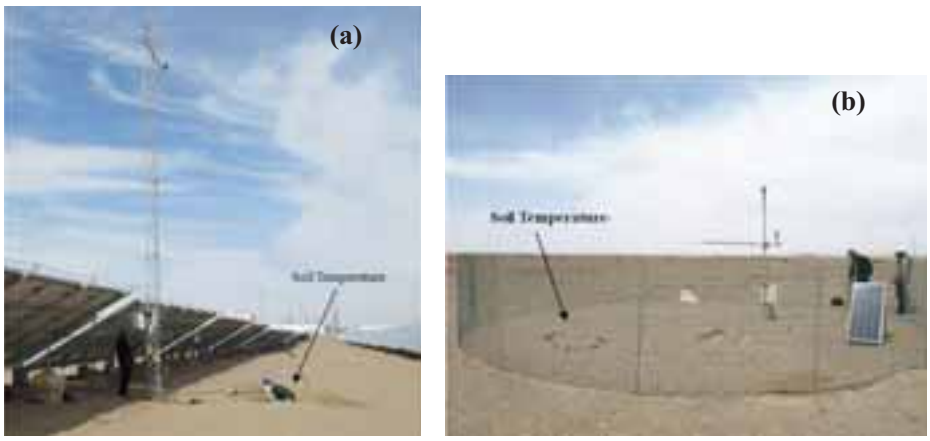

Fig. 1: The illustrations of the two sites in Golmud: (a) in the solar farm (Site A) and (b) in the region without PV (Site B).

2.2. Data and methods

The present work is based on data acquired at a 10-min step since October 2012. All the data have been passed through data quality control. All of the observation times are recorded in Beijing time. NR is deduced from the energy budget equation:

$$NR = (DSR - USR) + (DLR - ULR) \quad \text{(eq. 1)}$$

$$A = USR / DSR \quad \text{(eq. 2)}$$

where NR, DSR, USR, DLR and ULR are net radiation, downward and upward shortwave radiation and downward and upward long wave radiation (W/m^2), respectively. A is albedo (Tyagi et al., 2012). The energy balance equation is:

$$NR = H + LE + G + S_e \quad \text{(eq. 3)}$$

where H is the sensible heat flux, LE is the latent heat flux, G is the soil heat flux, S_e is the

solar panel electricity (Fig. 2). Due to the minimal precipitation in the Gobi area, the latent heat exchange is negligible. The land surface temperature (ST) is related to the surface long wave radiation by the Stefan-Boltzmann law (Wang and Liang, 2009):

$$ULR = \varepsilon_s \cdot \sigma \cdot ST^4 + (1-\varepsilon_s) \cdot DLR \qquad \text{(eq. 4)}$$

where ε_s is the broadband emissivity over the entire infrared region and σ is the Stefan-Boltzmann's constant (5.67×10^{-8} W· m^{-2}· K^{-4}). In the PV farm, 80% of the underlying surface is the ground, due to which, the emissivity ε_s is approximately 0.95. Therefore, ST can be estimated from Eq. (4). Soil thermal conductivity is calculated by the Harmonic method (Gao et al., 2009) as shown below.

The heat conduction equation (Horton et al., 1983) is:

$$\frac{\partial T}{\partial t} = k\frac{\partial^2 T}{\partial z^2} \qquad \text{(eq. 5)}$$

where T is the soil temperature (℃), t is the time (s), z is the depth (m), k is the thermal diffusivity, $k = \lambda / C_p$, λ is the thermal conductivity ($W\cdot m^{-1}\cdot ℃^{-1}$), and C_p is the volumetric heat capacity. The C_p and λ are assumed to be independent of depth and time.

For the Eq. (5), it can be solved without initial conditions in semi-infinite space, and its upper boundary condition is assumed as Fourier series:

$$T(0,t) = \overline{T}(0) + \sum_{i=1}^{n} A_i \sin(i\omega t + \Phi_i) \qquad \text{(eq. 6)}$$

The solution to Eq. (5) using superposition is:

$$T(z,t) = \overline{T}(z) + \sum_{i=1}^{n} A_i \exp(-B_i z) \times \sin(i\omega t + \Phi_i - B_i z) \qquad \text{(eq. 7)}$$

where $\overline{T}$ is the mean soil surface temperature, A is the amplitude of the diurnal soil surface temperature wave, Φ is the phase, n is the number of harmonics, $B_i = \sqrt{i\omega/(2k)}$ is the damping depth of the diurnal temperature wave. If the soil temperature at a depth of z_1 is the upper boundary, the formula for calculating the temperature of soil at any depth by the method of harmonic is:

$$T(z,t) = \overline{T}(z) + \sum_{i=1}^{n} A_i \exp(-B_i(z-z_1) \times \sin(i\omega t + \phi_i - B_i(z-z_1)) \qquad \text{(eq. 8)}$$

In the concrete calculation, the observed data of the two layers of soil temperature can be used to calculate the optimal estimation of the parameters (A_i, Φ_i) in Eq. (6), as well as the parameter (B) in Eq. (8) by using the least square method, thus obtaining the estimated value of soil thermal diffusivity (Horton et al., 1983). Taking the 5-cm soil temperature as the upper boundary (Eq. (6)), the least square method is used to fit different harmonic order numbers, with the second-order harmonic model having a high precision (correlation coefficient r = 0.998). Considering the simplification and precision of the model, the second-order harmonic model (n=2) is used as the model of the harmonic method, C_p =1.47×10^6 $J\cdot m^{-3}\cdot K^{-1}$, in this paper. Therefore, soil thermal conductivity can be estimated using Eq. (8).

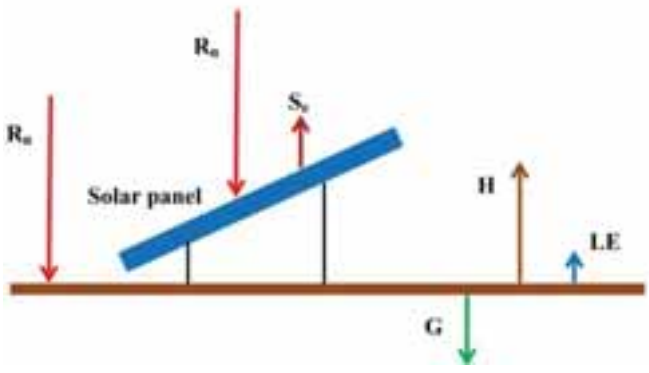

Fig. 2: The conceptual model of the heat balance near the surface in the solar farm

Tab.1: Summary of the instrumentations of sites A and B for the measurement presented in this paper.

Parameter (unit)	Sensor	Height above ground level	Accuracy	Sampling rate (min)	Averaging interval (min)
Air temperature (°C)	Vaisala HMP155A	2, 10 m in Site A; 2 m in Site B	±0.12°C (20℃)	1	10
Relative humidity (%)	Vaisala HMP155A	2, 10 m in Site A; 2 m in Site B	±1% (0~90% RH)	1	10
Short wave radiation incoming and outgoing ($W \cdot m^{-2}$)	Kipp and Zonen CNR 4 $0.31 < \lambda < 2.8$ μm	1.5, 10 m in Site A; 2 m in Site B	<1% (0~1000 W/m^2)	1	10
Long wave radiation incoming and outgoing ($W \cdot m^{-2}$)	Kipp and Zonen CNR 4 $4.5 < \lambda < 42$ μm	1.5, 10 m in Site A; 2 m in Site B	<1% (-250~250 W/m^2)	1	10
Soil temperature (°C)	Campbell 109SS-L	-5, -10, -20, -40, -80, -180 cm in Site A and B	±0.2℃ (0~70℃), ± 0.5℃ (-50℃)	1	10
Wind speed ($m \cdot s^{-1}$)	Gill WINDSONIC	2, 10 m in Site A; 3 m in Site B	±2%	1	10
Wind direction (°)	Gill WINDSONIC	2, 10 m in Site A; 3 m in Site B	±3°	1	10

3. Results and discussion

3.1. Comparison of the radiation field in the two sites

The surface radiation budget plays an important role in regional climate (Li et al., 2009). The intensity of incoming and outgoing radiative fluxes at the surface in the PV farm depends on the angle of inclination of the PV arrays and their exposure relative to the direction of the incoming solar beam, as well as on the PV system efficiency and the characteristics of the surrounding terrain (Matzinger et al., 2002; Kämpf et al., 2010; Zhang et al., 2016).

The observational data used in this study are from October 2012 to September 2013. The observations at a height of 10 m in the solar farm are 7.5 m higher than the perpendicular height of the PV array. The angle of the upward radiation sensor is 150°, with the field of view of the radiation sensor being the mixed underlying surface area with a 56-m diameter, due to which the radiation data at a height of 10 m is used to discuss the influence of PV array on the radiation field. Figure 3 shows the annual averaged diurnal variations of each component of the radiation budget and surface temperature at the two sites. Figure 4 shows the annual variation in radiation flux at the two sites, each black dot represents 10-min averaged value and Fig. 5 shows the annual variation in the monthly averaged albedo at the two sites.

There is no difference in the downward shortwave radiation (DSR) and the downward longwave radiation (DLR) between the two sites. Therefore, they are not analyzed.

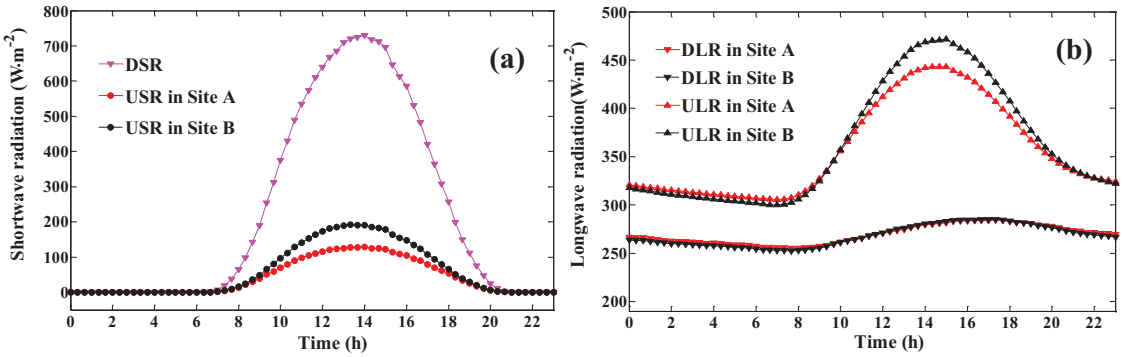
The upward shortwave radiation (USR) reached a peak of approximately 128.8 $W \cdot m^{-2}$ at 14:00 in the annual averaged diurnal variations at site A, and 193.7 $W \cdot m^{-2}$ at 14:00 at site B, as shown in Fig. 3(a). The daily cumulative value of the USR at site A is 3.54 $MJ \cdot m^{-2}$, while it is 5.02 $MJ \cdot m^{-2}$ at site B. The value in the solar farm is 1.48 $MJ \cdot m^{-2}$ lower than that in the region without PV, with the difference between the two sites being large. Due to the snow cover during November and December, the surface albedo is higher, which makes the USR on sunny days abnormally high (Fig. 4(a) and (a1)). The monthly averaged USR reached a maximum in June and a minimum in December at site A, while it reached a maximum in April and a minimum in January at site B (Fig. 4(a) and (a1)). The solar conversion efficiency of the solar panels is related to meteorological factors, mainly ambient temperature, dust, wind speed and relative humidity. This causes the peaks and valleys of USR to appear during different months for the two sites. The difference in the values of USR between the two sites is negative during the year, which is evident in Fig. 4(d). The ratio of the average annual USR at site A to that at site B is 0.7 (Table 2), indicating that the response of the PV array to the radiation fields is mainly to enhance the absorption of the downward shortwave radiation, leading to a significant reduction in the upward short wave radiation, with an influence of up to 30%. The difference in the USR at the two sites reached the maximum in March–April (spring), with a value of -20.7 $W \cdot m^{-2}$, while it reached the minimum in December–January of the following year (winter), with a value of -11.6 $W \cdot m^{-2}$ (Fig. 4(d)).

The upward longwave radiation (ULR) depends on the surface temperature raised to the power of four (Eq. (4)).

The ULR has diurnal variation with the surface temperature (Li et al., 2009). The ULR reached a peak of approximately 443.0 $W \cdot m^{-2}$ at 15:00 at site A, and 471.5 $W \cdot m^{-2}$ at 15:00 at site B in Fig. 3(b). The ULR at site A is clearly lower than that at site B during 11:00–18:00, while it is higher during 00:00–9:00, which is mainly due to the change in surface temperature, as shown in Fig. 3(e). The daily cumulative value of the ULR at site A is lower than that at site B, while the cumulative value of the ULR in the daytime at site A is lower than that at site B. The difference is 0.62 $MJ \cdot m^{-2}$. The cumulative value of the ULR at night is 0.12 $MJ \cdot m^{-2}$ higher than that at site B, since the PV plants have an insulating effect at night and a cooling effect during daytime. The cooling effect is more noticeable. The monthly average ULR reached a maximum in July and a minimum in January at the two sites, as shown in Fig. 4(b) and (b1). The difference in the values of the ULR between the two sites is negative over a period of one year. The difference in the ULR at the two sites reached the maximum in October, with a value of -8 $W \cdot m^{-2}$. The average annual ULR changed slightly, compared to that at site B. The impact of the PV array on the ULR is no more than 2% (see table 2).

The net radiation (NR) is a measure of the incoming radiation incident on the earth's surface, minus the outgoing energy radiated by the Earth itself. It is related to the four radiation components (Pessacg et al., 2013). The NR reached a peak of approximately 438.0 $W \cdot m^{-2}$ at 14:00 at site A, and 366.8 $W \cdot m^{-2}$ at 14:00 at site B, as shown in Fig. 3(c). The daily cumulative value of the NR at site A is 8.30 $MJ \cdot m^{-2}$, and 6.34 $MJ \cdot m^{-2}$ at site B. The cumulative value of the NR during the daytime at site A is 1.98 $MJ \cdot m^{-2}$ higher than that at site B and 0.02 $MJ \cdot m^{-2}$ little lower at night. Therefore, the impact of a photovoltaic array on net radiation is mainly during the daytime, which is the photovoltaic power station's main working time. The monthly averaged NR reached a maximum in June and a minimum in December in the two sites, as shown in Fig. 4(c) and (c1). The difference in the values of the NR between the two sites is positive over the entire year, with the difference being evident. The ratio of the average annual NR at site A to that at site B is 1.32, which indicates that the solar farm has been collecting energy. The difference of the NR at the two sites reached the maximum in August, with a value of 33.0 $W \cdot m^{-2}$, while it reached the minimum in December, with a value of 13.2 $W \cdot m^{-2}$.

Surface albedo is the most important parameter affecting the surface radiation budget. As seen from Fig. 3(d), the distribution of the albedos from the two sites are U-shaped, being higher in the morning and evening and lower at noon. When the solar elevation is low, the surface albedo varies greatly. However, with the increase in the solar elevation, the surface albedo decreases and tends to be stable. A large number of photovoltaic devices in the solar farm have a greater capacity to absorb the solar radiation, resulting in lower albedo. The daily average values of surface albedo in the PV farm and without the PV panel are 0.19 and 0.26, respectively. As shown in Fig. 5, the albedos change significantly with the seasons, being lower in summer and higher in autumn and winter. Each seasonal average of the surface albedo at site A is higher than that at site B. The monthly average albedo reached a maximum in November and a minimum in September in the PV area, while it reached a maximum in November and a minimum in July in the region without PV. The difference between the two sites was larger in November 2012 and March 2013, when the average value was 0.11, while it was smaller in May–July, when the average value was 0.05. The annual average values of albedo in the PV farm and the area without the PV panel are 0.19 and 0.27, respectively.



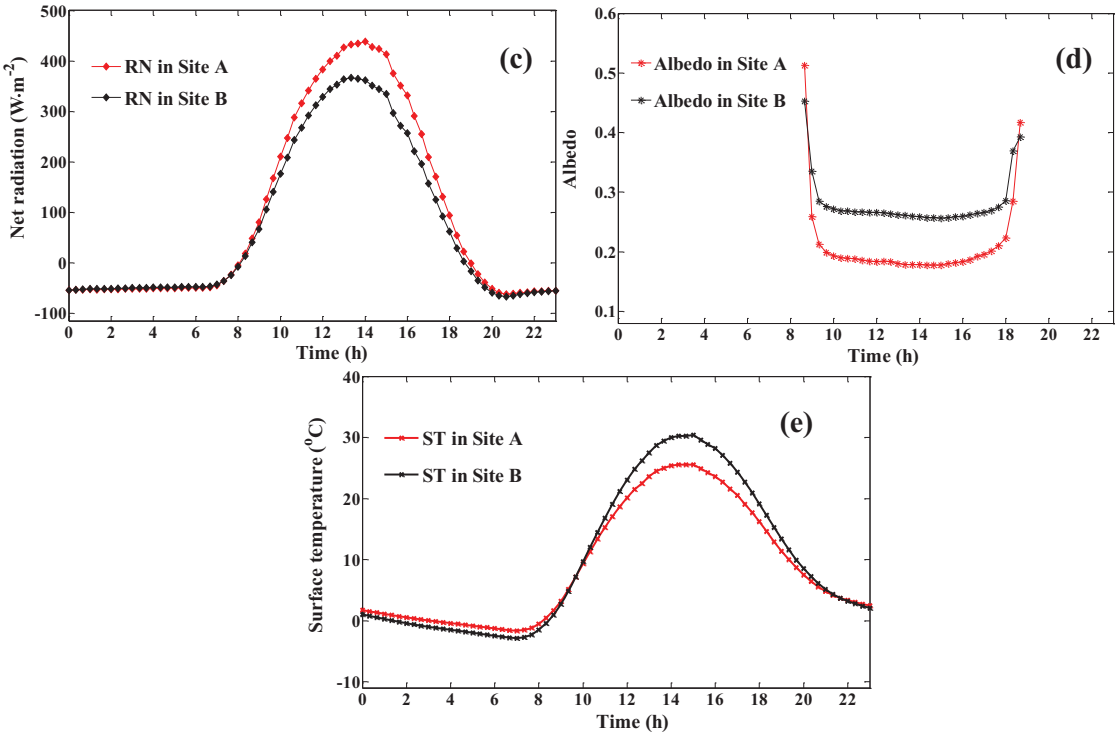


Fig. 3: Annual averaged diurnal variations of radiation components: (a) shortwave radiation, (b) longwave radiation, (c) net radiation, (d) albedo; and (e) surface temperature in the solar farm (Site A) and in the region without PV (Site B) in Golmud.

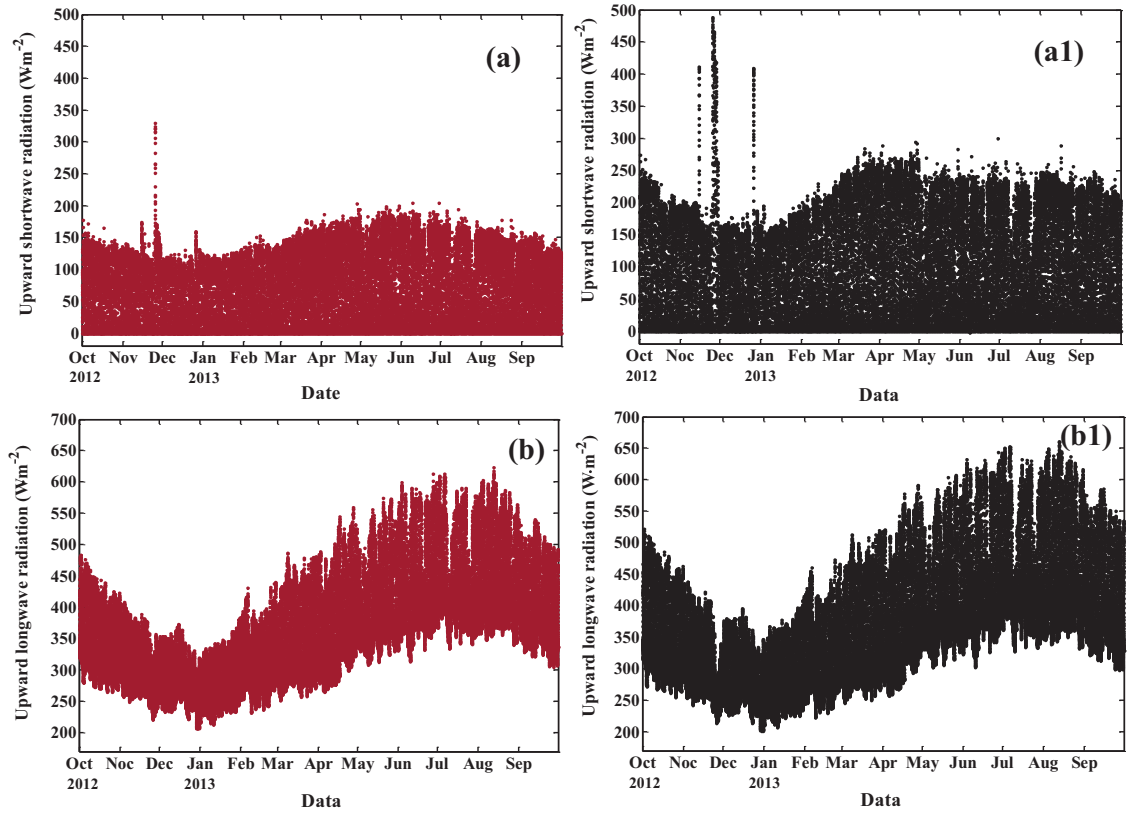

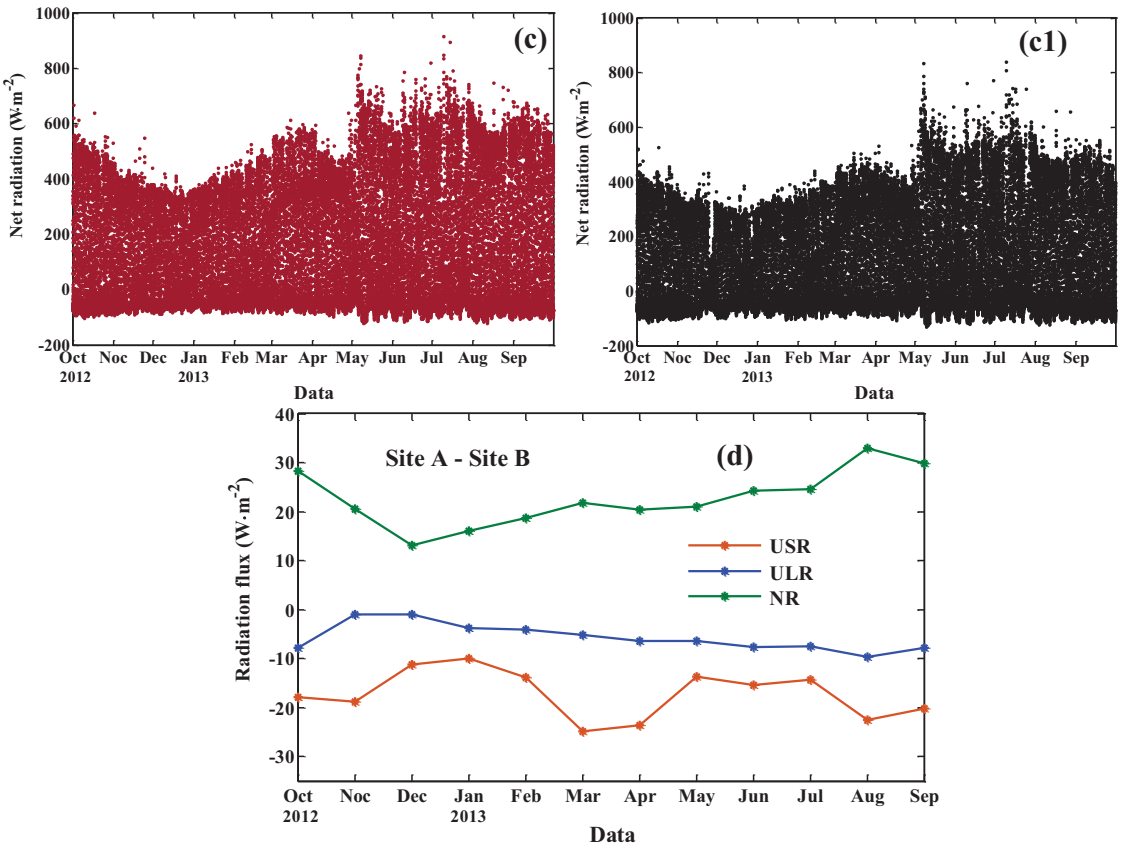

Fig. 4: Annual variation of radiation flux in the solar farm (Site A) and in the region without PV (Site B) in Golmud, where (a), (b) and (c) are the annual variations of USR, ULR and NR in Site A, respectively; (a1), (b1) and (c1) are the annual variations of USR, ULR and NR in Site B, respectively; (d) is the difference of monthly averaged radiation flux between the two sites.

	DSR (W·m^{-2})	USR (W·m^{-2})	DLR (W·m^{-2})	ULR (W·m^{-2})	NR (W·m^{-2})
Site A	221.83	40.97	269.13	356.17	93.81
Site B	223.37	58.15	267.81	361.87	71.16
Relative difference/%	0.69	29.54	0.49	1.58	31.83

3.2. Comparison of the soil temperatures at the two sites

Soil temperature is one of the most important physical properties in determining the rates and directions of physical

processes of the soil, including energy and mass exchange, evaporation and aeration (Gulser and Ekberli, 2004). However, very few studies have focused on the relationship between the soil temperature and a PV farm. In the present study, the soil temperature data obtained continuously at different depths and at different times of the day from the two sites, from October 2012 to September 2013, were analyzed to reveal the effects of PV arrays on soil temperature in Golmud.

Figure 6 shows the amplitude of the monthly averaged diurnal variation of the soil temperature at the two sites. It shows that the amplitude of the diurnal variation of the soil temperature at the two sites gradually decrease with an increase in soil depth. Moreover, the diurnal variation of the soil temperature at a depth of 5 cm is larger, while the change in the diurnal variation of the soil temperature below the depth of 80 cm does not exceed 0.3℃. The diurnal variation in temperature of each layer of soil between 5 and 40 cm in winter is significantly lower than that in spring, summer and autumn. The maximum value of the amplitude of diurnal variation at a depth of 5 cm at the two sites appeared in August, at 20.8℃ at site A, and at 31.7℃ at site B. The minimum value at site A appeared in January, at 4.6℃, while the minimum value at site B appeared in December, at 18.9℃.

The amplitude of the monthly averaged diurnal variation of the soil temperature at site A is significantly lower than that at site B in the shallow soil layer (5, 10 cm), which is mainly due to the existence of a large number of photovoltaic arrays in the solar farm, making it difficult for the solar radiation to spread in the soil during the daytime, with the soil heat not being able to spread outward easily during the night, resulting in a reduction of the diurnal variation of soil temperature in the solar farm. The thermal insulation effect of the photovoltaic array is particularly evident in the shallow layer of soil.

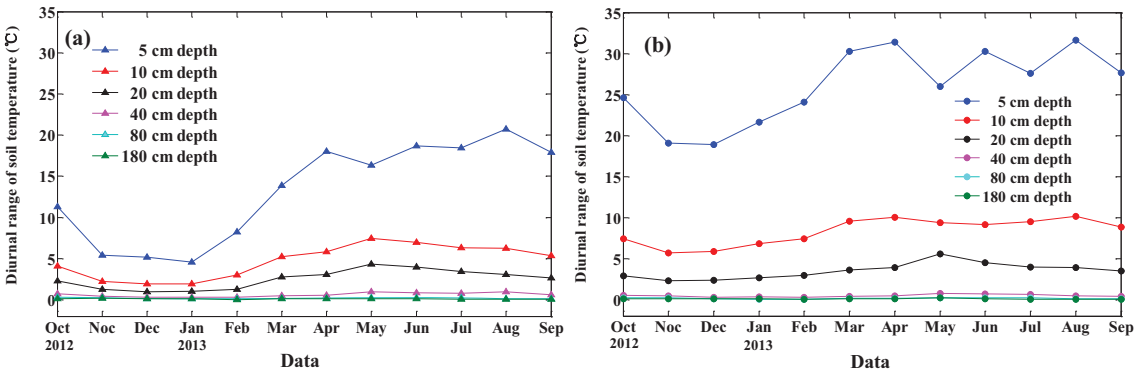

Fig. 6: The amplitude of the monthly averaged diurnal variation of the soil temperature: (a) in the solar farm (Site A) and (b) in the region without PV (Site B).

Figure 7 shows the annual variations of soil temperature at the two sites. As shown in Fig. 7, the changing trend of the annual variations at the two sites is accordant, showing waveform changes. The maximum average soil temperature values at depths of 5–80 cm at the two sites appear in August, while the minimum value appears in January. The maximum average soil temperature values at a depth of 180 cm at the two sites appears in September, while the minimum value appears in February. The average annual soil temperature values at depths of 5–180 cm at site A are 7.5, 7.5, 7.4, 7.6, 7.7, and 7.8℃, respectively, while those at site B are 9.5, 9.4, 9.5, 9.3, 9.4, and 8.9℃, respectively. In winter (December–February), the shadow area of the solar panels reached the maximum, falling onto the site where the soil temperature probes were buried, thus significantly reducing the soil temperature in the solar farm. In winter, the average soil temperature values at depths of 5–180 cm at site A were -10.8, -9.7, -9.1, -7.8, -5.0, and 0.2℃, respectively, while those at site B were -6.2, -5.4, -4.7, -3.2, -0.7, and 3.7℃, respectively. The soil temperatures at different depths in winter in the PV farm were evidently lower than those without PV. Hence, it can be said that the PV farm is a cooling system.

The annual range (annual variation amplitude) of soil temperature at a depth of 5 cm was the largest, with the annual range of soil temperature decreasing gradually, depending on the depth. The annual ranges of soil temperatures at depths of 5–180 cm at site A were 40.4, 37.8, 35.9, 33.4, 27.7, and 19.3℃, respectively, while those at site B were 35.3, 33.2, 31.8, 27.4, 22.1, and 13.6℃, respectively. The annual ranges of soil temperatures at different depths in the solar farm are higher than those in the region without PV.

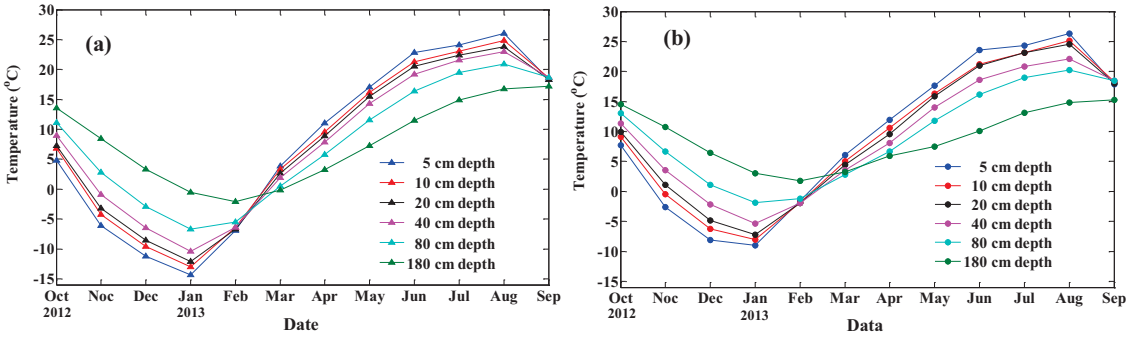

Fig. 7: Seasonal variations in soil temperature: (a) in the solar farm (Site A) and (b) in the region without PV (Site B) in Golmud.

In the PV farm, the presence of the photovoltaic array will affect the solar radiation received on the ground surface, as well as the heat radiating to the atmosphere, thus affecting the soil temperature. A T test was carried out for the daily mean soil temperature at the same depth at the two sites from October 2012 to September 2013 to analyze the influence of the PV array on soil temperature over a year. As shown in Table 3, the data are the P (Probability) values for the T Test (Huang, 1990) at the same depth at the two sites. There are significant differences in the soil temperature at different depths at the two sites from October to March of the following year at the level of 0.05. In addition, there are significant differences at a depth of 80 cm in April and July and at depths of 20 80 cm in August.

The difference between site A and site B at the different depths (the average daily soil temperature at site A, minus the average daily soil temperature at site B) is shown in Fig. 8, hereinafter referred to as the difference. As shown in Fig. 8, the difference in value at the different depths at the two sites from October to March of the following year is mostly below 0℃. Therefore, the average daily soil temperature value in the solar farm is smaller. The average difference in the values at depths of 5 80cm from October to March of the following year were -3.7, -3.4, -3.7, -3.7, and -3.5℃, respectively.

There is a notable feature, which can be seen in Fig. 8. The difference is very less between the two sites in summer. The possible reason is that the instability of atmospheric stratification of the surface layer and the surface turbulence is strong during summer daytime, resulting in a small temperature difference between the two sites. At the same time, the photovoltaic panels generate heat when they generate electricity during the day, causing the photovoltaic cell panels to have a heating effect on the air temperature of the surface layer, which is stronger in the summer than in the winter. It can also result in a smaller difference of soil temperature between the two sites.

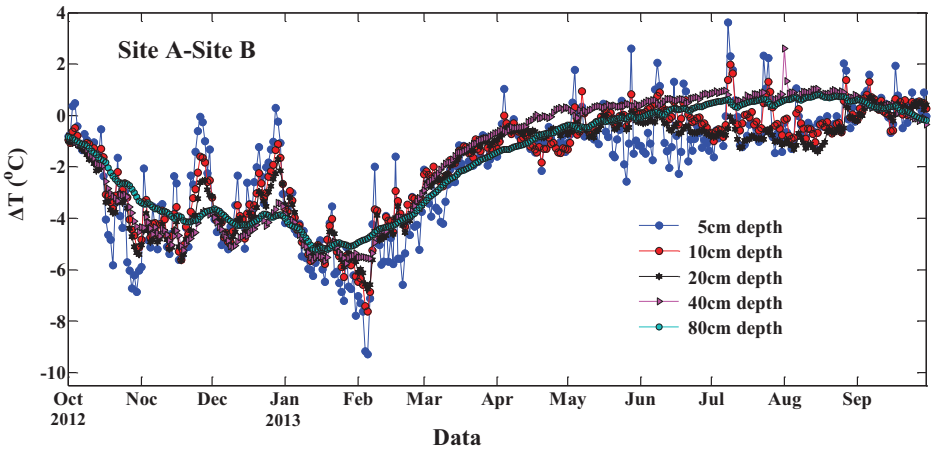

Fig. 8: Annual variations of difference value of different layers of soil temperature between the two sites

Figure 9 shows the annual variations of thermal conductivity at 5–20 cm depths at the two sites. Thermal conductivity in the soil may be explained as the quantity of heat flow through an area of soil per unit time and temperature gradient. The existing research shows that soil thermal conductivity is mainly influenced by soil texture and moisture content (Peterslidard et al., 1998). The soil texture of the two sites is the same; thus, thermal conductivity is mainly affected by the soil moisture content.

As shown in Fig. 9, the monthly mean thermal conductivity reached a maximum in May and a minimum in September at the two sites. Each monthly mean thermal conductivity at the PV farm is higher than that in the region without PV, with the difference being evident. The main reason could be the higher soil moisture in the solar farm. The photovoltaic panels increase the roughness, playing an important role in weakening the wind velocity. At the same time, solar radiation received by the surface in the solar farm is less than that in the region without PV. These factors decrease the evaporation of soil in the solar farm, thus increasing the soil moisture.

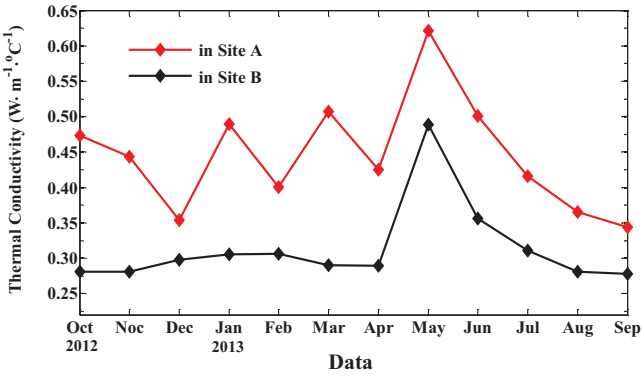

Fig. 9: Annual variation in the monthly mean thermal conductivity in the solar farm (Site A) and in the region without PV (Site B) in Golmud

3.3. Comparison of air temperatures at the two sites

The observational data we used are from May 2013 to April 2014. Figure 10 shows the diurnal variations of the 2-m air temperature and the differences (site A to site B) during the four seasons. July, October, January and April were selected to represent the four seasons of the year. The results show that the air temperature at a height of 2 m at the two sites is essentially the same during winter daytime, but in the other seasons, the daytime air temperature at the PV farm is higher than that in the region without PV. The maximum difference appears during the summer daytime, with a value of 0.7℃ (the summer daytime averaged value). This is because the solar panels enhance the local atmospheric turbulence flow and the heat transfer, as well as radiate heat during the day. Moreover, its effect of heating the air is greater during summer, when the irradiance is higher. As Fthenakis et al. (2013) observed, the PV module temperatures were consistently higher than those of the surrounding air during the day. The nighttime air temperature at a height of 2 m during the four seasons at the solar farm was higher than that in the region without PV arrays, since the solar panels have a heat preservation effect near the ground. The differences in values between the two sites were 0.1, 0.3, 0.2, and 0.1℃ in summer, autumn, winter and spring, respectively.

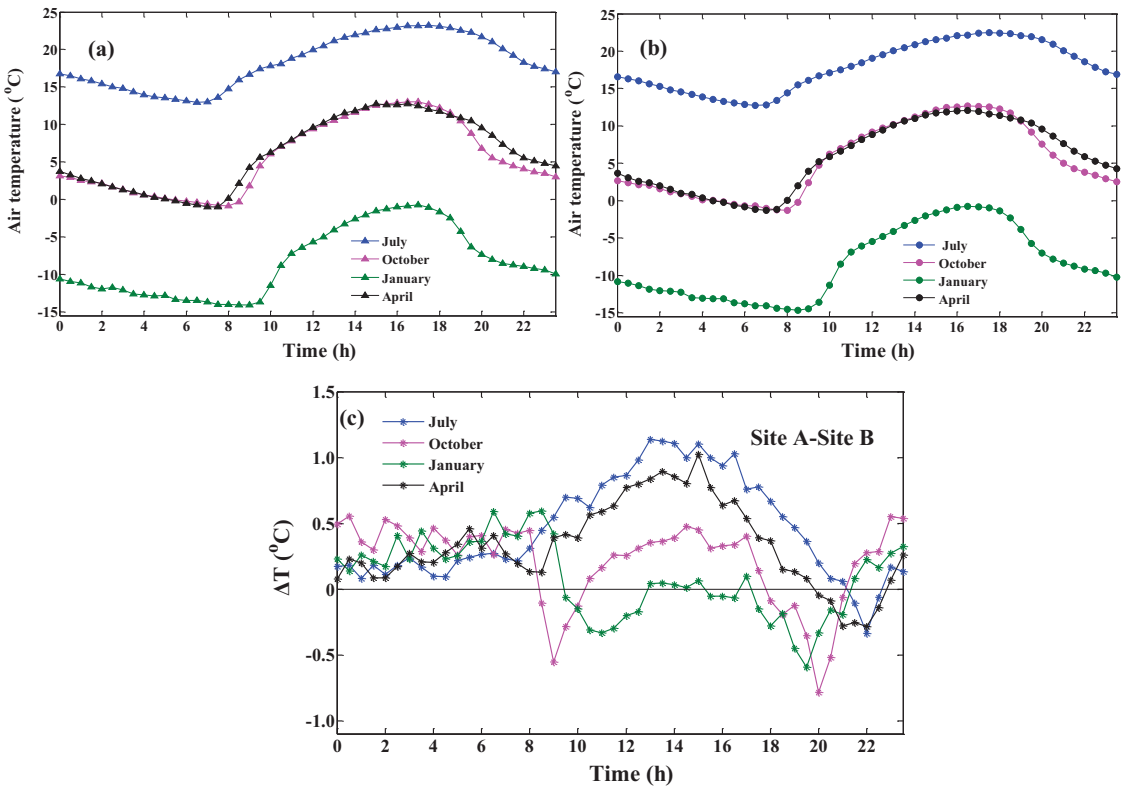

Fig. 10: Diurnal variations of 2 m- air temperature in the four seasons: (a) in the solar farm (Site A), (b) in the region without PV (Site B) and (c) difference between the two sites.

4. Conclusion

Based on the field observation data from the large solar farm and the region without a PV array in Golmud, the characteristics of surface radiation were analyzed. The results show that the total daily values of upward shortwave radiation and net radiation at the two sites are significantly different. The mean daily albedo at the solar farm is 0.19, while it is 0.26 in the region without PV. The annual mean of net radiation at the solar farm is evidently higher than in the region without PV, indicating that the solar farm is collecting energy. However, the PV array converts a part of the radiation energy to electrical energy for output, which can cause the surface layer temperature at the solar farm to be lower.

The characteristics of soil temperature were also analyzed. The results show that the daily range of soil temperature at a depth of 5–10 cm at the solar farm is lower than that in the region without PV farm. Therefore, the solar photovoltaic arrays demonstrated thermal insulation performance. The annual range of soil temperature at a depth of 5–180 cm at the solar farm was larger than that in the region without PV. The soil temperature at different depths during winter at the solar farm was clearly lower than that in the region without PV, indicating that the PV farm is a cooling system. The daily mean of the soil temperature at a depth of 5–80 cm from October 2012 to March 2013 was evidently lower than that in the region without PV array.

The characteristics of diurnal and annual variation features of the 2-m air temperature were analyzed at the two sites. The results show that the air temperature at a height of 2 m at the two sites is essentially the same during winter daytime, while during the other seasons, the daytime air temperature at the PV farm is higher than that in the region without PV. The maximum difference appears during the summer daytime, as the solar panels radiate heat during the daytime. This effect of heating the air is greater in summer. The nighttime air temperature at a height of 2 m during the four seasons at the solar farm is higher than that in the region without PV arrays, since the solar panels exhibit heat preservation effect near the ground.

A WAVELET DECOMPOSITION APPROACH TO IMPROVE MODELLING PERFORMANCE OF ARTIFICIAL NEURAL NETWORKS IN SOLAR ENERGY RESEARCH

Sajid Hussain and Ali Al Alili*

Department of Mechanical Engineering, Khalifa University of Science and Technology, Petroleum Institute, P.O.Box 2533, Abu Dhabi, the United Arab Emirates

Abstract

In solar energy research, estimating solar potential over a location of interest is an important step towards the successful planning of renewable energy projects. However, solar data are not available for every point of interest due to the absence of meteorological stations and sophisticated solar sensors. Therefore, the solar radiation has to be estimated with accurate solar radiation models. This paper presents a hybrid technique to increase the modeling performance of artificial neural networks (ANN), commonly used in solar radiation applications. A wavelet multiresolution is performed to decompose the meteorological data into different time and frequency scales before it is presented to the ANN models. As a result, improving the learning process of the ANN models. The proposed approach is compared to traditional ANN model and validated using well-known statistical validation metrics including coefficient of determination (R^2) and root mean square error (RMSE), mean bias error (MBE), mean absolute percentage error (MAPE), and t-statistics. In addition, wavelet cross spectrum (WCS) is used as a visual indicator of the model performance in time, frequency, and phase domains. The results show that the modeling performance of the ANNs is considerably improved from R^2 of 89.21% to 96.34%.

Keywords: *Solar radiation model, artificial neural network, wavelet analysis*

1. Introduction

There is an increasing concern over global warming, emission of greenhouse gases and climate change. This has encouraged the use of renewable energy sources as replacements to coal and oil fired electricity generation processes. Wind, hydro, solar, and geothermal are main sources of renewable energy. The United Arab Emirates, strategically located in the solar belt, has abundance of sunshine throughout the year where the yearly averaged GHI reaches around 6kWh/day (Islam et al. 2009). This gives the UAE an opportunity to harness solar energy and promote clean and green environment. Therefore, accurate solar resource assessment is an inseparable part of an efficient energy planning in the region. Solar radiation reaching the earth's surface are normally measured using different ground based sensors like pyroheliometers, pyranometers and radiometers. However, this process is expensive and cannot be implemented for every geographical region of interest. An alternate way is to model and predict the solar radiations using readily available economical measurements like T, RH, WS, and SSD. Models are trained and validated on historical data collected from ground based sensors at one particular geographical location and used to estimate the solar radiations at nearby locations. This highlights the importance of solar radiation models, their efficiency and accuracy.

Different statistically based (Hassan 2014), (Voyant et al. 2014), (Mohammadi et al. 2015), biologically inspired (Mohandes 2012), (Behrang et al. 2011), (İzgi et al. 2012) and hybrid (Salcedo-Sanz et al. 2014), (Babu and Reddy 2014), (Olatomiwa et al. 2015) models are used for solar radiation modeling. Artificial neural network (ANN) techniques are very common among biologically inspired models. ANN is used to model solar radiation either by using meteorological parameters (Cornaro et al. 2015), (Yacef et al. 2012) or satellite images (Lu et al. 2011), (Linares-Rodriguez et al. 2013).

Often, the modeling performance of the ANN is improved through hybrid techniques (Salcedo-Sanz et al. 2014) or different ANNs are used to model different seasons of the year or more specifically, to cater for temporal nonlinearities in the data. However, none of the considerations is given to spectral non-linearities present in solar and weather time series.

This paper proposes a relatively very simple technique based on wavelet multiresolution analysis. The novelty

doi:10.18086/swc.2017.22.02 Available at http://proceedings.ises.org

of this study is to analyze the time series, both in temporal and spectral domains. A wavelet multiresolution analysis is performed on the signals that decomposes the signals into different frequency and time resolutions, and different ANNs are trained accordingly. Other than modelling, the process filters out the noise present in the signal as noise can degrade the modeling performance of the ANN. This is reflected in the model performance indicators which penalize the model for not correctly modeling the noise components.

The rest of the paper is organized as follows. Section 2 introduces the methodology followed by simulations and discussions in section 3 and conclusions in section 4.

2. Wavelet Decomposition Combined with Artificial Neural Networks

2.1. Wavelet Multiresolution Analysis

In this section, complex time signals are decomposed or transformed into relatively simple parts through wavelet decomposition. Then modeling algorithms are applied on each decomposed part. In the end, all the parts are combined to construct the original signal. A time domain signal can be transformed into frequency domain signal by using the fast Fourier transform (FFT). Although, the frequency domain analysis offers excellent frequency resolution but no time resolution. This problem can be solved by using joint time–frequency analysis (JTFA) techniques like short-time Fourier transform (STFT) and wavelet transform (WT).

The WT applies a strategy where the decomposition of a complex signal is performed using varying time and frequency resolutions. WT is a convolution of a signal with a basis function $\Psi(t)$, called mother wavelet, and its dilated and translated components $\Psi_{d,s}(t)$, called daughter wavelets. Let us denote a time signal as $x(t)$ at time t, the continuous wavelet transform (CWT) of $x(t)$ is $W_x(d,s) = \int_{-\infty}^{+\infty} x(t)\,\Psi^*_{d,s}(t)dt$, where the operator * is a complex conjugate, and $\Psi_{d,s}(t) = \frac{1}{\sqrt{s}}\Psi\left(\frac{t-d}{s}\right)$, where d is translation in time, and s is dilation or scale operator. A discrete wavelet transform (DWT) of a discrete version $x(n)$ of the signal $x(t)$ is computed through a series of high-pass (`h[n]`) and low-pass (`g[n]`) filters, where an n level decomposition of the signal $x(n)$ is computed. This step decomposes the original signal into its detailed (D_1, D_2, …, D_n) and approximation (A_1, A_2, …, A_n) wavelet coefficients. A reconstruction step or inverse discrete wavelet transform (IDWT) with high-pass (`H[n]`) and low-pass (`G[n]`) filters is performed to get the original signal back as shown in Fig.1.

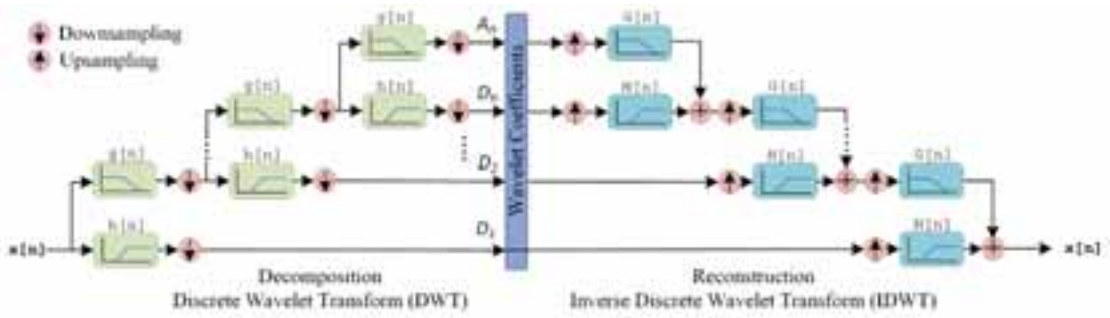

Fig. 1. Decomposition and reconstruction, DWT

The wavelet multiresolution analysis can be combined with ANNs to improve the modeling performance of traditional ANN. Each input variable $x(n)$ and output variable $y(n)$ are decomposed into their detailed and approximation wavelet coefficients through DWT. The decomposition process is stopped where R^2 is maximized. First level detailed coefficients of each input variable are used as input to an ANN to estimate first level detailed coefficient of the output. Similarly, second level detailed coefficients of the input variables are used as input to an ANN to estimate second level detailed coefficient of the output and so on. On the other hand, only n^{th} level approximation coefficients of each input variables are used to estimate n^{th} level approximation coefficient of the output variable. At the end, all estimated detailed and approximation coefficients of the output variable are combined through IDWT to construct an estimation of the original output signal. Figure 2 shows the process.

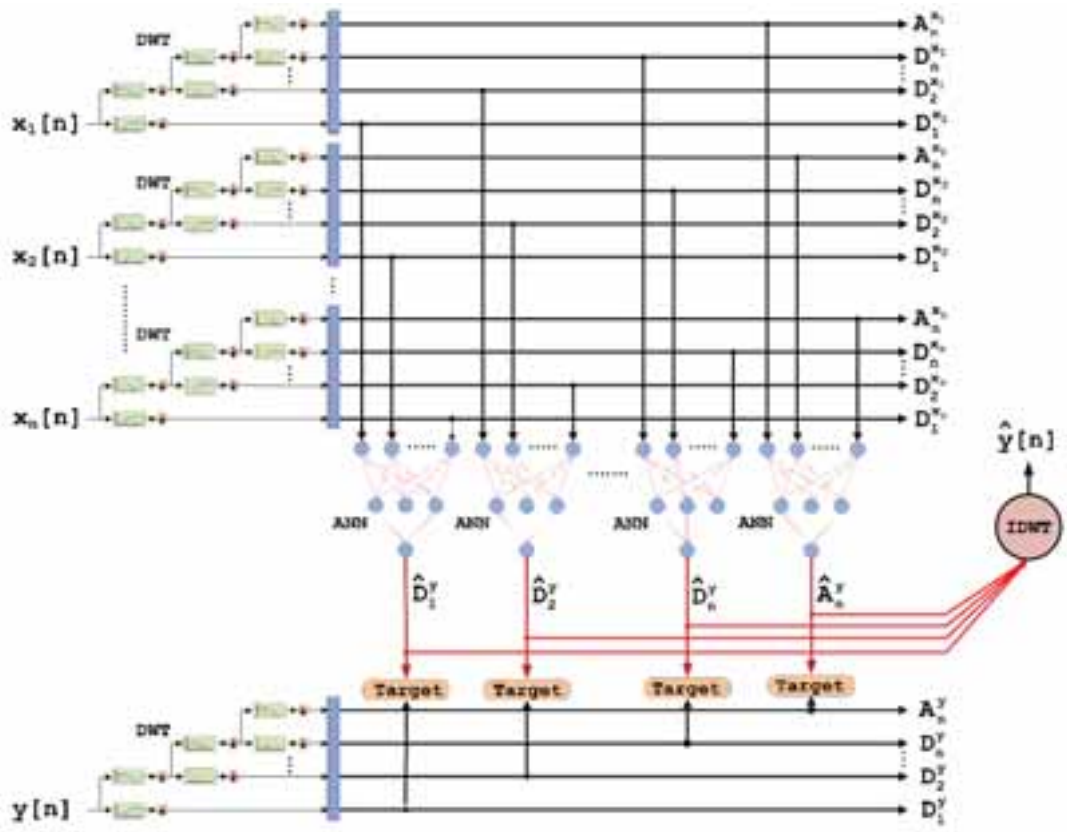

Fig. 2: Wavelet decomposition combined with ANN

2.2. Artificial Neural Network (ANN)

ANN simulates biological nervous systems and tries to mimic information processing capabilities of human brain. ANNs are successfully used in many real-world problems including non-linear function estimation, pattern identification, classification, regression, and forecasting. One of the most common ANN architecture used in research is Multi-layer perception (MLP). Among MLP, the widely used network architecture is feed-forward network with one hidden layer as shown in Fig. 3.

The input–output equations of the k^{th} neuron are as follows (Haykin 1994):

$$y_k = \Phi\left(u_k - \theta_k\right), \qquad u_k = \sum_{j=1}^{n} w_{kj} x_j \,. \qquad \text{(eq. 1)}$$

The input elements of the ANN are $x_1, x_2, ...x_n$ as shown in 3, the output of the summation is u_k , θ_k is a threshold, $w_1, w_2, ...w_n$ are the neuron's synaptic weights and $\Phi(.)$ is an activation function. The neural network has the ability to learn from its environment. In the learning process, synaptic weights of the ANN are updated through enforcement applied to the ANN from the environment. The learning rule has the following form

$$w_{kj}\left(n+1\right) = w_{kj}\left(n\right) + \Delta w_{kj}\left(n\right), \qquad \text{(eq. 2)}$$

where $\Delta w_{kj}\left(n\right)$ is the adjustment of the weight $w_{kj}\left(n\right)$ at n^{th} time-step. The computation of $\Delta w_{kj}\left(n\right)$ is performed through well-known back propagation algorithms including Levenberg-Marquardt optimization, steepest decent techniques and quasi-Newton methods (Haykin 1994).

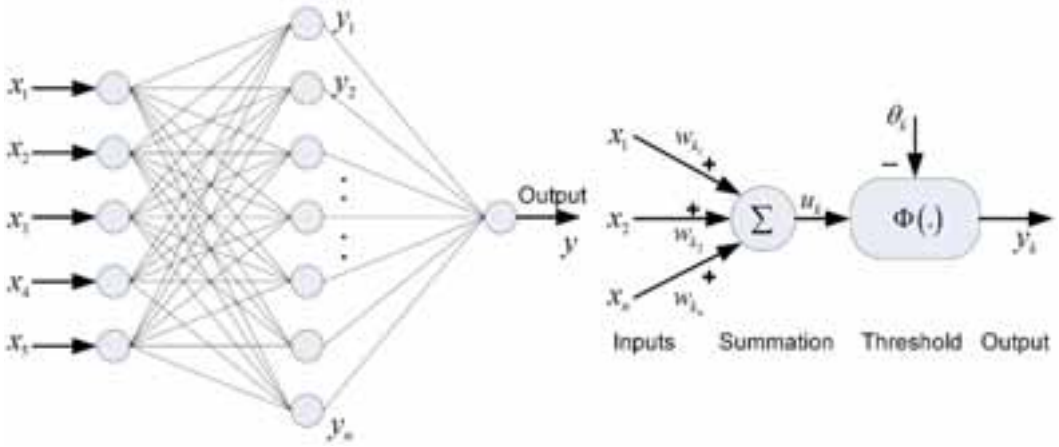

Fig. 3: Feed Forward Artificial Neural Network

2.3. Statistical Evaluation Metrics

The following statistical metrics are used to evaluate the model performance.

$$RMSE = 100\left(\frac{\sqrt{\sum_{n=1}^{N_t}\frac{(GHI-\widehat{GHI})^2}{N_t}}}{\sum_{n=1}^{N_t}\frac{GHI}{N_t}}\right)\%, \quad \text{(eq. 3)}$$

$$MAPE = 100\left(\frac{1}{N_t}\sum_{n=1}^{N_t}\frac{|GHI-\widehat{GHI}|}{|GHI|}\right)\%, \quad \text{(eq. 4)}$$

$$MBE = 100\left(\frac{\sum_{n=1}^{N_t} GHI-\widehat{GHI}}{\sum_{n=1}^{N_t} GHI}\right)\%, \quad \text{(eq. 5)}$$

$$R^2 = 100\left(1-\frac{\sum_{n=1}^{N_t}(GHI-\widehat{GHI})^2}{\sum_{n=1}^{N_t}(GHI-\overline{GHI})^2}\right)\%, \quad \text{(eq. 6)}$$

where root mean square error is RMSE, mean absolute percentage error is MAPE, mean bias error is MBE, and coefficient of determination is R^2. The terms $GHI, \widehat{GHI},$ and $\overline{GHI}$ are original, estimated and mean global horizontal irradiances. The total number of samples in the test data is N_t. In addition, *t*-statistics is performed where it is objectively determined whether a model's estimates are statistically significant. The *t*-statistics is calculated from RMSE and MBE as

$$t = \sqrt{\left(\frac{(N_t-1)MBE^2}{RMSE^2-MBE^2}\right)}. \quad \text{(eq. 7)}$$

The model's performance is better for smaller values of the t-statistics. In order to determine the statistical significance of the model's estimate, a critical t value from standard statistical tables has to be obtained for $\mathbf{1-\alpha}$ confidence level and $\boldsymbol{N_t-1}$ degrees of freedom (DoF).

3. Simulations and Discussions

3.1. Data Collection and Quality Control

Daily averaged data for ten years (2004 – 2013: 3650 samples), collected from Abu Dhabi international airport, UAE at Latitude of 24.22° N and Longitude of 54.65° E are used in this study. The data includes temperature (T : °C), relative humidity (RH : %), wind speed (WS : knots), sunshine duration (SSD : hours), and global horizontal irradiance (GHI : Wh/m^2). The data are checked for missing values by visual inspection. In addition, a multivariate statistical outlier detection using squared Mahalanobis distance is performed. A total of 109 (3%) samples are discarded as being outliers. This leaves a valid data of 3541 samples. Fig. 3 shows the time history of the cleaned data. The data are further normalized in the range of [-1 1], to be used for ANN training.

3.2. ANN Implementation

An MLP is initialized with four input neurons, ten hidden neurons, and one output neuron. The synaptic weights of the MLP are initialized randomly, and Levenberg–Marquardt algorithm is used for training. The stopping criteria are either maximum generations of 300 or MSE value of ≤ 0.02. The number of hidden layer neurons is an important parameter in the modeling process, and in this particular work, an MLP with ten neurons in the hidden layer is found reasonable. This number is found by a simulation experiment where an MLP is initialized with varying number of hidden layer neurons from 1 to 30, and for each MLP, the process of training, validation, and testing is repeated 30 times and the values of RMSE are recorded.

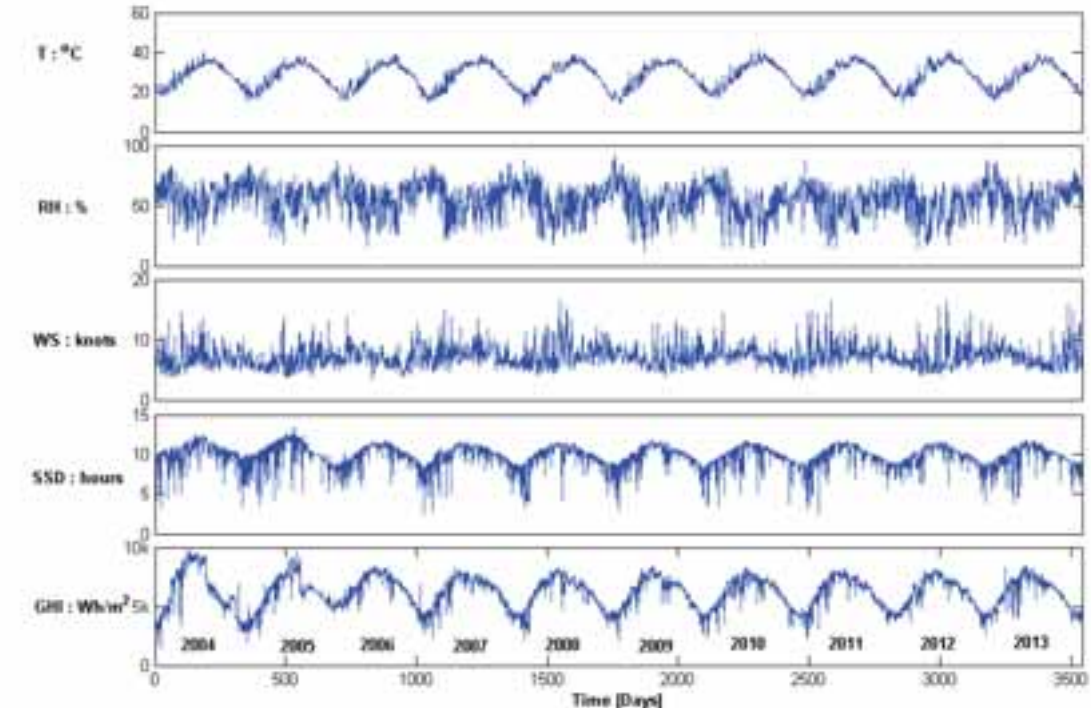

Fig. 4: Time history of the collected data

The MLP with low RMSE is selected for further modeling. The data are divided into training, validation and testing data sets of 2480 (70%), 530 (15%) and 530 (15%) data points, respectively. Fig. 5 shows the results with Fig.5 (a) plotting the time histories of measured and estimated GHIs without wavelet decomposition, using only standalone-MLP. Fig. 5 (d) shows time histories of measured and estimated GHIs with wavelet decomposition, the wavelet approach. Fig. 5 (b) and Fig. 5 (e) plots the results of regression analysis for both the standalone and wavelet approaches, respectively. Fig. 5(c) and Fig. 5 (f) plots the wavelet cross spectrum (WCS) analysis for both approaches. Further analysis of Fig. 5 reveals that wavelet-MLP approach improves the modeling performance of the MLP with R^2 of 96.34% and RMSE of 235.25 Wh m^{-2} day^{-1} (3.88%) as compared to the standalone-MLP approach with R^2 of 89.21% and RMSE of 415.54 Wh m^{-2} day^{-1} (6.83%). A WCS plot in Fig. 5 (c) reveals that in the case of standalone-MLP approach, a frequency component of 0.07×10^{-6} Hz (6-month on the frequency axis or y-axis) is not correctly modeled. A relative phase difference of 45° to 95° (direction of small black arrows inside the WCS plot) between measured and estimated GHIs is observed from the time stamp of 3200 to 3325 days on the time axis (see the red colored arrows indicated on the time axis or x-axis). On the other hand, this is not the problem with the wavelet-MLP approach and the relative phase difference is corrected as shown in Fig. 5 (f). The direction of small black arrows in the WCS plot is towards right most of the time. This concludes that standalone-MLP approach could not model the frequency contents of the GHI signal related to 6-month. However, when the signal is decomposed, with wavelet decomposition, into relatively simple parts, the problem vanishes. The value of R^2 is improved by 6.85%. In addition, looking closely at the time histories in Fig.5 (a), we clearly see the poor modeling performance of the standalone-MLP around time stamps of 3200 to 3325 days at time axis. This corresponds to the months of February, March, and April in the test year of 2013. The regression plot in Fig. 5 (b) reveals that the standalone-MLP model slightly overpredicts the values of GHI in the lower region on 3000 to 5000 Wh m^{-2} day^{-1}. However, this problem is improved in wavelet-MLP regression plot of Fig. 5 (e) because of the removal of

unwanted noise components. Overall, the modeling performance of the wavelet-MLP outperforms the standalone-MLP approach. The optimum wavelet decomposition level where R^2 is maximized is 6.

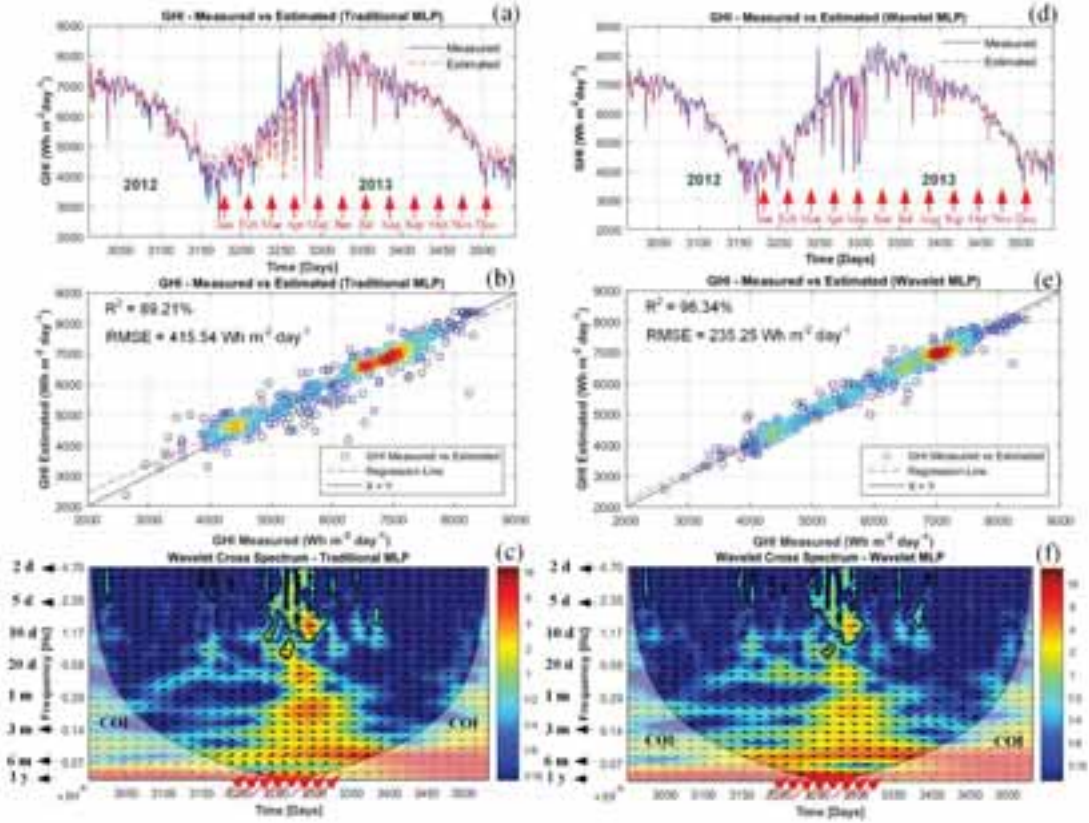

Fig. 5: ANN results (a) measured and simulated GHI, standalone-MLP (b) regression analysis, standalone-MLP (c) Wavelet cross spectrum, standalone-MLP, where relative phase arrows point right for in-phase and left for anti-phase coherence (d) measured and simulated GHI, wavelet-MLP (e) regression analysis, wavelet-MLP (f) Wavelet cross spectrum, wavelet-MLP, where relative phase arrows point right for in-phase and left for anti-phase coherence.

Table1. Model Comparisons

Model	Standalone approach					Wavelet approach				
	R^2 (%) [95% CI]	RMSE (%)	MAPE (%)	MBE (%)	*t*- stat	R^2 (%) [95% CI]	RMSE (%)	MAPE (%)	MBE (%)	*t*-stat
MLP	89.21 [0.87- 0.911]	6.82	5.15	-0.53	1.79	96.34 [0.959- 0.97]	3.89	2.98	0.11	0.59

4. Conclusion

This study models global horizontal irradiation (GHI) over Abu Dhabi, the United Arab Emirates using a widely used soft-computing algorithm in this domain, the artificial neural network (ANN). The suggested model use four sets of inputs: temperature (T), relative humidity (RH), wind speed (WS), and sunshine duration (SSD). The traditional ANN modeling approaches lack the ability to capture temporal and spectral dynamics present in the signals. In this paper, the complex input signals are decomposed into relatively simple time series with varying time and frequency resolutions using wavelet decomposition. ANN modeling is applied to these simple time series, and the modeled time series are combined to form an estimate of the final complex signal. The results show that the proposed strategy significantly improves the performance of traditional ANN. The maximum improvement is observed where the R^2 is improved by 6.83%. In addition, this paper presents a critical analysis of the results in time, frequency and phase domains. It is evident from the analysis that models work better when signals are de-noised, and frequency and phase coherence are achieved between measured and estimated solar radiations for critical and representative frequencies.

This study demonstrates the merits of wavelet-ANN models for solar radiations. However, further testing is required before the suggested techniques are applied to real-life applications. Tests are required for high-resolution data with quantification of potential uncertainties. There need to be rigorous tests at other geographical locations to assess the wider potential and versatility of the proposed wavelet-ANN models for solar energy applications.

Artificial Neural Networks (ANN) for the Prediction of Local Outside Temperatures and Solar Yields

Wolfgang Kramer, Moritz Bitterling

Fraunhofer Institute for Solar Energy Systems (Germany)

Abstract

Artificial Neural Networks (ANN) are the basis of a new intelligent control concept for residential heating systems developed at Fraunhofer ISE. This artificial intelligence based concept is able to predict data like local outside temperature, solar thermal yield, thermal behavior of a building and capacity level of a thermal storage based on measured data without using any physical model based simulation tool. This allows to improve energy efficiency and simplicity of control devices at the same time by considering the above mentioned predicted data. The current paper shows results of prediction by ANN for local outside temperature and solar yields of a solar thermal installation. The focus of the prediction method is not highest accuracy but simplicity of application, enabling low cost model predictive control. Accuracy of the local outside temperature prediction is doubled compared to a pure weather forecast data for the tested location. Solar yield prediction is also quite in line with real measurement data at the location investigated. The achieved prediction quality is reasonable and promising for improved heating system control.

Keywords: Artificial Neural Networks, Artificial Intelligence, Solar Thermal, Control, Prediction of Temperature, Prediction of Solar Yield, Heating System

1. Introduction

Similar to biological Neural Networks (brains), Artificial Neural Networks (ANN) are able to automatically develop strategies of operation based on experience in the past. The structure of ANN is motivated by the knowledge of research in Neural Science. For an introduction to Neural Networks see for example Gurney, 1997. It is obvious that such structures could be very beneficial for technical control tasks. For solar thermal heating applications ANNs seem to be useful for learning the individual thermal dynamics of a building including fossil fuel heating, the effects of passive solar heating (i.e. heating by sunlight hitting the building surface and passing window surfaces), shading and heat losses to the ambient, thus enabling the prediction of future temperature development in the building. Other applications are the prediction of storage temperature distribution and solar thermal yields of the installation. All these predictions do not need any physical model based simulation. The ANN is able to perform these predictions based on training from past measurement data, only. It is able to handle non-linear static and dynamic systems.

Thus, ANNs provide the back bone of a new self-learning control concept for solar thermal systems based on simple and cheap prediction methods. Local climate data, individual thermal behavior of buildings, solar passive and active gains can easily be forecasted without costly and tedious simulation. This allows not only a significant improvement of energy efficiency but also cost reduction installation and set-up of controllers.

This paper presents the description of the ANN method for the prediction of local outside temperatures and solar yields on a real building equipped with a solar thermal supported heating system. First prediction results are shown and discussed.

doi:10.18086/swc.2017.22.03 Available at http://proceedings.ises.org

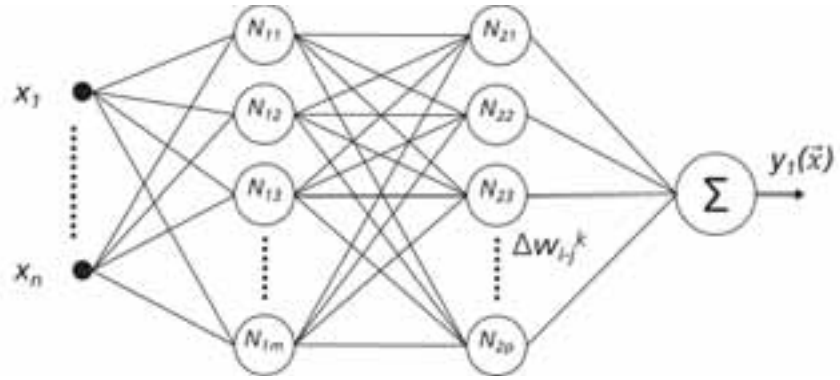

Fig. 1: 4-layer ANN Network with one input layer, 2 hidden layers and one output layer

2. Prediction using ANN Structures

ANN structures for the prediction of local outside temperatures and solar yields of a solar thermal installation have been developed at the authors' institution. The ANN models consist of a 4-layer ANN structure (figure 1) including one input layer, two hidden layers and one output. Input data x_1-x_m is normalized to +/- 1 before being transferred to the first hidden layer N_{11}-N_{1n}. The calculation procedure in each neuron N is presented in figure 2. Each normalized input value is multiplied by a weight W_i and summed up. An offset is added and the sum is passed through a transfer function. In our case this is hyperbolic tangent (*tanh*). The calculation scheme for the second layer is identical. In the last layer, which is the output layer, the output of the second hidden layer N_{21}-N_{2p} is summed up and extended in order to get the output value $y_1(\vec{x})$. Figure 1 shows the ANN.

A program code was developed to do training of the ANN. This means to determine the most suitable values of W_i for each neuron in order to get the best fit between measured input and output training data of the ANN. Main challenges of the training process are overfitting, convergence, termination method, being trapped in local minima, required processing power to perform an epoch of training and required RAM to perform an epoch of training.

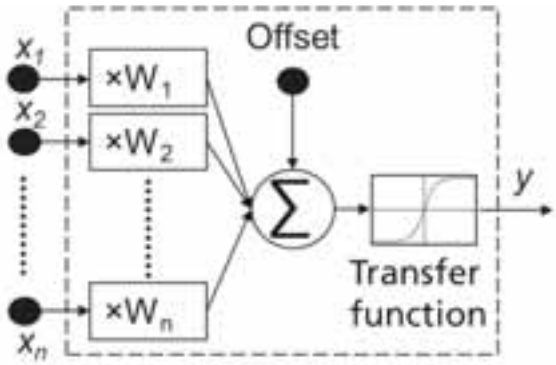

Fig. 2: Mathematical description of a neuron N_{ij}

Based the local conditions of weather data and a real individual building construction a trial and error approach was used to choose the most suitable topology. The most important criteria were accuracy of prediction, robustness of the training result and computation time. Overfitting can be avoided by minimizing the size of the ANN. A maximum of 2 hidden layers with not more than 15 neurons each proved to be appropriate for the application presented in this paper. The trials carried out showed that at least for the data that was available a simple termination rule could be defined by stopping the training after a fixed number of training epochs. The developed algorithm follows a supervised training approach and incorporates several training features including weight correction, momentum modification and temperature as described by Haykin 2005 in order to avoid being trapped in local minima. Required processing power and RAM does not seem to be a problem for the presented static ANNs. However, this has to be reevaluated for dynamic ANNs that will be used in further steps of the current work.

Training was based on measured training data from a real solar thermal heating installation, which was available for a complete year (2016) for the location of Marburg, Germany.

2.1. Prediction of Local Outside Temperature

Control of the heating system of a building is normally based on the measurement of the local temperature outside the building. Local outside temperature of a real building that is measured by a sensor mounted directly on the wall of the building differs obviously from reference temperature data of meteorological stations. When compared to local meteorological prediction, differences are expected to be even more important. On the one hand, this is due to inaccuracy in forecasting for a special location. In general, weather forecast does not account for very individual small scale local impacts on temperature. On the other hand, the local conditions of the mounting situation of the temperature sensor are not considered. This includes effects of wind, temporary exposure to irradiation, infrared cooling to the sky, heating by the wall of the building and error of local temperature measurement.

Thus, when trying to improve efficiency of a heating control system by considering future outside temperature development, it seems reasonable to use a more precise method of forecasting the local temperature. Instead of relying on weather forecast temperature only, ANN is able to deliver more precise information on future local temperature development. The big advantage of ANN is its self-learning capability. Just by automatically analyzing local measurement data such a system is able to predict local temperature development without any physical simulation model behind. The complex non-linear characteristics of the local climate is taken into account with this simple approach.

Such an ANN correlates real measured temperature and data from a weather forecast. Apart from the temperature data itself more variables like solar irradiation, wind speed and direction, hour of the day and day of the year are taken into account. This additional data deliver implicitly important information on the position of the sun, local shading, and heating by irradiation. The ANN is trained by combining historical locally measured temperature data and collected historical weather forecast data provided by meteoblue 2017.

Figure 3 shows the capability of an ANN to perform such a prediction. An ANN has been trained to predict the local outside temperature with a forecast horizon of one hour, based on historical data from a regional weather forecast provided by meteoblue and measurement data. The static ANN consisted of 4 inputs (temperature forecast one hour ahead (1), time (2), date (3) and current local temperature (4)), 2 hidden layers of 10 neurons each and one output (local temperature one hour ahead). Wind and irradiation data did not further improve the forecast. This is due to the fact that the sensor in this case never sees solar irradiation and is well protect from wind effects.

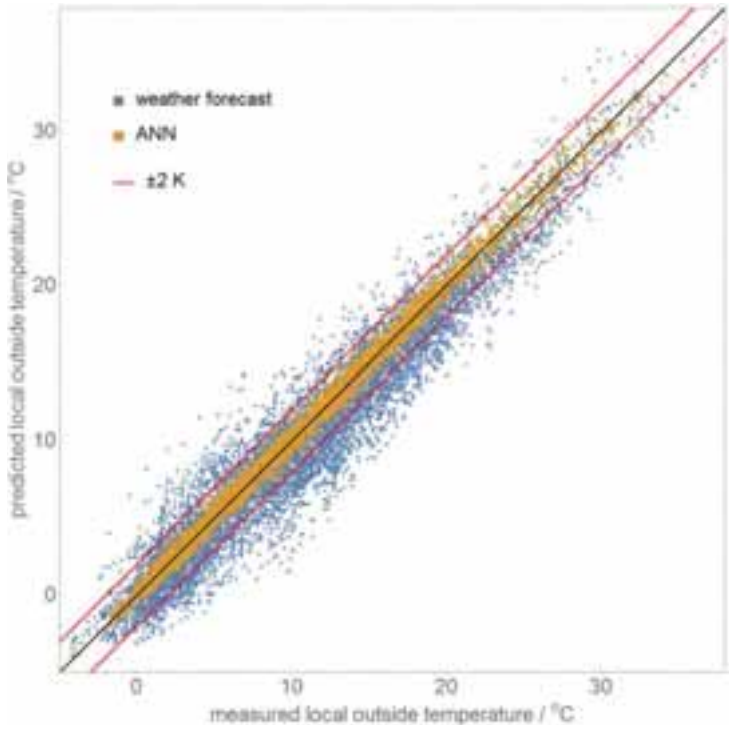

Fig. 3: Prediction of local outside temperature of a building

The results show an improvement in standard deviation from 1.9 K to 1.1 K when comparing pure weather forecast temperature data and ANN prediction with the real locally measured outside temperature. The mean deviation is corrected from 0.9 K to 0 K. At first glance this seems possibly disappointing. However, it has to be stressed that this improvement could be automatically generated in a real application without dealing with any tedious parameterization. Compared to many other prediction methods, it is somehow "for free".

2.2. Prediction of Solar Yield of a Solar Thermal Installation

A second ANN has been used to do a one-hour prediction of the solar yield. The product of temperature difference between collector inlet and outlet and the rotation speed of the pump was taken as an indicator of solar yield. The reason for using such an indicator instead of real yield data is the availability of data. In a future commercial application, data of real solar yield is not always available. Therefore, a control system has to work with such an indicator.

Training of the network has been performed with historical weather forecast data and measured data from one year. The appropriate ANN consists of two hidden layers with 12 neurons each. The input data given to the network were date (1), time (2), storage tank temperatures at top (3) and bottom (4) and predicted data from a weather forecast for radiation (5), ambient temperature (6) and cloud cover (7) as well as the measured solar heat input during the previous hour (8). The data was split into a training set and a validation set. Figure 4 shows quite reasonable agreement between prediction and measurement.

The accuracy of the predicted total daily solar yield is shown in figure 5. 80% of the daily solar yield data is predicted with an accuracy better than 15.2 % when compared to the average daily solar yield.

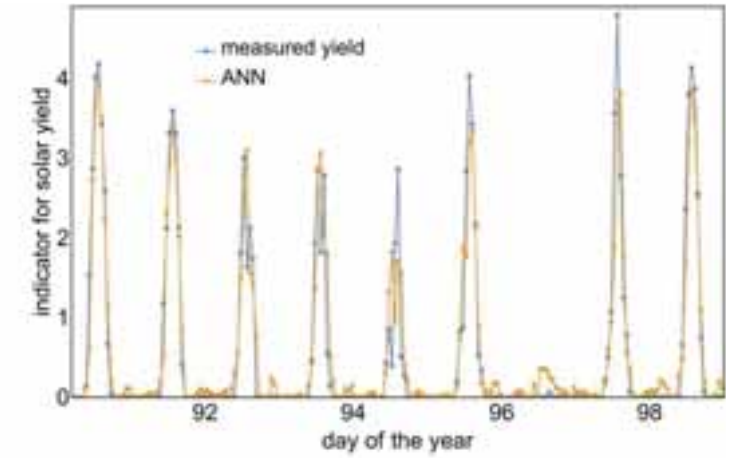

Fig. 4: Prediction of hourly mean solar yield indicator and comparison with measured data

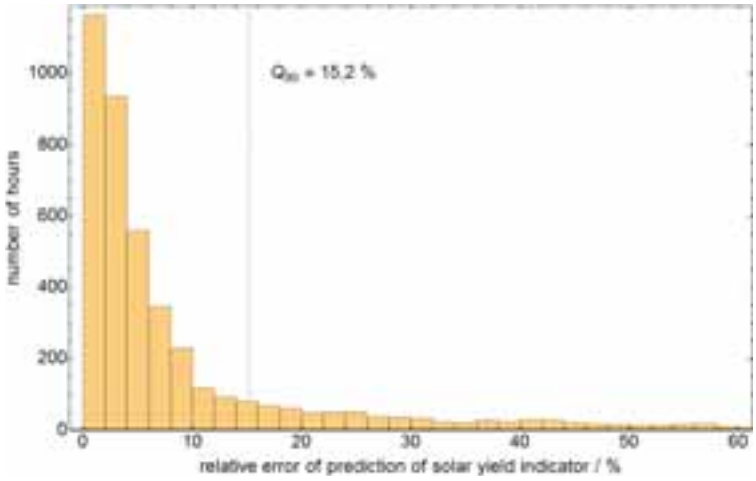

Fig. 5: Accuracy of prediction of solar yield indicator

3. Discussion of the Results

The results shown in this paper have been created by training ANNs for one single local site for one individual building in an urban environment in the city of Marburg, Germany based on real measured data and historical weather forecast data. The accuracy communicated is only valid for these individual conditions. Accuracy under different conditions is expected to be of similar magnitudes but have to be checked. In the case of the black box model ANN, this can only be done by statistical methods. A limited comparison of the ANN method presented with other statistical approaches for different sites and different types of training data showed comparable accuracy, though.

Answering the question of “How accurate is the ANN approach?” in a general sense is not possible. The ANN training approach can be regarded as a sort of sophisticated non-linear regression of input and output data. It is the same as asking how precise is a least-square method for linear correlation of data. This depends on the data, not on the method itself.

Unlike in simulations based on physical models, each site and building needs a new creation of an ANN model by training with individual data. The advantage of ANN is, that this model building procedure can be realized in an automatic way, whereas physical models often need tedious parameter identification for adjusting the model to individual conditions.

An important feature of ANN is that inaccurate input data is less of a problem than for other approaches, since

systematic inaccuracy is automatically compensated by the self-learning feature. The same holds for missing data or physically incomplete data with regard to the physical model. Simple weather forecast data, which is easily available for almost every place on earth, is sufficient to make the ANN approach work. For example calculating the solar yield of a solar thermal installation by a physical model needs a precise array of irradiation at any time. Such irradiation data is not easily available from simple weather forecast data. However, the ANN approach is able to process successfully such simple data. By feeding not only the ANN with the irradiation data from the weather forecast but also other inputs like time of the day, month, forecast of cloudiness, current outside temperature, temperatures of the thermal storage and others if necessary (i.e. barometric pressure, wind speed and direction, humidity etc.) the ANN is able to correlate these values with the individual output of the installation. This correlation inherently includes technical characteristics of the heating installation, thermo-physical properties of the building, passive heating, shading effects and others. As long as there is a systematic correlation of input data and the desired output (solar yield in this case), the system is able to generate a black box model describing this dependence. Accuracy depends on careful selection of input data, accuracy of input data, ANN topology and training method, of course.

4. Conclusion and Outlook

A new control approach using Artificial Neural Networks provide a powerful concept that could significantly improve energy efficiency and reduce cost at the same time. It is not expected, that ANN is more precise than other modelling approaches. Its strength is its simplicity in application by relying on local measured and simple weather forecast data, only. Parametrization as needed in physical models is not necessary. The ANN model describing individual characteristics of the building and the heating installation under local weather conditions can be created automatically. First results of using an ANN approach for predicting local outside temperatures and solar yields of a real installation show, that it is possible to use such an approach in order to avoid costly simulation methods. Future improvement is expected after more work on optimum ANN structures and training methods. Current work on ANNs with back propagation shows that dynamic ANN structures are even more appropriate for predicting future status several hours in advance. However, computational requirements and calculation speed have to be carefully monitored.

Further steps will include the prediction of inside room temperatures of a building and the development of the level of charge capacity in the thermal storage using the ANN approach and the implementation of complete control algorithm for a solar thermal heating installation. First results on the prediction of the stratification in thermal storage are also very promising (Kramer et al. 2017).

Further validation in order to provide information of the general applicability and limitations on different sites and in different buildings is needed.

5. Acknowledgment

This research was conducted within the project „Neuronale Netzwerke für die Anwendung in der Solarthermie“ (Neural Networks for the application in solar Thermal)(ANNsolar) and is supported by the German Ministry of Economics (Bundesministerium für Wirtschaft, BMWi) under the grant number FKZ 325548 and supported by the project executing organization PTJ Jülich. COMPARISON BETWEEN LEBARON-PEREZ AND DAL PAI-ESCOBEDO CORRECTION METHODS FOR DIFFUSE IRRADIANCE MEASURED BY THE *MEO* SHADOWRING METHOD

Alexandre Dal Pai[1], João Francisco Escobedo[1] and Enzo Dal Pai[1]

[1] São Paulo State University, School of Agricultural Sciences/UNESP, Botucatu (Brazil)

Abstract

This study aims to determine the effectiveness of two methods of correction of diffuse irradiance measured with shadowbands: LeBaron-Perez method and Dal Pai-Escobedo method. For the LeBaron-Perez method, we use the original coefficients and adjusted coefficients for the atmospheric conditions of Botucatu. Global, direct and diffuse solar irradiances were supplied by the Laboratory of Solar Radiometry of Botucatu. The period assigned for the study comprised the years 1996 to 2005. The results showed that the LeBaron-Perez correction model with the original coefficients are not suitable for correction of diffuse irradiance in Botucatu. Otherwise, the LeBaron-Perez model with adjusted coefficients and Dal Pai-Escobedo model are indicated for the correction of diffuse irradiance in Botucatu measured by shading ring with accuracy of 0.5%.

Keywords: Shading ring, diffuse irradiance, Correction Factors, anisotropy, Measurement Methods.

1. Introduction

Information of the solar potential are required in various industries and areas of society, with applications in climatology, architecture, agriculture, passive lighting, satellite studies, among others. In general, the information serves to supply solar energy conversion models, thermal comfort and energy balance.

Several weather stations, for practical reasons, measure, routinely, only the global radiation. Measures of direct and diffuse radiation are less frequent due to the high financial costs. However, it is possible to establish a database of global, diffuse and direct radiation with low financial investment. In this case, the global component is monitored by a pyranometer positioned in the horizontal plane of the locality, the diffuse component is monitored by a pyranometer placed under the shade of a shading ring and the direct component is obtained by the difference between the global and diffuse components.

This method of measuring diffuse radiation is known as shading ring method. Different assemblies are described in the literature and best known is the Drummond´s assembly (1956) (Fig. 1). In Drummond assembly, the pyranometer remains fixed and the shading ring moves parallel to the polar axis to compensate the variations in the solar declination. The Drummond assembly is currently the most widely used. An alternative assembly with low cost, easy operation and maintenance, was proposed by Melo and Escobedo (1994) - *MEO* assembly (Fig. 1). In this system, the shading ring is fixed with an inclined angle equal to the local latitude, and to compensate the solar declination, the pyranometer moves parallel to the local horizon plane on a moving base to stay under the shadow produced by the ring.

Despite having operational and financial advantage, shading ring method has the disadvantage of correction factors (CF) to offset the portion (LF) of diffuse irradiance barred by shading ring (Drummond, 1956; Kasten et al, 1983; Stanhill, 1985). 5% errors in the measurement of diffuse radiation can propagate up to 20% uncertainty in the estimate of direct radiation to high zenith angles (Lebaron et al, 1990). Correction factors are based on isotropic radiation, and consider only the use of geometric factors (radius and ring width) and geographic (latitude and solar declination).

doi:10.18086/swc.2017.23.01 Available at http://proceedings.ises.org

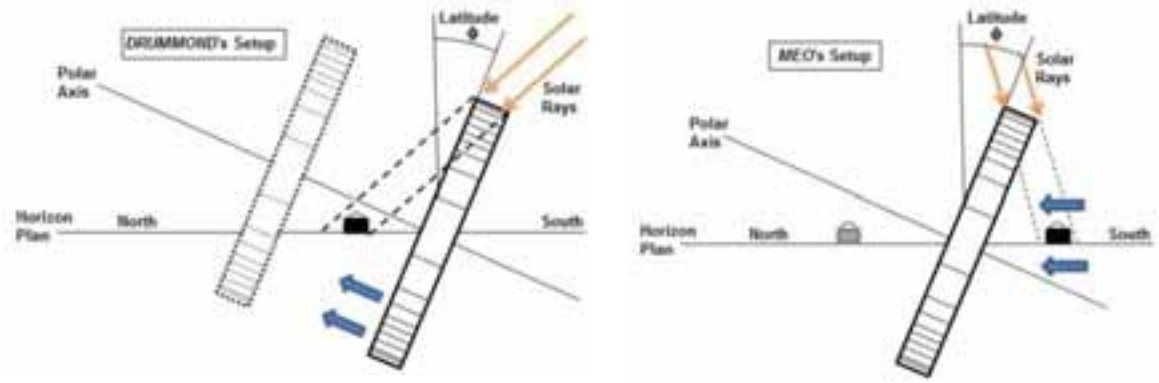

Figure 1 - Shading ring assembly: Drummond and MEO.

Several researchers have shown that the application of isotropic correction does not include atmospheric effects (turbidity, cloudiness, pollution, water vapor) that are responsible for anisotropy in the diffuse radiation. Kasten et al. (1983) and Pollard and Langevine (1988) introduced corrections based on anisotropic parameters such as K_T clearness index (ratio between the global irradiance I_G by the extraterrestrial irradiance I_O), zenith angle and atmospheric turbidity associated with isotropic correction to improve the accuracy of the measurement of diffuse irradiance by Drummond shading ring. Stanhill (1985) found that the anisotropic corrections showed spatial and temporal dependence, caused mainly by the different sizes and concentration levels of aerosols in the atmosphere. LeBaron et al (1990) proposed anisotropic correction models by combining three anisotropic parameters (zenith angle and brightness index) and an isotropic parameter (geometric and geographic), highlighting the K_T clearness index as the most significant parameter in the representation of anisotropic conditions. In this way, Iqbal (1983) recommends different anisotropic corrections to the ring as a function of K_T clearness index (3% to $0 < K_T < 0.30$; 5% to $0.30 < K_T < 0.65$ and 7% to $0.65 < K_T < 1$). Battles et al (1995) used the same parameters of LeBaron and developed two numerical correction methods through multiple linear regression: the first method uses all the parameters in a single equation, whereas the second uses geometric parameters, brightness and solar zenith angle grouped by four intervals of the K_T clearness index, a total of four numeric correction equations.

In this sense, the objective is to compare the efficiency of Lebaron-Perez and Dal Pai-Escobedo methods for correction of diffuse solar irradiance measured by the *MEO* shading ring assembly.

2. Materials and Methods

The study is based on global, direct and diffuse irradiance measurements provided by the Laboratory of Solar Radiometry, located at the Department of Bioprocess and Biotechnology, School of Agricultural Sciences / UNESP / SP (latitude 22º 54 'S, longitude 48º 27' W and altitude 716 m). There were used 10-years data (1996-2005), 75% intended for modeling and 25% for validation purposes. A computational routine was developed to separate the data, being three lines for modeling and 1 line for validation..

The city of Botucatu (Fig. 2) lies in a region of planting sugarcane and eucalyptus. It has about 130,000 inhabitants and is surrounded by an asymmetric embossing called Cuesta de Botucatu and the watersheds of the Tietê and Paranapanema. It has few industries and its economy is based on service delivery.

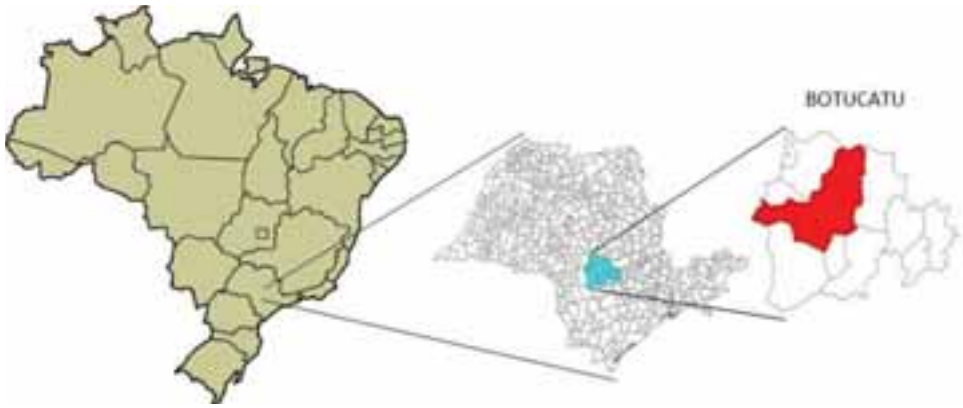

Figure 2 - Map of Brazil with state divisions showing the location of the study (Botucatu in the state of São Paulo)

According to the Köppen climate classification, the local climate is Cwa (humid subtropical climate), with hot, humid and rainy summers and dry winters and mild temperatures. The temperature and relative humidity values follow the astronomical variations, with maximum values of temperature and relative humidity in February (23.12 ° C and 78.25% respectively) and minimum temperature values in July (17.10 ° C) and relative humidity in August (63.97%). The rainy season occurs in the summer and spring, accompanied by high cloudiness. About 80% of the annual rainfall occurs during this period, with a maximum in January (246.2 mm). In the winter and fall seasons, the average rainfall is less than 100 mm per month, and minimum in August (36.1 mm). Regarding aerosols, industrial activity and motor vehicles are the largest emitters of aerosols in the atmosphere. However, as the Botucatu is full of sugarcane crops, the practice of harvest burning can emit large amounts of particulate matter in the atmosphere, especially in winter, where the removal by rain is minimal (Codato et al, 2008).

The global solar irradiance I_G was measured by an Eppley PSP pyranometer; the direct solar irradiance by an Eppley NIP pyrheliometer equipped with a ST-3 solar tracking device; and diffuse solar irradiance by an Eppley PSP pyranometer under the *MEO* shading ring (radius of 0.40 m width 0.10 m). Tab. 1 shows the operating characteristics of the measurement devices.

Table 1 - Operational characteristics of the global, direct and diffuse solar irradiance measurements.

Irradiance	**Global**	**Direct**	**Diffuse**
Sensor-brand	Eppley Precision Spectral Pyranometer	Eppley Normal Incidence Pyrheliometer	Eppley Precision Spectral Pyranometer
Sensibility	±7,45 µV/Wm²	7,59 µV/Wm²	±7,47 µV/Wm²
Spectral Range	295 – 2800 nm	295 – 2800 nm	295 – 2800 nm
Response time	1 s	1 s	1 s
Linearity	±0,5% (from 0 to 2800 W/m²)	±0,5% (from 0 to 1400 W/m²)	±0,5% (from 0 to 2800 W/m²)
Cosine effect	±1% (0º<Z<70º) ±3% (70º≤Z<80º)	–	±1% (0º<Z<70º) ±3% (70º≤Z<80º)
Temperature Dependence	±1% (from -20ºC to +40ºC)	±1% (from -20ºC to +40ºC)	±1% (from -20ºC to +40ºC)

Figure 3 – Global, diffuse and direct solar irradiance measurements.

The values of solar irradiance were monitored by an automatic data acquisition system model Datalogger 23X Campbell Scientific Inc with a 0.2 Hz frequency. Mean values were calculated every 5 minutes and stored in W/m^2 format.

The diffuse irradiance data measured by the MEO shading ring (Id_{ANEL}) were corrected using the geometric correction factors proposed by Oliveira et al (2002). True diffuse irradiance, called reference diffuse irradiance (Id_{REF}) was calculated as the difference between the global and direct irradiance. Of the 525 592 available data on ten years of monitoring, 47725 (representing 9.09% of total) were removed due to the application of filters shown in Tab. 2 (Kudish and Evseev, 2008). The cutoff values are due to misalignment, lack of electricity and internal reflections occurred in the shading ring caused by low solar altitude.

Table 2 - Quality control filters and results (Kudish and Evseev, 2008).

Solar Irradiance	Filter
Global	$I_G < I_O$
Direct	$I_b \leq Io$
Diffuse	$0{,}1\ I_G \leq Id_{ANEL} < I_G$
Diffuse Reference	$0 \leq Id_{REF} \leq I_o$

For LeBaron-Perez correction method (Lebaron et al, 1990), we calculated the zenith angle (Z), the clarity index Epsilon (ε) and the brightness index (Δ).

$$Z = \cos^{-1}[\sin\phi \sin\delta + \cos\phi \cos\delta \cos\omega] \quad (1)$$

$$\varepsilon = \frac{I_G - I_d}{I_d \cos Z} + 1 \quad (2)$$

$$\Delta = \frac{I_d . m}{I_o} \quad (3)$$

where ϕ is the local latitude, δ the solar declination, ω the hour angle, I_G the global irradiance I_d the diffuse irradiance uncorrected measured by the shading ring, m the optic mass and Io the extraterrestrial irradiance mass. The Dal Pai-Escobedo correction method (Dal Pai et al, 2011) uses the atmospheric transmissivity parameter K_T.

$$K_T = \frac{I_G}{I_o} \quad (4)$$

The original method of LeBaron-Perez used the geometric correction factors for Drummond assembly. As in Botucatu the diffuse irradiance measurement method uses the MEO assembly, the geometric correction factors were adjusted for such assembly. Equations (5) and (6) show the loss of fractions of assemblies Drummond (Drummond, 1956) and MEO (Oliveira et al, 2002), respectively, and the equation (7) the calculation of the geometric correction factors.

$$F_{lost-D} = \left(\frac{2b}{\pi R}\right).cos^3\,\delta \int_0^{w_z} \cos Z\, d\omega \tag{5}$$

$$F_{lost-MEO} = \left(\frac{2b}{\pi R}\right).\cos\delta.\left[\frac{\cos(\phi+\delta)}{\cos\phi}\right]^2 \int_0^{w_z} \cos Z\, d\omega \tag{6}$$

$$F_G = \frac{1}{1-F_{lost}} \tag{7}$$

where b is the width of the ring and R the radius of the ring. The evaluation of the correction model is based on MBE and RMSE statistical indicative (Stone, 1993) given by Eq. (8) and Eq. (9), respectively.

$$MBE = \left(\sum_i^N (y_i - x_i) \Big/ N\right) \tag{8}$$

$$RMSE = \left(\sum_i^N (y_i - x_i)^2 \Big/ N\right)^{1/2} \tag{9}$$

where y_i represents the ring diffuse irradiance, x_i the reference diffuse irradiance and N is the number of observations. The MBE is the simple deviation and a positive value indicates an overestimate, while a negative value indicates an underestimate. The RMSE is the standard deviation and is related to the dispersal of values from the average.

3. Results and Discussions

In this section are compared two methods of correction of diffuse solar irradiance measured by the shading ring. The first method used is based on LeBaron-Perez correction method (Lebaron et al, 1990), using four parameters for a sky conditions description (geometrical factor, zenith angle, clarity index and brightness index). The second methodology is based on the correction method of DalPai-Escobedo (Dal Pai et al, 2011), and used two parameters for description of sky conditions (geometric factor and atmospheric transmissivity).

The LeBaron-Perez correction model considers both isotropy and anisotropy conditions of the radiation. A geometric factor was proposed for isotropy conditions based on construction features of the ring, while zenith angle, clarity index and brightness index was assigned for anisotropy conditions. In this case, while zenith angle is responsible for the position of the sun in the celestial hemisphere and the optical path taken by the sun's rays, clarity index and brightness index are linked to measurements performed on surface and reflect the interaction of radiation with the atmosphere. Tab. (3) shows the parameter values used in the LeBaron Perez-correction model divided into four sets, which result in 256 sky categories. Two situations were present for geometric factors: one containing the values of the original model for Drummond assembly and one adjusted for *MEO* assembly at Botucatu.

Table 3 - Limit values used for the four parameters chosen to describe the corrections applied to the diffuse irradiance measured by the shading ring. The combination of these parameters allow 256 sky coverage categories.

Parameters			Groups			
			1	**2**	**3**	**4**
i	Zenith angle		0 to 35	35 to 50	50 to 60	60 to 90
j	Geometric factor	(*Original)*	1 to 1.068	1.068 to 1.100	1.100 to 1.132	1,132 to ---
		(*Adjusted*)	1 to 1.123	1.123 to 1.165	1.165 to 1.208	1,208 to ---
k	Epsilon		0 to 1,253	1.253 to 2.134	2.134 to 5.980	5.980 to ---
l	Delta		0 to 0,12	0.12 to 0.20	0.20 to 0.30	0.30 to ---

Once you have determined 256 categories of sky condition, corrections were calculated by the ratio of reference diffuse irradiance to not corrected diffuse irradiance. The advantage of Lebaron Perez-model is that these 256 classes represent a "scan" of more complex analytical formulas and, since these values are tabulated, the computational time in processing is more efficient. Tab. 4 and Tab. 5 show the correction factors obtained for Lebaron Perez-correction method. In Tab. 4 are shown the original coefficients developed using Drummond assembly. In Tab. 5 are shown the adjusted coefficients for Botucatu for *MEO* assembly.

Table 4 - Correction factors for each parameter category. (LeBaron-Perez model with original coefficients)

1244	1.144	*1444*	1.230	*2244*	1.144	*2444*	1.230	*3244*	1.205	*3444*	1.287	*4244*	1.030	*4444*	1.169

The categories consist of the zenith angle parameters, geometrical factor, epsilon and delta, when combined, result in 256 categories. The groups was carried out by the indices "i", "j", "k" and "l", which represent, respectively, the zenith angle, geometrical factor, epsilon and delta, and each of these indices can take values from 1 to 4 depending on their range (Tab. 3). Thus, the cluster was determined by means of a number consisting of four digits in the format "ijkl". For example, the category 4321 describes a state with zenith angle ranging from 60 to 90, the geometrical factor of 1.100 to 1.132, epsilon 1.253 to 2.134 and delta 0 to 0.12. Some categories were not filled with solar irradiance data due to physical limitations of the parameters. In this case, the correction factor was adopted an average of the geometrical factor.

Tab. 4 shows the original correction factors proposed by LeBaron et al (1990), developed for the assembly of Drummond, ranging from 0.925 to 1.248. The largest corrections occurred for low cloudiness and high brightness index (delta), typical of the days of high solar declination. Minor corrections occurred for high cloudiness, wherein the isotropic behavior of the radiation is more evident.

We adjusted LeBaron-Perez's methodology for Botucatu atmospheric conditions and MEO shadow ring's assembly (LeBaron Perez-adjusted model). Tab. 5 shows the adjusted coefficients. Corrections ranged from 0.934 to 1.470. The largest correction also occurred for low cloudiness, showing great influence of the anisotropy. The lowest correction value occurred for high situation zenith angle and brightness index, probably linked to reflections inside the shading ring.

We also use the Dal Pai-Escobedo correction model, which is based on geometric factor (isotropy) and K_T atmospheric transmissivity (anisotropy). Tab. 6 shows the numerical factors used by the Dal Pai-Escobedo correction model for four K_T atmospheric transmissivity intervals.

Table 6 - Correction factors based on K_T atmospheric transmissivity intervals (*MEO* shading assembly).

K_T Interval	**Correction Factors**
$0 \leq K_T < 0.35$	0.975
$0.35 \leq K_T < 0.55$	1.034
$0.55 \leq K_T < 0.65$	1.083
$0.65 \leq K_T < 1$	1.108

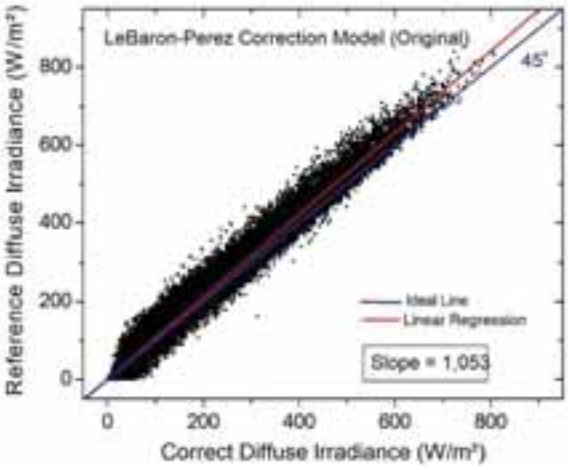
To validate the correction models, corrected diffuse irradiance were compared with reference diffuse irradiance by means of MBE and RMSE statistical indicators. MBE shows the long-term model behavior, with an underestimating or overestimating by the model. RMSE shows the dispersion of the model around the measure. Tab. 7 shows MBE, RMSE and slope, while Fig. 4 shows the graphs between reference diffuse irradiance and corrected diffuse irradiance by the correction models (LeBaron-Perez (Original), LeBaron- Perez (Adjusted) and Dal Pai-Escobedo).

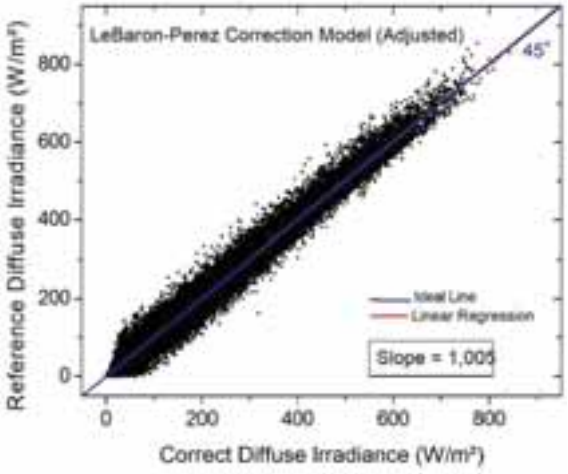
Table 7 - MBE, RMSE and slope for reference diffuse irradiance and corrected diffuse irradiance (LeBaron-Perez (Original), LeBaron-Perez (Adjusted) and Dal Pai-Escobedo).

Correction Model	**Statistical Indicators**				
	MBE (W/m^2)	**MBE (%)**	**RMSE (W/m^2)**	**RMSE (%)**	**Slope**

LeBaron-Perez - OR	-9,52	-5,93	22,87	14,24	1,053
LeBaron-Perez - AJ	-0,74	-0,46	17,32	10,79	1,005
Dal Pai-Escobedo	-0,02	-0,01	18,11	11,28	0,999

The worst performance was given to the model LeBaron-Perez correction with original coefficients, with an underestimation of 6% and dispersion of 14.3%. This result was expected, since the original model coefficients were developed for a different atmospheric condition of Botucatu, both aerosols, water vapor and clouds. This model was significantly improved when setting the coefficients for atmospheric situation of Botucatu, causing a reduction in MBE (~ 0.5%) and RMSE (~ 11%). A good performance was also attributed to Dal Pai-Escobedo correction model, with low values of MBE (- 0.01%) and RMSE (11.28%). With respect to slope, Lebaron-Perez adjusted and Dal Pai-Escobedo correction models had the same great performance, with slope closer to 1. Overall, LeBaron-Perez (Adjusted) and Dal Pai-Escobedo correction models exhibit the same order of accuracy in correction of diffuse irradiance measured by the shading ring. Dal Pai-Escobedo correction model takes a small advantage by presenting less parameters to classify the sky.





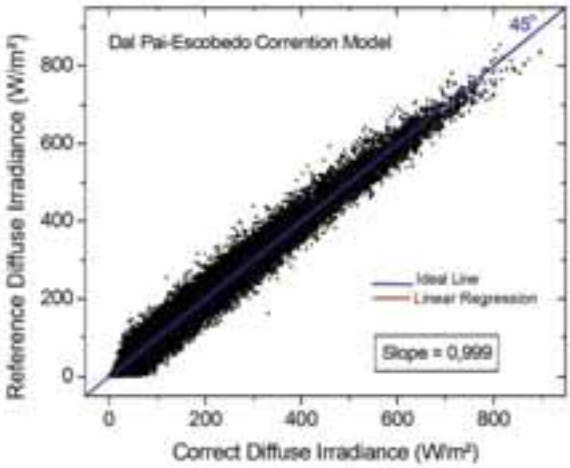


Figure 4 - Comparison between the diffuse irradiance reference and corrected diffuse irradiance by the correction models: a) LeBaron-Perez (Original). b) LeBaron-Perez (Adjusted). c) Dal Pai-Escobedo.

4. Conclusion

Our results allowed the following conclusions:

a) Lebaron-Perez correction model with the original coefficients, is not suitable to correct diffuse irradiance measured in Botucatu with the *MEO* shading ring method.

b) Lebaron-Perez correction model, when adjusted for Botucatu sky conditions, can be used to correct the diffuse irradiance measured by the *MEO* shading ring method.

c) Dal Pai-Escobedo correction model is suitable to correct diffuse irradiance measured by the *MEO* shading ring method.

d) Lebaron-Perez (Adjusted) and Dal Pai-Escobedo correction models has the same efficiency to correct diffuse irradiance.

e) We recommend Dal Pai-Escobedo correction model to correct diffuse irradiance because it uses fewer parameters.

Solis Clear Sky Scheme: Extension to High Turbidity, Development and Validation

Pierre Ineichen

University of Geneva, Institute for Environmental Sciences,
Department F.-A. Forel for environmental and aquatic sciences

Abstract

The Solis clear sky model is a spectral scheme based on radiative transfer calculations and the Lambert–Beer relation. Its broadband version is a simplified fast analytical version; it is limited to broadband aerosol optical depths at 700nm lower than 0.45, which is a weakness when applied in countries with very high turbidity such as China or India. This paper aims to extend the validity of the model to higher aerosol optical depth values. In 2014, Zhang published a modification of the scheme to extend its validity to aerosol optical depth values up to 6.5, but this extension is only applicable for the beam irradiance component and presents some weakness for very high turbidity values. In a first step, we tried to apply a correction to the Zhang adaptation. In order to extend the use of the original simplified version of Solis for high turbidity, we developed a new version of the broadband Solis, valid for the three components, global, beam and diffuse, and for the four aerosol types defined by Shettle and Fenn.

Keywords: Solis scheme, clear sky, radiation model, radiative transfer, high turbidity, water vapor

1. Introduction

The clear sky Solis scheme was first developed within the Mesor European program whose subject was the *management and exploitation of solar resource knowledge*. In 2008, Ineichen published a broadband analytical version of the Solis model for rural aerosol type, and in 2010 a version in the form of an excel tool for the four types of aerosols as defined by Shettle and Fenn. These versions were limited to aerosol optical depth values aod_{700} lower than 0.45. The anthropogenic heating and transportation activities conducted to a serious increase of the turbidity in countries like India or China. Looking into the limitations of the state of the art clear sky models, it appears that none is applicable for high turbidity. Indeed, for example, Gueymard CPCR2 model (Gueymard 1989) is limited to β turbidity values lower than 0.4 (which correspond to an aod_{700} of 0.64 for rural aerosol type, α = 1.3), Gueymard REST2 (Gueymard 2003) is limited to β = 1 (aod_{700} = 1.6, rural aerosol), Bird's model (Bird 1980) is defined for visibility values up to 23 km (which corresponds to an aod = 0.27) and the ESRA clear sky scheme (ESRA 2000, Rigollier 2000, Geiger 2002) was developed for Linke turbidity values T_L not exceeding a value of 7 (i.e. an aerosol optical depth aod_{700} = 0.44 for a 2 cm water vapor column). As the 2003 and 2008 versions of Solis diverge for high turbidity as shown by Zhang (2014), an extension of the model for higher turbidity values is needed.

This paper presents a validation and an adaptation of the model for the beam component extended by Zhang, and the development and validation of a new version of the analytical Solis scheme valid for the three radiation components, the global, the beam and the diffuse, and the four aerosol types, urban, rural, maritime and tropospheric.

2. The Solis scheme

The Solis scheme (Mueller 2004) is a model based on LibRadTran radiative transfer calculations (Mayer 2005, 2010). The basis of the model is the Lambert-Beer attenuation relation:

doi:10.18086/swc.2017.23.02 Available at http://proceedings.ises.org

$$I_{bn} = I_o \cdot \exp(-M \cdot \tau) \qquad \text{(eq. 1)}$$

where I_o is the extraterrestrial irradiance, I_{bn} the normal beam irradiance reaching the ground, M the optical air mass and τ the total atmospheric optical depth. This expression of the atmospheric transmittance is valid for monochromatic radiation, and the optical depth is then constant over the air mass range. Due to the non-linear nature of the exponential function, the Lambert-Beer relation has to be modified to extend the expression to wavelength bands; it takes then the following form:

$$I_{bn} = I_o \cdot \exp\left(-\frac{\tau}{\sin^b h}\right) \qquad \text{(eq. 2)}$$

where h is the solar elevation angle and b the fitting parameter obtained from RTM calculations at two different solar elevation angles.

When dealing with global irradiance, the Lambert-Beer relation is no longer applicable because of the back scatter effects, but remains a relatively good approximation, and

$$I_{gh} = I_o \cdot \exp\left(-\frac{\tau}{\sin^g h}\right) \cdot \sin h \qquad \text{(eq. 3)}$$

is a good fitting function for the horizontal global irradiance (Mueller 2004).

The source of the incoming diffuse irradiance is the attenuation of the beam radiation due to scattering process and it cannot be described in term of attenuation of the incoming radiation. Nevertheless, skipping the sin h term, the modified Lambert-Beer relation also works well:

$$I_{dh} = I_o \cdot \exp\left(-\frac{\tau}{\sin^d h}\right) \qquad \text{(eq. 4)}$$

At high aerosol load, *Io* has to be enhanced for the global and diffuse irradiance calculations, and a common modified *Io'* irradiance is defined for the three radiation components. The final expression of the model has then the following form:

$$I_{bn} = I'_o \cdot \exp\left(-\frac{\tau_b}{\sin^b h}\right) \quad I_{gh} = I'_o \cdot \exp\left(-\frac{\tau_g}{\sin^g h}\right) \cdot \sin h \quad I_{dh} = I'_o \cdot \exp\left(-\frac{\tau_d}{\sin^d h}\right) \qquad \text{(eq. 5)}$$

where τ_b, τ_g and τ_d are respectively the beam, global and diffuse total optical depths, and b, g and d the corresponding fitting parameters obtained from RTM calculations.

3. Zhang extension validation

To extend the range of the model application, Zhang added two terms in the extinction equation for the beam component, one for the aerosol optical depth K_{aod} , and one for the water vapor column K_w. These two terms are constant and defined in order to have a smooth behavior at $aod_{700} = 0.45$ which is the original Solis *aod* limitation (i.e. a null derivative for $aod_{700} = 0.45$).

We made a validation of the extended model against data evaluated with the Radiative Transfer Model (RTM) LibRadTran for a wide range of aerosol optical depths values, water vapor column and altitudes. As the Zhang extension shows slight deviations for low water vapor column and high turbidity values when plotting the modeled beam irradiance against the correspondent value calculated with the help of the LibRadTran radiation transfer model (see Fig. 1, left), we adapted the Zhang extension coefficient K_{aod} by making it *aod* dependent. This allowed to slightly better aligning the dots on the 1:1 diagonal as illustrated on the right graph of Fig. 1.

For altitudes from sea level to 7000 m, water vapor from 0.05 cm to 10 cm and *aod* from 0 to 7, and a solar elevation of 60°, the results are the following:

- Zhang extension $mbd = 0.2\%$ $sd = 4.7\%$
- Zhang + Ineichen $mbd = 0.2\%$ $sd = 2.8\%$.

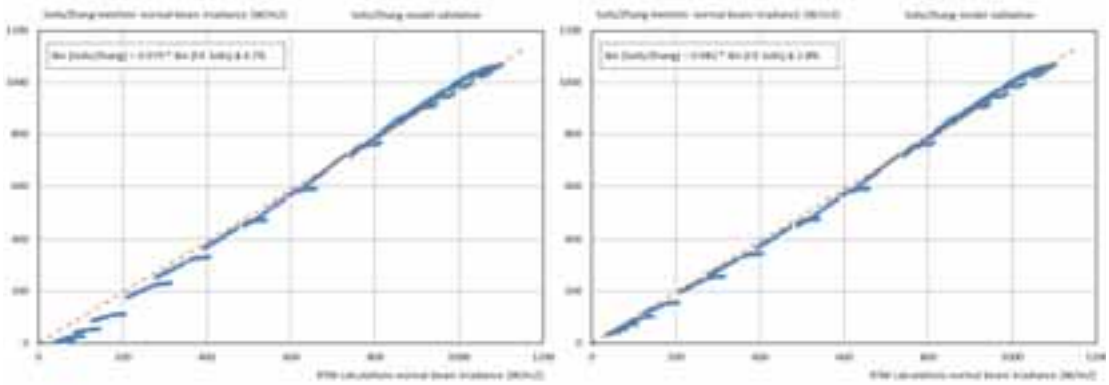

Fig. 1: Normal beam validation for the Zhang extension (left) and the Zhang-Ineichen correction (right)

4. Solis extension to high turbidity

The weakness of the Zhang extension is that it derives only the beam component. To circumvent this problem, we developed a Solis-2017 version that is applicable for values of *aod* up to 7. This means that the model goes up to very high atmospheric aerosol load, but one has to keep in mind that above *aod* = 2, it is not clear that the turbidity can be considered as an aerosol optical depth, but a turbidity due to bigger particles like sand, or in our countries, high altitude thin clouds. Nevertheless, it is important that in on-line automatic production processes, the model does not diverge and still derive coherent values, even with some discrepancies with ground measurements.

4.1. Model development

In a first step, we made spectral calculations with LibRadTran for the following parameters:

Tab. 1: aerosol types, altitudes, optical depths and water vapor columns values for the RTM calculations

aerosol type	altitude	aod_{550}	w [cm]
urban	sea level	0.01	0.01
rural	500m	0.03	0.03
maritime	1000m	0.05	0.05
tropospheric	2000m	0.1	1
	3000m	0.15	0.15
	4000m	0.2	0.2
	5000m	0.4	0.3
	6000m	0.7	0.5
	7000m	1	1
		1.5	1.5
		2	2
		3	3
		4	4
		5	6
		6	8
		7	10

These RTM calculations permit to generate the seven coefficients that drive the model: I_o', τ_b, b, τ_g, g, τ_d, and d. The next step is to develop an analytical formulation for these coefficients with the 4 input parameters given in Tab. 1.

The analysis of I_o', τ_b, and τ_g shows a similar behavior for these three parameters. The first analyzed dependence is with the aerosols optical depth *aod*. A third order polynomial model is applicable for the three parameters of the form:

$$I_o'/I_o = a \cdot aod^3 + b \cdot aod^2 + c \cdot aod + d \quad \text{(eq. 6)}$$

The behavior for I_o' and τ are represented on the Fig. 2 below.

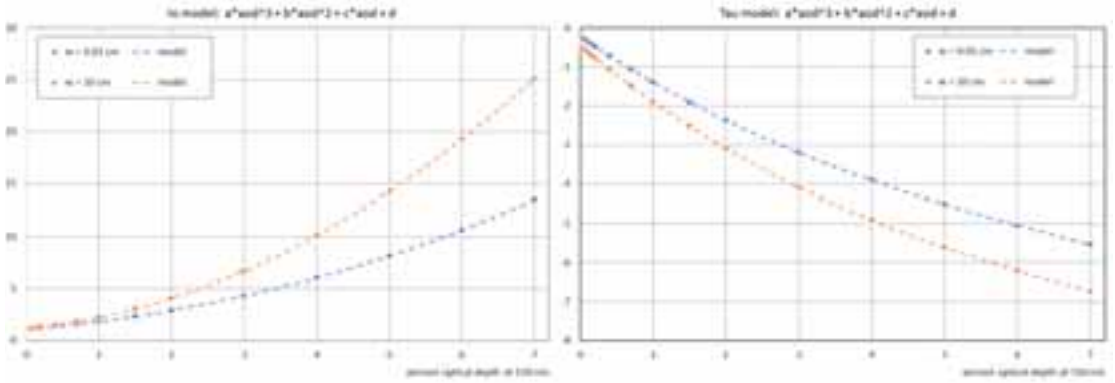

Fig. 2: Normal beam validation for the Zhang extension (left) and the Zhang-Ineichen correction (right)

We then analyzed the dependence of each of the a, b, c and d coefficient of equation 6 with the atmospheric water vapor content. The behavior of the four coefficients shows a water vapor dependence of the form:

$$n = n1 \cdot w^{0.5} + n2 \cdot \ln(w) + n3 \quad \text{(eq. 7)}$$

The best fits of two of these coefficients are given on the Fig. 3

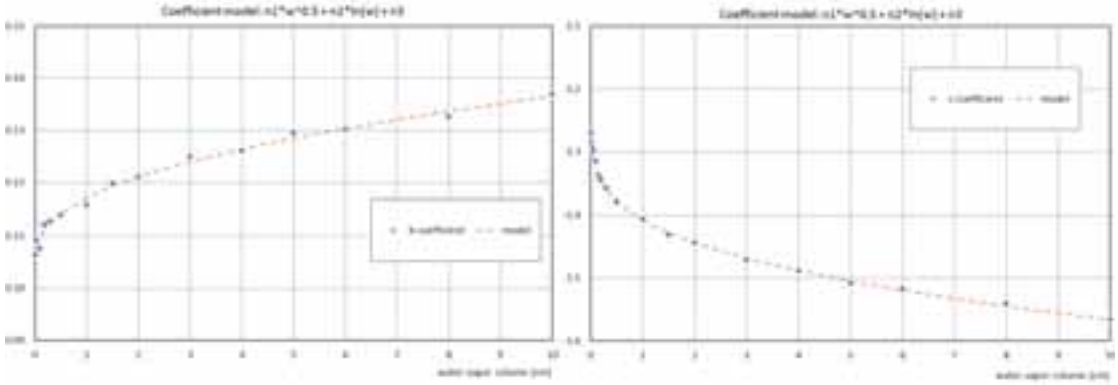

Fig. 3: Behavior of two of the cubic equation coefficients with the water vapor column

Finally, the dependence of the three above coefficients with the altitude, respectively the normalized atmospheric pressure p/p_o (the pressure p at a given altitude normalized by the corresponding sea level pressure p_o) is analyzed. It appears that a linear regression gives the best results.

The model has then the following form:

$$a = a_1 \cdot w^{0.5} + a_2 \cdot \ln(w) + a_3 \quad \text{(eq. 7a)}$$
$$b = b_1 \cdot w^{0.5} + b_2 \cdot \ln(w) + b_3 \quad \text{(eq. 7b)}$$
$$c = c_1 \cdot w^{0.5} + c_2 \cdot \ln(w) + c_3 \quad \text{(eq. 7c)}$$
$$d = d_1 \cdot w^{0.5} + d_2 \cdot \ln(w) + d_3 \quad \text{(eq. 7d)}$$

and each of the n_i coefficient is obtained with a linear function of p/p_o

$$n_i = n_{i1} \cdot p/p_o + n_{i2} \quad \text{(eq. 8)}$$

Finally, the inputs for the model for I_o', τ_b and τ_g, consist of the aerosol optical depth at 550 nm aod_{550}, the water vapor content of the atmosphere w and the relative atmospheric pressure p/p_o. The corresponding coefficient are given in a 3x3x2 matrix.

For τ_d, the best correlation we found is a relation with to τ_b and τ_g that has the form:

$$\tau_d = e + f \cdot \tau_g + g / \tau_b + h / \tau_g^2 + i \cdot \tau_g / \tau_b \quad \text{(eq. 9)}$$

The exponents of the sin (h) in the Lambert-Beer function are respectively best fitted as follow:

$$g = c_{a1} + c_{a2} \cdot \ln(w) + c_{a3} \cdot \ln(aod) + c_{a4} \cdot \ln(w)^2 + c_{a5} \cdot \ln(aod)^2 + c_{a6} \cdot \ln(w) \cdot \ln(aod) \qquad \text{(eq. 10)}$$

$$b = c_{b1} \cdot w^{\,cb2} \cdot c_{b3}^{\,aod} \qquad \text{(eq.11)}$$

$$d = c_{d1} + c_{d2} \cdot \ln(w) + c_{d3} \cdot aod + c_{d4} \cdot aod^2 + c_{d5} \cdot aod^3 + c_{d6} \cdot aod^4 + c_{d7} \cdot aod^5 \qquad \text{(eq. 12)}$$

4.2 Parameter validation

The validation of the seven parameters of the model is expressed as scatter plots between the modeled parameter and the corresponding LibRadTran calculated parameter. The validation points should be aligned on the 1:1 diagonal. On the graphs are also given the average parameter value, the mean bias difference *mbd*, the standard deviation *sd* and the correlation coefficient R^2. An illustration is given on Fig. 4 for I_o' and the *a* coefficient, urban aerosol type.

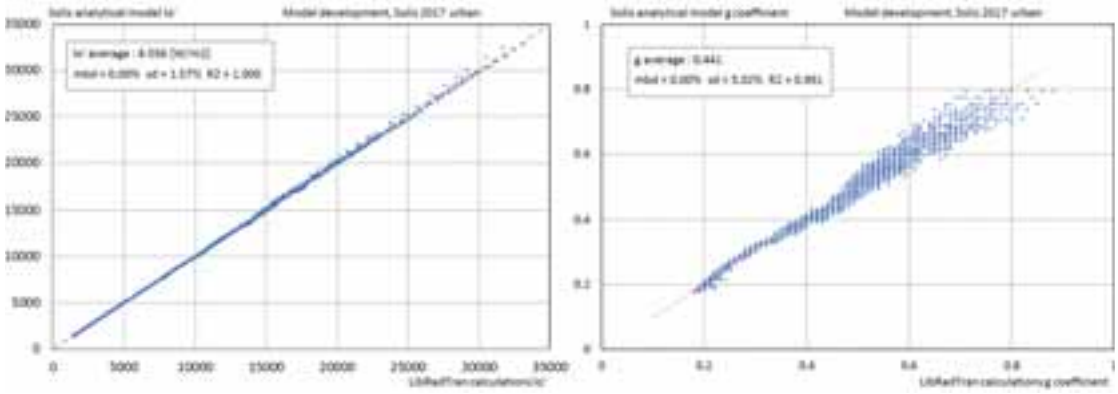

Fig. 4: I_o' and *g* coefficient validation

The average, *mbd* and *sd* values cannot be taken as an absolute validation of the precision as all the values calculated from the input matrix (altitude, *aod* and *w)* have the same weight. Nevertheless, it gives a good idea of the roughness of the parameter best fit. These values are given in Tab. 2.

Tab. 2: Average, *mbd*, *sd* and R^2 for the I_o', τ_b, *b*, τ_g, *g*, τ_d, and *d* model.

	Io'				τ_g				*g*

4.3 Irradiance validation

In the same way, the validation of the irradiance components is expressed as scatter plots and the usual first order statistics. Here again, due to the unweighted input matrix, the validation values obtained give not an absolute precision of the model. The scatter plots given on Fig. 5 below illustrate the behavior of the model. They represent the modeled values plotted against the corresponding values evaluated from RTM calculations, urban type aerosols, for the three components.

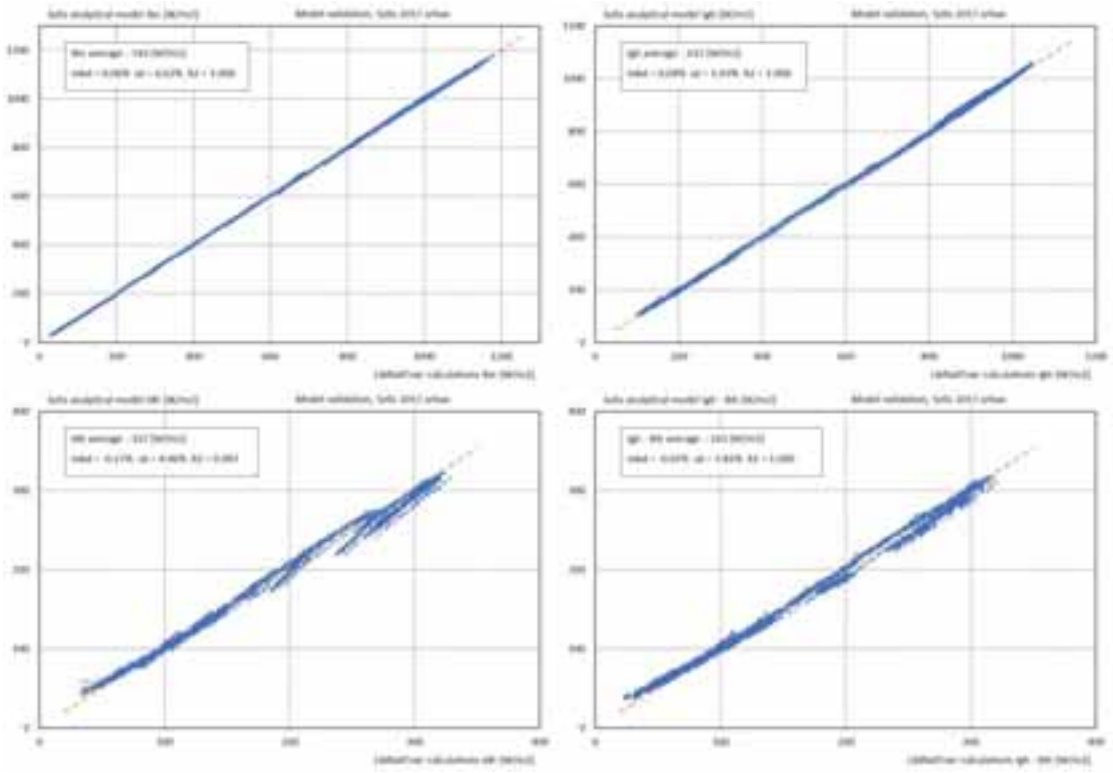

Fig. 5 Irradiance model validation

To obtain the diffuse component, there are two possibilities: the use of the model coefficients τ_d and d, or to evaluate it from the global and the beam components with the use of the closure equation $I_{dh} = I_{gh} - I_{gh}$. The diffuse obtained from the closure equation looks slightly better on Fig. 5, but it presents negative values for very low solar elevations.

The corresponding values are given in Tab. 3

Tab. 3: Average, *mbd*, *sd* and R^2 for the irradiance components.

	I_{gh}				I_{bn}				I_{dh}			
aerosol type	average	mbd	sd	R2	average	mbd	sd	R2	average	mbd	sd	R2
rural	727	0.4	3.9	1.000	549	0.0	4.7	1.000	223	0.5	7.3	0.998
urban	632	0.3	6.5	1.000	543	0.3	3.4	1.000	167	-0.3	6.8	0.997
tropo	740	0.2	4.7	1.000	559	-0.3	6.8	1.000	227	0.4	6.6	0.999
maritime	753	-1.3	16.7	0.997	519	-3.0	17.7	0.999	266	1.6	10.7	0.998

All the development and validation graphs for the urban aerosol type are given in the annex.

4.4 Components coherence

To visualize the behavior of the model and the coherence between the irradiance components, the model trends are represented for four typical values of aerosols optical depths *aod* (0.5, 0.9, 1.5 and 6) and a value of w = 1cm for the atmospheric water vapor column on Fig. 6. The ozone amount is taken constant at a value of 340 Dobson units, the aerosol characteristics is of urban type, and the albedo coefficient at 20%. On the left graph, the diffuse fraction I_{dh} / I_{gh} is represented versus the global clearness index K_t ($Kt = I_{gh} / I_o \sin h$), and on the right graph, the beam clearness index K_b ($K_b = I_{bn} / I_o$) versus the global clearness index. The Linke turbidity values T_L, evaluated from the aerosol optical depth and the water vapor column are also indicated on the graphs.

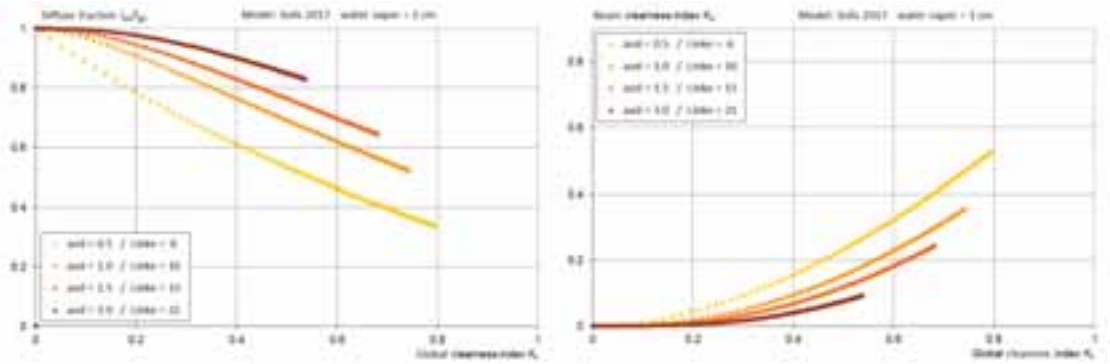

Fig. 6 Trends for the diffuse fraction and the beam clearness index versus the global clearness index

4.5 Validation on ground data from Geneva and Jaipur

The model should be validated against ground measurements acquired in highly polluted conditions. At this time, we had no access to such data (ground irradiances and *aod*); therefore, a preliminary validation is done on data acquired in Geneva for the years 2004 to 2011 where the *aod* is pretty low, and Jaipur with *aod* values up to 2.5 for 17 months in 2016 and 2017.

The average aerosol optical depth in Geneva is of order of 0.17 with a maximum of 0.5 during polluted episodes. As no specific aerosol optical depth values are measured in Geneva, we used one of the best state of the art model, REST2 (Gueymard 2004), to retrieve by retrofit the *aod* following the method described in Ineichen (2016). The clear sky condition selection is also described in Ineichen (2016). The results, illustrated on Fig. 7, are slightly better than for Solis 2008 (Ineichen 2016).

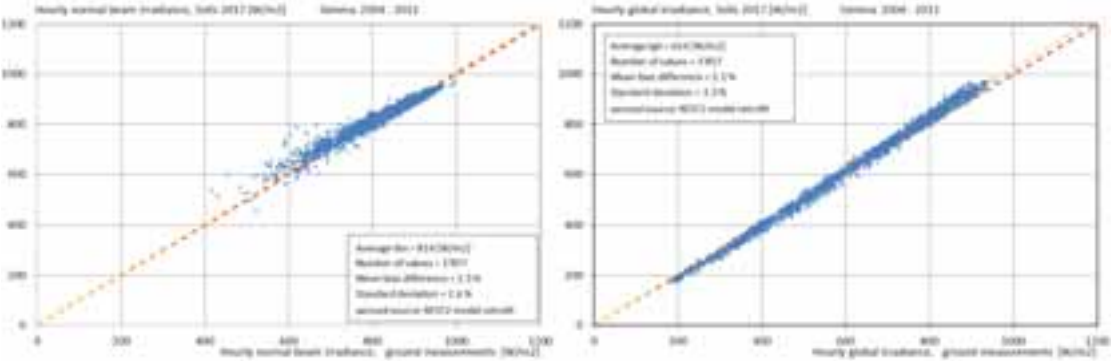

Fig. 7 Validation against ground data acquired in Geneva. The *aod* is retrofitted with REST2

For Jaipur, the aod_{550} values can reach 2.5, as this exceeds the REST2 limitations, we obtained values by retrofit with the use of Molineaux *bmpi* model (1998). The graphs are given on Fig. 8.

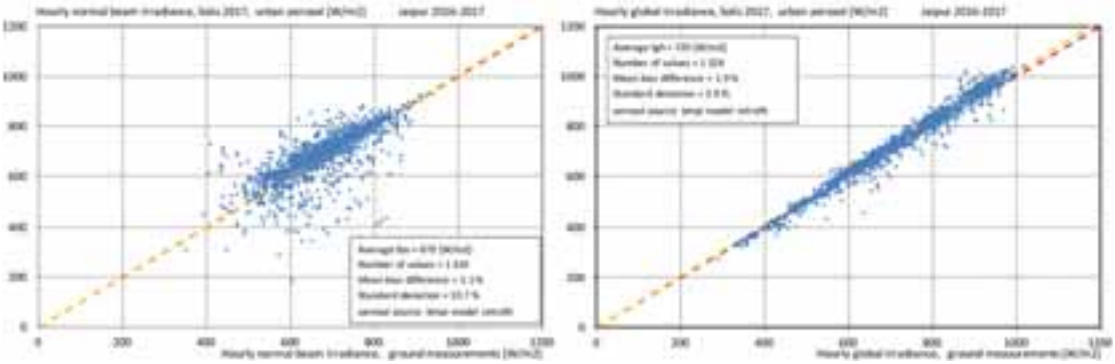

Fig. 8 Validation against ground data acquired in Jaipur. The *aod* is retrofitted with *bmpi* model.

It can be seen that the dispersion is higher, especially for the beam irradiance. This is due to the higher turbidity values, conditions for which it is difficult to determine the aerosol type. The extinction of the beam

irradiance can also be due to high altitude thin clouds or variability in the atmospheric water vapor column (evaluated from ground temperature and humidity).

5. Conclusion

When dealing with satellite images to derive the irradiance components on a wide space scale and every 15 minutes, the computer time should be as short as possible. The analytical Solis clear sky scheme was developed to fulfill this requirement but had the weakness to be limited to aerosol optical depth values lower than 0.45. The new analytical Solis scheme is valid for *aod* up to seven, even if very high values are not realistic as an optical depth; it is probably more due to bigger particles like sand, or in our countries, thin high altitude clouds. Nevertheless, in contrary to other clear sky models, this permit to produce coherent irradiance values, even with questionable input values.

The new Solis clear sky scheme is valid for aerosol optical depths values aod_{550} from 0.02 to 7, atmospheric water vapor w content from 0.01 to 10 cm, and altitude from sea level to 7000 m, and four aerosol types as defined by Shettle and Fenn. For the urban, rural and tropospheric aerosol types, the validation against the original RTM calculations presents no bias and a standard deviation lower than 1% for the global and the beam component, and 3% for the diffuse. When dealing with maritime aerosol type, the standard deviation is respectively 2.2%, 3.4% and 4% for the global, the beam and the diffuse components.

A preliminary validation against ground measurements acquired in Geneva and Jaipur gives a mean bias difference of 2%, a standard deviation of 3-4% for the global component, and a mean bias difference of 1.3% with a standard deviation of 2.6% and 10.7% for the beam component for respectively Geneva and Jaipur.

6. Nomenclature

I_{gh}	horizontal global irradiance	*aod*	aerosol optical depth
I_{bn}	normal beam irradiance	τ	total atmospheric optical depth
I_{dh}	horizontal diffuse irradiance	w	atmospheric water vapor column
I_o	sun-earth distance corrected solar constant	α	particle size exponent
K_t	global clearness index	β	turbidity coefficient
K_b	beam clearness index		
mbd	mean bias difference	M	optical air mass
sd	standart deviation	T_L	Linke turbidity
R^2	correlation coefficient	p	atmospheric pressure at the considered altitude
h	solar elevation	p_o	atmospheric pressure at sea level

Evaluation of Solar Energy Losses for the Heliostat-to-Receiver Path of a Tower Solar Plant for Different Aerosol Models

Abstract

The efficiency of solar tower plants is impacted twice by atmospheric aerosols. First, aerosols attenuate the direct solar irradiance reaching the heliostats, and then reduce the irradiance reflected by these heliostats while it propagates to the receiver. The aerosol transmittance from the top of atmosphere to the ground is well modeled by many radiative transfer codes, but its counterpart for the heliostat-to-receiver slant path has only been estimated for a very limited number of ideal atmospheric conditions. In this work, the solar losses for the heliostat-to-receiver slant paths are extensively analyzed for different aerosol models, atmospheric conditions, and mirror-to-tower geometries by performing detailed simulations with the MODTRAN radiative transfer code. Reductions up to 30% of the solar irradiance incident on distant heliostats can occur under moderately turbid situations, due to the concentration of aerosols near the ground. It is found that site elevation is not a significant factor, contrary to what was anticipated, according to an old empirical model of the literature.

Keywords: Solar tower plants, transmission losses, aerosol models, atmospheric attenuation, CSP.

1. Introduction

The accurate evaluation of the irradiance reaching the receiver of a Tower Solar Power plant (TSP) is of primary importance to prepare its design, and later evaluate its actual performance. The literature mentions numerous radiative transfer models (e.g., SMARTS, libRadtran, or MODTRAN) that can derive the spectral aerosol transmittance from the top of the atmosphere to the surface with sufficient accuracy for normal plant operation, provided that the bulk aerosol optical properties are known over the vertical column. Most of these models, however, are not suitable to easily predict the atmospheric radiation losses over the heliostat-to-receiver slant path. Such calculations are complex, time consuming, and require specific inputs (such as vertical aerosol profiles) that are usually not known. Moreover, most models (with the notable exception of MODTRAN, or its predecessor, LOWTRAN) are not designed to calculate the radiation transmission over short slant paths in any arbitrary direction. Some efforts were conducted several decades ago to derive simple empirical parameterizations from detailed modeling and obtain such results in a more accessible form. Examples include the empirical Pitman and Vant-Hull model (1981), as well as modules that are part of the DELSOL and MIRVAL CSP design codes, for instance. The main drawback of this approach is the extremely limited number of possible atmospheric conditions, i.e., lack of general validity. In this respect, the range of possible atmospheric conditions that these simplified models can handle is limited to a few visibility values only (typically 23 km and 5 km). Originally, such values were assumed to describe clear conditions and hazy conditions, respectively.

In recent years, this topic has gathered renewed interest, so that new studies have been conducted to improve this type of algorithm (Gueymard et al., 2017; Hanrieder et al., 2016, 2017; Sengupta and Wagner, 2012). Previous investigations by the authors have shown that the attenuation specifically caused by water vapor near the surface was significant, albeit small in comparison to that of aerosols (Gueymard et al., 2017; López et al., 2016). In addition, the measurement of horizontal visibility for the specific needs of the TSP industrial sector has progressed, with the development of several low-cost automatic devices, such as forward-scatter-based visibilimeters (Hanrieder et al., 2017). Some of the first studies using the latter technology report that visibility

doi:10.18086/swc.2017.23.03 Available at http://proceedings.ises.org

values are commonly much higher than 23 km (López et al., 2017). These results constitute a motivation to conduct more in-depth studies, with the goal of better understanding the effect of variable atmospheric conditions on the attenuation of solar radiation after reflection by heliostats.

In this work, an extensive and detailed analysis of the aerosol transmittance is undertaken with MODTRAN for heliostat-to-receiver slant paths of varied lengths. Five aerosol models are used along with four atmospheric profiles and two different ground elevations. The combination of these aerosol models with the water-temperature-pressure profiles at each ground level generates a total of 40 different model atmospheres. The resulting large range of atmospheric conditions is analyzed in this study, with the underlying goal of developing a general simplified model.

2. Methodology

2.1 Slant atmospheric attenuation

The aerosol-induced irradiance attenuation A taking place along the mirror-to-receiver slant path is evaluated (in percent) by means of the following expression:

$$A = 100\,\frac{G_{bT0}-G_{bT}}{G_{bM}} \qquad \text{(eq. 1)}$$

where G_{bT0} is the reflected direct normal irradiance (DNI) reaching the receiver at the top of the tower assuming no aerosol, G_{bT} is the reflected DNI reaching the receiver but assuming the presence of aerosol, and G_{bM} is the DNI incident on the mirror (Fig. 1). The atmospheric conditions are assumed identical for both G_{bM} and G_{bT}. In this way, eq. (1) represents the percent fraction of energy loss due exclusively to aerosol extinction along the slant range considered. Additional extinction is expected, and would be caused primarily by water vapor (Gueymard et al., 2017; López et al., 2016).

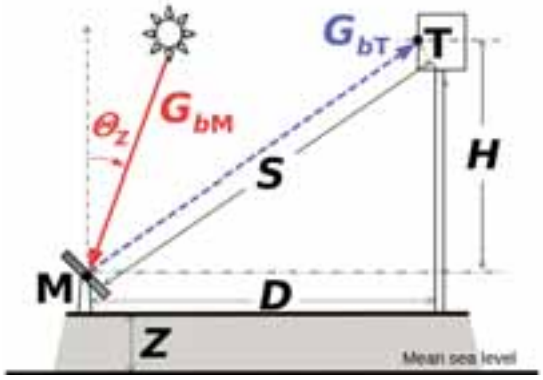

Fig. 1: Schematic description of a solar power tower plant, and nomenclature.

The irradiance incident on the mirror M, G_{bM}, and the irradiance reaching the tower receiver T reflected by the mirror (Fig. 1) may be obtained as:

$$G_{bM} = \int_{\lambda 1}^{\lambda 2} T_{\lambda M} G_{b\lambda 0}\,\mathrm{d}\lambda \qquad \text{(eq. 2)}$$

$$G_{bT} = \int_{\lambda 1}^{\lambda 2} \rho_{\lambda} T_{\lambda M-T} T_{\lambda M} G_{b\lambda 0}\,\mathrm{d}\lambda \qquad \text{(eq. 3)}$$

$$G_{bT0} = \int_{\lambda 1}^{\lambda 2} \rho_{\lambda} T_{\lambda M-T0} T_{\lambda M} G_{b\lambda 0}\,\mathrm{d}\lambda \qquad \text{(eq. 4)}$$

where $G_{b\lambda 0}$ is the extraterrestrial spectral irradiance, $T_{\lambda M}$ is the atmospheric spectral transmittance for the Sun-to-Mirror path (which depends on the abundance of various atmospheric constituents, and thus varies over time), $T_{\lambda M\text{-}T}$ is the spectral transmittance for the Mirror-to-Tower slant path taking into account the aerosol load, $T_{\lambda M\text{-}T0}$ is also the spectral transmittance for the Mirror-to-Tower slant path but considering no aerosols in the slant path, and ρ_λ is the mirror's spectral reflectance (set to 1 here for the sake of simplicity in this work). The integration limits are fixed to λ_1 = 0.28 μm and λ_2 = 10 μm. Following López et al. (2016), the solar zenith angle of the DNI incident on the mirror is varied incrementally from 0º to 89º, as shown in Table 1. Although TSP plants do not operate under large solar zenith angles, values higher than 80º are considered here in order to analyze the trend of transmission loss under these extreme limits.

Tab. 1: Values of the MODTRAN inputs used to obtain the simulated database.

Inputs to MODTRAN	Values
Θ_Z (degrees)	0, 10, 20, 30, 40, 50, 60, 70, 80, 85, 89
H (m)	100, 200, 250
D (km)	0.15, 0.5, 1, 2, 4
Z (km)	0, 1
Vis (km)	23, 50, 75
Aerosols Model	Rural, Maritime, Urban, Tropospheric, Desert
Atmospheric Model	MLW, MLS, Tropical, USSA

MODTRAN version 4v1r1 (Berk et al., 1989) is the radiative transfer code selected here for its remarkable capability of computing short-range transmittances. MODTRAN is the successor of LOWTRAN, which was used initially to demonstrate the impact of near-surface atmospheric constituents on the slant attenuation (Vittitoe and Biggs, 1978). MODTRAN is used parametrically to calculate each irradiance value in eqs. (2-4) for a number of specific atmospheric conditions. In particular, transmittances $T_{\lambda M\text{-}T}$ and $T_{\lambda M\text{-}T0}$ are obtained using MODTRAN's slant-path option, which evaluates the high-resolution spectral transmission between two points at finite distance—the mirror and the receiver, in the present case. MODTRAN considers the detailed effects of any vertical variation in atmospheric constituents, as well as the optical effects caused by atmospheric refraction and earth curvature..

2.2 Visibility and optical characteristics of aerosols

MODTRAN evaluates the radiative impact of aerosols as a function of their abundance. The latter is reported in terms of "visibility", whose definition needs to be clarified here. In meteorological terms, visibility is an old *subjective* estimation technique based on a human observer's evaluation of the maximum distance at which distant objects can be distinguished against a contrasting background, usually the sky. Modern instruments, like visibilimeters or transmissometers, now provide an *objective* evaluation of visibility, which is referred to as "meteorological optical range" (MOR), according to Koschmieder's law (Koschmieder, 1925):

$$MOR = \frac{\ln\left(1/\varepsilon\right)}{\sigma} \qquad \text{(eq. 5)}$$

where σ is the air extinction coefficient at 550 nm and ε is the threshold contrast between an object and the background. According to the World Meteorological Organization (WMO, 2014), ε must be set to 0.05 to obtain MOR. Another definition, referred to as "meteorological range" (MR) in MODTRAN, uses a more optimistic threshold contrast ε = 0.02:

$$MR = \frac{\ln\left(1/0.02\right)}{\sigma} \qquad \text{(eq. 6)}$$

It is straightforward to perform the conversion between these two definitions: MR = 1.306 MOR. The relationship given by eq. (5) or (6) may be deceptively simple, however, since its derivation depends on a number of serious assumptions (Middleton, 1952). Even though MODTRAN and its predecessor, LOWTRAN, use the term "visibility" to describe the aerosol input, what is actually meant is MR, which is highly confusing, since it is different from MOR. Kneizys et al (1980) acknowledged the difference between MR and observer (subjective) visibility, V_{obs}, and indicated that MR ≈ (1.3 ± 0.3) V_{obs}. (The coefficient 1.3 simply represents the ratio MR/MOR = ln(1/0.02)/ln(1/0.05).) Hence, MOR is just a technical term for what was previously known as "observer visibility", or V_{obs}. In what follows, the abbreviation VIS is used to conform to MODTRAN's usage, even though the intended variable name is MR.

One key issue of using VIS to describe the optical impact of aerosols is the limited number of monitoring sites, mostly at airports. Hence, access to actual local data is difficult in practice. In comparison, there are many more sources of data that provide the aerosol optical depth (AOD), based on ground measurements with sunphotometers, chemical transport models (and derived reanalysis models), or space borne remote-sensed observations. Additionally, visibilimeters installed at airports have a very limited range, typically 20 km (Gueymard, 2012), which is not enough to provide the precise inputs needed here. A relationship between VIS and AOD is thus desirable, so that VIS can be estimated from AOD observations, or vice versa. Experimental studies have shown that the two variables are only weakly correlated in practice, due to a number of difficulties (Wilson et al., 2015). For the present study, what is important is the theoretical correspondence between VIS and AOD, as specifically applicable to MODTRAN. This desired relationship is built in SMARTS (Gueymard, 2001) to allow the conversion of VIS to AOD or vice versa. Table 2 provides the needed information to allow comparisons between the results presented here (based on VIS) and those provided in other studies that are rather based on AOD (Sengupta et al., 2012).

Tab. 2: Approximate equivalence between Meteorological Range (as used in MODTRAN), Visibility, and Aerosol Optical Depth at 550 nm, based on SMARTS simulations.

Meteorological Range (km)	Observer/Subjective Visibility (km)	AOD at 550 nm
5	3.8	1.1730
10	7.7	0.6667
15	11.5	0.4744
20	15.4	0.3686
23	17.7	0.3251
25	19.2	0.3014
50	38.5	0.1596
75	57.7	0.1126
100	76.9	0.0901
150	115.4	0.0667
200	153.8	0.0549

Various aerosol loads are considered in this study by means of three surface visibility values: 23, 50 and 75 km (higher visibilities correspond to lower aerosol optical depths, as shown in Table 2). Various aerosol models are available in MODTRAN, and can be selected in order to analyze the effect of the optical properties of each possible aerosol type on transmission losses. Five common aerosol models are selected here: rural, maritime, urban, tropospheric, and desert (Tab. 1). The desert aerosol model is an important aerosol type since it is representative of arid and semiarid regions, which are favorite emplacements for TSP plants due to the high DNI resource there. The desert aerosol model is dependent on wind speed, leading to the expectation that the slant-path attenuation will increase with wind speed. This is mainly due to the hematite contained in sand particles, which leads to selective absorption at visible wavelengths, becoming more pronounced when it is entrained as wind speed increases (Longtin et al., 1988). In this first analysis, wind speed is fixed to 10 m s^{-1}, corresponding to the reference value given in MODTRAN.

2.3 Other variables

Since the concentration and mixture of aerosol particles have variable vertical profiles, the potential influence of ground elevation on transmission losses is explored by considering two site elevations, Z = 0 km and 1 km above mean sea level. For elevated sites (e.g., Z = 1 km), MODTRAN´s modeling is more elaborate than at sea

level. The aerosol densities below 6 km are subjected to vertical compression, in such a way that the aerosol sources are moved up to that altitude. Hence, the energy loss computation may be performed using visibility observations at the elevated site, which eliminates the need for additional calculation (scaling between sea level and the actual site elevation). In other words, MODTRAN transparently takes into account the fact that the aerosol concentration near the surface at an elevated site is normally larger than in the free atmosphere at the same altitude.

In addition to the above variables, which are explicitly related to the aerosol effect, the impact of different atmospheric water-temperature-pressure profiles on the transmission losses by aerosols is also analyzed by means of four built-in standard atmosphere models: Mid-Latitude Winter (MLW), Mid-Latitude Summer (MLS), Tropical, and U.S. Standard Atmosphere (USSA). The spectral distribution of DNI both at the mirror and at the receiver is modified according to the atmosphere model. Consequently, the transmission loss by aerosols can also be expected to differ. All the gaseous concentrations (such as water vapor) are set to the reference values imposed by the selected atmosphere model.

Finally, different slant ranges are considered between mirror and receiver. The geometries selected here attempt to mimic the typical configurations encountered in current or future TSP plants. Three tower heights, H, are used (100, 200 and 250 m), as well as five values for the horizontal mirror-to-tower distance D (0.15, 0.5, 1, 2 and 3 km). The resulting combinations of H and D represent a large range of possible geometries, which is needed to generalize the results.

3. Results

3.1 Effect of zenith angle

Figure 2 shows the transmission losses, A, or "energy losses" due to aerosols alone, as a fraction of G_{bM} for a set of atmospheric conditions: eleven zenith angles between 0º and 89°, three slant ranges, S, corresponding to the combination of a single tower height (H = 100 m) with three mirror-to-tower horizontal distances (D = 0.15, 1, and 4 km), ground at sea level (Z = 0 m), and three visibilities (23, 50, and 75 km). All five aerosols models are used here, combined with the MLS atmosphere.

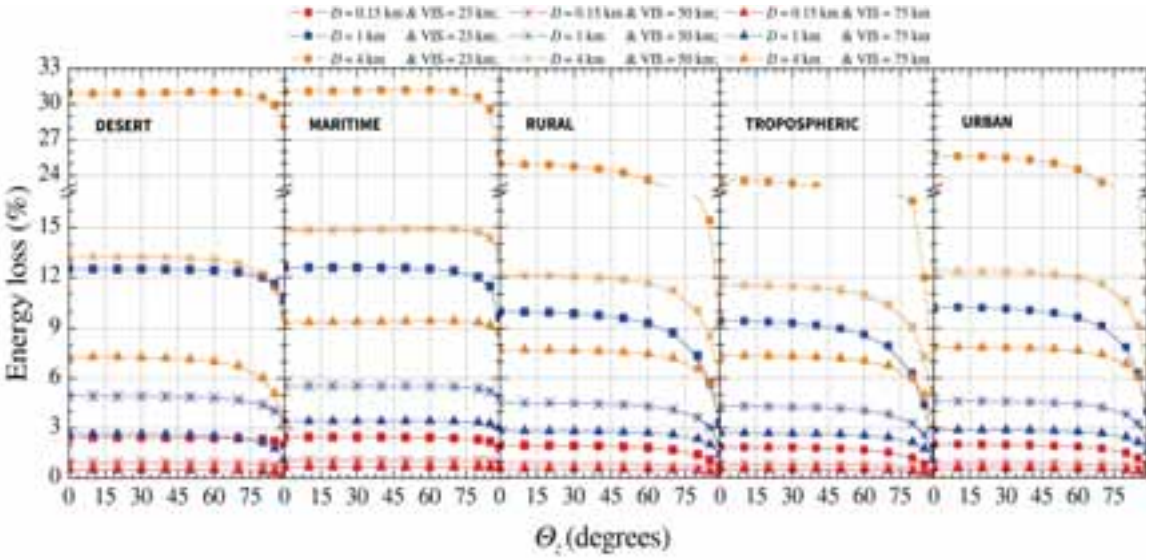

Fig 2. Energy losses in the mirror-to-receiver slant path versus zenith angle for five different types of aerosol, using the MLS Atmosphere, three visibilities (23, 50 and 75 km), a tower height of 100 m, three horizontal mirror-to-tower distance (D = 0.15, 1 and 4 km) and a site at sea level (Z = 0 m).

For short distances (D = 0.15 km), the energy losses are almost constant for any visibility and any aerosol model. The impact of zenith angle is also found negligible over the normal operation range of TSP plants. In contrast, when slant range increases (using D = 1 and 4 km), the energy losses corresponding to the rural, urban and tropospheric aerosol models show a higher dependence with zenith angle, and get stronger when D increases. When the sun rises and Θ_Z decreases from 75º to 30º, energy losses increase by 2% in the case of rural

and urban aerosols, and even more for tropospheric aerosols. This relationship with zenith angle is also observed for the energy losses that are specifically due to water vapor (López et al., 2016). The type of aerosol mixture is important here, since desert or maritime aerosols do not produce this marked zenith angle dependence, at least for $\Theta_Z < 80^o$. The results shown in Fig. 2 are representative of those corresponding to the other tower heights, horizontal mirror-to-tower distances, ground elevations and atmospheric profiles.

3.2 Effect of atmosphere model

Similar to Fig. 2, Fig. 3 shows the calculated energy losses as a function of zenith angle for a slant range corresponding to a tower height H = 100 m, a mirror-to-tower horizontal distance D = 1 km, ground at sea level (Z = 0 m), and two different visibilities, 23 and 75 km. The five aerosols models and all four atmosphere models are used here to evaluate their combined effects.

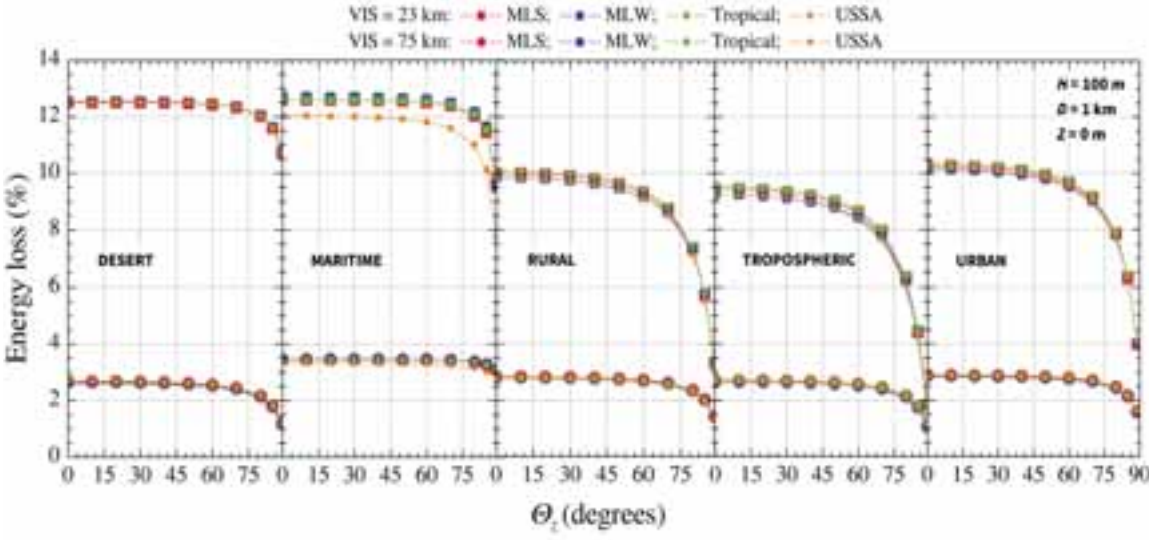

Fig 3. Energy losses in the mirror-to-receiver slant path versus zenith angle for five different types of aerosol and four atmosphere models, using two visibilities (23 and 75 km), a tower height of 100 m, a horizontal heliostat-to-tower distance D = 1 km, and a site at sea level.

In general, it is found that the atmosphere model has little impact, if not negligible. With the desert aerosol model, for instance, all four atmosphere models provide the same energy loss for each of the two visibilities (23 km and 75 km), with maximum energy losses of about 13% and 3%, respectively. This means that the desert aerosol model appears insensitive to changes in meteorological conditions such as temperature, pressure, relative humidity, or water vapor content. This tendency is also observed with the remaining four aerosol models when used under very clear conditions (VIS = 75 km). Moreover, under such ideal conditions, all types of aerosol mixtures yield a similar energy loss of ≈3%, except for the maritime aerosol (≈3.5%). When visibility reduces to 23 km, the energy losses exhibit a weak dependence on the type of atmosphere model, with differences lower than 0.5%. The only exception is when the USSA atmospheric model is used along with the maritime aerosol, which leads to energy losses lower than 1% compared to what is obtained with the MLS, MLW or Tropical atmospheres. This is likely caused by the high sensitivity of the optical properties of maritime aerosols to variations in relative humidity. As a matter of fact, the aerosol mixtures of oceanic origin have significantly different properties compared to continental aerosol types, in particular (Shettle and Fenn, 1979). In the lower atmosphere, the MLS, MLW and Tropical atmospheres have vertical profiles of relative humidity that are similar between each other, but significantly different from the USSA model.

3.3 Effect of ground elevation

Site elevation has been identified as a critical factor by Pitman and Vant Hull (1982), and thus deserves attention. Its effect is analyzed here by evaluating the energy losses for two surface elevations (Z = 0 and 1 km), while parametrically varying the sun's zenith angle and using the MLS atmosphere for various conditions: H = 100 m, D = 1 km, the five aerosol models, and two visibilities. The results appear in Fig. 4a for VIS = 23 km and Fig. 4b for VIS = 75 km. It is observed that the elevation effect seems negligible in all cases, since the energy losses are almost identical for any input configuration at a specified Z. This is contrary to the Pitman and

Vant-Hull (1982) conclusions, which was not expected. A likely explanation for this discrepancy is that MODTRAN (used here) and LOWTRAN (used by Pitman and Vant Hull, among others) differ on how they consider visibility at an elevated site. This is directly related to the vertical aerosol scaling that is performed transparently by MODTRAN (but not in LOWTRAN), as mentioned above. It is also possible that the assumptions and results provided here, which are relative to aerosol-induced losses only, are not exactly compatible with those of Pitman and Vant Hull. This will require further scrutiny.

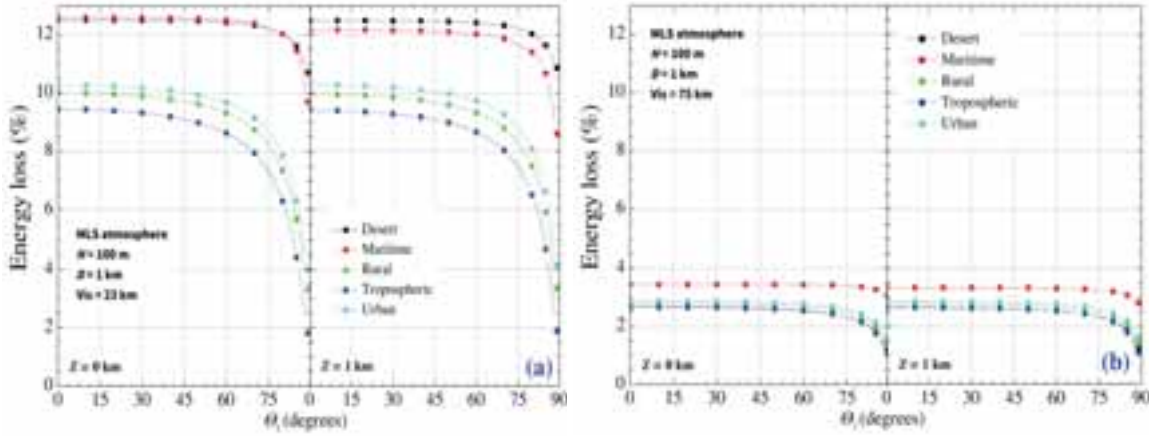

Fig 4. Energy losses versus zenith angle for five types of aerosol and two visibilities: (a) VIS = 23 km, and (b) VIS = 75 km. The MLS atmosphere, a tower height of 100 m, a horizontal mirror-to-tower distance *D* = 1 km, and two ground altitudes (*Z* = 0 and 1 km) are selected in both cases.

3.4 Effect of slant path range

The last parameters to be analyzed are those determining the length of the slant path *S* followed by the reflected sun rays from the mirror up to the receiver at the top of the tower: the horizontal mirror-to-tower distance *D* and the tower height *H*. Figure 5 displays the energy loss for a fixed zenith angle (Θ_z = 30º) and various combinations of *D* and *H*, per the values listed in Table 1. Under very clear conditions, corresponding to VIS = 75 km, the energy loss is not sensitive to variations in tower height, even though the aerosol concentration normally decreases with elevation in the free atmosphere. It is possible that this lack of sensitivity reflects the crude vertical resolution (1 km) of aerosol and atmosphere models in MODTRAN.

Desert, rural, tropospheric and urban aerosol determine similar energy losses, ranging from < 1% for *D* = 0.15 km, up to 7% for *D* = 4 km. The attenuation due to maritime aerosols is slightly higher, reaching a maximum of 9%. When a lower visibility (23 km) is considered, the influence of *H* on *A* is weak for large distances (*D* > 2 km), and becomes imperceptible for short distances (*D* < 2 km). Only the attenuation due to maritime aerosols shows any dependence on tower height. The results for the other atmospheres are similar to this.

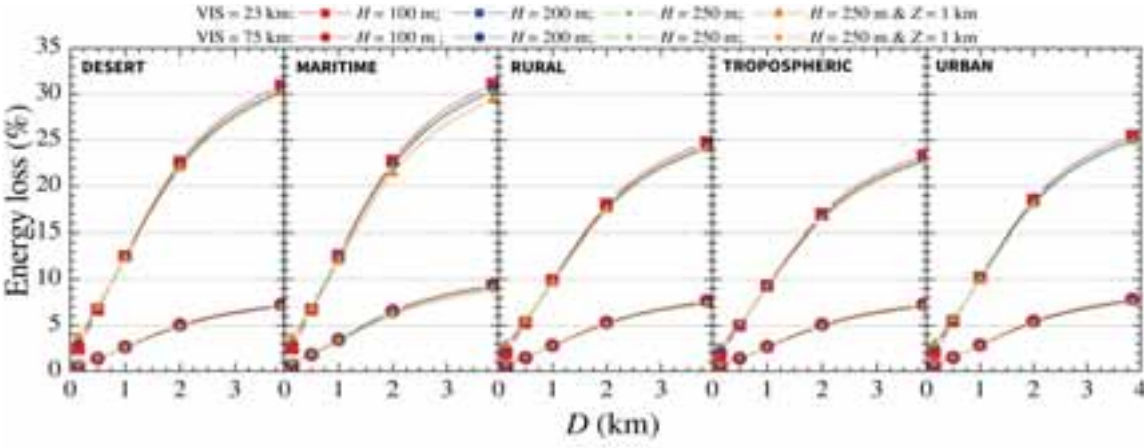

Fig 5. Energy losses vs. horizontal mirror-to-tower distance for five different types of aerosol. All cases use the MLS atmosphere, two visibilities (23 and 75 km) and three tower heights (*H* = 100, 200 and 250 m). In addition, the red, blue and green lines correspond to *Z* = 0 km, whereas the orange line is for *Z* = 1 km.

3.5 Generalized results

The results provided above show how energy losses depend on a number of variables. Some of these variables have more impact than others. Because of the intricacies of all the implied relationships, it is desirable to derive a simplified, generalized model. Results for the desert and maritime aerosols are similar, but differ from those obtained with the other three aerosol models. A simplification thus consists in considering only two distinct groups of possible aerosols: Either desert/maritime or rural/urban/tropospheric. In each group, the energy losses do not vary much with aerosol type, so that an aerosol-independent average can be used for simplification. Moreover, since tower height, atmosphere model, surface elevation and zenith angle have no significant effects, the only remaining critical factors are VIS and *D.* Plots providing the energy loss *A* as a function of VIS and *D* for each aerosol group appear in Fig. 6. As could be expected, *A* is a strong function of both VIS and *D*. *A* is also affected by the aerosol group, but to a lower extent—particularly for high visibilities. In theory, these plots can also be used to rather relate *A* to AOD and *D*, using the data in Tab. 2. As noted above, however, the relationship between VIS and AOD is not an exact one under real conditions. Hence, additional studies would be needed to better establish the relationship between *A* and on-site AOD observations, for instance.

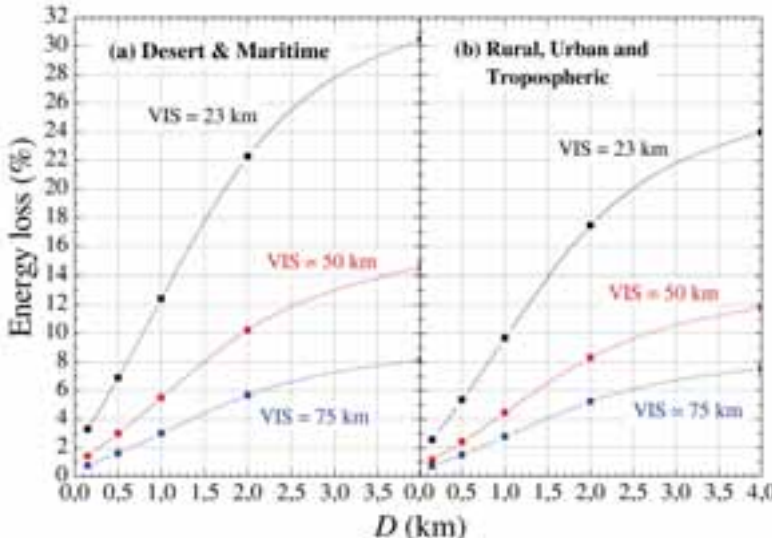

Fig. 6. Generalized results relating the energy lost between a mirror and the tower receiver to VIS and horizontal distance *D* for two distinct groups of aerosols.

4. Conclusions

For Tower Solar Plants (TSP), the energy losses for the mirror-to-tower slant path caused by the presence of aerosols near the ground have been analyzed as a fraction of the DNI incident on the mirror. Many different configurations of possible TSP geometries and atmospheric conditions were employed to generate the transmission losses, using the MODTRAN spectral atmospheric code with its slant-path option. A first result obtained here is that the energy loss does not appreciably depend on the specific atmosphere model that can be selected in MODTRAN (e.g., mid-latitude winter, mid-latitude summer, tropical or USSA). This leads to an important simplification, since the energy loss caused by aerosols can be properly calculated for any site using only one atmospheric profile. Similarly, the energy loss is virtually independent from the sun's zenith angle (up to ≈75°), and does neither depend on ground elevation, nor on the TSP's tower height. The main atmospheric variable driving the energy loss caused by aerosols is visibility (or more precisely, "meteorological range", per MODTRAN's definition). Selecting various types of aerosol (rural, urban, tropospheric, maritime, or desert) leads to different energy losses and different dependences on the sun's zenith angle. However, the five aerosol models may be reduced to only two categories: (i) 'optically thin aerosols', consisting of the rural, urban and tropospheric aerosols, which yield maximum energy losses lower than 25% for a 23-km visibility and 4-km horizontal distance; and (ii) 'optically thick aerosols' composed of the desert and maritime aerosols, generating maximum energy losses of 30% for the same visibility and distance.

Taking some possible simplifications into account, all results can be synthesized into two plots (one for each aerosol group) that provide the aerosol-induced energy losses at any site as a function of visibility and horizontal mirror-to-tower distance. A theoretical correspondence between visibility, as defined here, and aerosol optical depth is also provided, in case visibility measurements are not available. Finally, the present results will allow the development of future parameterizations of the transmission losses, based on only a limited number of essential variables. In addition, the proposed results can be used as benchmark values for assessing the performance of other models of the literature, such as those used in various CSP design codes.

Assessment of Hydrokinetic Potential in the Umbeluzi Basin, Mozambique

Summary

Hydrokinetic turbines can play a pivotal role in providing electricity access to remote areas in Mozambique, as stand-alone isolated mini-grids. However, the suitable sites for application of Hydrokinetic Turbines throughout the country are not known, hence the need for this research. The study was done to evaluate electricity generation based on hydrokinetic turbines in the Umbeluzi basin. For this purpose, the following methods have been applied: 1) Frequency analysis using historical data of river stream velocity to generate velocity duration curves (VDC); 2) comparison of stream flow velocity to the design velocity of the hydrokinetic turbine and comparison of the rotor diameter of hydrokinetic turbine to the depth of the river to enable the evaluation of the feasibility of installation of the turbine in the basin. The results show that low flow velocities characterize the Umbeluzi River, hence no considerable potential sites for installations of hydrokinetic turbine. However, 444 W can be extracted in station 638 using dual axial turbine (Under Water Electric kit).

Key-words: **Hydrokinetic Turbines, Resources, Assessment**

1. Introduction

Mozambique has 27.2 million inhabitants and only about 20.2 % have access to electricity. Almost 97% of the total household energy needs are still met by traditional biomass fuels (wood and charcoal). Biomass meets 78% of the country's energy needs, followed by hydro (13%), oil products (7%) and 2% from other resources (IRENA, 2012; Mahumane, G. & Mulder, P., Nadaud, 2012). Total installed hydropower capacity is 2187 MW of which 2075 MW is from Cahora Bassa hydropower plant (IHA, 2015). Hydropower generation potential is estimated at 12,000 MW of which only 2,200 MW (Uamusse, Tsamba, Matsinhe, & Persson, 2015) has been exploited. The potential of small hydropower plants (<10 MW) is 1000 MW (Klunne, 2013) of which only 2.63 MW has been exploited. In fact, small hydropower compares well with other supply technologies; however, over 36 years large-scale hydropower projects dominated Mozambique's energy plans targeting neighboring countries market, especially South Africa.

Mozambique is a large country with widely dispersed; mostly rural population (70%) and no ambitious grid extension plans can reach the entire country in the short and medium term (IRENA, 2012).Other options such as small hydro therefore have to be explored to increase access to electricity. One of the options for harnessing kinetic energy from river currents is by using hydrokinetic turbines. However, the suitable sites for application of Hydrokinetic Turbines throughout the country are not known, hence the need for this research.

Hydrokinetic systems harness energy from natural water movement (kinetic energy) to generate electricity or provide mechanical power. The systems have been successfully powering rural communities such as 1.2 kW in Brazil (Els, 2008; Souza, j., Els & Diniz, J. & Wehrman, 2008); 5 kW in Ruby(Sornes, 2010), 200 W in Peru(Sornes, 2010)and pumping water for irrigation system in Sudan (M. J. Khan, Bhuyan, Iqbal, & Quaicoe, 2009). In Mozambique, the potential of hydrokinetic turbines is being studied at Eduardo Mondlane University (UEM) in partnership with University of Brasilia (UnB).

Traditionally, one way to validate water resources as adequate energy alternative is to evaluate its power potential available at the sites. For the case of hydrokinetic systems, the important parameter for this evaluation are: flow velocity and water depth of the rivers. This is the basic information required for system design and energy planning, especially to ensure that energy supply and demand decisions are compatible with overall goals for national sustainable development while diversifying energy resources.

1.1 Principle of Hydrokinetic Power

Through conservation of energy, the power existing at a point in the cross-sectional area of a stream of water flowing at a given speed can be obtained using Equation 1.

doi:10.18086/swc.2017.23.04 Available at http://proceedings.ises.org

$$P_k = \frac{\rho}{2} A_c V^3 \quad \text{(eq. 1)}$$

Where P_k is available kinetic power, ρ is density of water (1000 kg/m^3), Ac is the cross-sectional area of the extraction and, V is the flow velocity (m/s). Hydrokinetic power is often reported as a power density, which is the power normalized to unit are:

$$\frac{P_k}{A_c} = \frac{\rho}{2} V^3 \quad \text{(eq. 2)}$$

Computation of the kinetic power depend on the cross-section area, which is either the river cross-sectional area for assessment of the total energy in then river, or the area of the device that will be used to extract the kinetic energy (NRC-CHC, 2010). For the purpose of this study, the cross-sectional area of the river is used to estimate power potential.

1.2 Extractable Hydrokinetic Power

When considering the use of a device to extract the available power, the cross-sectional area of the device that intersects the flow is taken as the area of interest and the total efficiency of the device and associated power system in converting the kinetic power into electrical power has to be considered. Thus, the generated power (Pg) given as:

$$P_g = Cp \frac{\rho}{2} A_s V^3 \quad \text{(eq. 3)}$$

Where Cp is power coefficient of the turbine and A_S is the swept rotor area of the turbine given as:

$$A_s = \pi \frac{D^2}{4} \quad \text{(eq. 4)}$$

Where D is the rotor diameter of the turbine, Л=3.14

Considering the Betz limits as the maximum turbine efficiency, the power extractable from a turbine is given as:

$$P_{g-Max} = 0.593 \frac{\rho}{2} A_s V^3 \quad \text{(eq. 5)}$$

1.3 Hydrokinetic technology and rural electrification

This section describes—in brief—the hydrokinetic turbines used for feasibility evaluation of hydrokinetic power with the river. Detailed technology review can be found in (Verdant Power Canada, 2006), (M. J. Khan et al., 2009)and (Lago, Ponta, & Chen, 2010).

The Amazon aquacharger shown in figure 1 has ability to charge up to five 12 V or 24 V batteries simultaneously (Anyi & Kirke, 2010). The EnCurrent turbine shown in Figure 2 is a vertical axis Darrieus cross-axis turbine available in both ducted and non-ducted. The non-ducted configuration uses a 1.6 m diameter and 0.8 m tall turbine, it requires a minimum water velocity of 2 m/s to provide effective power output. However, as stated by (J. Khan, 2006), the turbine has ability to generate 0.4 kW power output at 0.9 m/s. In their website, (New Energy Corporation, 2014)), announce the use of Encurrrent turbine in powering rural community in Ruby at central Alaska.

Figure 1: Amazon AquaCharger

Figure 2: EnCurrent HydroTurbine

The Axial flow turbine (figure 3) was designed by University of Brasilia to attend specific rural electrification projects with installed capacity from 300W up to 2000W(Els, R. & Junior, 2015) and was installed in Suriname village. The system provide power to school, health centre and hybrid solar dryer (Els, 2008). Under Water Electric Kit shown in figure 4, is designed to operate in river, tidal and ocean currents. The turbine with rotor ranging from 2 to 5 m operates in extremely low velocities of 0.20 m/s or less (Verdant Power Canada, 2006). However, Anyi & Kirke(2010) discuss that the axial flow turbine with diameter ranging from 0.8 – 2.7 m can be used to generate a practical amount of electrical power from water between 0.5 - 2 m/s up to 100 kW.

The Garlov-Darrieus Helical Turbine, shown in Figure 5 consists of a rotor with 2 to 4 blades, whose extremities are fixed to disks, forming only one set that rotates together with generator. The turbine is available in several diameters: 1.25 m, 1.5m, 2.5 m, 3.0 m, and 6.0 m. The smallest turbine developed by Alternative Hydro Solutions is 1.25 m diameter and 0.5 m height (Verdant Power Canada, 2006). The turbine starts producing power at approximately 0.60 m/s, according to studies done in 2004 (Sornes, 2010; Verdant Power Canada, 2006).

Figure 3: Axial Cross flow –UnB (Viana, 2014)

Figure 4: Under Water Electric

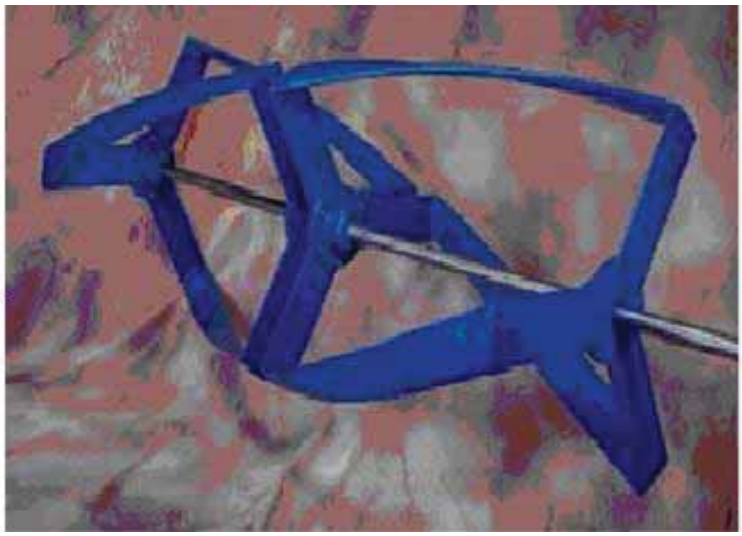

Figure 5: Garlov Helical Turbine

Turbines specification and their operation requirement are shown in table 1.

Table 1: Output Power of Axial and Cross-Flow Hydrokinetic Turbines

Device	Minimum River Depth requirement (m)	Stream Flow Velocity requirement range (m/s)	Rotor diameter (m)	Power Output Capacity
Amazon Aquacharger turbine	1.75	0.45- 1.5	1.8	500 W at 1.5 m/s
Under Water Electric Kit Turbine(twin unit)	2	0.20	2 - 5	100 kW
Garlov Helical Turbine	2.5	0.6-1.3		0.7 kW at 1.3 m/s
EnCurrent Hydro Turbine	0.8	1.5-2.5	1.6	10 kW at 1.5 m/s
Axial-Flow (UnB) Turbine	1	1.5	0.8	20 kW

2. Methodology

This study was based on frequency analysis of historical data, survey on hydrokinetic technologies for river application, hydrokinetic resources studies approaches and field survey. Preliminary data for desk analysis were collected from Department of Water Resources under National Directorate of Water in Mozambique.

2.1 Area of study

Umbeluzi is an international river shared by Swaziland, Mozambique and South Africa; it originates in Swaziland close to the border with Mozambique. It covers a total area of 5,400 km^2, of which 40% in Mozambican, 58% in Swaziland and the remaining 2% in South Africa (Joel das Neves Tembe and Aristides Baloi, 2001). The basin and Umbeluzi river main course are shown in Figure 6.

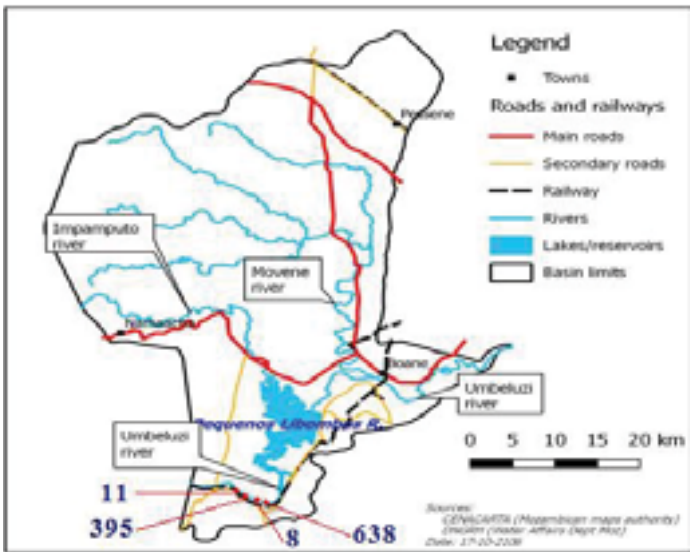

Figure 6: Umbeluzi Basin and its tributaries rivers. Source: CENACARTA (2016)

The main course of the Umbeluzi River runs in the East direction and discharges into Indian Ocean through Espirito Santo estuary at the southern Maputo bay. The main course consists of two tributaries, Mbuluzane River in Swaziland and Movene River in Mozambique (Juizo, D.,Liden, 2008). The table below indicates the sites (stations) were the study took place.

Table 2: Stations studied

Station number	Latitude	Longitude	Altitude
8	26:5:41 S	32:19:30 E	3
11	26:11:46 S	32:7:17 E	63
395	26:5:15 S	32:14:32 E	17
638	26:2:11 S	32:23:1 E	99

2.2 Stream Flow Velocity flow Characterization of the Main Maputo's Hydrological Basins

The study has used Frequency Analysis using historical data of velocity of river streams to generate velocity duration curves (VDC). VDC are graphical plot of stream velocity against the corresponding percent of time that the stream velocity is same or is exceeded. It describes the variability of the stream velocity. VDC were generated arranging velocity data in descending order and the percentage probability, Pp, of any magnitude, V, being exceeded calculated using Equation 6.

$$Pp = \frac{m}{N+1} \times 100\% \qquad \text{(eq. 6)}$$

Where P_P is percentage probability (%), m is number of the velocity (rank), N is number of the data in the list.

2.3 Evaluation of the feasibility for Installation of hydrokinetic turbines in the Umbeluzi main course

The evaluations of the feasibility for installation of hydrokinetic turbine in the Umbeluzi basin was done through comparison of the velocity of the stream versus the design velocity of the hydrokinetic turbines, and comparing the rotor diameter of the hydrokinetic turbines to the depth of the river, then evaluate the feasibility for installation of hydrokinetic turbines in the Umbeluzi River.

2.4 Hydrokinetic and Extractable Power

Assuming hydrokinetic turbines maximum efficiency 0.593 stated by Betz limit, extractable power was computed using Equation 5. However, this was done for stream section which equally had the minimum water

depth matched with the specific turbine requirement, such as station number 638. The turbines used for energy evaluation at these stream sections are respectively Under Water Electric kit (UEK), the ducted cross-axis by UnB and EnCurrent.

The energy evaluation was based on the stream flow velocities which is more than 90% of time available throughout the year.

2.5 Field Measurements and Equipment

River depth and flow velocity through main Umbeluzi channel was carried out at Goba and Mafavuca communities. The flow velocity of the river was directly measured using Gurley 572771 current meter shaft. Area of each sub-section was determined by directly measuring width and depth and computed using Equation 7.

$$A_i = W_i \times D_i \quad \text{(eq. 7)}$$

Where A_i is sub-sectional area, W_i, D_i area the correspondent width and depth of each subsection. The flow velocity in each sub-section was estimated at selected vertical locations in the water column.

3. Results and Discussion

3.1 Characterization of Umbeluzi River Flow Velocity

Umbeluzi basin consists of 37 hydrometric stations most of them built in 1950s. For the purpose of this study, four Gauging Stations have been used to characterize Umbeluzi River flow velocity. Figure 7 up to Figure 14 show Umbeluzi River Flow Velocity hydrographs and velocity duration curves from Goba Village (where the river enters Mozambique from) up to Boane Village.

The observations of stream flow of Umbeluzi at Station 11, downstream Goba Village is shown in figure7. The curve was plotted using monthly averaged values of 5 years (1981-1985).

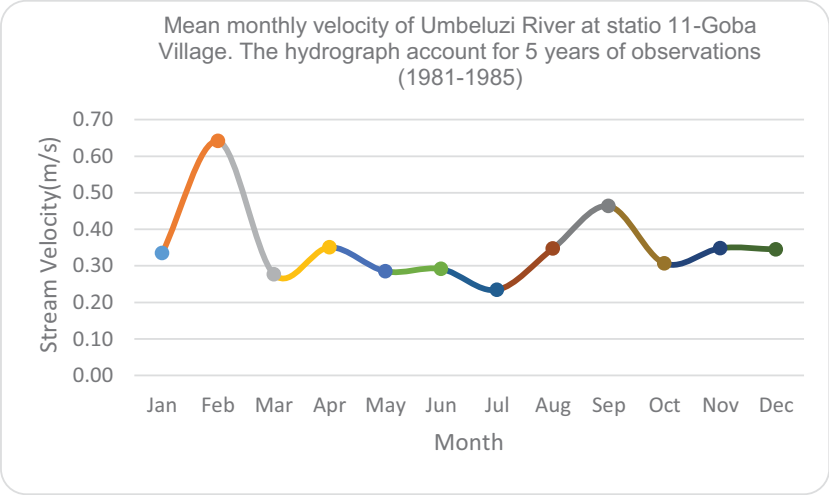

Figure 7: Umbeluzi Mean Monthly Velocity-Station 11 at Goba Village

From the hydrograph (mean monthly flow velocity variation) in figure 7, it can be noted that the maximum flow velocity of 0.64 m/s is reached in February. The minimum stream flow is 0.23 m/s observed in July However, with the exception of February, the stream flow velocity of Umbeluzi at this site is in the range of 0.23 m/s to 0.4 m/s. Figure 8 shows the time each stream flow is available throughout the year.

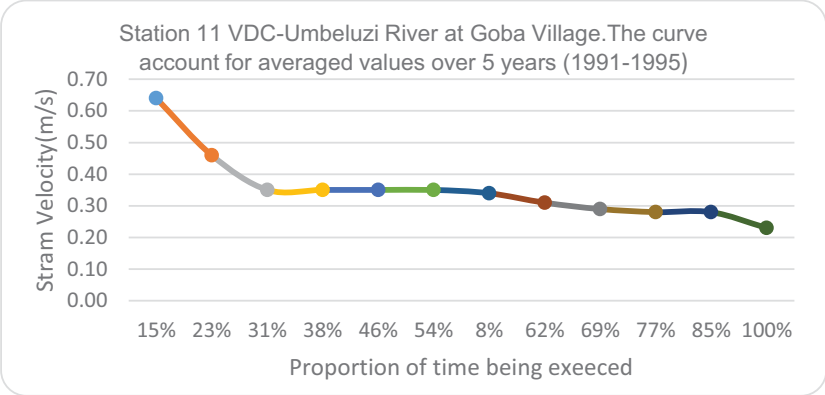

Figure 8: Umbeluzi Velocity Duration Curve-Station 11 at Goba Village

Looking at velocity duration curves (Figure 8) it can be drawn that (with reference to period 1981-1985), the stream velocity of 0.20 m/s is 92% of time available, and 0.64 m/s is 15% of time available throughout the year. However the firm velocity for energy generation should be available 100% of time all days of the months.

From 1982 to 1983, the river depth is in average of 0. 7 m. In 1984, the river reached 2.4 m of minimum water depth. At Station 638, the fluctuation of flows velocity through the years is very high. Such behaviour is shown in the hydrograph of figure 9.

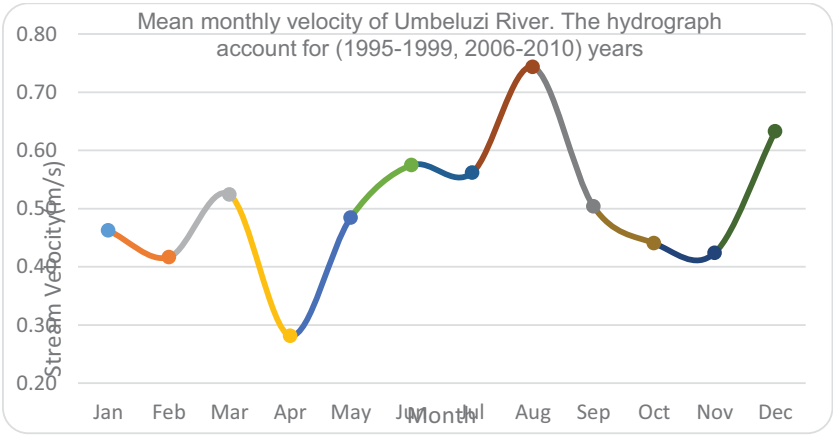

Figure 9: Umbeluzi Mean Monthly Velocity-Station 638

The Flow velocity data, taken as averages for the time in analysis (1995-1999, 2006-2010) show that the stream flow velocity ranges from 0.28 to 0.74 m/s where the maximum was registered in August.

The availability of firm velocity for hydrokinetic turbine installation in the last ten years (1995-1999, 2006-2010) of observation shows that 0.28 m/s is 92% of the time available, while above stream velocity of 0.6 m/s is only 8% time available (Figure 10). This means that, the river flows at 0.28 m/s from January to December and 0.6 m/s during less than one month.

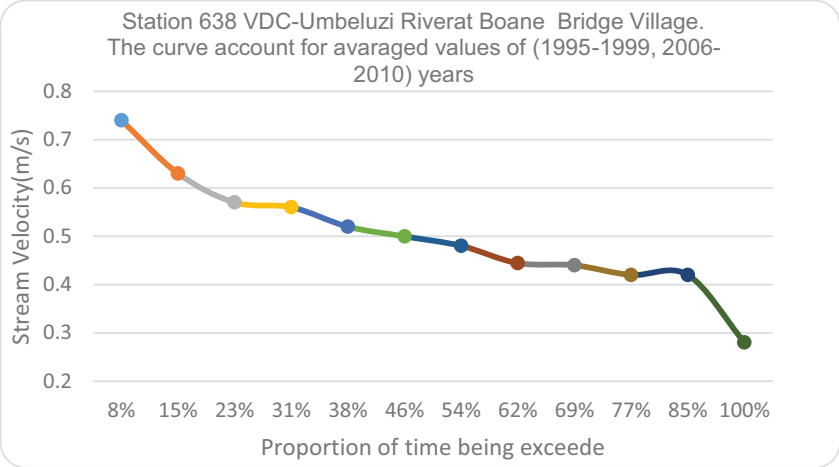

Figure 10: Umbeluzi Velocity Duration Curve-Station 638

According to figure 10, at this stream section 638, Umbeluzi registers 5.91 m and 2.64 m maximum and minimum water depth respectively.

Toward downstream, at Station 395, the maximum and minimum river depth of Umbeluzi are 1.0 and 0.55 m respectively. The stream velocity throughout the month can be seen from hydrograph curves of figure 11.

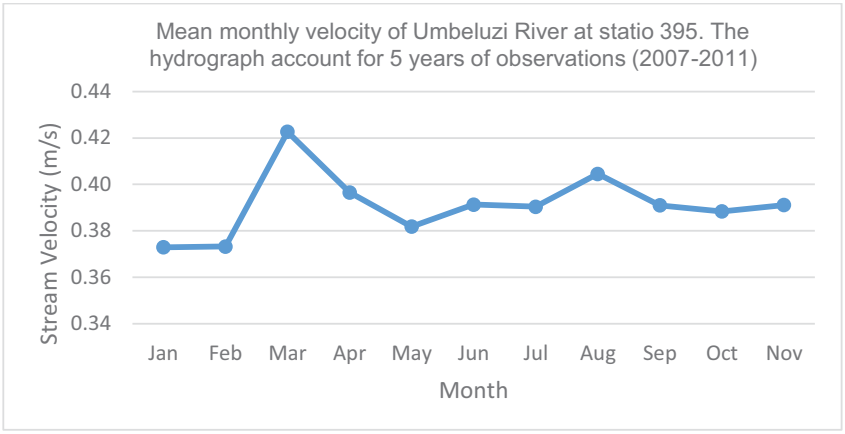

Figure 11: Mean Monthly Velocity Over Umbeluzi River-Station 395

During four years of observations (2007, 2008, 2009, 2010 and 2011 curves) Umbeluzi reached the maximum flow velocity during March and August being 0.42 m/s and 0.40 m/s respectively. The minimum stream flow velocities occurred in January and February. From May up to August, the stream flow increases from 0.38 m/s to from 0.40 m/s. From August to December, it drops from 0.40 m/s to 0.38 m/s. Figure 12 shows the time such range of stream flow can be harnessed for hydrokinetic application.

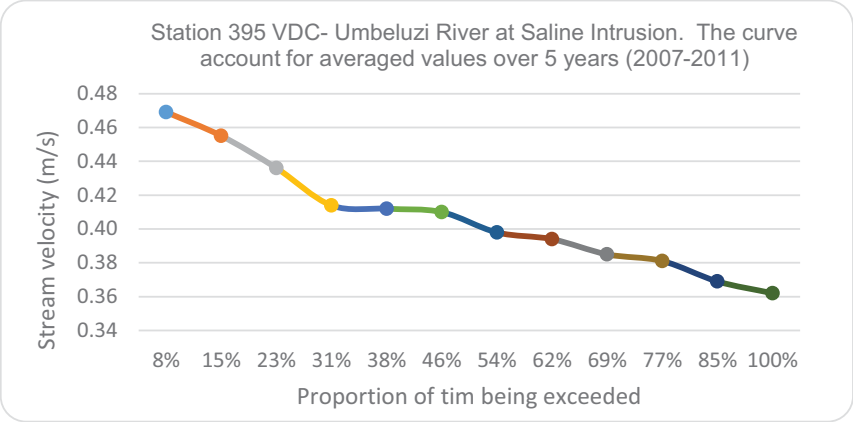

Figure 12: Umbeluzi Velocity Duration Curve-Station 395

As it can be seem from figure 12, Velocity Duration Curves above 0.36 m/s is 100% of time of the year available (From January to December) while 0.47 m/s is 8% of time available throughout the year. It means that the firm stream flow available for energy generation and provide power all months is 0.37 m/s.

The last stream flow observation was done at Station 8, whereby Umbeluzi River observes maximum and minimum water depth of 5.3 and 0.55 m respectively. Its mean monthly stream flow velocity it is shown in figure 13.

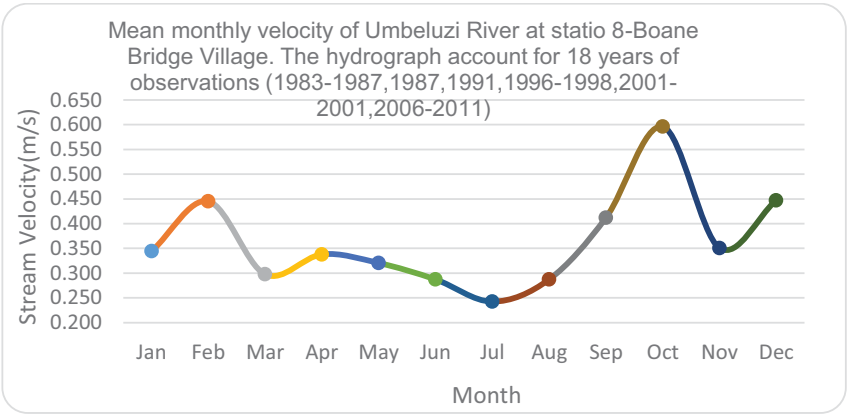

Figure 13: Mean Monthly Velocity over Umbeluzi Main Course-Station 8, Boane Village

The hydrograph curve of figure 13 shows that the stream velocity ranges from 0.3 m/s to 0.60 m/s from March to July. In February, has reached 0.44 m/s while October, Umbeluzi reaches 0.6 m/s. Figure 14 shows the analysis of stream flow velocity availability at station 8.

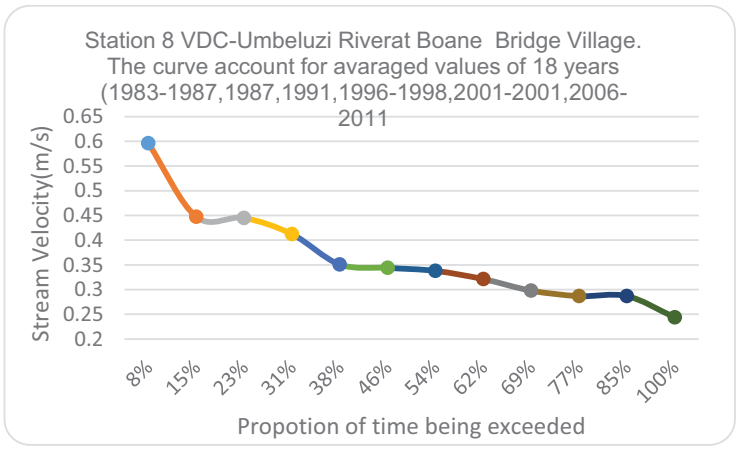

Figure 14: Umbeluzi Velocity Duration Curve-Station 8 at Boane Village

From Velocity Duration Curves shown in Figure 14, it is figured out that 0.244 m/s of flow velocity is 100% of time available throughout the year while 0.60 m/s is 8% of time available. Thus, similar to the station 395, 0.24m/s is the firm flow available for energy generation during all months at this section.

3.2 Feasibility for Installation of Hydrokinetic Turbines in the Umbeluzi River

The following analysis was done with reference to turbines operation requirements in natural current river flows provided in table 1. The parameters analyzed are: river flow velocity and river depth compared to operational flow velocity of the turbines and their rotor diameter (for axial type) or the height of the turbine (in case of cross-flow turbines type).

In Goba Village (station 11), the velocity duration curves plotted from 1981 to 1985 show that the river flow velocity of 0.20 m/s is 100% of time available (Figure 8). The minimum water depth observed from 1981 to 1985 is 0.69 m. In such flow velocity, Under Water Electric Kit (Figure 4), could be used to extract kinetic energy. However, the turbine requires 2 m of minimum river depth, which is not available at the site.

At Station 638, the last five years of observation (2007,2008, 2009, 2010 and 2011) show the stream velocity of 0.28 m/s is 100% of the time available and the stream velocity of 0.40 m/s is available 85% of the time throughout the year (see Figure 10). At this stream section, Umbeluzi River registered 5.9 m maximum and 2.64 m minimum of water depth.

The maximum and minimum river depth at Station 395 is 1.0 and 0.455 m. Stream flow velocity 100% of time available throughout the year is 0.36 m/s (see Figure 12).

At Station 8 located in Boane Village, Umbeluzi River observes a maximum and minimum water depth of 5.3 and 0.55 m respectively. Figure 14 shows that less than 0.244 m/s of flow velocity is 100% of time available throughout the year.

Looking at the turbines specification in table 1 and compared to the river flow velocity, it is found that the river meets operating flow velocity of Under Water Electric Kit at stations 11, 638 and 395. However, when the river depth is brought into comparison with the turbines specification, only Under Water Electric Kit could be used to extract kinetic energy at station 638, as the minimum river depth is 2.64 m, matched with 2 m rotor diameter.

3.3 Evaluating Extractable Power by Under Water Electric Kit Turbine

Under Water Electric Kit (UEK) is claimed to operate under extremely low velocities (Verdant Power, 2006). Therefore, it will be used to evaluate the hydrokinetic potential in station 638. At this section, the natural stream flow conditions are: 0.42 m/s is 85% of time available (see Figure 10); the stream cross-section area is 4.24 m^2 and minimum river depth of 2.64 m.

The hydrokinetic power available in the river computed using Equation 1 is 157.07 W and the extractable power by the turbine with 2 m rotor diameter computed by equation 5 results in 69.01 W (see Table 2). If the cross-section area of the river is strangulated from 4.24 m^2 to 2.12 m^2, the stream flow increased up to 0.84 m/s. The hydrokinetic power available in the river, calculated using equation 1 is 628.27 W and the extractable power by the turbine, using Equation 5 result in 552.09 W, which is enough to meet the basic needs of 10 households at World Bank standards for rural electrification using solar energy.

Table 3: Increased Flow Velocity and Output Power by the use of Under Water Electric Kit

Cross-section Area (m^2)		Flow Velocity (m/s)		Hydrokinetic Power (W)		Extractable Power (W)	
A_{c0}	4.24	V_0	0.42	P_{K0}	157.07	$P_{g\text{-}max0}$	69.01
A_{c1}	2.12	V_1	0.84	P_{K1}	628.27	$P_{g\text{-}max1}$	552.09

4. Conclusion

Hydrokinetic technology are designed to supply power for low demand communities living close to the rivers, hence increase the provision of energy services in rural areas. However, its exploration is dependent on availability of the water resources at the site, which are the river flow velocity and river depth. In that context:

Umbeluzi flows at 0.60 m/s maximum velocity, which is 8% of time available. Flow velocity ranging from 0.23 to 0.36 m/s is 100% of time available throughout the year. In addition, almost all stations have registered the minimum river depth in a range from 0.55 to 0.7 m.

Comparing the range of flow velocities to the turbines requirements, it is found that low flow velocities for hydrokinetic technology characterize Umbeluzi River. However, kinetic energy can be extracted at station 638 if augmentation device is used to strangulate the river channel. The river flow at 0.42 m/s is 100% of time available throughout the year in an average cross-section area of 4.24 m^2.

The extractable power using Under Water Electric Kit is 69.01 W. However, if the cross-section area is reduced from 4.24 to 2.12 m^2, the flow velocity increases from 0.42 to 0.84 m/s. The corresponding extractable power is 552.09 W, useful to charge some batteries.

Solar Cooking and Clean Cook Stoves

Towards a homogenous drying rate using a solar fruit dryer

Abstract

Solar fruit drying has the potential to reduce food insecurity in developing nations. One possible technique for drying fruit is to use solar dryers. This technique is easy to use without requiring high investments. However, the drying technique can be challenging. One problem is that the drying rate could be different depending on where in the dryer the process takes place. At the beginning of the dryer, the air is dry and warm while at the exit it has picked up moisture from the products and has cooled down. This could result in severe problems for the user. One possible solution is to have an arrangement that inverts the direction of the airflow periodically. This means that the entrance and the exit of the air are shifted. Thus, the drying rate evens out. Results from the performed simulations shows that the difference in drying rate comparing the fastest with the slowest drying rate in the dryer can be reduced from approximately 110 % to 10 % with this approach. Furthermore, this paper also describes how weather condition for a design day was established. This weather condition can be used for more accurate estimates regarding drying rates and temperatures in the solar dryer.

Keywords: Solar drying, food processing

1. Introduction

Even though absolute/extreme poverty and starvation has decreased over the latest decades (UN 2010; The World Bank), there is still food shortage and malnutrition in many developing nations. This is despite a fast economic growth in some developing countries. One of these countries, Mozambique, had a Human Development Index (HDI) ranking of 180 out of 188 countries despite the HDI value being 75 % higher than in 1980 (UNDP, 2015). Food security is lowest in the south of the country where almost one third of the people suffers from food insecurity (World Food Programme, 2016). At first sight, this appears strange as there is plenty of food grown in the country. However, large amounts of the grown food are either not harvested or are lost after the harvest due to spoilage (FAO, 2011). As much as 25 % to 40 % of the harvested fruit is estimated to be lost, mainly due to a lack of small-scale preservation techniques that do not require infrastructure (Feed the Future, 2011).

Preservation techniques such as aseptic filling and canning would in principle be possible solutions, however, this would require large investments and infrastructure which are often not available in these areas today. Freezing and other techniques that require large amounts of electricity are not an option due to the lack of an electric grid in rural areas. In Mozambique, approximately 80 % of the population is not connected to the electric grid (SIDA 2014). Unfortunately this problem is the same for fruit drying using electrical heaters. Drying of, for instance, fruit is otherwise an attractive technique as it needs no energy after the actual drying. The fruit can also be stored for long periods of time ranging up to several years, depending on the type of fruit and final moisture content after drying (Rahman & Perera, 2007). Drying could become a viable solution in developing nations if the electricity problem could be overcome. Furthermore, in order to have a preservation technique that plays a role for a large part of the society, the technique must be scalable as well as easy to use, cheap and reliable.

doi:10.18086/swc.2017.24.01 Available at http://proceedings.ises.org

One possible solution for this is to use solar driven dryers. The technique uses little to no power to run, is cheap and is simple to use. The work presented in this paper is part of a larger project where an interdisciplinary research group is focusing on finding suitable technical and social solutions for this drying technology. The main objective in this project is to find solutions for drying fruit juices made from juicy fruits like tangerines and oranges that have high spoilage rates (Affognon et al., 2015). The technique that has been developed for drying juices is called Solar Assisted Pervaporation (SAP). It involves the use of semi-permeable membrane bags which are filled with juice, clamped shut and then placed horizontally in the sun to dry. With adequate solar irradiation and ventilation, water vapour is able to pass through the semi-permeable membrane layer of the bag resulting in a shelf-stable dried product after two to three days (Phinney et al., 2015). Solar drying has traditionally been seen as unhygienic since the product is fully exposed to the open air, but with the SAP technique, microorganisms and larger pests are not able to penetrate the bag which greatly reduces the food safety risk (Phinney et al., 2015). Earlier work within the project has shown that even if the bags are directly exposed to solar radiation, a cooler wind passing over the bags can drastically reduce the drying flux. This result supports the need of a solar dryer that can pre-heat the air that passes over the bags in order to maintain the highest drying flux possible. The pre-heat of air would increase the temperature to a level not favourable to microbial. In addition, not radiating the fruit directly could be beneficial as the sun light could activate the degradation of vitamin or pro-vitamin in the fruits. Direct irradiation could potentially also form a crust on the inside of the bags, which would then lead to lower drying rates (Mills-Gray, 2015). By using an indirect drying technique, the heating of the fruits become more adjustable and less fluctuating over time as the dimensions and materials of the solar collector will determine the drying conditions (Kumar et al., 2015).

The initial indirect solar dryer design that was developed for SAP is shown in Fig. 1. The air is heated in the solar collector and this hot air passes to the drying tower.

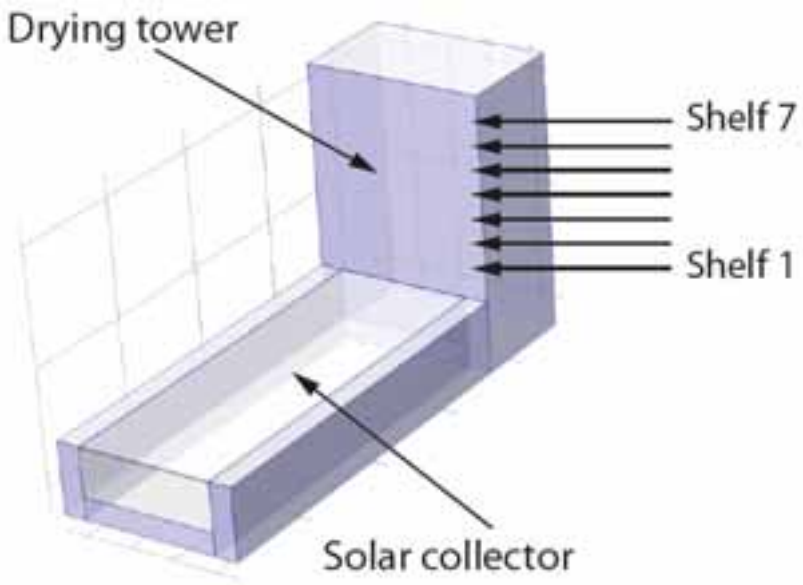

Fig. 1: The solar dryer with the solar collector and the drying tower.

Earlier reports have shown that the drying rate of the product (i.e. bag) is dependent on at least air temperature, air speed and the relative humidity of that air (Blanco-Cano et al., 2016; Phinney et al., 2015). Furthermore, Olsson (2016) showed that the drying rate in a passive drying tower, illustrated in Fig. 1, is strongly dependent on where the bag is placed in the drying cabinet. As the air is dryer and warmer at the entrance of the cabinet, the drying rate is also higher here. As the dry air picks up moisture from the bags at the entrance region, the relative humidity increases. Furthermore, as this process is energy demanding the temperature will also decrease. As a consequence of this, the drying rate is reduced for bags placed at the top of the cabinet. This is a serious problem for the successful implementation of this technique. The target group for the technique, i.e.

farmers in rural Mozambique, are too busy to spend time shifting bags around in the drying tower in order to reduce the uneven drying rates. Furthermore, keeping track of the time for when to shift the bags will also add problems for the user. A high drying rate reduces problems relating to mould growth and the evenness is important for a homogeneous quality of the dried products. It is therefore very important that the drying rate is both high and even.

Understanding the process of solar drying needs understanding of the physical boundaries and the driving forces, i.e. the weather conditions. Running simulations with full weather data is time consuming and often inconvenient during a development phase of a new collector type. In this type of process, rough estimates are often more suitable. In order to do this, a typical weather situation for the process is needed. This is not well established today. Earlier work presented is based on reasonable guesses for typical weather situations Olsson (2016).

Investigated problems:

Shifting the bags in the drying cabinet has the potential to increase the evenness in the drying rate. Furthermore, using real weather data rather than assumed values will affect the calculated drying rates in the cabinet. The research questions are therefore;

- To what extent can the evenness in drying rate be increased by either shifting the positions of the bags in the cabinet or reversing the flow in the dryer tower?
- To what extent is the drying rate affected by using real weather data? And, can a characteristic weather situation be identified?

The evenness is measured as a relative difference in drying rate between the bags that dry the fastest and the slowest.

2. Method

The performed simulations are based on a program described in Olsson (2016). The program is built in Maple 2015 (Maple) which is a software mainly used to analytically solve and evaluate mathematical problems, but can also be used as a programming tool. The model consists of two parts; the solar collector and the drying tower, see Fig. 1. The solar collector has a constant airflow going through it, user defined insulation on the sides and bottom and a single layer of glazing on the top which can let through sunlight. The absolute humidity and the air temperature calculated at the outlet of the collector will then act as input values for the drying tower and thus determine the initial drying conditions. The drying cabinet consists of four walls impermeable to sunlight and has an airflow going from its bottom to its top. Inside the cabinet, a certain amount of shelves are located on which SAP-bags can be placed. The drying rates of the SAP-bags are then calculated for each shelf depending on the air velocity and the relative humidity at each shelf.

The program was used in order to calculate the drying rate for bags placed at seven different shelves in the drying tower. The placement is indicated in Fig. 1. The drying rate was used in order to calculate the evenness depending on shelf position in the tower. Furthermore, the consequences of shifting around the bags in the drying tower were also calculated. For this shifting simulation: the bags placed on shelf 7 were shifted with the bags on shelf 1 after 30 minutes. Bags on shelf 6 were shifted with bags on shelf 2 and the bags on shelf 5 were shifted with the bags on shelf 3. The bags on shelf 4 were left without being shifted.

The characteristic weather for fruit drying in Mozambique was found by creating a constant weather condition that results in the same total drying over a three months period as would be the result using the real measured weather over the same three months. The point in doing this is mainly to have a typical design condition for the solar drying technology. Using the characteristic weather will result in better estimations for drying capacities. Included in the characteristic weather is radiation, temperature and relative humidity. As can be seen in Fig. 2 the temperature and the relative humidity varies considerably less than the irradiation. Therefore these two parameters where calculated to be the arithmetic mean value during the period. After these values

were established, the irradiation level for the characteristic weather situation was calculated. This was carried out by means of iteratively running simulations changing the characteristic radiation. When the total drying over the three month period was the same using the characteristic weather situation as using the real weather data the characteristic radiation was found. Fig. 2 shows a typical weather situation during two days. The black line shows the irradiation on a horizontal surface, the blue line shows the ambient temperature and the red line shows the relative humidity. The dashed blue and red lines are the arithmetic mean values of the temperature and the relative humidity during the active time of operation, in this case from 8:00 to 16:00. The dashed black line is the irradiation used in the calculation program in order to get the same total drying during operation (i.e. running a simulation using the fixed values shown with dashed lines or running a simulation using the weather data will produce the same total drying effect). The grey shaded area indicates the time that the solar dryer is assumed to be in operation. The figure is used only as an illustrative example of the method.

The drying of the SAP bags in not a linear function of the irradiation or the temperature or even the relative humidity Olsson (2016). Therefore, a change in for instance the relative humidity in the drying tower will lead to a compensation of the irradiation in the calculated characteristic weather. In order to evaluate how important this none linearity is the characteristic weather was calculated for two different versions of the solar dryer. The two different versions of solar dryers will create two different drying conditions and therefore two different characteristic weathers. One with a drying tower with a cross section measuring 0.2 m · 0.2 m with 2 SAP bags per shelf. The other tower with a cross section that measures 0.4 m · 0.4 m and has 10 SAP bags per shelf. Both cases use a 2.4 m² large solar collector unit. This creates two different conditions in the dryer. In the larger tower, the air will move with a lower speed and the air will also become more humid in the upper layer. Other details on the dryer are discussed in Olsson (2016). This test was carried out in order to see how sensitive the characteristic weather is to changes in the solar collector.

The simulations were performed assuming a horizontal collector. Furthermore, the characteristic weather was evaluated for two operation times, 8 hours per day and for 4 hours per day. Fig. 2 is an illustration of the characteristic weather for the 8 hour case.

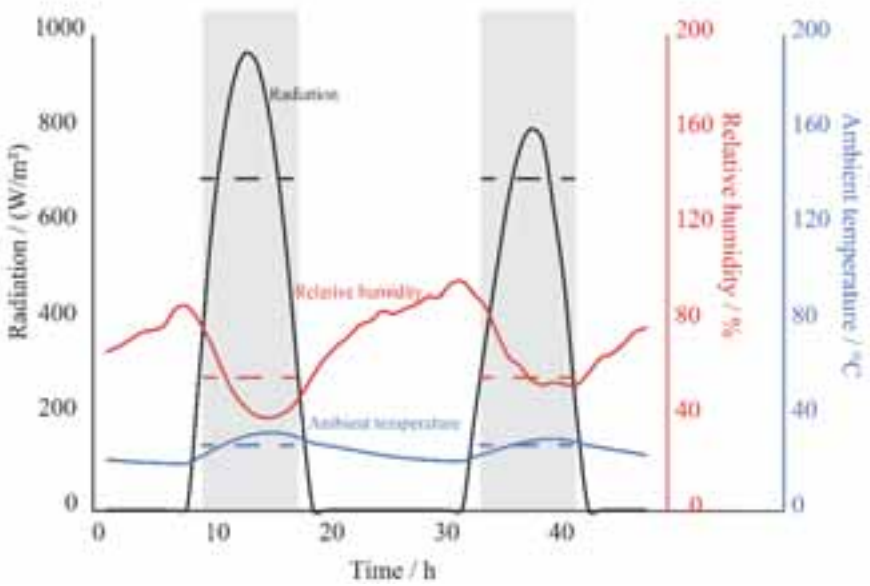

Fig. 2: Illustration of the characteristic weather for the 8 hour drying case during a two day period. The black line shows the radiation, the red line shows the relative humidity and the blue line shows the ambient temperature. The dashed lines shows the characteristic weather during this period.

Hourly weather data was obtained for Maputo, Mozambique using Meteonorm 7.0. Data was selected from beginning of May to end of July as this is the period for tangerines in Mozambique.

3. Results

Fig. 3 shows the results from a simulation where the drying rate per square metre of SAP-bag per hour was calculated over one week in the beginning of May. The results are based on a simulation that uses real weather data. The drying tower was set to be 0.4 m · 0.4 m and there was 10 bags placed per shelf. The left figure shows the drying rate for the SAP bags placed on the different shelves. The placement of the shelves is shown in Fig. 1. The results show the highest drying rate at the first shelf and a decreasing drying rate moving up in the tower. During the peak hour on the first day, the difference in drying rate between shelf 1 and shelf 7 is approximately 110 %, i.e. bags on shelf 1 dry more than twice the rate of bags placed on shelf 7. To the right is a calculation where the bags have been shifted every 30 minutes. The mixed mode, i.e. the right figure, shows that this difference in drying rate is reduced to 10 % between bags placed on shelf 4 and bags placed and shifted on shelf 1 and shelf 7.

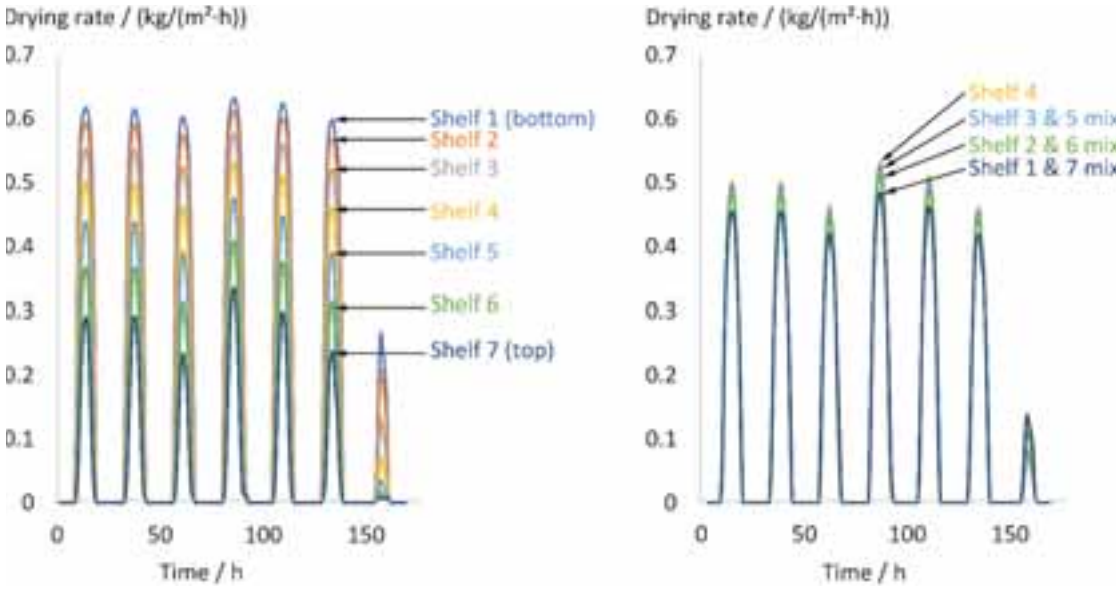

Fig. 3: The drying rate at different shelves during one week. The left figure shows constant position (shelf) for the bags. The right figure shows drying rate where the bags are shifted continuously over the week.

The characteristic weather found for the two different solar dryers using the 4 hour and the 8 hour daily drying period is presented in Table 1. By using the values presented in Table 1, the same total drying as using a full weather file in the simulation tool is obtained.

Tab. 1: Characteristic weather for two types of dryers and for two drying times

Calculated value	Low concentration of SAP bags in the dryer		High concentration of SAP bags in the dryer	
	4 hour period	8 hour period	4 hour period	8 hour period
Temperature / °C	25	25	25	25
Relative humidity / %	50	50	50	50
Irradiation / (W/m²)	700	530	740	575

4. Discussion

The calculations performed in order to evaluate the effects of shifting the positions on the bags in the dryer showed great potential in order to get a more even drying rate. However, shifting the bags manually will be

very time consuming and this will likely not be carried out by the user. This could lead to accidental spoilage of fruit. Instead, it would be preferable if the dryer was built in such way that this was carried out automatically. One alternative could be to build a collector that has double collectors, one before the drying section and one after the drying section. The airflow can then be controlled with a fan to change the direction of the flow every 30 minutes. Doing so will give the same result as continuously shifting the bags, i.e. shelf 1 will be shelf 7 as the airflow direction changes. The price for such a product will be higher but it will likely allow for operation without causing unnecessary work for the user. Alternatively, a small fan can be installed inside the drying tower in order to mix the air. Other techniques could be possible.

The characteristic weather was concluded from an analysis based on using all the days during May, June and July. Doing so also includes cloudy cold days. During such days the user is not as likely to start drying fruits. Therefore it might be more reasonable to establish a characteristic weather not based on days including such weather. Such selective picking of suitable drying days would lead to a higher characteristic radiation for the collector. However, if the drying process is longer, for instance a couple of days, then the cloudy day might come in the middle of the drying process and there is no chance to abort the drying and start over. Instead the cloudy days will be included. This analysis can be stretched further for a more complete conclusion. Furthermore, the analysed weather data comes from Maputo in the south of Mozambique. Using weather from the central or the northern parts might result in a different characteristic weather. Nevertheless, it was decided that the reached values are accurate enough for the purpose of preliminary design considerations.

However it is also important to understand that there are many characteristic weather situations that will result in a specific total drying over the three months. For instance reducing the temperature but increasing the solar radiation simultaneously will keep the drying constant. Therefore it's impossible to find one specific weather situation that is the only solution to the given problem.

There is a small difference in what characteristic weather should be used depending on the setting of the dryer. More SAP bags and thus higher relative humidity combined with a lower airflow in the tower results in a somewhat higher characteristic irradiation. However, this difference is very small, in the order of 5 % to 10 %. This is seen comparing the irradiation levels in Table 1, 700 W/m² compared to 740 W/m² and 530 W/m² compared to 575 W/m². Thus, this difference can be neglected.

5. Conclusion

The uneven drying rate can be drastically reduced if the SAP bags are shifted within the drying tower. Shifting the bags every 30 minutes, or more realistically changing the airflow direction, was shown to reduce the difference in drying rate from approximately 110 % to 10 % between the highest and lowest drying rates.

A characteristic weather could be determined and are presented in Table 1. For longer drying periods, i.e. longer than 8 hours, the characteristic weather is typically 25 °C a relative humidity of 50 % and approximately 550 W/m² of solar radiation. For shorter drying periods where only the peak hours of the day is used the solar radiation can be assumed to be somewhat more than 700 W/m². The none-linearity in the drying process discussed in the method section was indicated to have only small effects. Varying the drying tower cross sectional area and number of SAP bags per shelves within the above stated limits will not affect the characteristic weather to a significant degree and this effect can be ignored.

Summary

Injera is a traditional staple pancake and it is part of the daily dish to most of the one hundred million population in Ethiopia and Eritrea. The conventional baking method uses either biomass in rural areas or Electricity in majority of urban areas. A direct solar fryer for Injera baking application is developed as an alternative to the conventional baking methods. The solar fryer system uses a 1.8m rim diameter dish covered with aluminum reflective sheet. The system employs an aluminum baking plate of 550 mm diameter, 12.5 mm thickness and is equipped with two axis manual tracking. The direct solar fryer model has two possible operational modes; the continuous heating-baking mode and the alternating heating-baking mode. The experimental result show that the initial heating up time in both modes was in the range of 30 to 45 minute and this initial heat up time was comparable to the conventional baking process. In the initial heat up period, the plate has reached an average temperature of 120 to 130 ℃ in the continuous type model and 160 to 180 ℃ in the alternating type model, which was sufficient surface temperature to initiate a baking activity. The baking process in the continuous type model has taken an average of 5 minutes while the subsequent additional heat up time was 2 minutes giving an average baking time of 7 minutes per Injera. The alternating type model has slower heating time at each consecutive baking activity. The direct solar fryer will provide a baking power of 563W with a system thermal efficiency, including the collector efficiency of 37 %.

Key words: Injera, solar baking, Solar Fryer, baking time, baking power, baking energy

1. Introduction

Injera also written as enjera is an endemic staple food in Ethiopia and Eritrea. Injera is made from the flour of tiny grain locally called teff (Eragrostis tef), a species of in the genus Eragrostis, native to Ethiopia and Eritrea [Mekonnen et al, 2014; Aptekar, 2013; Demissie, 2000]. The teff flour is mixed with water, on average of 30 % to 70 % proportion respectively on mass basis and a sourdough as starter. The mixture in the form of runny dough is left to ferment for few days, usually 3 to 5 days. The sourdough starter and the fermentation process makes the Injera to be mildly sour taste. The fermented dough is then baked into large flat pancake by pouring into a hot clay pan. The dough then stays in the hot clay until the water boiling temperature is reached and as a result, water bubbles scape the pancake forming thousands of tiny craters, traditionally referred as 'eyes' giving it spongy honeycomb like structure while the bottom surface, which comes in contact with the baking hot surface, is relatively smooth. The fully cooked injera then becomes thin, soft and slightly spongy.

Injera is part of the daily dish to most of the one hundred million population in Ethiopia and Eritrea. The Injera, placed on flat serving utensil, is consumed with different toppings or stews, traditionally called "wat". There are similar variants to Injera worldwide. Such variant include "*canjeero"* (also known as "*lahooh"* or "*lahoh"* in Somalia and Djibouti [Abdullahi et al, 2001], "*kisra*" in Sudan and South Sudan, "mandazi" in Kenya, "Lahuhua, pita and falafel" in Yemen and the middle east, "Baghrir" or "beghrir" in the Maghreb region, "chapatti" and "puri" in India, pan fried cakes, paratha, vada and mutuan in Asia and tortilla and navaho fry bread in North America [Gallagher, 2011].

Similar to the worldwide pancake frying process, Injera making process is an energy intensive activity. The household sector in Ethiopia accounts for about 89% of the total energy consumption and with 96% of this energy contributed from biomass (firewood, cow dung and agricultural residue) (Energypedia, 2017; Asfafaw et al, 2014; GiZ, 2011). Majority of the domestic energy requirements is for baking and cooking purposes, accounting for about 60% of energy consumption (Gebreegziabher, 2004, 2007; RPTC, 1998). This makes the injera making activity as the most energy-consuming process in every household in Ethiopia.

Nomenclature

Q_{baking}	*Baking energy [kJ]*
m_{dough}	*Mass of dough [Kg]*
$C_{p,dough}$	*Specific heat capacity of the dough [kJ/(Kg. K)]*
T_{bt}	*Baking temperature [K)*
T_i	*Initial temperature of the dough [K]*
m_w	*Mass of the evaporated water [Kg]*
Δh_{ev}	*Enthalpy of vaporation of water [kJ/Kg]*
x_w	*Moisture content of the dough (water mass fraction) [ ]*
$C_{p,w}$	*Specific heat capacity of water [kJ/(Kg. K)]*
x_t	*Teff mass fraction in the dough [ ]*
$C_{p,t}$	*Specific heat capacity of teff [kJ/(Kg. K)]*
Q_{plate}	*Plate stored energy [kJ]*
P_{plate}	*Plate heating power [kW]*
$t_{process}$	*Time taken for the whole baking process [sec]*
q_s	*Heat flux supplied to the receiver [W/m^2]*
G_b	*Beam irradiance [W/m^2]*
ρ_c	*Reflectance of the concentrating dish [ ]*
$(\tau\alpha)_e$	*Effective transmittance and absorptance of the receiver surface [ ]*
γ_{rsf}	*Receiver shading factor [ ]*
C	*Area concentration ratio [ ]*
$\dot{Q}$	Heat supply to the receiver [W]
A_r	Receiver aperture area [m^2]
A_a	Concentrating satellite dish aperture area [m^2]
η_{opt}	Optical efficiency of the parabolic dish [ ]
Q_{in}	*Input solar energy [kJ]*
h_L	Overall heat transfer coefficient [W/M^2.K]
$\eta_{th,plate}$	Thermal efficiency of the receiver [ ]
$\eta_{th,baking}$	Thermal efficiency of the of the overall baking process [ ]

The conventional baking process mostly employs a traditional large size clay plate (locally called ‘mitad’) with 500 to 600 mm in diameter and 20mm thickness. This traditional baking clay has relatively low thermal property hence it requires higher amount of heat than for typical for boiling. The conventional baking method uses either biomass in rural areas or Electricity in majority of urban areas. Biomass based baking process is inefficient, poses pollution hazard and it is becoming expensive due to limited biomass resource in the country while electricity access is very low as majority of Ethiopians live off grid. Therefore, the development of alternative technology for Injera baking application will have significant contribution in the energy consumption profile and socio-economic aspect of the country.

From Ethiopian perspective, a solar energy-based technology is the most promising alternative to the existing energy resource for Injera baking application. Injera baking is high-energy intensity application. The baking process occurs in the temperature range of 130 ℃ to 220 ℃ at an energy consumption of approximately 1MJ/kg of Injera and with a baking time of 180 seconds to 240 seconds. Ethiopia is endowed with abundant solar energy, with daily average solar radiation of 5 kWh/m^2 [Anwar et al, 2014]. Solar energy can be converted into thermal energy as per the baking process energy consumption requirement more easily and in a sustainable way than other alternative energy sources such as biomass, wind, hydropower and geothermal energy.

Solar energy based Injera baking technology can be either a direct system [Gallagher, 2011] or an indirect system [Asfafaw et al, 2014; Maxime et al, 2013]. The direct system uses direct illumination of the solar radiation into the illumination surface (bottom surface) of a baking pan while the Injera is baked at its baking surface (the top surface). Such direct system is suitable for outdoor baking activity. The indirect system uses heat transfer fluid (HTF) to transport thermal energy from the solar energy collector and/or absorber to the application, in which case again the HTF may heat the baking plate directly or the thermal energy in the HTF

is transferred and stored in other thermal energy storage materials, such as solar salt or thermal oil. The direct system is simpler and cost effective while the indirect system will be more complicated and with high cost. The intention of this study is to develop simple and cost effective direct solar fryer for Injera baking application and analyze the performance of the solar thermal technology.

The Injera baking process would pose two main challenges for any type of solar energy based Injera baking technology. The first challenge is due to the size of the traditional Injera, which is about 50 to 60 cm in diameter. This implies that the baking process demands the provision of uniformly distributed heat on larger size baking pan. This would be a challenge as the solar radiation is reflected into a larger area baking pan while the radiation is being focused from the larger solar concentrators. Furthermore, while Injera is prepared softer and thinner, other variant of pancakes seems to be made thicker and taken drier at the end of the baking process. Due to that, Injera baking process will require relatively more uniformity in temperature distribution over the larger size baking plate. The second challenge is the requirement of high intensity of heating of the baking process. This challenge requires the availability of sufficient beam irradiance and an employment of an appropriate solar collector size.

While many designs of the direct system type exist for cooking application or baking of smaller size staple foods; a solar fryer of large size specifically for injera baking application is designed and reported by Gallagher [Gallagher, 2011]. In this system, a 1.2 m diameter solar collector with quasi focus is employed to heat a 0.46m diameter baking pan, which is designed for cooking 0.42 m diameter slices of injera bread. A mirror below the pan directs the radiation to the pan bottom, which is coated with a low-emissivity black absorber. The mirror uses flat, hexagonal panels of aluminized polyester (Mylar) to provide relatively uniform illumination across most of the pan bottom. The baking pan can be stationary at the quasi focus of the mirror assembly (i.e. simultaneous heating and baking) or it can be taken in or out of the dish in north-south direction while pouring the dough and while removing the baked injera and put back into the dish for heating in the remaining time of the baking process (i.e. discontinuity of heating during the baking process).

One of the main challenges in applying the Gallagher prototype to developing country like Ethiopia is the difficulty and challenge of making the quasi focus solar collector which is comprised of flat and hexagonal mirrors. Therefore, due to manufacturing difficulty, such collector will literally be subjected to significant radiation loss if adapted and redeveloped. In this regard, the core design condition of attaining relatively uniform illumination on the backside of the baking plate will be affected, if not it will be significantly expensive. The second challenge is the upscaling of any concept by itself. In upscaling, the challenge of attaining relatively uniform temperature distribution over the baking surface of the plate has to be addressed either by attaining uniform illumination or by employing baking plate material and optimized plate thickness that will ensure optimum conduction process, in turn that will lead to relatively uniform temperature distribution over the baking surface of the plate.

Traditionally, Ethiopia's Injera is with the size of 500 mm to 600mm in diameter. Therefore, the social acceptance of the traditional staple food demands the development of a solar fryer prototype that will enable to bake an Injera of the above size, while the Gallager prototype is designed for 420 mm slice of Injera. The work by Gallagher is used as a basis for the design and development of a direct solar fryer as reported in detail in this research. This newly developed system is an up scaled and an alternative version while addressing the possibility of conducting solar baking with larger size direct solar fryer. An extensive experimentation of baking process is also conducted and the performance of the system is evaluated. This direct solar fryer system for baking application is with the largest fryer size and no other such large area-frying panel has been reported so far.

2. Design of the direct solar fryer

2.1 Geometrical design of the solar fryer system

The solar fryer system uses a dish, cheap and widely available in the market with 1.8m rim diameter (focal length 0.684 m and dish depth 0.296 m) and by gluing aluminum reflective sheet (Miro high reflective 95) on the dish. The solar fryer is designed for an outdoor application, hence here called a "direct solar fryer". The direct solar fryer is made with a baking pan or plate made of aluminum (through casting process at local workshops). The optimum thickness and the high heat conductivity property of the Aluminum plate ensures

there exists relatively uniform temperature distribution on the baking surface of the plate.

The solar fryer model is designed with a baking pan size of 550 mm in diameter and 12.5 mm in thickness. The solar fryer has two possible operational modes. The first operational mode is the configuration that enables simultaneous heating and baking process here referred as "*solar fryer with continuous heating and baking mode*" while the second mode is the configuration that enables heating and baking to be conducted alternatively, here referred as the "*solar fryer with alternating heating and baking mode*". These two modes of the solar fryer are illustrated in figure 1 and figure 2 respectively.

The baking plate can be placed at a distance of 5 to 8 cm distance above or below the focal point, illuminating major part of the heating surface, about 40 to 70% of the plate surface, which gives 25 to 15 concentration ratio respectively. This focusing is done by using the telescopic adjustment structure on the dish support. The plate support structure is also provided with additional rotational motion to allow small inclination during initial heat up period and at consecutive heating and baking periods thus to increase the efficiency of the radiation absorption at the illumination surface of the plate. In the continuous type model, the telescopic adjustment will also help to compensate the seasonal declination of the sun, combined with seasonal translational adjustment of the plate support about orthogonal direction to the axis of rotation of the dish collector.

The system uses two axis manual tracking. The first manual tracking (i.e. the dish rotation about an axis of rotation which pass through the focal point of the dish coupled with the plate rotation during initial heating period) is intermittently adjusted throughout the day. The second manual tracking (i.e. the wheel rotation attained by the roller support coupled with the rotation at the bearing) needs to be adjusted at an average of 10 minutes or at the interval of every baking. In this model, the baking process is conducted under no shading, giving some level of discomfort to the user as a result of the radiation exposure while baking.

2.1.1 Continuous heating and baking mode

The solar fryer with continuous heating and baking mode is indicted in figure 1. In this solar fryer, the baking plate is heated from its bottom surface (i.e. the illumination surface) while baking is conducted at its top surface. The plate can be constantly placed near the focus, enabling simultaneous heating and baking or be moved in and out of the dish for short period during dough pouring and baked Injera removing activity, while in the remaining time the plate will be in heating and baking mode. The choice of these two modes basically depends if the user would like to access the baking plate inside the dish or by moving out of the dish for dough pouring and baked Injera removing activity.

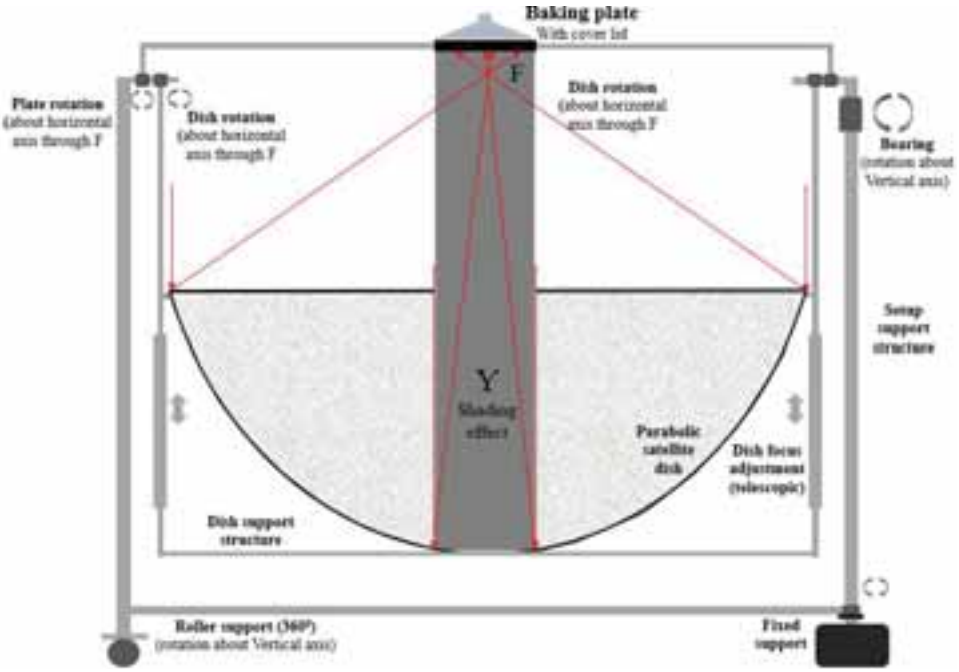

Figure 1: The direct solar fryer with continuous heating and baking mode

2.1.2 Alternative heating and baking mode

The solar fryer with alternative heating and baking mode is indicated in figure 2. In this *model*, heating and baking occurs alternately and on the same surface of the plate, while the backside of the plate is covered with insulation. The plate-dish assembly can easily be rotated at the rim of the dish, which is close to the mass center of the whole assembly. This system provides the baking process to be conducted under the shading of the dish, giving some comfort to the user. In this system, the baking energy requirement is obtained from the stored thermal energy of the plate.

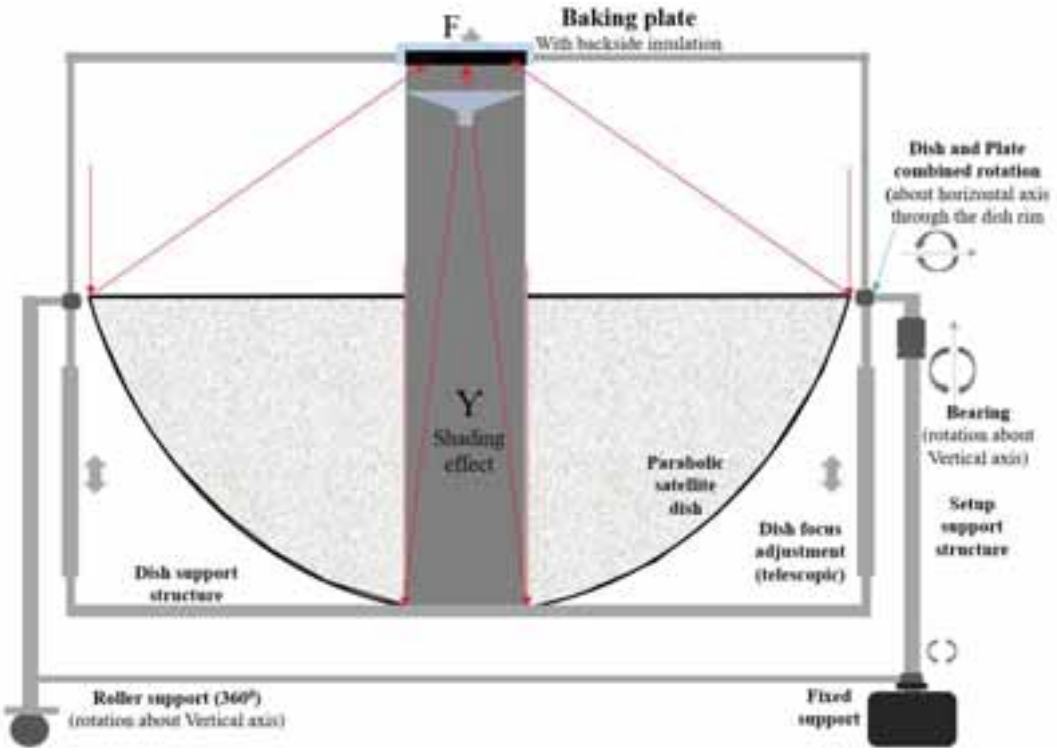

Figure 2: The direct solar fryer with alternative heating and baking mode

2.2 Thermal design of the system solar baking application

The thermal design of the solar fryer is based on the Injera baking energy requirement. An average Injera of 550 mm to 600 mm in diameter is made from 550 g dough, which in turn is made of 70% and 30% proportion (by mass) of water and teff flour respectively. Upon completion of the baking process, the dough is heated from room temperature 25 ℃ to water boiling temperature of 100 ℃ as a result about 25% of the moisture content of the dough is evaporated at the end of the baking process. The baking energy requirement is therefore the thermal energy consumed for raising the temperature of the dough and the latent heat of vaporization of the 25% water content. Mathematically, this baking energy [kJ] can be given by;

$$Q_{baking} = m_{dough}\, C_{p,dough}\, (T_{bt} - T_i) + m_w \Delta h_{ev} \qquad \textit{(Eq. 1)}$$

During the baking process, the mass (m_{dough}) and specific heat capacity ($C_{p,dough}$) of dough varies with time. Therefore an average value for the m_{dough} and $C_{p,dough}$ shall be taken, considering the value of these parameters at the beginning and end of the baking process. The average specific heat capacity of the dough can be given by;

$$C_{p,dough} = x_w\, C_{p,w} + x_t C_{p,t} \qquad \textit{(Eq. 2)}$$

The baking plate is a receiver or an absorber and it acts as a buffer storage during the baking process. This stored energy [KJ] is given by;

$$Q_{plate} = \left(mC_p\right)_{plate} \left(T_f - T_i\right) \qquad \textit{(Eq. 3)}$$

The solar fryer average capacity in terms of heating power can be given by

$$P_{plate} = \frac{Q_{plate}}{t_{process}} \quad \textit{(Eq. 4)}$$

The useful energy of the baking process is the thermal energy consumed for the baking activity, i.e. Q_{baking}. But sometimes, the stored thermal in the baking plate itself can be considered as part of the useful energy. In such case, the total thermal energy from the system will be the sum of the baking energy and the thermal energy stored in the baking plate.

$$Q_{thermal} = Q_{baking} + Q_{plate} \quad \textit{(Eq. 5)}$$

The input energy is the solar radiation falling on the collector. This solar radiation is reflected into the fryer, illuminating major part of the bottom surface of the aluminum plate. The heat is then transferred through conduction radially and vertically to the top surface of the baking plate (3D heat transfer). The optimum thickness and the high heat conductivity property of the Aluminum plate ensures there exists sufficiently uniform temperature distribution on the baking surface of the plate. The heat flux, q_s [W/m^2] and the heat flow rate, $\dot{Q}$ [W] supplied to (received by) the receiver surface is given by;

$$q_s = G_b \rho_c (\tau\alpha)_e \gamma_{rsf} C \quad \textit{(Eq. 6)}$$

$$\dot{Q} = q_s A_r = q_s \frac{A_a}{C} \quad \textit{(Eq. 7)}$$

The receiver shading factor, γ_{rsf} and the optical efficiency of the parabolic solar collector, $\boldsymbol{\eta}_{opt}$ are defined as;

$$\gamma_{rsf} = \frac{A_a}{A_r} = 1 - \frac{1}{C} \quad \textit{(Eq. 8)}$$

$$\eta_{opt} = \rho_c (\tau\alpha)_e \gamma_{rsf} \quad \textit{(Eq. 9)}$$

The thermal energy efficiency of the solar fryer is determined as a ratio of the useful energy to that of the input solar energy. Temperature measurement is taken on the heating and baking surface of the plate in order to determine the heat transfer of the overall baking process.

The input energy to the solar collector, Q_{in}, the useful energy delivered by the collector and gained in the receiver plate, Q_{plate} and the thermal efficiency of the receiver, $\boldsymbol{\eta}_{th,\,plate}$ and the thermal efficiency of the baking process, $\boldsymbol{\eta}_{th,\,baking}$ are given by;

$$Q_{in} = G_b A_a \gamma_{rsf} \quad \textit{(Eq. 10)}$$

$$Q_{plate} = q_s A_r - h_L A_r (T_r - T_a) = \left(mC_p\right)_{plate} \left(T_f - T_i\right) \quad \textit{(Eq. 11)}$$

$$\eta_{th,plate} = \frac{Q_{thermal}}{Q_{in}} \quad \textit{(Eq. 12)}$$

$$\eta_{th,baking} = \frac{Q_{baking}}{Q_{in}} \quad \textit{(Eq. 13)}$$

The *solar fryer mode with* continuous heating and baking mode will have lower heating and baking time hence relatively higher efficiency while in the alternative heating and baking mode the heating and baking time will be larger resulting reduced efficiency.

2.3 Solar tracking and application time

The solar fryer is designed and provided with two application modes. The continuous type model is more preferable for applications areas and time in which the sun is in relatively overhead position thus the dish inclination angle is in the range of $\pm 15^0$ from the vertical position. Such conditions can be easily obtained in Ethiopia when the local time is in the range of 10:00 to 15:00. The alternating type model provides more flexible in terms of solar inclination, as heating and baking are conducted alternatively. Therefore, while the alternatively type model is equally applicable in the above time, it is more preferable if an application is required for the remaining time of the day i.e. early morning and late afternoon, provided if there is sufficient solar radiation.

2.4 Injera quality assessment

The performance of the direct solar fryer is also determined qualitatively based on the quality of Injera as compared to quality of Injera baked by conventional baking process, such as electrical baking. The quality of the baked Injera is determined qualitatively by physical inspection of its size (thickness), colour, eye formation, underside appearance, texture and taste. This physical property is qualitatively evaluated with the respective physical property of Injera baked by conventional baking methods, such as electrical mitad.

3. Experimental methods and materials

A prototype developed for the direct solar fryer model is shown in figure 3, with the prototype in a) indicates for the continuous heating and baking mode of operation while the prototype in b) indicates for the alternative heating and baking mode of operation.

a) b)

Figure 3: the direct solar fryer model a) with continuous heating-baking mode b) with alternative heating-baking mode

Extensive experiments on the two models were carried out, thereby to evaluate the thermal performance of the system by conducting temperature measurement on the different points on the baking plate, mass and solar radiation measurement. The experimental setup is shown in figure 4.

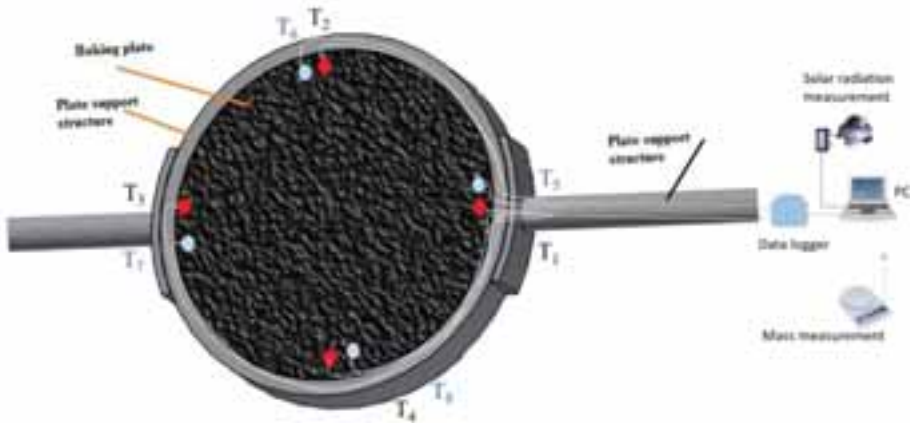

Figure 4: schematics of the experimental setup for temperature, solar radiation and mass measurement

Eight thermocouple (k type) were used to measure temperature at the surface of the baking plate. For the continuous mode, the temperature measurement on the illumination side is denoted as T_1, T_2, T_3 and T_4 and the baking surface as T_5, T_6, T_7 and T_8. Similarly, for the alternative mode, the temperature measurement on the illumination (or baking) side is denoted by T_1, T_2, T_3 and T_4 while the backside (insulated side) of the plate is denoted by T_5, T_6, T_7 and T_8. During the analysis, an average of these temperature measurements were calculated, indicated as $T_{av,\ baking\ surface}$, $T_{av,illumination\ surface}$ and $T_{av,\ plate.}$ Solar radiation measurement using the Delta T instrument (SP1 sunshine pyranometer) were conducted, measuring global (G) and diffuse irradiance (G_d). Mass measurement of the dough and the baked Injera were also taken.

4. Result and discussion

In this research, the thermal performance of the direct solar fryer with two mode of operation i.e. the continuous heating and baking mode and the alternative heating and baking mode is analyzed and presented. The performance of the direct solar fryer is presented in terms of heating-baking temperature profile, power, energy consumption and thermal efficiency, as discussed in the following sections.

4.1 Heating and Baking Temperature Profile

The temperature profile of the heating-baking process for the direct solar fryer model with continuous heating and baking mode is indicated in figure 5. The initial heating up of the plate has taken an average of 30 minutes until it reaches a baking temperature of 120 ℃ to 130 ℃, which was sufficient surface temperature to initiate the baking activity. The heat distribution was also relatively within acceptable uniformity, with an average temperature difference between the bottom illumination and upper baking surface of 3 ℃ while the instantaneous difference was between 0 to 10 ℃.

For the solar fryer with the alternating heating baking mode, the plate has reached an average temperature of 160 to 180 ℃, which was sufficient to initiate the baking process. The average temperature drop per each baking was about 40 ℃ (170-130 ℃), which indicated the thermal energy storage requirement of the baking plate.

In comparison to the conventional baking process, the temperature profile of the heating and baking process was similar as this temperature profile was independent of the type of energy utilized, rather the baking energy requirement of the process.

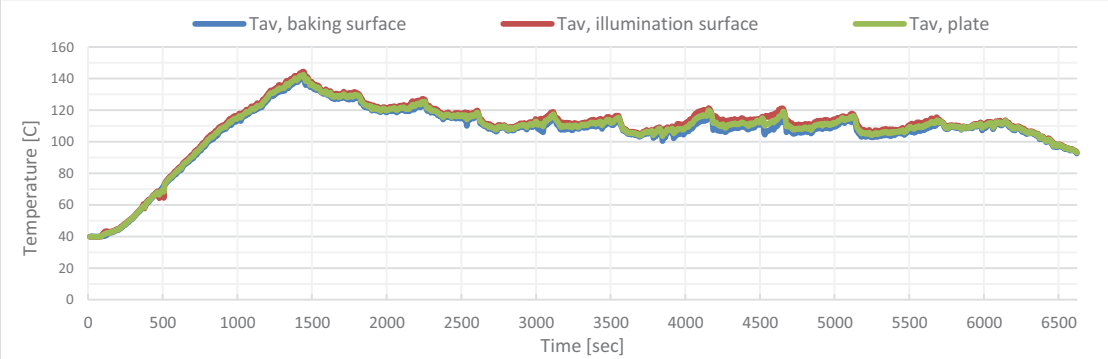

Figure 5: Heating and baking temperature profile for the alternative solar fryer model with continuous heating and baking mode
[Note: the result here is from an experiment taken on March 16, 2017 at Mekelle Ethiopia. Similar result has been obtained on experiments taken on 10th and 11th of February; 15th and 17th of March; 11th, 12th and 13th of May; 16th 17th and 19th of June 2017]

4.2 Heating and Baking Time

As indicated in figure 5, each baking activity using the continuous heating and baking mode fryer has taken an average of 5 minutes while the subsequent additional heat up time is 2 minutes, giving an average baking time of 7 minutes per Injera. The direct solar fryer with the alternating heating and baking mode requires larger heating time at each interval of baking process, as the plate needs to store thermal energy for the subsequent baking process.

In comparison to the conventional baking process, both modes of the direct solar fryer have the same degree of initial heating time. The subsequent heating-baking time for both models is slower than the conventional baking process while the solar fryer with the alternating heating-baking mode is even slower. The conventional baking process usually requires an initial heating time of about 30 minutes while the subsequent heating-baking time is about 3-5 minute per Injera.

4.3 Baking Power and Energy

The heating and baking power requirement for the direct solar fryer model with continuous heating and baking mode is indicated in figure 6. The area under the power curve in figure 6 will give the total thermal energy from the sun, the thermal energy stored in the baking plate and the energy consumption for the baking process. The average plate stored energy was about 153kJ per Injera and this was equivalent to 563W of baking plate power.

The average direct solar intensity has been 932W/m^2 and considering the collector size, this is equivalent to 2kW available energy from the solar radiation. Considering an aluminum material reflectivity of 95 % and other factors (i.e. pan surface reflectance, pan shading effect and dish estimated defect) combined effect of 72% will give 1538 W capacity of incoming radiation from the solar collector, thus about 37 % of the solar radiation reaching the illumination surface was converted into the baking plate power.

The overall energy consumption of the direct solar fryer model with continuous heating and baking mode is indicated in figure 7. The baking energy was determined to be 1150 kJ/Kg of Injera or 450 kJ per Injera. The solar fryer thermal efficiency ($\eta_{th,baking}$) including the solar collector efficiency, was determined to be 37 % while the thermal efficiency ($\eta_{th,plate}$), by including the plate stored energy as a useful energy was about 65%. The low thermal efficiency was attributed as the baking plate is very large (550 mm in diameter and 12.5mm thickness) in order to meet the traditional Injera size, prompting higher surface convective and radiative heat losses. The solar fryer would have been more efficient if it was smaller size but that will have social acceptance problem because of its smaller Injera size. Large size solar fryer compromises efficiency and baking time; the larger the size the less efficient and the larger baking time but it satisfies the traditional Injera size requirement.

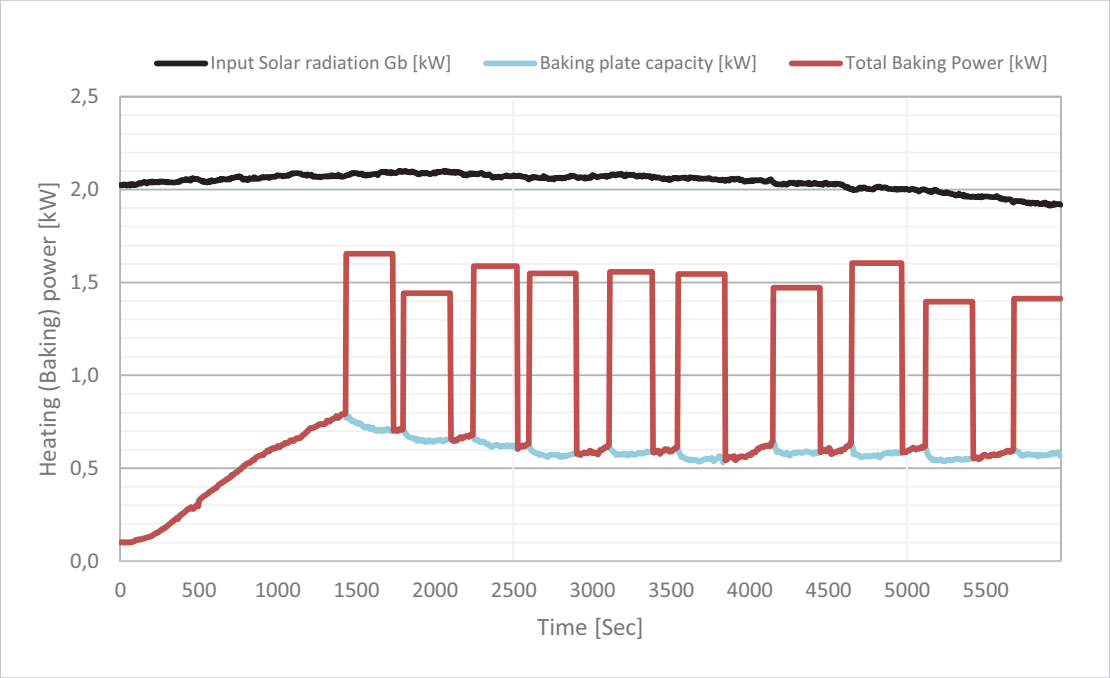

Figure 6: Heating and baking power for the direct solar fryer model with continuous heating and baking mode

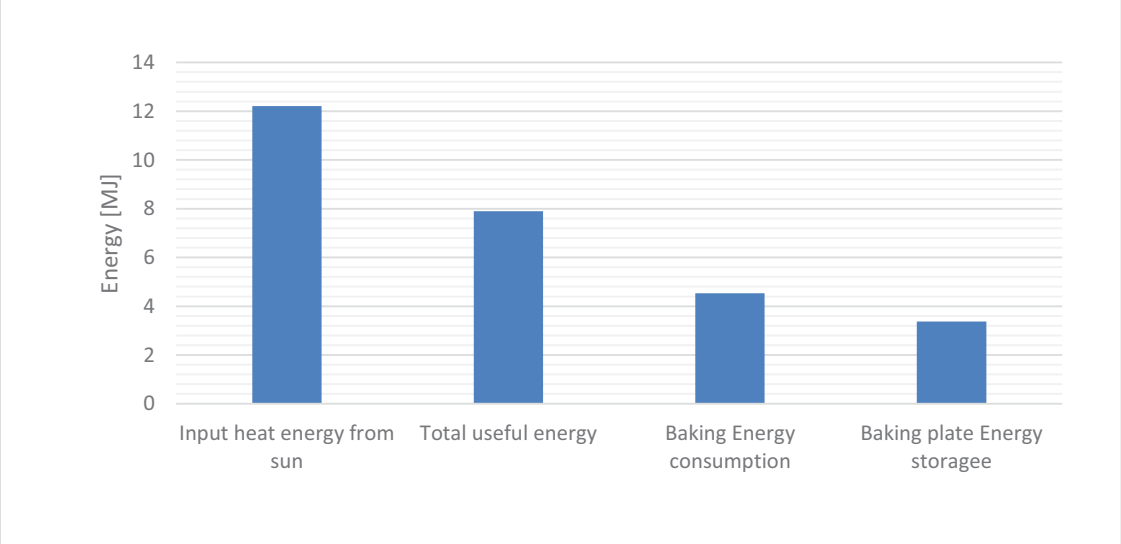

Figure 7: Overall energy consumption of the direct solar fryer with continuous heating and baking mode

4.4 Quality of the Injera

The quality of the baked Injera is as indicated in figure 8. It can be seen that the quality of the Injera with respect to the physical property of size (thickness), color, eye formation, underside appearance, texture and taste is very good and it is the same as any Injera baked with the conventional baking system.

Figure 8: quality of the Injera from the direct solar fryer with continuous heating and baking mode

5. Conclusion

This research has demonstrated solar injera baking using a large size direct solar fryer. The solar fryer was designed to address simplicity in the system and its application. The solar fryer is effective, with 37% thermal efficiency while enabling to harvest cost-free solar energy. The system can be used for injera baking application in a single household, small group rural households or small scale Injera baking business individuals or groups. The only limitation of the application is when there is no sufficient solar radiation such as in cloudy days or if a baking application is required during off sunshine hours, such as at night. For such cases, a backup alternatives should be provided.

Abstract

This work investigates sustainability as a characteristic of renewable energy systems with the goal of improving the rigor of how it is applied. This work is based upon 20 years of developing and deploying sustainable solutions to villages in the Nepal Himalayas and particular to the village of Moharigaun (near Jumla) since 2002. Sustainability has been used in at least four different ways when applied to renewable energy systems which are described and contrasted. In addition, sustainability is analyzed using a systems engineering approach so they are recognized as non-functional properties impacting stakeholder value. Stakeholders of these systems include users, system developers, various relevant government entities and investors. A set of more rigorous definitions are then given along with suggestions on how the definitions can be applied. The work concludes with suggestions for additional work on sustainability.

Keywords: Renewable, Pico Hydro, Sustainability, Energy Systems

1. Introduction

As described in [1,2,3], the Rural Integrated Development Services (RIDS) has been developing methods to enhance the living conditions of remote mountain communities in Nepal since 1996. The approach taken by RIDS is holistic and contextualised to geographical region, local cultural values and belief systems, meteorology and governmental policies. This approach improves the long term success of the deployed systems. Those solutions include:

1) Pit Latrines: Used for individuals and communities to improve overall village hygiene and sanitation.

2) Smokeless Metal Stoves: They are used for cooking the local available dishes, room heating and heating of water for tea and personal hygiene (through a separate attached stainless steel water tank).

3) Basic Indoor Lighting: Local energy resources such as water, solar energy or wind are used for pico-hydro power plants, solar photovoltaic systems based on the local context and small scale wind turbines, to generate electricity for basic access to indoor lighting with low wattage while LED lights.

4) Clean and sufficient Village Drinking Water Supply: Water supplies from the communities' owned water sources are designed and built for safe and sufficient drinking water for all.

The development of these four solutions, called the "Family of 4" (http://www.rids-nepal.org/index.php/Family_of_4.html) has resulted in a new understanding of sustainability that has important, synergistic benefits. This is due in part to a recognition that the needs of all stakeholders, especially of the end-users' expressed verbally, must be taken into account when considering sustainability.

Prior workers have investigated sustainability. In [4], for instance, the authors provide several examples of how sustainability is applied such as economic, energy, agriculture and then attempt a common definition. However, their definition does not account for long term continuance of systems and neglects critical stakeholders such as investors. In [5], the authors take a systems approach and investigate sustainability across multiple levels of complex systems. While this is a valuable contribution, the authors emphasize environmental engineering and focus only on systems themselves. As a result, they don't account for stakeholder needs.

doi:10.18086/swc.2017.24.03 Available at http://proceedings.ises.org

This work is a unique contribution since it recognizes sustainability of renewable energy as a non-functional system property, often called "quality attributes" of a system, of particular importance to stakeholders. As a result the needs of the stakeholders are paramount. This approach is critical for deployment of renewable energy solutions to remote villages since it allows other stakeholders to listen to their self-identified needs, enabling a better understanding of the local stakeholder essential requirements through long term local engagement. This work also considers other stakeholders such as financial backers of renewable energy solutions. This group of stakeholders is a critical partner required for long term success. However, financial stakeholders often have a different perspective and motivations for requiring "sustainable" solutions, though based on current and "ear tickling" development theories rather than on detailed baseline surveys and long term understanding of the end users' context and self-identified needs. In addition, this work proposes a sustainability measurement system so that it can be optimized. Emphasis upon sustainability as a non-functional system property and upon stakeholder needs is the focus of this work.

2. Sustainability as a Non-Functional Requirement

It is common in systems engineering to use 'ilities' to describe non-functional system properties. Examples are reliability, portability, quality, maintainability, and durability [6]. One benefit of using "ilities" is that they allow the system designer and user community to perform system architecting trade studies with a focus on a balanced solution with the potential to meet stakeholder needs [7]. From this perspective, sustainability is one of many different stakeholder needs that must be met to ensure value delivery over the life cycle of the system. Once a full set of "ilities" and their relative importance has been established, trade studies can be a useful tool for choosing the preferred system architecture as described in [8].

One trade study method is to use a quality function deployment matrix as described in [9]. This method uses criteria (ilities in this case) which are assigned a weighting, W_k. Each system architecture option is evaluated against the criteria (ilities) and assigned a value, V_k, which represents the capacity of the architecture to achieve the criteria. The score for each architecture option is then calculated using.

$$Score = \sum_{k=1}^{n} W_k V_k \tag{1}$$

The result of this approach is a system architecture baseline that can be further developed.

The importance of system architecting using "ilities" for this work is that shows that sustainability is one of many system level non-functional properties that must be considered when developing highly contextualized green energy solutions.

3. Four Uses of Sustainability In Highly Contextualized Renewable Energy Systems

There are at least four different uses of sustainability when applied to green electric power systems for remote villages. While each of the definitions may have common stakeholder interests as a concern, each of the definitions also address interest of specific stakeholders.

The first is Investor Centric Sustainability. The deployment of renewable energy solutions requires financial backing which is just as true for large multi-mega Watt solar power systems as it is for pico-hydro electric systems. Most financial backers want to supply a onetime investment (or investment over a fixed time frame) and after the investment period is over, they expect the system to continue without any further investment.

True enough that future expansion may require additional funding, but the goal of the financial backer is a system that continues to perform its function without additional investment. This is the case for investors in for-profit power generation ventures with an expectation of a return on their investment and it is true for financial backers in non-profit power generation systems. The investor in a non-profit power generation system expects their investment to continue to deliver value to the users after the investment period has ended.

Financial backers of non-profit power generation systems expect that the deployed system will continue well after they have invested. Moreover, non-profit power system investors will often expect the system the system to sustain expansion to new users without additional investment. This is due, in part, to the fact that some non-profit investors desire their investment to continue to deliver value as a personal legacy. Investor Centric

Sustainability is an important driver to proper system architecting since it can mean the difference between attracting and not attracting investment.

The second is Environmental Sustainability. This understanding is what most individuals think of when they hear the word sustainable. It means that the deployed system will deliver value to users with minimal or zero negative impact to the environment.

The third is Physical Sustainability. The concept is that the deploy system can be sustained and maintained by the resources gathered as revenue from the operation of the system. This requires a maintenance plan and financial plan (often user payment for energy services/units) which funds required maintenance as required.

The fourth is Growth Sustainability. This type of sustainability refers to the capacity of the system to sustain value delivery as the system itself grows and increases in scope. This requires a long term plan (≥20 years) for how the system will be expanded over time. Growth sustainability includes the idea that the solution can serve as an example for others to implement. In this case, the system is sustainable when its energy services can be delivered as the user community grows over the decades and when the system can be replicated by others.

4. Measurement of Sustainability

Sustainability can be measured. For instance, the long term financial sustainability of the system can be analyzed according to income sources once the system is deployed. Some percentage of the local population will be able to contribute to Maintenance Sustainability and some percentage of new residents will be able to contribute to Growth Sustainability. Contribution (financial, human resource, land, etc.) goals can be established and compared to actual levels to understand trends and lessons learned for future deployments.

5. Conclusions

Sustainability has been analyzed as a non-functional system property of rural green power systems. The method of using “ilities” to architect the solution was described. Four uses of sustainability were also described. Finally, a method for measurement of sustainability has been proposed.

Abstract

Pulp and paper mill effluent treatment and detoxification methods have been extensively investigated resulting to varying efficiencies and capital and operational costs. The main toxic component in the mills' effluent is modified lignin, which is difficult to degrade by convectional effluent treatment systems applied by most mills. This study aimed at using natural photo catalytic degradation of methylene blue using anodised pigmented and non-pigmented titanium plates to optimise anodising time and voltage. Titanium plates were anodised at varying voltages and times in a mixture of sulphuric and hydrofluoric acids. Irradiation of aqueous solution of methylene blue was done using varies anodised pigmented and non pigment plates in a batch reactor cell. Absorbance of each photo catalysed solution was determined every five minutes after a dark phase of fourteen minutes using a laser light source. Absorbance was then converted to transmittance, which gave photo catalytic reactivity of plates. The study revealed that photo catalytic reactivity of pigmented titanium plates was higher than non-pigmented. Photo catalytic reactivity also increased with increase in anodising time and voltage. Anodised plate at 200volts for 120 seconds and pigmented with photo catalytic reactivity of 62.325×10^{-3} was found to be the best to degrade methylene blue. Application of this optimised plate on Kraft Pulp mill effluent showed reduction in COD, BOD, turbidity, colour and total suspended solids. However effluent pH and electrical conductivity increased. COD, BOD, turbidity and colour removal efficiency improved on introduction of wood ash leachate (electrolyte) in photo catalytic activity. The study recommended the use anodised titanium plates using natural ultra violet energy aid by an electrolyte to treat Kraft pulp and paper mill effluent.

Keywords: pulp and paper, methylene blue, Photo-catalytic degradation, titanium oxide

1. Background

Pulp and paper industry started during ancient times and since then it has remained to be a very important industry in the development of many countries (Hossain and Rao, 2014; Raj *et al*., 2014). The pulp and paper industry is important as a result of its major roles of paper and paper products in many areas of human activities. It has contributed immensely to gross domestic products of both developing and developed economies over a long period time (FAO, 1998, Kamali and Khodaparast, 2015). The Pulp mill sector utilizes a huge amount of lignocellulosic materials and water during its operations and processes. In the recent past the sector has been faced with ever changing and stringent regulations of its effluent discharge standards with high possibilities for the same to continue in the future. Pulp and paper production has long been recognised as a significant point source of contaminants and toxic components to aquatic life (Gupta, 1994; Sumathi and Hung, 2006; Monte, *et al.,* 2009; Hossain, and Ismail, 2015). Several compounds with varying toxicological significance have been identified in pulp and paper liquid effluent. Effluent from the mills contain chlorinated lignosulphonic acids, chlorinated resin acids, chlorinated phenols and chlorinated hydrocarbon among others (Mahida, 1981; Thompson, *et al*, 2001; Chandra *et al*., 2007; Mehta, *et al.,* 2014; Barapatre and Jha, 2016).

doi:10.18086/swc.2017.25.01 Available at http://proceedings.ises.org

Treating and detoxifying effluent is a significant challenge to pulp and paper mills, and is an integral part of their operation in order to meet ever changing discharge standards for several pollutants and toxic materials (Kamali and Khodaparast, 2015). Several effluent treatment methods have been investigated extensively and they include use of activated carbon, membrane adsorption, cationic coagulation, polymer addition, ultrafiltration, biological and chemical oxidation, electrochemical, electro-coagulation, photo-catalysis among many more (Hilleke, 1991; Bellew, 1978; Orori, *et at*, 2007; Etiegni, *et al*, 2010; Chandra *et al.,* 2012; Cong,et. al., 2012; Chandra *et al*., 2013; Hossain and Ismail, 2015, Saez *et al.,* 2013; Zongo *et al.,* 2009; Barapatre and Jha, 2016).

2. Material and Methods

2.1. Study Area

Effluent samples for this study were obtained from Mufindi Paper Mills (MPM) situated in Mgololo valley close to Mafinga town in Mufindi District, Iringa province, in the United Republic of Tanzania. The mill is located about a latitude of 08º55'S and longitude of33º32'E on an altitude of1600 meters above sea level. The area has a mean temperature of 21-25^{o}C (Massawe, *et al,* 2016). MPM produces 35000 metric tonnes of pulp and 28000 metric tonnes of paper, with approximately 70 percent of its rated capacity. The main raw materials for the mill are from pine and eucalyptus plantations owned by company (Sutton and Olomi, 2012). MPM has three Kraft pulping digesters each with a capacity of 40m^3. MPM has two fourdrineer paper machines running on different revolutions per minute depending on the paper grade being manufactured. Its main products are packaging materials of various grades and specifications, including Kraft Liner, Sack Kraft, Bag Kraft, Deckle and Grammage (Sutton and Olomi, 2012)

MPM mill has instituted measures to reduce pollution to receiving water by chemical recovery system in which pulping chemicals are recovered through combustion of organics. The mill has not installed a closed white water system, which is very important in the reduction of fibers losses and chemicals. There is need for MPM to install micro-screens on paper machines to cut down fiber loss. The brown coloured combined mill effluent from pulp washing and papermaking sections is passed through trash screens to remove large suspended solids. The screens are designed with effluent volume of 1800m^3/hr of 50mm and 15mm manual and mechanical bars spacing respectively. The effluent is passed through a single primary clarifier (turbo circulator) employing an air flotation principle. The clarifier is designed with a flow of 1080 m^3/hr with a maximum flow of 1800 m^3/hr. The diameter of the clarifier is 43m and 4m peripheral water depth with inlet suspended solid load of 5500kg/day with a total suspended solid removal efficiency of 88-98% (Sutton and Olomi, 2012).

After clarification the supernatant effluent flows into specially designed aeration lagoon fitted with four of 45-watt electrically operated surface aerators. The detention time in the aeration lagoon is approximately 7 days. After aeration the supernant effluent flows to settling pond where it takes approximately 5 days. Thereafter the effluent drains slowly through a swamp into river Kigogo Ruaha. River Kigogo Ruaha drains into River Luhuji that drains into River Kilombero, which drains into River Rufiji that into Indian Ocean.

2.2 Anodising and pigmenting of titanium plates

Titanium grade two foil of 0.3mm thick (TiGr2-FL-230-01-02) was obtained from William Gregor Limited shop. The foil was cut into pieces measuring 20mm by 80mm (plates). The plates were degreased in acetone for five minutes and thereafter thoroughly rinsed in distilled water. Before anodizing, each plate was further cleaned by immersing it in a mixture of Nitric acid (1 molar), Hydrofluoric (1molar) and distilled water in a ratio of 13:1:7.5 for 15 seconds and quickly rinsed using a lot of distilled water. Anodizing of titanium was carried out in a one litre cell with varying times and voltages. Anodising time varied from 30, 60, 90 and 120 seconds Anodizing voltage also varied from 60, 80, 100, 120, 140, 160, 180 and 200 volts. Anodising electrolyte was made of double distilled water, sulphuric acidic (18M) and Hydrofluoric (1M) in the ratio of 972:27:1 respectively. The distance between the electrodes and anode was kept at 1cm and was held constant for all anodising reactions. The electrolyte was continuously stirred using a magnetic starrier. Anodized plates were

pigmented using 0.1M solution of copper (II) sulphate electrolyte at 12volts for 5 seconds. The anode was made of copper plate fixed at distance of 3cm from titanium cathode plate. Each plate was pigmented separately using a fresh electrolyte in orders to obtain similar pigmenting results. Annealing of titanium plates was accomplished in a furnace at a temperature of 450^{o}C ±5^{o}C for three hours.

2.3 Optimum anodizing conditions

Plate 1 show a fabricated reactor used in this study. Each of the plate was used at a time in the reactor with 60ml of 1.5×10^{-5}M of methylene blue. Optimization of anodizing variables was achieved through a fabricated cell reactor utilising the principle of laser light absorbance by methylene blue. Methylene blue was chosen because of its close chemical structure and bonding to that of lignin, which is the main component found in the pulp paper mill effluent. Two anodizing variables (anodizing voltage and time) were investigated that mainly affect catalytic efficiency of phenyl compounds. The reaction was run for 14 minutes of dark and 46 minutes of UV phase. Absorbance was measured at an interval of 2 minutes during dark phase and 5 minutes during UV phase. The dark phase was important to allow the solution to be homogenous and any adsorption to take place. Absorbance was used to determine the level of degradability of methylene during the experiment. Absorbance was obtained from the concept of laser light intensity before and after going through the solution.

Plate 1: Fabricated reactor unit for optimization of anodised titanium plates

Natural solar ultra violet was used with all experiments carried out between 11.30am and 2.30pm when the UV was between 360-400nm. Absorbance was then converted to transmittance using the Beer Lambert relationship. The best linear relationship between time and transmittance was then determined. The gradient of a linear relationship gave reactivity of each plate that was used to optimise the two variables of interest in the study. Optimised conditions were then used to prepare titanium plates that were used to treat effluent from Kraft mill of Mufindi Paper Mills.

2.4 Effluent treatment efficiency

Plate 2 shows a set-up of photo catalytic effluent treatment unit used in the study. A photo catalytic unit was fabricated with an equal width and length of 24cm and 20cm depth using 4mm clear transparent glass. Twenty four (24) optimized titanium plates measuring 30mm by 80mm were prepared and carefully stuck on a 4mm-thick glass substrate using silicon. Three litres of the effluent was used for each photo catalytic effluent treatment. One side of the stuck titanium plates were held 2cm above effluent surface with a gentle slope ending in the effluent to complete the current flow with the effluent. Using an electric pump (magi-200) a thin layer of effluent was continuously circulated over the plates while exposing it to direct natural ultra violet rays for 6

hours. Regularly the set up was tilted towards direct sun rays for higher light intensity. Effluent from the Kraft pulping mill was subjected to a combination of different photo catalytic effluent treatment combinations. Combined treatments included, photo catalytic alone (PHCALON) and photo catalytic with wood ash leachate as an electrolyte (PHCASH). A control effluent treatment was set by allowing the effluent to circulate over a plain transparent glass (PHOALON). Treated effluent samples were then allowed to settle overnight and the supernant was analysed for colour, turbidity, pH, biochemical oxygen demand, chemical oxygen demand, total solids, total suspended solids and electrical conductivity.

Plate 2: Fabricated photo catalytic effluent treatment unit

3. Results and Discussion

3.1 Methylene Blue Degradation

Rate of degradation, Absorbance, transmittance of methylene blue gave the reactivity varies titanium anodized pigmented and non pigmented titanium plates. The titanium plate with highest reactivity on methylene blue was then use in treatment of a Kraft pulp and paper mill effluent.

3.2 Absorbance of Methylene Blue

Plate 3, 4, 5, and 6 show selected absorbencies of methylene blue with time. Generally, absorbance decreased for all anodised titanium plates experimented in this study. Absorbance decreased but transmittance increased because some bonds causing colour may have been broken. When more bonds were broken then methylene blue underwent further decolourization. Decrease in methylene blue absorbance is attributed to its degradation by natural UV catalysed by anodised titanium plates, which consequently reduced the ability of the solution to absorb more UV light. The higher the rate of degradation the better the catalytic activity of anodised plates employed.

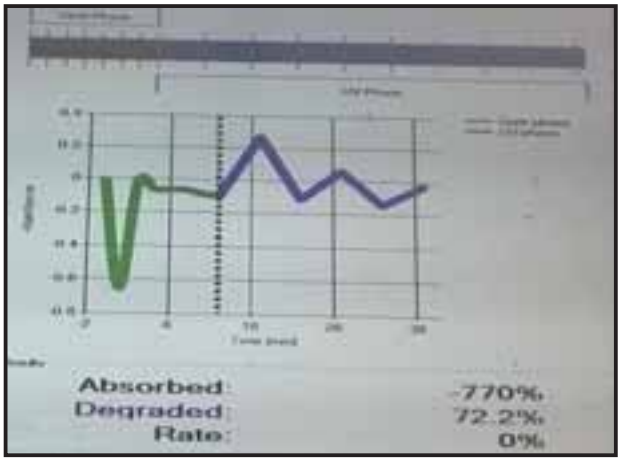

Plate3: Degradation of methylene Blue without titanium plate

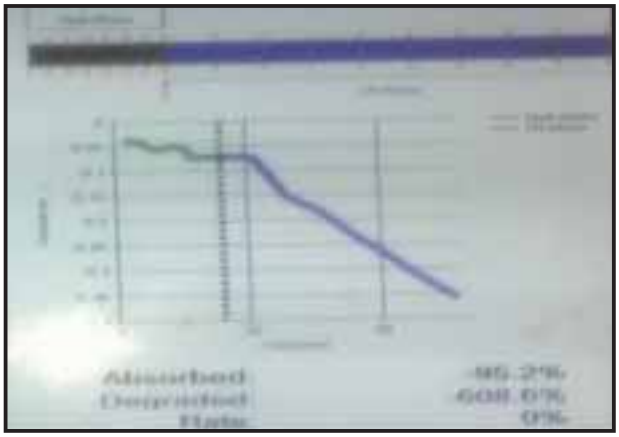

Plate 4: Degradation of methylene Blue with titanium plate anodised at 200 volts for 120 seconds and pigmented

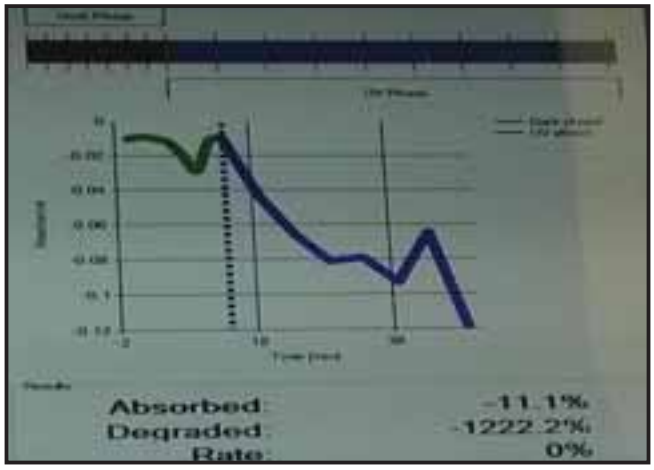

Plate 5: Degradation of methylene Blue with titanium plate anodised at 180 volts for 120 seconds and non-pigmented

Plate 6: Degradation of methylene Blue with titanium plate anodised at 180 volts for 120 seconds and pigmented

3.3 Transmittance of Methylene Blue

Figure 7 show selected transmittance during methylene blue degradation by natural UV catalyzed by anodized titanium and non pigmented plates. The best relationship between transmittance and degradation time of methylene blue for various plates were linear relationships with values for R-squared ranging from 0.9564 to 0.9802. R-squared values closer to one indicated a very good relationship between transmittance and degradation. The relationship takes the first order reaction equation in which the gradient is the rate of reactivity of anodized titanium plates while transmittance is the intercept and degradation time varying.

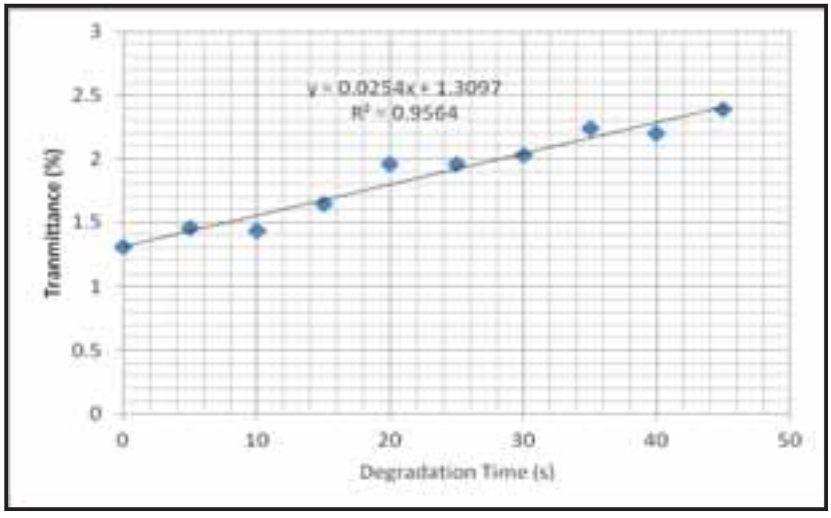

Figure 7: Transmittance of methylene blue using Natural UV catalysed by anodised titanium plate at 160 volts for 120 seconds and non-pigmented

3.4 Degradation Rate of Methylene Blue

Table 1 show means reactivaties of various anodised titanium plates during methylene blue degradation at different using natural Ultra Violet solar radiations. Highest degradation of methylene blue was noted with a plate that was anodised at 200volts for 120 seconds and pigmented using copper solution. The lowest reactivity was noted in non pigmented titanium plates anodised for 30 seconds. There was a significant difference

(P≤0.05) among reactivity of plates anodised at different voltages and times. Further there was a significant difference (P≤0.05) in reactivity between anodised pigmented and non pigmented plates. Furthermore, result indicted that there is significant (P≤0.05) interaction between anodising time and voltage.

Table 1: Mean Reactivity of titanium plates anodised at various voltages and time

	Reactivity × 10^{-3}

3.5 Reactivity Trends of Anodized Titanium plates

Further analysis of relationship among reactivity, time and voltage for pigmented and non-pigmented plates is shown on figure 8 for selected plates. The best relationship of reactivity with voltage of titanium anodised and pigmented plates for degradation of methylene blue were logarithmic relationships apart from plated anodised for 30seconds. For all plates with logarithmic trends gave R-squared ranging from 0.9871 to 0.9565. These implied that rate of degradation of methylene blue increases with increase in anodising voltage and time but diminish for pigmented plates.

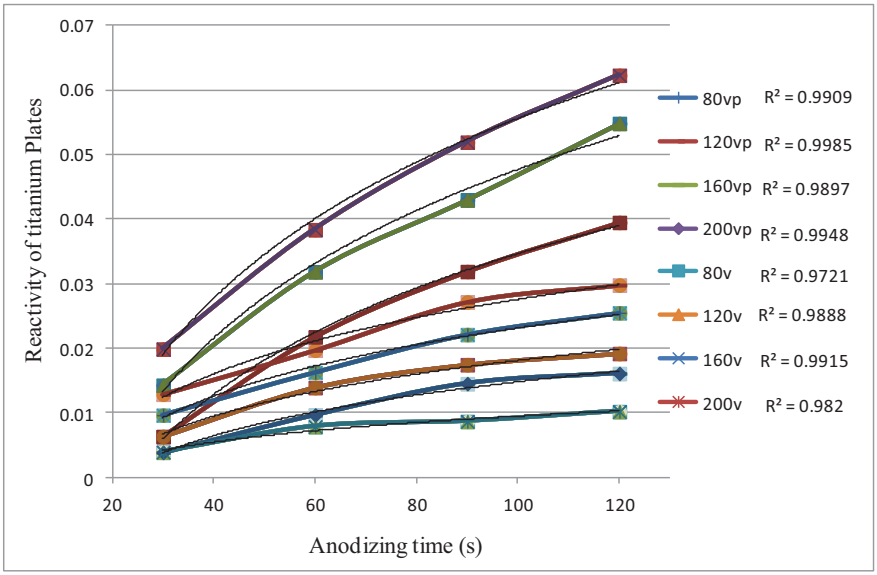

Figure 8: Reactivity trends of selected titanium plates

Only plates anodised for 30 seconds and pigmented showed that the best relationship was linear with R-squared being 0.9818. It therefore imply that better reactivity of plates can be achieved through longer anodizing times. It is also probable that reactivity rate for plates anodised at low voltage for instance that of 60, 80 and 100 volts might follow a logarithmic trend if anodising time was increased beyond the end point time (120 seconds) used

in this study. Reactivity increased with increase in anodising time but the rate slowed as anodising time increased. The best relationship between reactivity and time for non pigmented plates was logarithmic. Obtained R-squared values range between 0.9685 and 0.9685 for all plates tested, which indicates a good relationship. However, a good liner relationship (R-squared of 0.9822) was obtained for anodising time of 30 seconds.

3.5 Effluent Treatment Efficiency

Table 2 shows the treatment efficiency of optimised titanium plate applied in treatment of a pulp and paper mills effluent. Effluent COD reduced by 24.8%, 74.2% and 48.3% for PHOALON, PHCASH and PHCALONE respectively. The obtained COD final values were significantly different ($P \leq 0.05$) among all the treatment combinations. Effluent BOD was also reduced by all treatment combinations by 15.3%, 76.7% and 61.6% by PHOALON, PHCASH and PHCALONE respectively. Treated effluent colour increased for PHOALON (16.7%) but reduced by 80.7% and 58.5% for PHCASH and PHCALONE respectively. PHOALON does not involve titanium plates therefore is more of aeration of the effluent without degradation. Therefore, the probable reason for increase in colour for PHOALON could be that lignin compounds were oxidised resulting into more coloured compounds than before treatment. This finding conger with Haslam (1987) assertion that explained why biological degradation of the pulp mill effluent results in increase in effluent colour. Effluent turbidity reduced by over 23.8%, 82.7% and 86.5 by PHOALON, PHCASH and PHCALONE respectively. The final turbidity values for PHOALON, PHCASH and PHCALONE were significantly different ($P \leq 0.05$).electrical conductivity reduced of lecheate. PHALON and PHCALONE but increased for PHCASH. The increase in electrical conductivity increased for PHCASH because of dissolved mineral introduced to the effluent by the wood ash Total suspended solids (TSS) reduced by 34.4%, 70.8% and 45.5% for PHOALON, PHCASH and PHCALONE respectively. Total Dissolved Solids reduced for PHOALON (46.5%) and PHCALONE (8.5%) but increased by 19.5% for PHCASH. For PHCASH the increase might have been due to introduction of the wood ash leachate with more chemical constituents. Total Solids (TS) reduced for PHOALON (44.3%) and PHCALONE (15.4%) and increased for (PHCASH)

Table 2: Effluent treatment efficiency by PHOALON, PHCASH and PHCALONE

* Percent increase

4. Conclusions and Recommendations

The study revealed that photo catalytic reactivity of pigmented titanium plates was higher than non-pigmented titanium plates. Titanium plates anodised at various voltages and times had different photo catalytic reactivity. Reactivities of titanium plates anodised increased as anodising time and voltage increased. The study revealed that a pigmented plate and anodised at 200volts for 120 seconds with photo catalytic reactivity of 62.325×10^{-3} was the best to degrade methylene blue. The plate was then used to treat and detoxify Kraft pulp and paper mills

effluent. The study revealed that effluent treatment efficiency was higher for photo catalytic aided by wood ash leachate compared with photo catalytic alone using anodised pigmented titanium plates. However, effluent treatment efficiency was low for photo degradation alone for most physical chemical characteristics such as COD, BOD, colour and turbidity. Percent electrical conductivity, pH TDS and TS increased for photo catalytic aided by wood ash leachate. Therefore, it was recommended that application of photo catalytic aid by wood ash leachate in treatment of Kraft pulp and paper mill effluent is viable and can be applied.

Solar Heat for Industrial and Agricultural Processes

Medium temperature solar thermal installation for industrial thermal storage of bituminous

Mircea Bunea, Catherine Hildbrand, Sara Eicher, Alexis Duret, Stéphane Citherlet

HEIG-VD, LESBAT, Solar Energy and Building Physics Laboratory
Avenue des Sports 20, CH1400 Yverdon-les-Bains, Switzerland

Abstract

In this article, the performance analysis of a medium-temperature solar thermal installation integrated at the Colas Suisse SA industrial site in Yverdon-les-Bains (CH) is presented. The innovative collector system supplies energy for the temperature maintenance of bituminous products and provides part of the heating needs of the administrative building in the industrial site. The initial objective of Colas Suisse SA was to cover approximately 60% of the thermal energy demand of the site with solar energy. Field measurements provided an insight into the overall operation of the installation during 2015 to 2017. Despite improvement of the system, the performance of the collector field both in terms of energy and financial aspects was found below the expected values. On the other hand, simulations have shown the potential for improvement offered by the current installation. Despite non-optimal operation of the solar installation, a life cycle impact assessment have indicated interesting potential primary energy savings and greenhouse gas reductions.

Keywords: solar thermal, medium temperature collectors; industrial applications; bituminous storage; numerical simulation; measurements

1. Introduction

In Europe, the industrial sector accounts for one fourth of the total final energy consumption (Eurostat, 2015) of which more than two-thirds is used for heating purposes (IRENA, 2015). Moreover, 26% of these process heating concerns low temperatures (< 100°C) while 19% uses heat between 100 and 400°C (Krummenacher & Muster, 2015). A huge potential exists to provide low to medium temperature processes with heat from existing conventional and advanced collector technologies. It is, therefore, very important to capitalise on this technical potential as today solar energy is reported to cover less than 0.1% of current industrial heat demand (Mauthner et al., 2016).

In 2012, as part of its emission reduction plan, Colas Suisse, a Swiss subsidiary of Colas International, world leader in construction and maintenance of transport infrastructure, decided to overhaul the heating system of its industrial site in Yverdon-les-.Bains so that 60% of its thermal energy demand is met through solar energy. A real application of solar thermal integrated in the road construction industry is presented here, where heating needs for bitumen and emulsion storage can be met by temperatures below 200 °C. The thermal and environmental evaluation of this real solar thermal installation is described based on field measurements and numerical simulations.

Bitumen and emulsions are used in road construction, an industry largely relying on fossil fuels, to provide low to medium temperature heat demands. The operating temperature for bitumen emulsion ranges from 60 to 75°C while for bitumen it ranges from 160 to 200°C. These hot products must be stored, transported and used hot to maintain their workability. Conscious of the important potential of solar heating in the industrial context, but also of the economic and environmental issues related to fossil energy use, COLAS Switzerland, has implemented a medium temperature solar thermal system to maintain its bituminous products tanks at the required temperature. The objective was to maximise the share of heat provided by solar heating and optimise the overall energy system.

2. System description

The industrial site located in Yverdon-les-Bains (CH) is composed of a building and the bituminous storage installation situated next to the building. The advantage of this sector is that road construction in Switzerland operates only in the summer season from April to September when solar energy is most available.

A solar collector field was integrated to this industrial site during 2012, but several problems related to wrong hydraulic setups and failures of the control system were identified and therefore important modifications of the installation were performed at the beginning of 2015. The new hydraulic scheme is shown in Fig.1.

Thirty-five solar collectors type C2 (175 m^2 aperture area) manufactured by SRB Energy were installed on the site to cover an important share of the thermal energy demand of the industrial site. These collectors are flat plate collectors placed in front of two cylindrical mirrors and requires no solar tracking device. They present a very high efficiency at temperatures above 200 °C due to the ultra-high vacuum inside the collector (10-8 mbar at ambient temperature). Thermal oil is used as heat transfer fluid for this system.

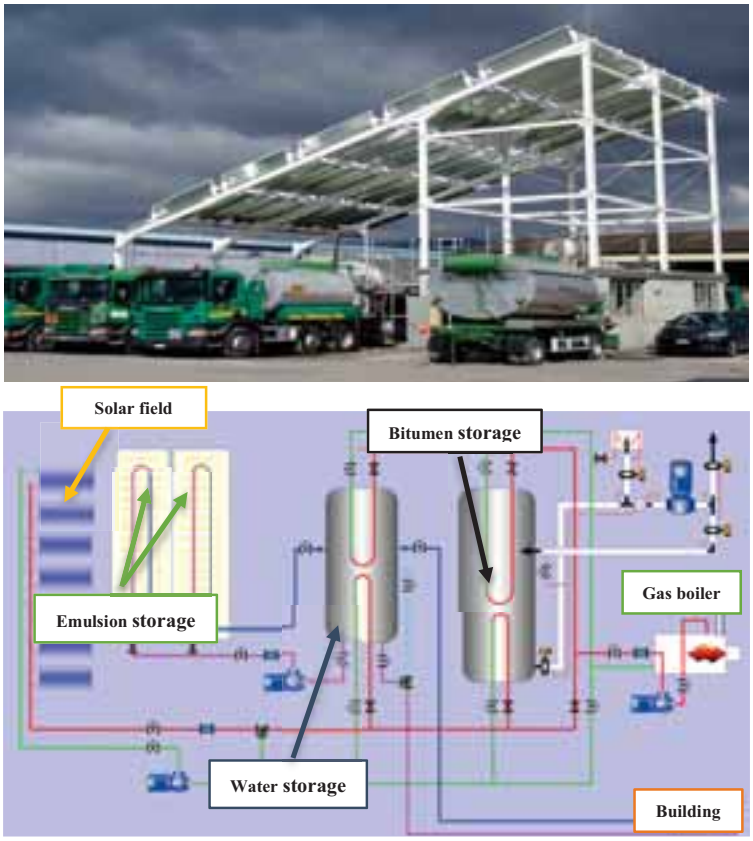

Fig. 1: Picture of the solar installation (up); Simplified representation of the solar thermal installation at COLAS SA after technical modifications (down)

For this particular site, energy is supplied at two different temperature levels:

- Between 50 and 90°C for space heating and domestic hot water for the building as well as to keep emulsions (mixture of water and bitumen) at a specific temperature.
- Between 160 and 190°C for bitumen storage, also depending on the bitumen's characteristics.

Four storage tanks are also present on the site (see Fig. 1): two 50 m^3 emulsion storages, one 70 m^3 bitumen storage and one 27 m^3 water storage. The latter is used for both building and emulsion heat demand. With the exception of the water storage tank, all other tanks have a variable filling level as the tanks are daily loaded and unloaded depending on the demand.

The solar energy deliver priority is to the water tank in order to lower the operating temperatures of the solar collector field and implicitly maximise collectors' efficiency. If this storage reaches the set point temperature,

solar energy is delivered to the bitumen storage at higher temperature level. Whenever solar energy is not available, a 250 kW back-up gas boiler supply the required energy. For further details on this solar thermal installation, please refer to Bunea et al. (2016).

3. Field measurements results

Follow-up field measurements and monitoring of the installation have shown the operation of the system as a whole from April 2015 to September 2017.

Bunea et al. (2016) have shown detailed analyse of the system for one year operation. It has been highlighted that the solar yield is strongly influenced by the overall system management. Therefore, it is very important to supply solar energy for low temperature applications (space heat and emulsion needs) in order to optimise collector's efficiency.

Measurement of the collectors' efficiency have shown an important discrepancy between the accredited test values and the measured ones, see Fig. 2. Differences observed for the optical efficiency (15%) can be partly explained by eventual dust or bituminous particles deposits on the collector glasses and mirrors. A thermographic analysis of the solar collectors' field has further suggested that the thermal insulation of the UHV is also not fully ensured for some collectors. Consequently, global efficiency of the collector field is compromised. Differences may also appear as the curve from the certification tests (blue) is given for a fixed irradiation of 800W/m^2 while the measurements are done considering real time fluctuating conditions.

For high operating temperatures, the difference with the theoretical efficiency of the collector exceeds 50%. This highlights the fact that extrapolation of certified tests results beyond 100°C is not appropriate for evaluating these solar thermal collectors.

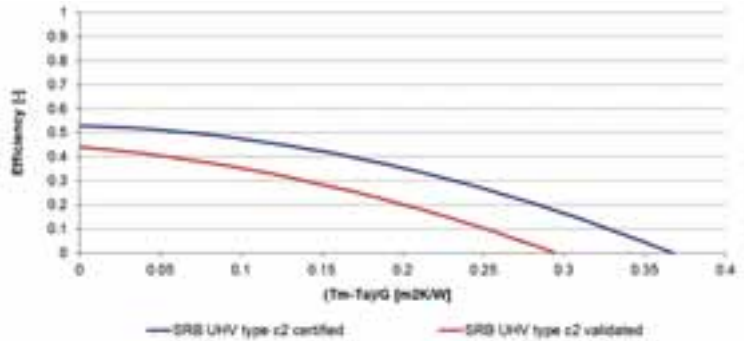

Fig. 2: Comparison of SRB type C2 collector efficiency from certification testing and field measurements

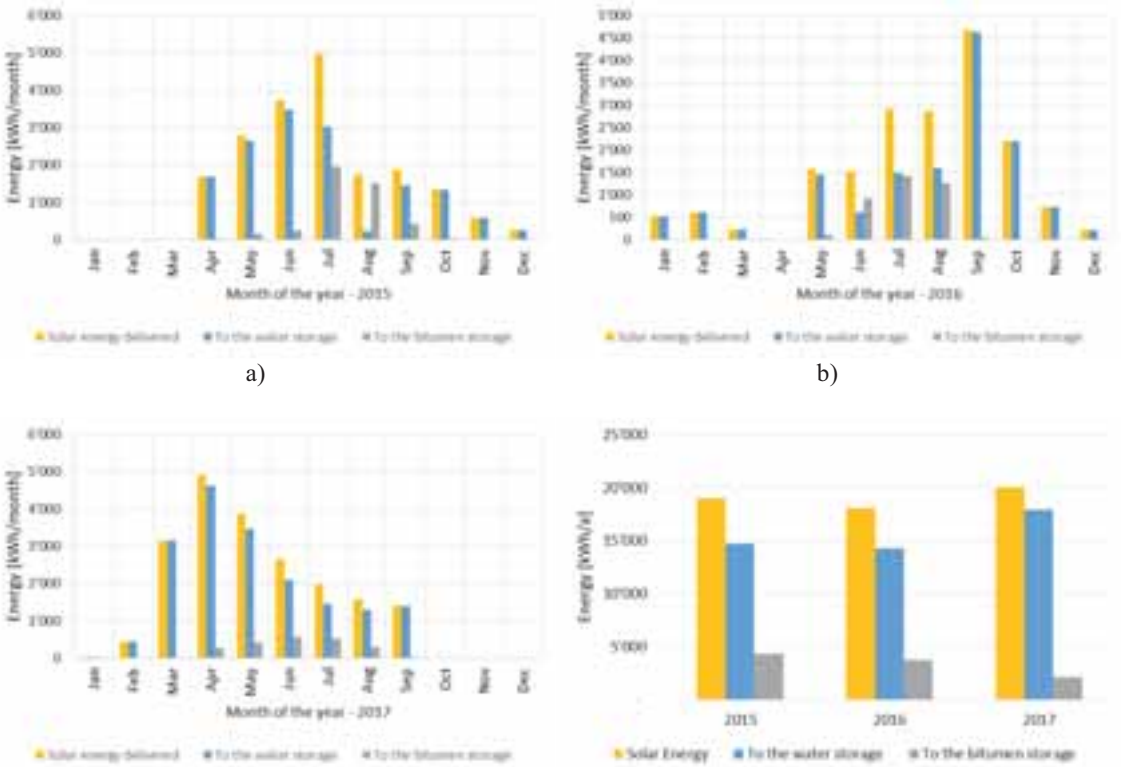
This section presents the evolution of the system operation during three full bitumen seasons from April 2015 to September 2017. Globally it can be seen that the bitumen loaded and unloaded activites in the tank are constantly decreasing every year, which means less activity for Colas and implicitly lower energy consumption, see Fig. 3. The reason for this low activity is the large number of roads built and/or repaired before 2015 that imply no important road work after that. This points out the strong irregularity of the consumption profile over the different years.

Fig. 3: Quantity of bitumen loaded and unloaded in the bitumen tank

This low activity has also an impact in the solar field production due to a decreasing energy demand, but Fig. 4 shows that the solar yield is relatively constant over the years. This happens because the control management gives priority to the low temperature heat demand and therefore most solar energy is delivered to the water storage with only 10 to 21% of solar energy delivered to the bitumen storage yearly.



a) b)

c) d)

Fig. 4: Solar energy delivered to the system. a) in 2015, b) in 2016, c) in 2017 and d) yearly

Fig. 4 also indicates that the solar production profile over one year is also very different not only because weather conditions vary, but particularly because of the high irregularity of the demand profile due to the different construction sites and their specific demand for a given year. The control strategy and the eventual breakdowns occurred at different points of the system can also affect considerably the solar efficiency. For example, a breakdown in the emulsion system in August 2015 caused a drastic decrease in solar production, with sensibly the same weather conditions as July. Under this configuration, solar collectors delivered energy mainly to the bitumen storage, operating at higher temperatures, which greatly reduced the efficiency of the solar thermal system. Another breakdown of the system forced the operator to completely shut off the solar pump from March to early May 2016, reducing to 0 the solar energy delivered to the system during this period.

The year 2017 was characterised by the non-utilisation of the emulsion products stored on site, a strategic decision taken by Colas. Consequently, the reduction of the low temperature energy demand during the bitumen season decreased the solar yield during the summer of 2017. This points out, once again, the tremendous influence of the heat demand on the heat supply for low exergy production devices like solar thermal collectors.

As the solar collectors supply energy to the water tank, their performance changes from that when energy is delivered to the bitumen tank due to their different operating temperature. To illustrate this Fig. 5 shows a comparison of the performances under these two supply configurations against the daily radiation.

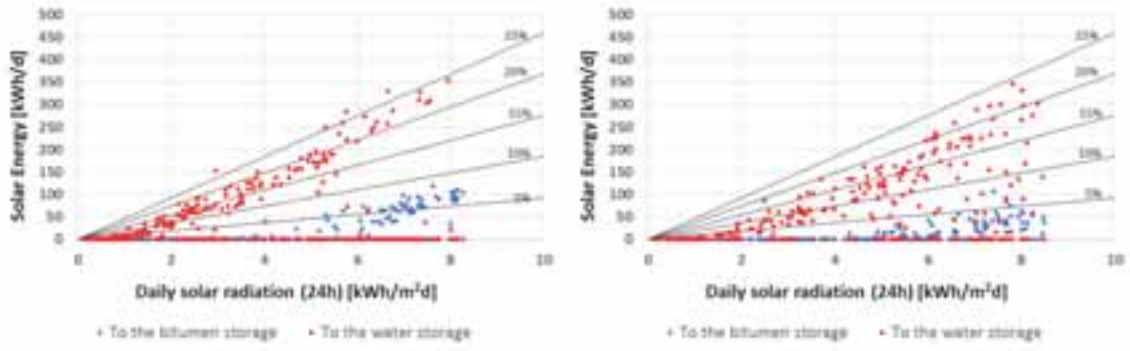


Fig. 5: Performance distribution of solar collectors. a) for 2016, b) for 2017

Overall, the performance is below expectations under all operating modes. The distributions indicate that the collectors' performance decrease when charging the bitumen tank (blue dots) with values below 10%. However, when delivering energy to the water tank (red dots) the performance is improved and could reach 25%. In this case, scattering of the data is more pronounced because of the different utilisation modes of the water tank. Data points at 0% performance correspond to days where the collectors' pump was operating but no heat was delivered to any of the two tanks. This happens because the operating temperature is lower than the storage tanks temperature. Consequently, 35% of the total energy used by the solar pump was spent for circulation only, clearly revealing a controller malfunction.

An evolution of collector's efficiency can be observed between the two years of operation and this for both operation modes. In 2016, when delivering energy to the water storage, the collector field operated with a mean efficiency around 20%, while in 2017 the efficiency decreases at around 15% for this application. Additionally, when delivering energy to the bitumen tank a decrease from ~7% in 2016 to less than 5% in 2017 is observed. The main reason for this decrease could be related to the vacuum loss inside the solar collectors, increasing the thermal losses of the collector itself.

Another point highlighted during this project was the important energy consumption needed for heating a few meters of hydraulic ducts used for loading and unloading the bitumen tank. These pipes are constantly maintained at 220°C to enable sufficient fluidity and proper workability of the bitumen. Fig. 6 shows that in the first years of operation the energy consumed for this circuit was in the range of the energy used for maintaining several tons of bitumen in temperature. Advised by LESBAT, different measures were applied in 2017 by Colas, acting both on the control management and on the thermal insulation of the pipes. These measures enabled a reduction of this consumption to less than 50% of the energy needed for bitumen maintain in temperature during 2017.

Fig. 6: Breakdown of energy delivered by the gas boiler

4. Numerical simulation results

Numerical simulations of the installation performed with Polysun, showed the potential for energy management improvement. A parametric study was carried out to study the effect of different operating and design parameters on the overall installation performance. For example, improving emulsions processing with heat provided by solar energy or gas boiler through the water storage could result in 25% increase of the annual solar production, see Fig.7. In addition, improvements of the collector efficiency could double the current annual solar production.

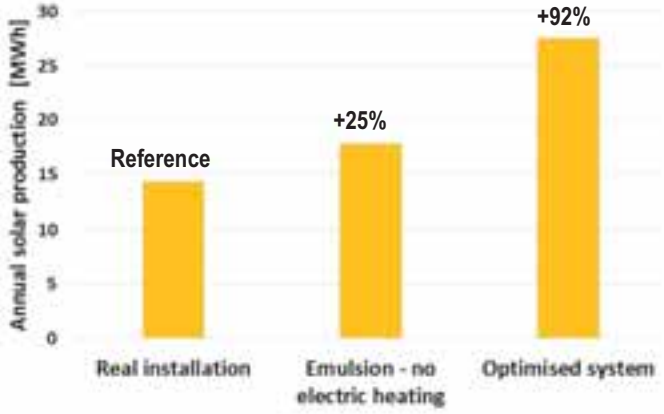

Fig. 7: Simulated annual solar production through system optimisation

Other simulations to predict the effect of other parameters such as collector surface area or type, on the annual solar production, demonstrate that the installation as a whole could absorb much more solar energy, see Fig. 8.

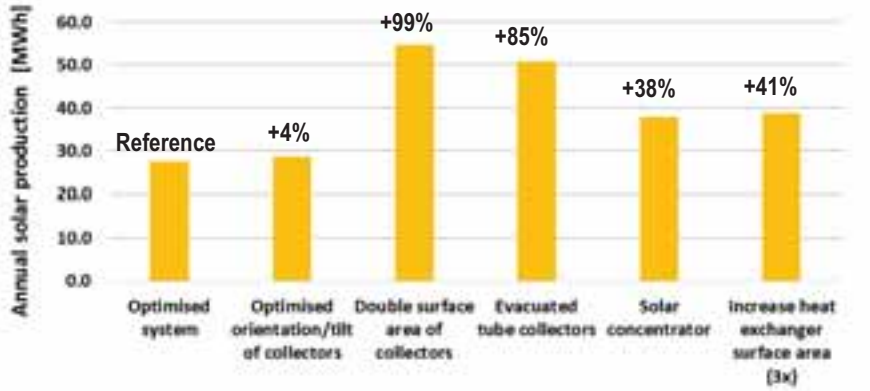

Fig. 8: Comparison of the predicted annual solar production for different configurations

It can be seen that optimisation of the orientation and tilt of current installed collectors do not significantly increase the annual solar production. However, doubling the collector surface area could potentially double this production mainly because the share of solar heating in the reference, optimised installation, is still minimal. Interesting to notice is the 85% increase in solar production by replacing the SRB collectors with evacuated tube collectors with equivalent aperture area. This type of collector is, nevertheless, not able to provide heat in the temperature range of bitumen processing, the primary reason for considering solar thermal integration in this industrial process.

The use of solar concentrators also indicates an increase in solar production (up to 38%). In all these simulations, most of the solar energy harvested is supplied to the water tank but solar heating of the bitumen tank presents a better efficiency when compared with the two other collectors. Disadvantages of this technology are the additional investment and operating costs as well as the increase of the effective space occupied by the system. Finally, following observations that the heat exchanger performance in the tanks was not optimal, simulations were used to investigate the effect of varying the heat exchanger surface area on the annual solar production. As the heat exchanger area is increased the solar production increases considerably, demonstrating that the actual heat exchange surface is largely undersized.

5. Financial analysis

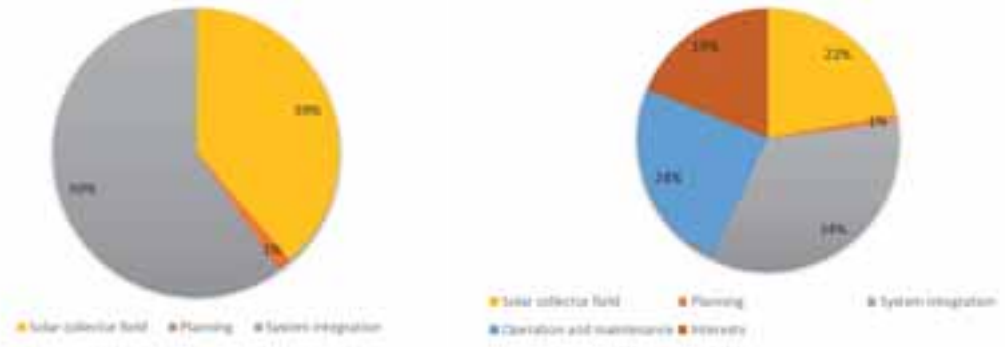
In order to estimate the financial efficiency of the solar system installed by Colas in Yverdon-les-Bains and to evaluate the solar energy cost, a short financial analysis was conducted taking into consideration costs given by the industrial partner and measurements operated on site.

The total system investment cost was evaluated at 365 kCHF (1'984 CHF/m^2 – aperture area). Data and assumptions made for cost evaluations are given in Table 1 and the breakdown of these costs is given in Fig. 9 a). This shows the low share (39%) of the solar collector field compared to the system integration (60%). The imposing stainless steel structure designed to hold the collector field was very costly and significantly increases the overall system cost. Moreover, this structure required some modifications after its installation in order to meet local standards in terms of aesthetics.

Tab. 1 Financial analysis – Data and assumptions

Data/assumption	Value
Investment cost	380'200 CHF
Subsidies	15'000 CHF
Operation & Maintenance costs	8'000 CHF/y
System life span	20 years
Interest rate	3 %
Annuity factor	6.72 %

The price of this system is therefore much higher than conventional prices for solar thermal installations (Mauthner et al., 2016), but it must be considered that this was a pilot project, first of its kind, and almost everything was custom made. Of course, there is a lot of room for cost optimisation, starting with canceling the holding structure and improving the maintenance of the system. The solar collector manufacturer should also try to reduce the collector costs for a better competitiveness on the market.



a) b)

Fig. 9: Solar system cost breakdown for the Colas industrial site: a) Investment costs, b) costs over the life span

Energy costs were evaluated using the uniform capital recovery method. By adding the operating and maintenance costs to the total investment cost and taking into account the interest rate, the cost of solar energy is obtained and can be compared to other conventional energy sources. These costs were calculated for both the real operation of the system and for an optimised system as presented in the previous section (numerical simulations).

The results give 1.80 CHF/kWh in the actual operation mode which is far from being satisfying and the reason for this high energy cost is mainly the investment cost, but also the non-optimal system operation. With an optimised system, the price is reduced to 1.18 CHF/kWh which is much better, but it is still 10 times higher than the actual price of natural gas paid on site. Therefore, an estimation of this price was calculated with an optimised investment cost, not taking into account the holding structure, and reducing by 50% the operating and maintenance spending. The result gives 0.47 CHF/kWh, which can be acceptable for this kind of pilot project.

Furthermore, if evacuated tube collectors were used instead of the SRB collectors the price could be reduced to 0.11 CHF/kWh considering an investment cost of 500 CHF/m^2. This price could be easily reached for important collector fields, without special holding structure (Mauthner et al., 2016). In this case, solar energy can be

considered as competitive with any other energy source, but once again, this system could only provide low temperature level energy demand and could not supply the bitumen storage tank.

6. Life cycle impact assessment results

A life cycle impact assessment was carried out to quantify the environmental impacts of the solar installation. Methodology details and indicators considered in this study have been described elsewhere; please refer to Bunea et al. 2016 for additional information.

5.1 Impact of the solar installation

The analysis aims to estimate the environmental impact of the solar installation (solar collectors, pipework components and supporting structure) to compare to the potential energy savings it could possibly bring. Energy consumption of the installation was defined based on monthly simulations. Fig. 10 shows that impacts from the supporting structure are the major contributor from the overall solar installation.

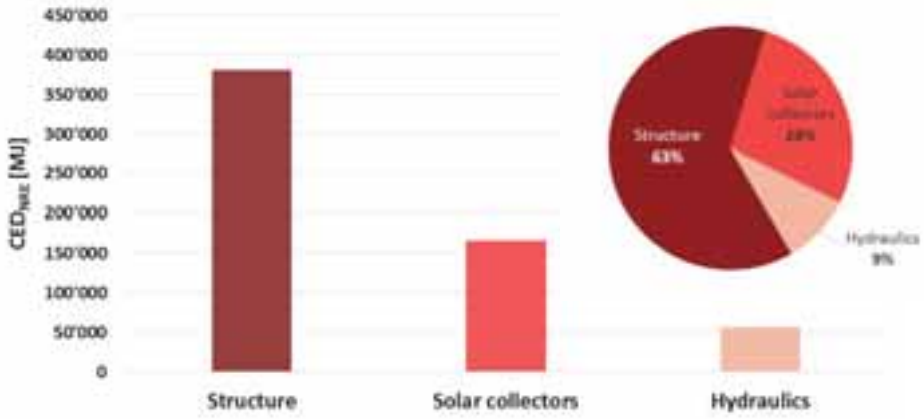


Fig. 10: Calculated environmental impacts of the solar installation, CED_{NRE}

5.2 Potential environmental savings

The potential environmental savings of using a solar thermal installation in this type of heating process are compared to a solar-free installation. Three installation configurations are considered:

- No solar thermal system
- Solar thermal system (current installation)
- Solar thermal system (optimised case)

The impacts related to energy use in the form of gas and electricity as well as impacts from material components of each configuration are presented in Fig. 11.

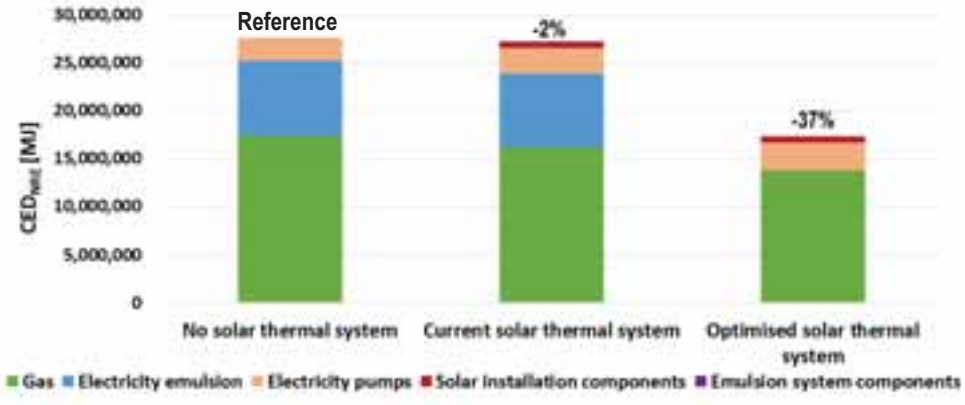

Fig. 11: Comparison of CED_{NRE} for different configurations

Integration of a solar thermal system in this type of industrial process potentially contributes to primary energy savings. This value is quite low for the case of an installation operated under current real conditions. The reasons are twofold: emulsion heating is primarily electric which greatly contributes to increase of the CED_{NRE}; secondly, under these conditions solar production is penalised because of the low water tank energy demand. In contrast, primary energy savings are more pronounced in the case of the optimised system since emulsion heating is now entirely supplied either with solar or gas. This configuration also results in an increase of the solar production, which directly affects gas consumption.

An environmental cost-benefit analysis showed that the energy savings brought by the solar installation could be compensated the additional material impacts within twelve years. This time is reduced to two years if the installation operates under optimal conditions, see Table 2.

Tab. 2 Payback time of the environmental cost of modifications

Configuration	CED_{NRE}
Current solar thermal system	11.5 ans
Optimised solar thermal system	1.2 ans

7. Conclusion

The behaviour and performance of a medium–temperature solar industrial process for bitumen storage was investigated based on measurements and simulations for subsequent optimisation of the process. Measurements over 30 months of operation revealed a very variable consumption profile over the year, but also from one year to another. Important differences, up to 50% at 220°C, between the certified performances of the solar thermal collectors and measured were observed during this project and consequently low specific solar production, around 100kWh/m2. The reason for this low productivity is not only the poor performances of the collector itself, but also the non-optimised control management of the system.

Simulations show that there is room for improvement and that the solar production could be roughly doubled if the system operates as designed. Furthermore, simulations prove that the heat exchangers designed for both thermal storages are undersized. Increasing solar collector area results in higher solar productivity, but still relatively low annual collector field efficiency. Evacuated tube collectors are shown to be a cost-effective configuration for this system, but these collectors could only supply energy at low temperature level and not to the bitumen tank, as the system was designed initially.

The financial analysis shows a cost of solar energy supplied to the system at 1.80 CHF/kWh. This value could be reduced to 1.18 CHF/kWh in the case of an optimised system, but it is still very high when compared to conventional energy prices. The highest share in the investment cost is not generated by the collector field, but by the system integration and mainly by the supporting structure. Therefore, with a lighter system integration and a better operation and maintenance management, the energy cost can achieve 0.47 CHF/kWh, which can be acceptable for a pilot project.

The life cycle impact assessment of the solar installation showed that, as for the investment cost, the infrastructure impacts predominate over the entire life cycle, accounting for over 60% of the total CED_{NRE}. Energy savings brought along by the solar installation more than compensate the additional material and energy related impact of integrating such a system. Less than 2 years environmental return on investment periods were found in the case of an optimised solar bitumen storage system.

Xi'an University Of Architecture and Technology

Abstract

A solar heating household biogas digester system (System C) coupled with auxiliary heating source and operational control system is proposed in this paper. The mathematical model and TRNSYS simulation model of the system were established. Firstly, the heating effect of System C was compared with that of System A (without auxiliary heating and temperature control system) and System B (with auxiliary heating system and without temperature control system). Secondly, the influence of the insulation thickness and the collector area on solar fraction was analyzed. The results show that System C could keep the temperature fluctuation range of manure at ±1°C under the setting condition. Besides, the solar fraction of the system C is higher than the system B, the daily energy net production of System C is higher than that of the system A and B with the value of 19.2 kWh. The solar fraction increased with the insulation thickness increased as logarithmic function, which has the most significant growth rate when the collector area is 14 m^2. In addition the solar fraction increases with the increase of the collector area in the form of sigmoid function. The research results provide a basis for the optimization design of solar heating household biogas digester system.

Keywords: Solar heating; Household biogas digester; TRNSYS simulation; Solar fraction

1. Introduction

The household biogas digesters can provide residents with the necessary energy (biogas) for cooking, lighting, heating and deal with the manure waste of people and livestock. Household biogas digesters are widely used all over the world, especially in developing countries such as China and India (Surendra, Takara, & Hashimoto, 2014). In recent years, the biogas industry of China has developed rapidly. China had possessed 41.93 million household biogas digesters by 2015 (Academy of state administration of grain, 2017).

Temperature has a significant influence on biogas production rate. Three fermentation processes exist, corresponding to different fermentation temperatures, namely, thermophilic fermentation (45-60 °C),mesophilic fermentation (25-40°C),and normal temperature fermentation (10-25 °C) (El-Mashad, Zeeman, & van Loon, 2004a).When the temperature of the manure is lower than 10°C, the biogas production of the digester is very little (Kocar and Eryasar, 2007). During the winter in northern of China, a large number of digesters have been idled due to less biogas production. However, the insufficient energy supplied by the biogas digester and the energy demand of heating and hot water in winter increases rapidly form a sharp contradiction with. Therefore, it is the key to solve this problem that increase the biogas production of the digester by improving the temperature of digester.

At present, many heating methods for the digester such as coal fired boiler heating, electro thermal membrane heating, biogas boiler heating, solar heating and heat pump heating were proposed (Li, Guo, & Qin, 2011). Some heating methods are not suitable for the household biogas digester due to the constraints of economical and environmental conditions. The solar heating for biogas digester has become the research focus with the advantages of less pollution, lower manufacture and operation cost. Hassanein et al. (2015) proposed a passive heating technique to increase the temperature of the biogas digesters using two solar greenhouses, one surrounding the digester and the other heating the digester inlet. The simulation results showed that the digester with the modifications could reach adequately high temperatures in the winter. Although the cost of solar passive warming technology is low, the range of manure temperature increasing is limited, so the biogas production of biogas digesters is still little, which can only meet the needs of cooking.

The system consists of high efficiency solar collectors and other equipment is also the main research direction of

doi:10.18086/swc.2017.26.02 Available at http://proceedings.ises.org

solar heating digesters. Axaopoulos, et, al. (2001), proposed an active solar heating biogas digester system, and established the corresponding system mathematical model. The performance of the system is studied both by simulation and experiment, and the results show that the system could efficiently increase the manure temperature and reduce the heat loss of the digester envelope at the same time. The energy required for the digester heating in the system is directly supplied by solar collectors, so that the temperature of the manure is subject to fluctuations in the solar radiation. However, the biogas production rate will decrease when the manure temperature changes more than 3 °C (Zhang, et al., 2016). El-Mashad et al. (2004b) and Pollard & Blanchard (2014) have designed a solar heating digester system with auxiliary heater. When the energy supplied by solar collector is insufficient, the auxiliary heat collector is worked to ensure that the digester runs under relatively stable conditions. But the system above may run abnormally for them without any monitor and control system of manure temperature, auxiliary heating source and the solar collector, which leads to the lower system efficiency and solar fraction and larger conventional energy consumption.

In this study, a solar heating digester system with auxiliary heater and heating control system is proposed. The heating effect for the biogas digester and net energy production performance of the system under different system forms were compared through TRNSYS simulation. Besides, the influence of the insulation thickness and the collector area on solar fraction was analyzed.

2. System description and Modelling

2.1 System description

As shown in Fig. 1, the solar heating household biogas digester system is composed of heating collection and heating utilization loop, the above loop were connected by heat storage water tank. The heating collection loop is consisted of flat plate collector, circulation pump-1, expansion tank and pipeline. The heating utilization loop is consisted of underground biogas digester, heating coil, heat storage tank and auxiliary heater. The energy collected from solar collector is used to heat the digester and the extra heat is storaged in the heat storage water tank in the day time. The heat in the water tank is transferred to heat the digester and the insufficient energy is supplied by the auxiliary heater in the nighttime. The control system automatically controls the opening and closing of the components according to the pre-set control strategy by monitoring the temperature parameters in the system loop.

2.2 Assumptions

There are several assumptions used for establishing mathematical model of the solar heating household biogas digester system:

(1) Physical properties of the soil, digester material, and insulation material are uniform (Perrigault, Weatherford, & Martí-Herrero, 2012).

(2) During biogas fermentation, microbial heat generation is neglected (Hashimoto, & Chen, 1979).

(3) The heat carried by the biogas flow during biogas fermentation is neglected.

(4) Liquid manure in the digester is assumed to be water.

(5) The temperature of the manure in the digester is uniform.

2.3 Mathematical model description

The mathematical model of the solar heating digester system consists of the system energy balance equation and the mathematical expressions of the subcomponent. The energy balance equation of the system could be written as:

$$\rho_m V_m c_m \frac{dT_m}{d\tau} = Q_{heating} - Q_{cover} - Q_{floor} - Q_{wall} - Q_{feed} \quad \text{(eq.1)}$$

$$Q_{heating} = Q_{col} + Q_{aux} - Q_{loss} \quad \text{(eq.2)}$$

$$Q_{loss} = Q_{loss,\,aux} + Q_{loss,\,tank} + Q_{loss,\,pipes} \quad \text{(eq.3)}$$

where; c_m is the manure specific heat capacity, J kg^{-1} K^{-1}; ρ_m is the manure density, kg m^{-3}; V_m is the manure volume, m^3; T_m is the manure temperature, °C; τ is the time, s; $Q_{heating}$ is the heat supplied by the heating system, W; Q_{cover} is the heat losses through the digester cover, W; Q_{wall} is the heat losses through the digester wall, W; Q_{floor} is the heat losses through digester floor, W; Q_{feed} is heat required to raise temperature of the influent manure to the operating

temperature, W; Q_{col} is the heat supplied by the solar collector, W; Q_{aux} is the heat supplied by the auxiliary heater, W; Q_{loss} is the total heat loss of the system, W; $Q_{loss,\ aux}$ is the heat loss from heater to environment, W; $Q_{loss,\ tank}$ is the heat loss from water tank to environment, W; $Q_{loss,\ pipes}$ is the heat loss from pipes to environment, W.

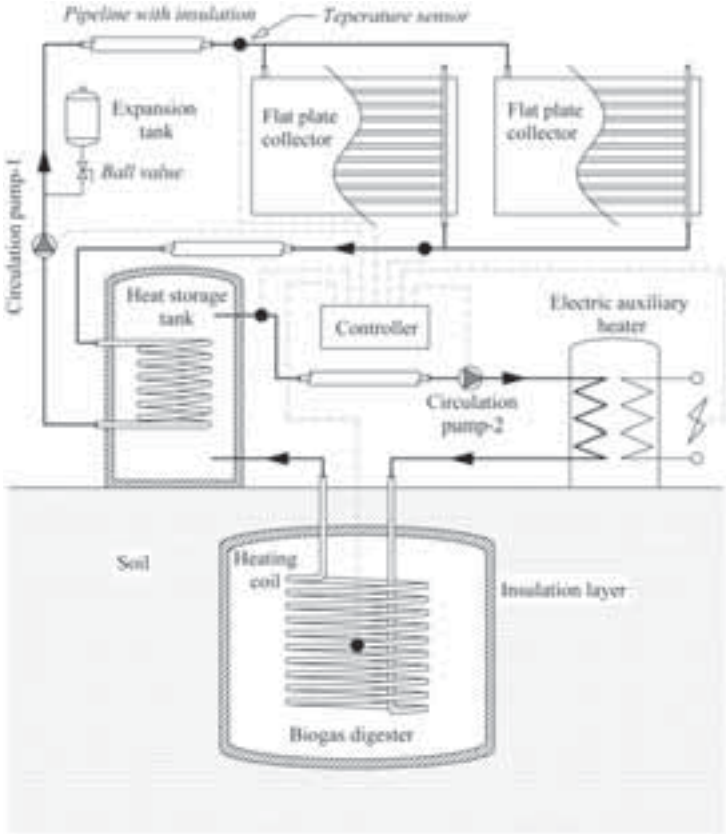

Fig 1. Schematic of the solar heating household biogas digester system

2.3.1 Energy delivered from solar collectors and auxiliary heater

The heat gain from the solar collector can be calculated using following equations (Duffie & Beckman, 1991):

$$Q_{col} = A_{col} I_T \eta_{col} = m_{hm} c_{hm} (T_{co} - T_{ci}) \quad \text{(eq.4)}$$

where A_{col} is the solar collector area, m^2; I_T is the solar radiation rate on the collector surface per unit area, W m^{-2}; η_{col} is the collector efficiency, dimensionless; m_{col} is the mass flow through the collector, kg s^{-1}; c_{hm} is the specific heat capacity of heat medium, J kg^{-1} K^{-1}; T_{co} is the temperature of the fluid flowing out of the collector, °C; T_{ci} is the temperature of the fluid flowing into the collector, °C.

$$\eta = F_R (\tau\alpha)_n - F_R U_{col} (T_{ci} - T_{amb}) \quad \text{(eq.5)}$$

where F_R is the overall collector heat removal efficiency factor, dimensionless; $(\tau\alpha)_n$ is the cover transmittance and the absorber absorptance of the collector at normal incidence, dimensionless; U_{col} is the overall thermal loss coefficient of the collector per unit area, W m^{-2} K^{-1}; T_{amb} is the ambient temperature, °C.

$$F_R = m_{hm} c_{hm} [1 - \exp(-A_{col} U_{col} F' / m_{hm} c_{hm})] / (A_{col} U_{col}) \quad \text{(eq.6)}$$

where F' is the collector fin efficiency factor, dimensionless.

The heat gain from the auxiliary heater can be calculated using following equations:

$$Q_{fluid} = m_w c_w (T_{set} - T_{ai}) \quad \text{(eq.7)}$$

$$Q_{loss,\ aux} = U_a (\bar{T} - T_{amb}) + (1 - \eta_{aux}) Q_{max} \quad \text{(eq.8)}$$

$$Q_{aux} = Q_{max} \quad \text{(eq.9)}$$

$$Q_{\text{aux}} = Q_{\text{fluid}} + Q_{\text{loss, aux}} = \frac{m_{\text{w}} c_{\text{w}} (T_{\text{set}} - T_{\text{ai}}) + U_{\text{a}} (\bar{T} - T_{\text{amb}})}{\eta_{\text{aux}}}$$

(eq.10)

where Q_{fluid} is the rate of heat addition to the water, W; m_{w} is the mass flow rate of water flowing into the auxiliary heater, kg s^{-1}; c_{w} is the water specific heat capacity, J kg^{-1} K^{-1}; T_{set} is the set temperature of heater internal thermostat, °C; T_{ai} is the inlet temperature of auxiliary heater, °C; U_{a} is the overall loss coefficient between the heater and its surroundings, W; $\bar{T}$ is the average temperature of fluid in heater, °C; η_{aux} is the efficiency of auxiliary heater, dimensionless; Q_{max} is the maximum heating rate of heater, W.

The solar fraction is calculated by (Deng et al. 2016):

$$f = \frac{Q_{\text{solar}}}{Q_{\text{solar}} + Q_{\text{auxiliary}}} \quad \text{(eq.11)}$$

where Q_{solar} is the heat supplied by the collector, W; $Q_{\text{auxiliary}}$ is the heat supplied by the auxiliary heater, W.

2.3.2 Heat transfer between digester and soil

Household biogas digesters are usually buried underground, and those heat transfer process are affected by the surrounding soil temperature and soil thermal properties. Therefore, the function of soil temperature field and soil physical parameters are needed to establishing the heat transfer model of the digester (Liu, Chen, & Li, 2017).

The soil initial temperature field can be calculated by (Zhang, Ren, & Mei, 2007):

$$T_{\text{s}}(z, \tau_0) = T_{\text{ave}} + A_{\text{w}} \exp\left(-z\sqrt{\frac{\pi}{ak}}\right)\cos\left(\frac{2\pi}{k}\tau_0 - z\sqrt{\frac{\pi}{ak}}\right) \quad \text{(eq.12)}$$

where T_{ave} is the annual average temperature of ground surface, °C; A_{w} is the annual temperature fluctuation of ground surface, °C; k is the annual fluctuation period, h; a is the soil thermal diffusivity, m^2 s^{-1}; and τ_0 is the initial time, s.

The amount of heat loss from digester to the soil can calculated by:

$$Q_{\text{cover}} = \frac{(T_{\text{m}} - T_{\text{s}}) A_{\text{cover}}}{\left(\frac{1}{h_1} + \frac{\delta_1}{\lambda_1} + \frac{\delta_2}{\lambda_2}\right)} \quad \text{(eq.13)}$$

$$Q_{\text{wall}} = \frac{(T_{\text{m}} - T_{\text{s}}) A_{\text{wall}}}{\left(\frac{1}{h_2 \pi d_1} + \frac{1}{2\pi\lambda}\ln\frac{d_2}{d_1} + \frac{1}{2\pi\lambda}\ln\frac{d_3}{d_2}\right) H} \quad \text{(eq.14)}$$

$$Q_{\text{floor}} = \frac{(T_{\text{m}} - T_{\text{s}}) A_{\text{floor}}}{\left(\frac{1}{h_3} + \frac{\delta_1}{\lambda_1} + \frac{\delta_2}{\lambda_2}\right)} \quad \text{(eq.15)}$$

where T_{s} is the soil temperature, °C; h_1, h_2, h_3 are the convective heat transfer coefficient of inner surface of cover, wall, floor, respectively, W m^{-2} K^{-1}; λ_1 is the thermal conductivity of digester, W m^{-1} K^{-1}; δ_1 is the wall thickness of digester, m; λ_2 is the thermal conductivity of insulating layer, W m^{-1} K^{-1}; δ_2 is the wall thickness of insulating layer, m.

The heat loss caused by manure feeding can be calculated by the formula:

$$Q_{\text{feed}} = m_{\text{f}} c_{\text{m}} (T_{\text{m}} - T_{\text{f}}) \quad \text{(eq.16)}$$

where m_{f} is mass flow rate of the feed liquid, kg day^{-1}; T_{f} is the temperature of the feed liquid, °C.

2.3.3 Biogas production rate

A methane production model was proposed during the anaerobic fermentation process, calculated as (Chen, & Hashimoto, 1978):

$$\gamma = \frac{B_0 S_0}{HRT\,\beta_{\text{methane}}}\left(1 - \frac{K}{HRT \cdot \mu_{\text{m}} - 1 + K}\right) \quad \text{(eq.17)}$$

where γ is volumetric biogas production rate, m^3 CH^4 m^{-3} digester day^{-1}; B_0 is biochemical methane potential, m^3 CH4 kg^{-1} VS; S_0 is influent VS concentration, kg m^{-3}; HRT is hydraulic retention time, days; K is the kinetic constant, dimensionless; and μ_{m} is maximum specific growth rate of micro-organisms, day^{-1} β_{methane} is percentage of methane content in biogas.

K is a kinetic parameter related to the influent VS concentration, and is expressed as:

$$K = 0.6 + 0.0206\text{e}^{0.051 S_0} \quad \text{(eq.18)}$$

Pham et al. (2014) predicted the dynamic methane production based on the Chen et al. (1978) model, making it available for the performance prediction of UHBD. Concurrently, Hashimoto (1982) proposed a relationship between the maximum specific growth rate of microorganisms and the temperature under mesophilic and thermophilic fermentation as:

$$\mu_{\text{m}} = \begin{cases} 0.0026\text{e}^{0.1319 T_{\text{m}}} & 15°\text{C} \le T_{\text{m}} \le 30°\text{C} \\ 0.013 T_{\text{m}} - 0.129 & 30°\text{C} < T_{\text{m}} \le 60°\text{C} \end{cases} \quad \text{(eq.19)}$$

2.3.4 Heat storage tank with immersed heat exchanger

$$\rho_{\text{w}} V_{\text{w}} c_{\text{w}} \frac{\text{d}T_{\text{w}}}{\text{d}\tau} = Q_{\text{hx}} - Q_{\text{in, out}} - Q_{\text{loss, tank}} \quad \text{(eq.20)}$$

Where ρ_{w} is the water density, kg m-3; V_{w} is the manure volume, m3; c_{w} is the water specific heat capacity, J kg^{-1} K^{-1}; T_{w} is the water temperature, °C; Q_{hx} is the heat transfer between the water and the heat exchanger, W; $Q_{\text{in, out}}$ is the heat taken by the hot water, W.

2.4 TRNSYS simulation model description

According to the system mathematical model established in the 2.3 section, the TRNSYS system simulation model (TRNSYS, 2012) is further established, and the details of the model are shown in Fig. 2. The meteorological parameters used in the system simulation are imported by Type 109, the solar collector adopts Type 73, and the auxiliary heat source adopts Type 2b. The coupled heat transfer model of digester and soil (J. Zhao et al., 2008) is consist of the ground coupling model (Type 707b) and thermal storage tank (Type 534) to calculate heat loss through the digester envelope to the ground and hourly manure temperature. The periodic manure feeding was imported into dates readers (Type9e) and New Equation to calculate heat transfer from manure inflow.

The biogas production model is embedded into the solar heating digester system model by using the New Equation to calculate the amount of biogas production during the operation of the system. The detailed TRNSYS components and parameters adopted were explained in Table 1.

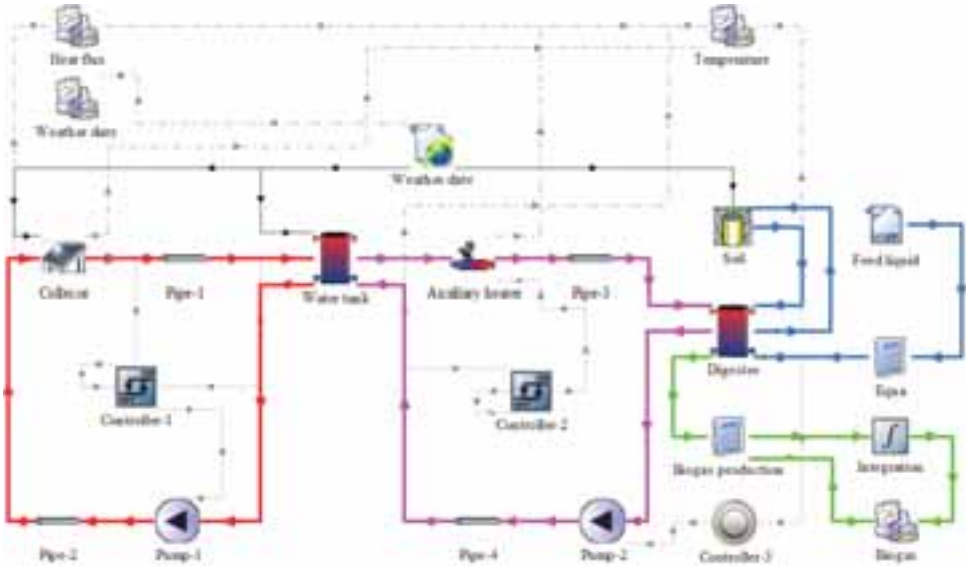

Fig 2. TRNSYS model of the solar heating digester system

Table 1. The main components of the TRNSYS simulation program

Components	Key parameter	Descriptions
Type 73 (flat-plate solar collector)	Collector area: 2, 8, 14, 20, 26 m^2; Bottom, edge loss coefficient: 0.56 W m^{-2} K^{-1}; Collector fin efficiency factor: 0.7;	Calculate the heat supplied by the solar collector
Type 707b (ground coupling model)	Mean surface temperature: 11.64 °C; Amplitude of surface temperature: 18.73 °C; Day of minimum surface temperature: 5 day; Soil column radius and height: 10, 10 m;	To calculate the energy exchange through the bottom, top, and sides of a digester that is entirely buried beneath the ground surface
Type 534 (biogas digester)	Digester radius and height: 1.3, 1.5 m; Thickness of insulation layer: 0, 30, 60, 90, 120, 150 mm; Number of tank nodes: 1 Length of coiled tubes: 32.68 m; Coiled tubes thermal conductivity: 0.33 W m^{-1} K^{-1}; Coil diameter: 1.3 m; Number of tubes: 8; Coil pitch: 0.1 m;	The hourly manure temperature is calculated by heat balance calculation。The gas production rate and total gas production of biogas digester are further calculated
Type 4c (heat storage tank)	Tank volume: 0.5 m^3; Tank heat loss coefficient: 0.5 W m^{-2} K;	The extra heat stored in the heat storage tank, which plays a role in peak shaving and valley filling
Type 6 (auxiliary heater)	Maximum heating rate: 3 kW; Efficiency of auxiliary heater: 0.95;	Added to supply heat when the collector heat is insufficient
Type 109 (TMY-2 weather data)	Import typical meteorological year weather date;	Used for the optimization analysis
Type 1502 (simple thermostat)	Setpoint temperature for stage: 35 °C; Temperature dead band: 1 °C;	Keep slurry temperature at 35±1 °C
Type 2b (controller)	Upper and Lower dead band dT: 1, 8 °C;	Control whether the heat medium flows through the collector
Type 2b (control auxiliary heater)	Upper input temperature Tl: 50 °C; Upper and Lower dead band dT: 0, 5°C;	Control the start-stop of the auxiliary heater
Type 3d (pump)	Flow rates of the solar system and the heat supply were 0.4, 0.4 m^3 h^{-1}, respectively;	Drive system to circulate
Type 31 (pipe)	Pipe length: 8 m; Inside diameter: 0.02 m; Loss coefficient: 0.14 0.5 W m^{-2} K^{-1};	Connect each equipment unit and calculate heat loss of pipeline

The control logical diagram of the solar heating digester system are shown in Fig 3. The control system consists of solar collector control, auxiliary heating control and biogas digesters heating control subsystem. As shown in Fig 1, Firstly, the solar collector inlet and outlet water temperature, heat storage tank outlet water temperature and the manure temperature were monitored by the control system. Secondly, the temperature above would be compared with the temperature or the temperature difference set before. Finally, the automatic control of the heating system were achieved by controlling on and off of the circulating pump and auxiliary heater. The control logic details are as follows:

- The control logical of heat collection system: Comparing the inlet and outlet temperature of the heat collector, the pump-1 opens at next moment when pump-1closes at present and the temperature difference ⩾8 °C, and

the pump-1 closes at next moment when pump-1opens at present and the temperature difference ⩽1 °C.

- The control logical of auxiliary heater: The auxiliary heater closes at next moment when the auxiliary heater opens at present and the outlet temperature of the heat storage tank ⩾ 50 °C, and the auxiliary heater opens at next moment when the auxiliary heater closes at present and the outlet temperature of the heat storage tank ⩽ 45 °C.
- The control logical of digester heating system: The pump-2 closes at next moment when pump-2 opens at present and the temperature difference ⩾1°C, and the pump-2 opens at next moment when pump-2 closes at present and the temperature difference ⩽-1°C.

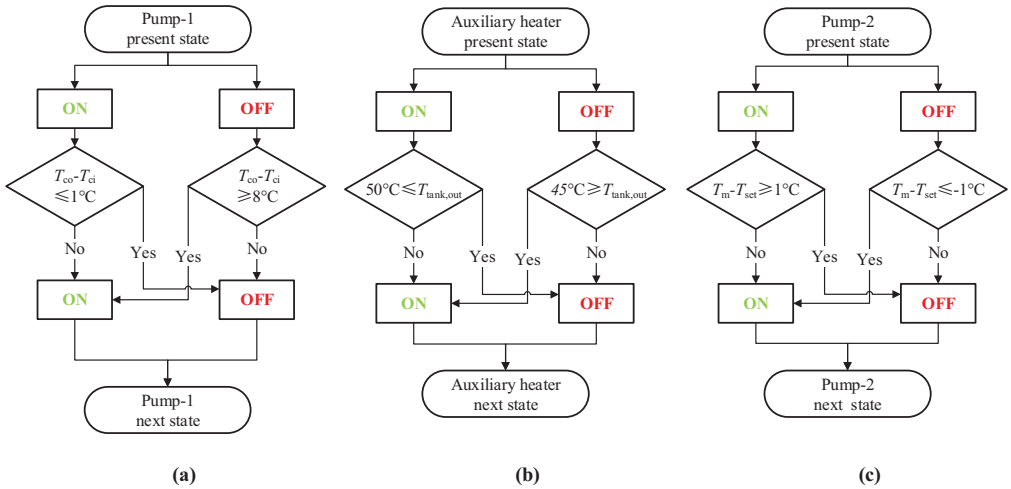

Fig 3. Control logical diagram of the solar heating digester system. (a) the control of heat collection system, (b) the control of the auxiliary heater, (c) the control of the digester heating system.

3. Results and discussion

3.1 Weather data

Lhasa (latitude 29 ° 36 'N, longitude 91 ° 06' E) is located in the Qinghai-Tibet Plateau, the solar energy in this region is abundant and suitable for solar heating digester system application. The weather parameters includes the hourly horizontal solar radiation intensity, the hourly outdoor dry bulb temperature and the underground 1m and 2m soil temperature derived from TRNSYS are shown in Fig 4. The difference of horizontal solar radiation intensity of Lhasa in different seasons is small, and the annual average solar radiation intensity is 227.4W m^{-2}. The outdoor air temperature difference between winter and summer is about 25 °C, and the lowest temperature in winter is about -10 °C. The soil temperature at underground 1m is greater than 0°C throughout the year, and the soil temperature at underground 2m is greater than 5°C throughout the year.

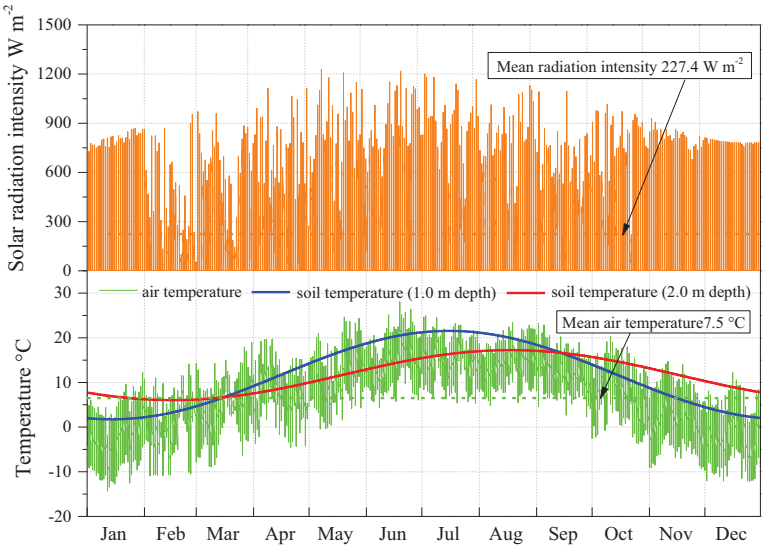

Fig. 4: Outdoor meteorological parameters in Lhasa

3.2 System form optimization analysis

The operation performance of three different forms of solar heating biogas digesters is compared and analyzed. The system A has no auxiliary heat source and no temperature control system, the system B has auxiliary heat source but no temperature control system, the system C has both auxiliary heat source and temperature control system. The polar temperature is 35 °C under the condition of medium temperature fermentation (Y. Lu et al., 2016), so the biogas fermentation temperature in system C is set to 35 °C. The simulated manure temperature under different system forms are shown in Fig5. As shown in Figure, The biogas digester keeps at 6-8°C when it without any heating system, and its biogas production can be basically ignored. The manure temperature of System A is significantly higher than the system without heating measures, the manure temperature can be increased to 25 °C before February, the manure temperature in February to March decreased significantly for cloudy days in February to March is larger than other months(Fig4).

The manure temperature in system B is the largest among three system forms, the manure temperature keeps at 50 °C before February, and the manure temperature decreased continually in February to March. The results shows that the auxiliary heater continually operated has consumed amounts of conventional energy, and the manure temperature fluctuates greatly when the solar radiation is insufficient. The manure temperature of the system C is basically the same as the design temperature, the manure temperature fluctuation is about ±1°C before February and increased slightly which is no more than 3 °C in February and March.

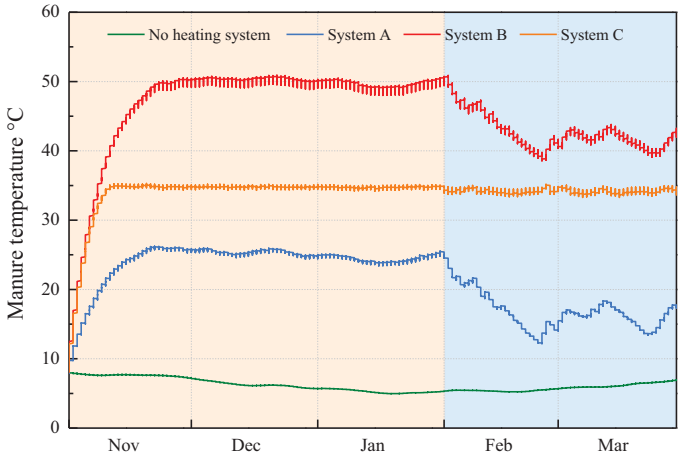

Fig. 5: The simulated manure temperatures under different system forms

Fig. 6 shows heat supply biogas production and the system net energy production of three system forms. As shown in figure, the heat supplied by System B to the digester is the most, followed by System C, and System A provide the least amount of heat. 71% of the heat provided by the auxiliary heater in System B, while 42% of the heat provided by the auxiliary heater and 58% is supplied by the collector in System C. The biogas production of the System B is the largest among three system due to its higher manure temperature. The daily biogas production of System B is 1.41m^3 larger than that of System C, and 4.35m^3 than that of System A. The daily net energy production refers to the converted heat of daily biogas production minus energy consumed by the auxiliary heater. The daily net energy production of System C is the largest (19.2kWh), and daily net energy of System B is the smallest (8.6kWh). The results showed that the performance of System C is better. However, the solar fraction of System C is not high, so it is better to improve the solar fraction of the system by optimizing the components in system.

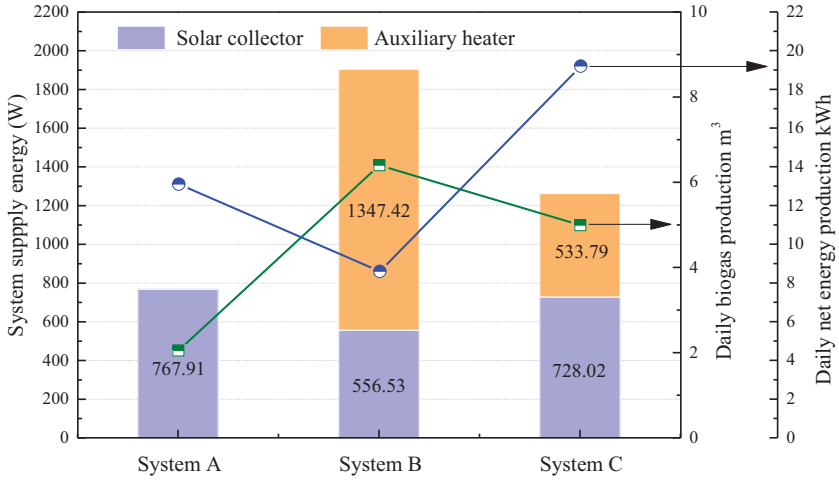

Fig. 6: System Heat supply, daily biogas production and daily net energy production under differant system forms

3.3 The influence of the thickness of insulation layer on solar fraction

The heat supply of the system could be reduced by decreasing digester heat loss. Therefore, the solar fraction can be improved by reducing the energy supply of auxiliary heater under the condition of solar collector area unchanged. Fig. 7 shows the variation of the solar fraction with the insulation thickness. The solar fraction increase logarithmically with the increases of insulation thickness, and the growth of solar fraction is not obvious when the thickness of insulation layer exceeds 120mm. Accordingly, it is necessary to comprehensively compare the increase of investment with the insulation thickness increase and the decrease of the operating cost caused by the reduction of the auxiliary energy to select the economical insulation thickness. Besides, the increase of insulation layer thickness is not significant to enhance solar fraction of the system when the collector area is larger or smaller. The solar fraction increased from 0.47 (no insulation) to 0.73 (150 mm insulation) when the collector area is set as 14 m^2.

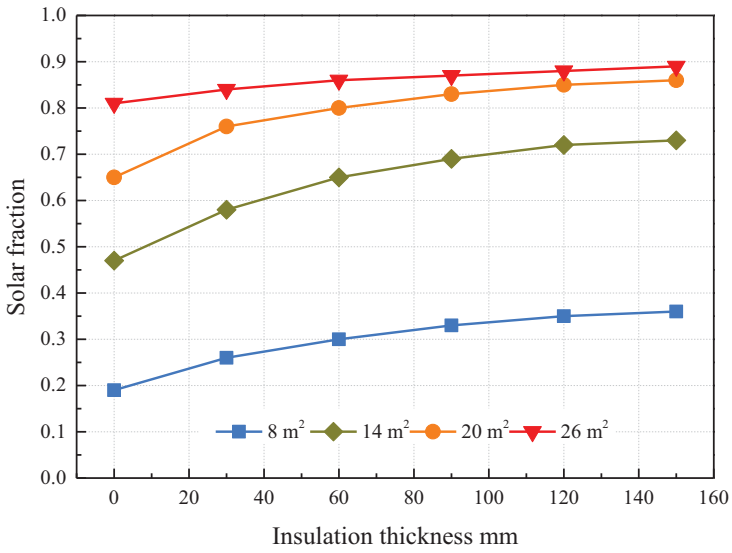

Fig. 7: The variation of the solar fraction with the insulation thickness

3.4 The influence of the collector area on solar fraction

The heat production of the heating collection loop can be directly improved with the increasing of the solar collector area, and then the solar fraction of system can be improved. Fig 8 shows the variation of the solar fraction with the collector area. The solar fraction increases with the increase of solar collector area in the form of the sigmoid function. The solar fraction increases most (from 0.33 to 0.69) when the collector area is increased from 8 m^2 to 14 m^2. Hence, it is also necessary to select the appropriate collector area in combination with economic factors.

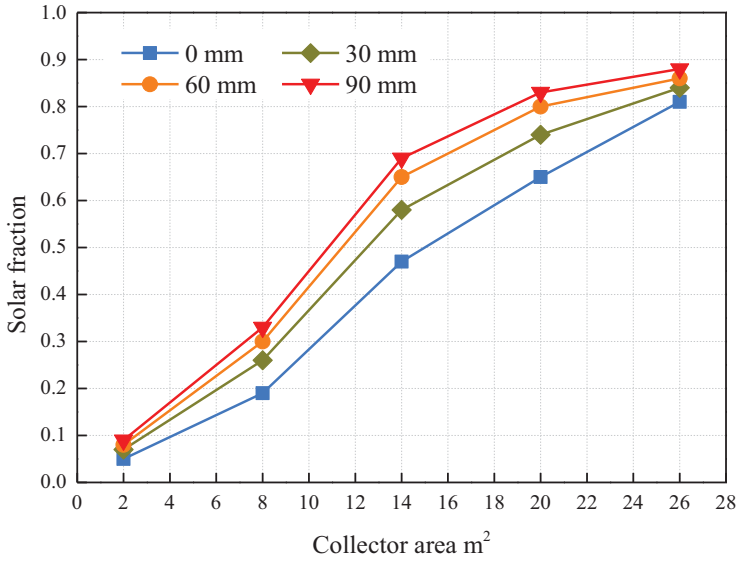

Fig. 8: The variation of the solar fraction with the solar collector area

4. Conclusion

In this study, the mathematical of the solar heating household biogas digester system and the simulation model based

on TRNSYS were established. The conclusions drawn from the results are stated as follows:

- System C could maintain the stable operation of the biogas digester under the designed conditions, and the range of temperature is about ±1 °C. Besides, the solar fraction of System C is higher than that of System B. The daily net energy production of System C is the highest among three system forms with the value of 19.2 kWh.
- The solar fraction increased with the insulation thickness increased as logarithmic function, which has the most significant growth rate when the collector area is 14 m^2.
- The solar fraction increases with the increase of the collector area in the form of sigmoid function. The solar fraction increases most (from 0.33 to 0.69) when the collector area is increased from 8 m^2 to 14 m^2.

Abstract

This work investigates the integration of a solar furnace (SF) into the smelting processes of copper in a flash furnace under Chilean solar irradiation conditions. A computer model of a 1 MW_{th} solar furnace, inspired by the French solar furnace in Odeillo, with a total heliostat specular area of 2,835 m² was developed and the annual energy contribution of the SF for copper smelting in a flash furnace was simulated. Economic benefits through fossil fuel savings in three different flash furnaces were compared with the investment costs for a SF for a lifetime of 50 years. Furthermore, reductions in greenhouse gas emissions ($CO_{2\text{-eq}}$-emissions) through fuel saving were calculated. The results show that, depending on the fuel type used in the flash furnace, up to 24% in $CO_{2\text{-eq}}$-emissions and up to 10% of lifetime costs can be saved.

Keywords: Solar Furnace, Chile, Smelting, Copper, Greenhouse Gas Emissions

1. Introduction

Metal smelting requires huge amounts of thermal energy. Usually, this energy demand is covered by liquid fossil fuels or electricity. While the utilization of solar energy for electricity generation and medium temperature thermal applications is widespread, yet there is no commercial use of solar energy for high temperature applications like metal smelting.

Solar furnaces (SF), like the French solar furnace in Odeillo (Fig. 1), collect and reflect direct solar radiation

Fig. 1: French solar furnace in Odeillo (World's Largest Solar Furnace n.d.)

with 63 heliostats onto a parabolic shape (concentrator) which in turn is redirected into a receiver. In the focal point temperatures up to 3,800 °C can be reached (Trombe, Le Vinh 1973). Currently, solar furnaces are used in research institutions only, e.g. for high temperature calcium carbide (CaC_2) formation (Paizullakhanov, Faiziev 2006), for smelting (Abdurakhmanov et al. 2008a) or material testing (Neumann 2005), (PROMES b).

Chile's economically most important produced metal is copper, which contributed 88% to Chilean export shipment values from the mining sector in 2015 (Servicio Nacional de Geología y Minería 2016). The fossil fuel consumption for copper production amounted 21.9 TWh in 2014, of which 7% were needed for smelting (Fundación Chile n.d.). The use of solar energy for metal smelting might have the potential to reduce costs and

doi:10.18086/swc.2017.26.03 Available at http://proceedings.ises.org

greenhouse gas emissions through replacing fossil fuels. Therefore, this work investigates the technical and financial potential of the integration of solar furnaces into high temperature smelting of copper under Chilean conditions as well as possible reductions in $CO_{2\text{-eq}}$-emissions.

2. Previous Work

Funken et al., from the German Aerospace Center DLR, developed a mini-scale SF powered rotary kiln for smelting 1 kg of aluminum scrap (Funken et al. 2001). They report a duration for smelting in the range of 0.5 to 6 h, depending on irradiance conditions (Cologne, Germany) and the achieved temperature. Additionally, a large scale solar kiln (capacity: 8 t) was designed and the heliostat field was optimized. The benefit of the applied solar smelting was the reduced amount of resulting flue gas that had to be cleaned. Furthermore, cost savings due to avoided fuel consumption can be expected. This concept is further investigated in the SOLAM project, a German-South African research initiative (DLR 2015). Abdurakhmanov et al. investigated different types of smelting furnaces using the large solar furnace in Uzbekistan (Abdurakhmanov et al. 2008b).

3. Integration of a solar furnace into copper smelting

3.1 Weather data

The solar resource website *Explorador Solar* provides both typical meteorological years (TMY) data files in an hourly resolution and weather measurement datasets in a 10-minute resolution (Ministerio de Energía 2017). To achieve a higher accuracy, a TMY was developed based on the weather measurement datasets from *Crucero 2*, which is located 45 km from Chuquicamata, the world's largest open-pit copper mine (latitude: -22.1647°, longitude: -69.339777°). For the selection of representative months, the direct normal irradiation (DNI) was used as the only criterion, since this is the most influencing parameter on the performance of a SF. The DNI values from the developed TMY are shown in Fig. 2. Clearly this location exhibits exceptional high solar irradiation.

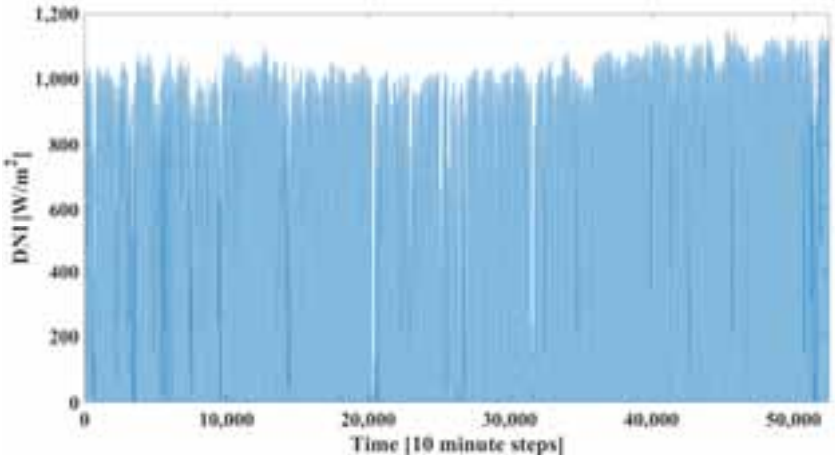

Fig. 2: DNI values from developed TMY based on *Crucero 2* measurements

3.2 Development of a solar furnace model in Matlab

Fig. 3 shows the subcomponents of the developed SF model. The layout of the heliostat field and the design of the concentrator is based on the French SF in Odeillo (PROMES a). The formulas to compute the time-variant cosine loss factor and the time-dependent orientation of each heliostat are taken from (Stine, Geyer 2001). The resulting total thermal power output of the SF system is calculated according to eq. (1).

$$P_{SF} = A_{Heliostat} \cdot DNI(t) \cdot \eta_{rh} \cdot \eta_{rc} \cdot \eta_{sbh} \cdot \eta_{sbc} \cdot \eta_{int} \cdot \eta_{aa} \cdot \eta_{circ} \sum^{n_{Heliostats}} \eta_{cos,i}(t) \qquad \text{eq. (1)}$$

The cosine loss factors were calculated for each heliostat separately to achieve more accurate results. The values from the other efficiencies are given in Appendix I.

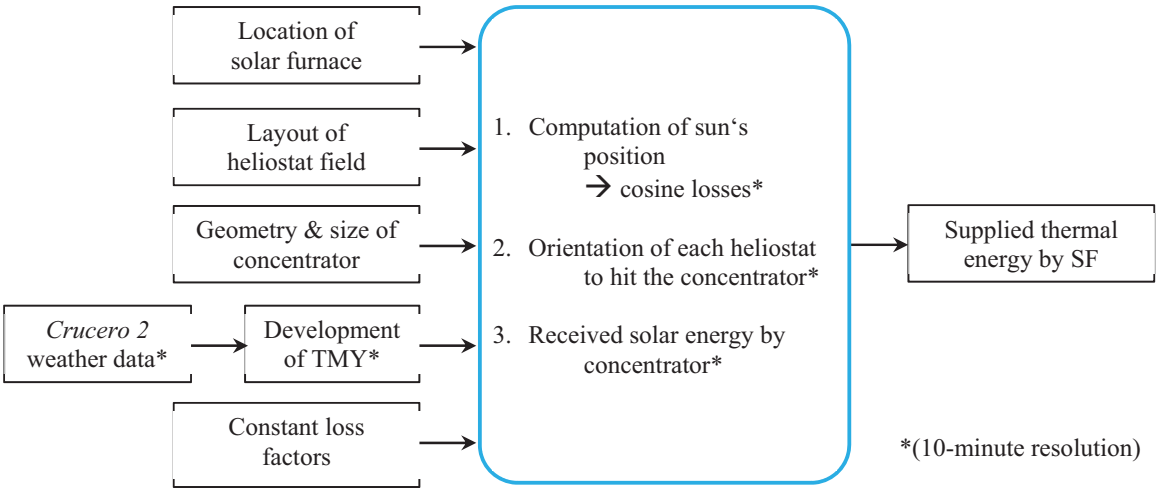

Fig. 3: Subcomponents of developed SF model

Fig. 4 shows a plot of the modelled SF in Chile.

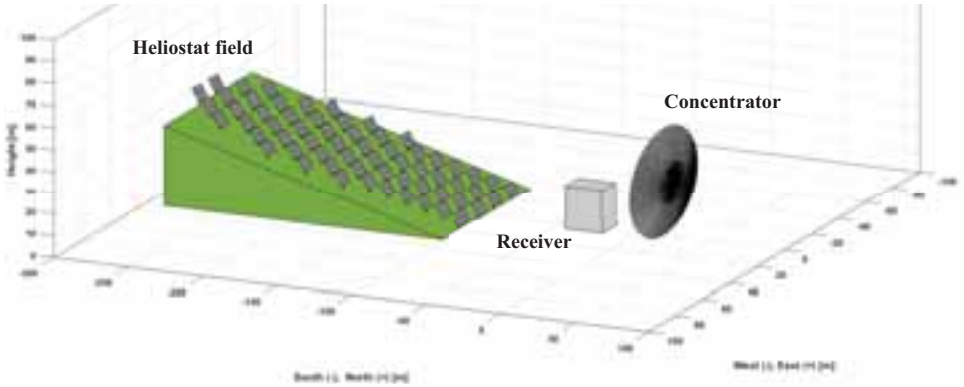

Fig. 4: Plot of the modelled SF and heliostat field located in Chile

In Fig. 5 the simulated thermal output of the SF is shown. We can clearly observe that most of the time the output of the SF exceeds the design point of 1 MW_{th}, due to high DNI irradiation found in northern Chile. It is

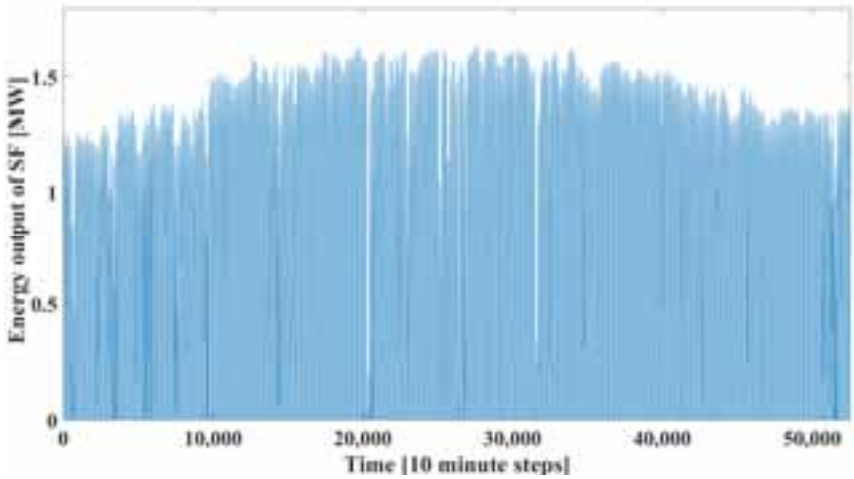

Fig. 5: Thermal output of the modelled SF, located in Chile

interesting to observe, that in winter time on the southern hemisphere the performance of the SF is higher than in summer. This can be explained by two factors: first, the DNI in northern Chile is constantly high throughout the whole year; secondly, the field performance of a point-focusing heliostat field is better in winter time when the sun hangs low in the sky.

3.3 Integration into copper smelting

The basic concept for the implementation of a SF into the copper smelting process is shown in Fig. 6. In this work we investigate three different flash furnaces, which need additional fuel for maintaining the thermal equilibrium. The thermal energy delivered by the SF contributes to the thermal equilibrium in a flash furnace and thus allows savings in fossil fuel consumption.

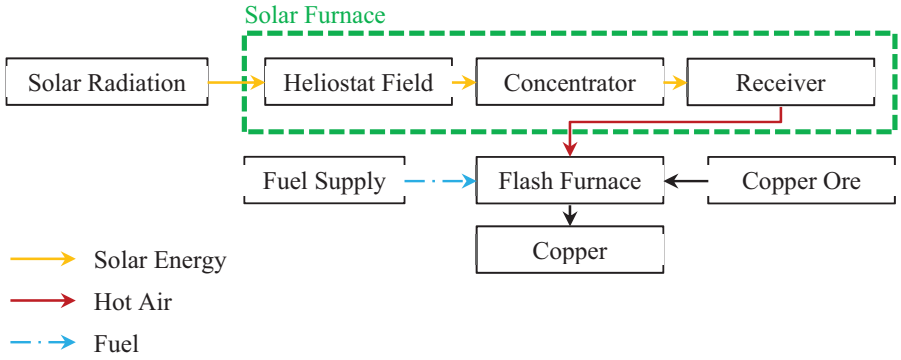

Fig. 6: Basic concept of the implementation of a solar furnace (SF) into the copper smelting process in a flash furnace

The properties of the investigated three flash furnaces are shown in Tab. 1, based on (Schlesinger 2011).

Tab. 1: Data of three flash furnaces used for cost analysis, based on (Schlesinger 2011)

	Flash furnace 1	**Flash furnace 2**	**Flash furnace 3**
Start of operation	1983	1972	1971
Concentrate feed [t/d]	2,000 (23-29% Cu)	2,241 (29.2% Cu)	3,830 (28.8% Cu)
Matte production [t/d]	1080 (54-56% Cu)	1129 (63.3% Cu)	1895 (64% Cu)
Fuel consumption [kg/h]	198.2 (Bunker C)	1,200 (Coal)	147 (Coal) + 404 (Diesel)
Fuel costs [USD$_{2017}$/h]	69	54	350
$\dot{m}_{Fuel}$·LHV [MW]	2.18	9.6	6.27

Since the fuel type varies among different flash furnaces, we took all three different fuels into account. Tab. 2 contains the characteristics of the fuel types.

Tab. 2: Lower heating values (LHV), specific $CO_{2\text{-eq}}$-emissions and costs of considered fuel types (Fürkus n.d.; Emission factors in kg CO2-eq per unit)

Fuel	**LHV [kWh/kg]**	**Specific $CO_{2\text{-eq}}$-emissions [kg$CO_{2\text{-eq}}$/kWh]**	**Costs [USD$_{2017}$/kg]**
Hard Coal	7.80	0.32	0.045
Diesel	11.83	0.3	0.85
Bunker C	11.00	0.29	0.35

3.4 Costs of the solar furnace

To estimate the costs of a SF, we adapted the specific costs for a heliostat from (new energy update 2017) and updated the figure to USD$_{2017}$, using an average inflation rate of 2%/a. This leads to specific heliostat costs of 147.9 USD$_{2017}$/m². Furthermore, we assume that heliostat costs constitute a share of 40% of total costs of a thermal CSP system (i.e. excluding “balance of plant”, “thermal energy storage” and “power block” from the cost components of a CSP power tower), based on the cost breakdown from (IRENA 2012). Finally, we assume annual operation and maintenance ($O\&M_{annual}$) costs as 5% of the initial investment. For the SF in Chile, a

heliostat field consisting of 63 heliostats (45 m² each) was designed (cf. Appendix II). With this information we calculate:

$$I_0 = \frac{147.89 \frac{USD_{2017}}{m^2} \cdot 63\ Heliostats \cdot \frac{45m^2}{Heliostat}}{40\%} = 1{,}048{,}170\ USD_{2017} \qquad \text{eq. (2)}$$

$$O\&M_{annual} = I_0 \cdot 5\% = 52{,}409\ USD_{2017} \qquad \text{eq. (3)}$$

Due to the fact that the French SF was completed in 1970 and is still in operation, a lifetime of T=50 years is assumed (Trombe, Le Vinh 1973). Taking into account an interest rate of *i*=2.5% (Chile Interest Rate 2017), we determine the present value PV_{SF} of the solar furnace as follows:

$$PV_{SF} = I_0 + O\&M_{annual} \cdot \frac{(1+i)^T - 1}{i \cdot (1+i)^T} = 2{,}534{,}597\ USD_{2017}$$

4. Results

The developed SF model calculated an annual thermal energy output of 4.66 GWh/a for the location in Northern Chile. To determine monetary savings, we assume that this energy output reduces the fossil fuel consumption of the flash furnaces each year. This gives us the net present values of the fuel costs of the three flash furnaces (FF1, FF2, FF3) without and with the integration of a SF for a lifetime of 50 a, as shown in Fig. 7. We can observe, that under the described assumptions, the integration of a SF is profitable for FF1 (-10%) and FF3 (-8%). Since in FF2 cheap coal is used, the integration of a SF is not profitable (+13%). "SF Costs" is the net present value of the SF, taking into account the investment costs I_0 and the annual O&M costs over the course of 50 a.

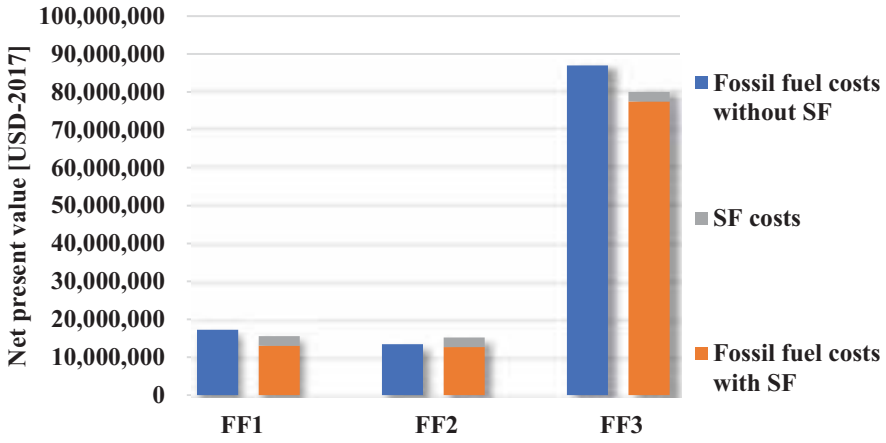

Fig. 7: Net present values of fuel costs for three flash furnaces, without and with the integration of a solar furnace

In Fig. 8 reductions in $CO_{2\text{-eq}}$-emissions through the integration of a SF are depicted. We can clearly see that the integration of a SF can reduce $CO_{2\text{-eq}}$-emissions. For FF1, FF2 and FF3 the savings are 24.4%, 5.6% and 8.9%, respectively.

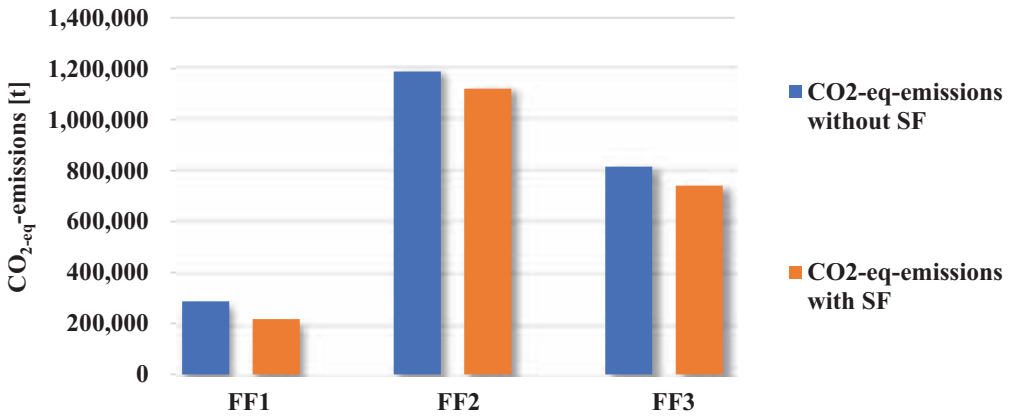

Fig. 8: CO_{2-eq}-emissions for three flash furnaces, without and with the integration of a solar furnace, after 50 a

5. Conclusion and outlook

In this work, we investigated the economic benefits as well as reductions in CO_{2-eq}-emissions through the integration of a solar furnace (SF) into copper smelting in Chile. A solar furnace was modelled in Matlab and the annual thermal energy production in the North of Chile was simulated. A SF with the same design as the French SF in Odeillo, located in Chile, would generate around 4.66 GWh/a. Depending on the type of fuel that is used in a flash furnace, up to 10% of fossil fuel costs and 24% in CO_{2-eq}-emissions could be saved. The results show, that it can be advantageous in economic and environmental terms to put more efforts in the research on solar aided metallurgy. Future research should focus on the concrete development of a solar aided flash furnace, taking into account specific metallurgical requirements during the smelting process.

Thermal Model Development for Solar Greenhouse Considering Climate Condition

Homa Esmaeli[1], Ramin Roshandel[1]

[1] Sharif University of Technology, Department of Energy Engineering, Tehran (Iran)

Abstract

Water crisis in the Middle East, leads policy makers to consider development of greenhouses on large scale. Typical greenhouses usually use energy carriers like natural gas and gasoline to provide suitable microclimate for plants. The consequence of greenhouse development will be huge amount of fossil fuels consumption, producing CO_2 and forcing loads to gas, gasoline and electricity networks. Considering excellent solar energy potential in the Middle East, solar greenhouses seems to be an innovative solution.

In this research, after studying different solar greenhouse experiences around the world, a successful model has been chosen, redesigned and improved. Solar greenhouse is designed to utilize solar energy by its passive energy system and minimize external energy demand. In order to investigate its performance, a mathematical thermal model has been developed to predict inside air temperature, which is the most important parameter in greenhouse performance. Solar Greenhouse Thermal Model (SGTM) is based on solar collector analysis and trombe wall calculations in buildings, it receives hourly climate data (solar radiation, wind speed and ambient temperature) and calculate hourly solar greenhouse inside air temperature during the year. SGTM has been validated and can be used to predict solar greenhouse inside air temperature in any region.

Results of using SGTM show that solar greenhouse is suitable for Tehran climate condition, and it works passively without auxiliary heating system in the winter, but it needs auxiliary cooling system in the summer. Sensitivity analysis indicates that the greenhouse size play a vital role in its thermal performance. So, there is an optimal size for solar greenhouse in each climate condition.

Keywords: Solar Greenhouse, Thermal Model, Solar Energy, Water Crisis

1. Introduction

World is dealing with several concerns, Water-Food-Energy nexus is one of them that has great impacts on people life directly. However, the water nexus may be more important than the others in the Middle East. Agriculture sector uses 84 percent of total water usage in the MENA region (Statista (2015)), which indicate essential actions must have done. Development of Greenhouses in large scale is one of the solutions which has attracted the attention of policy makers and leads them to consider development of greenhouses on large scale.

Greenhouses are designed to provide suitable microclimate for growing plant efficiently. Higher production per area, less water consumption and higher production quality are the main advantages of greenhouses but greenhouses consume energy carriers like natural gas, gasoline and electricity to provide desired microclimate. So, the consequence of greenhouses large scale development will be huge amount of fossil fuels consumption, producing CO_2 and forcing loads to gas, gasoline and electricity networks.

The Brundtland Commission's report (1988) defined sustainable development as "development which provides the current generations needs without compromising the future generations ability to meet their own needs", which imposed the idea of limitations by the state of technology on the environment's ability to meet present and future needs. Sustainable development concept and great solar energy potential in Middle East make solar greenhouses to seem an interesting idea and an innovative solution.

Passive design of solar greenhouse is utilizing solar energy for heating without any additional heating system, specifically it supports the idea of maximizing solar gain and minimizing heat loss to eliminate the dependence of fossil fuels for heating/cooling (Schiller and Plink (2016)) . Santamouris et al. (1994) categorized solar greenhouses in passive solar greenhouses and active solar greenhouses. Passive solar greenhouses have an integrated design to collect heat or the greenhouse works as a solar collector, the design is based on maximizing the solar gains but active solar greenhouses have equipment separated from the greenhouse to utilize solar energy, and an independent heat storage system. Several passive heating and cooling systems have been used in solar

doi:10.18086/swc.2017.26.04 Available at http://proceedings.ises.org

greenhouses around the world, Sethi and Sharma (2007 and 2008) reviewed and evaluated them and discussed the representative application of each technology, also they studied several cases for each technology and drive experimental equations for evaluating these technologies. These researches focused on heating and cooling systems that used on different structure designs.

There is a kind of solar passive greenhouses mainly located in northern region of China (Wang et al. (2014)), they are used to grow vegetables in the winter without any auxiliary heating. The building parameters have an important impact on the solar energy utilization and temperature in the greenhouse (Tong et al. (2013)). Tong et al. (2013) reviewed all researches that discussed solar greenhouse building parameters, they concluded all the building parameters are related to each other and to the local climate condition in solar passive greenhouse system and they should be analyzed together.

In this study, in the first step after studying different solar greenhouse experiences around the world, a successful model has been chosen, redesigned and improved, considering principles of solar passive design. Secondly, an innovative mathematical thermal model has been developed to predict inside air temperature annually in any climate condition, in order to investigate its performance. Thirdly, sensitivity analysis has been done on structural parameters to investigate effect of structural parameters on thermal performance of solar greenhouse.

2. Methodology

2.1. Solar Greenhouse Design

In order to design a solar passive greenhouse, orientation toward sun, insulate the areas that do not collect solar energy and underground, maximizing the light and heat in winter and reduce it in summer, using thermal storage techniques and supplying sufficient ventilation are the main principles that should be considered (Schiller and Plink (2016)).

Also, van't Ooster et al. (2007) represent a systematic procedure to develop a zero fossil greenhouse concept for the Netherlands. This design procedure contains following steps:

- Step 0: Design objective definition
- Step 1: Brief of requirements definition
- Step 2: Required functions definition
- Step 3: Working principles definition
- Step 4: Conceptual designs derivation
- Step 5: Conceptual designs evaluation

A solar passive greenhouse is designed based on above design principles. This is a south oriented elliptic shape greenhouse, covered by transparent material and a thermal insulation cover to prevent heat loss at night, a thermal storage wall (layered) is installed in the north of the greenhouse (Fig.1). Solar radiation transmits into the greenhouse during the day, south oriented elliptic shape roof from east to west collect solar radiation from sunrise to sunset efficiently, then is absorbed by heat storage wall and soil of the ground, which increase their temperatures because absorbed solar radiation is converted to sensible heat. Temperature difference between the surfaces and inside air causes heat transfer via convection, into the thermal storage wall via conduction, to store heat in it and keeping greenhouse warm at night, and into the ground via conduction. Part of absorbed solar energy is transformed into the latent heat by crop transpiration and evaporation from wet surfaces.

Thermal insulation covers the elliptic shape roof to prevent heat loss during the night. Stored heat in thermal storage wall transfers through convection to keep inside air warm.

Solar photovoltaic panels and solar collectors can be installed in the roof to supply electricity demand of greenhouse (for irrigation, lightening, fans, motors, climate control system, etc.) and to supply additional heat demand.

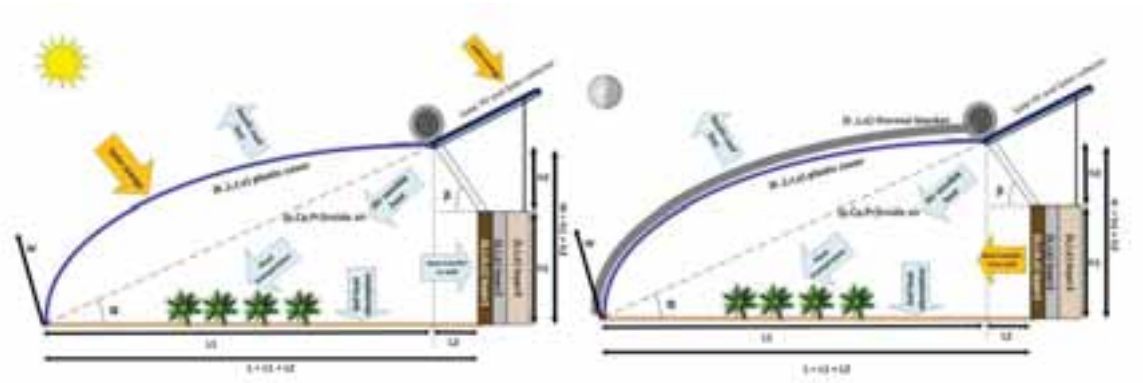

Figure 1: Cross sectional conceptual view, heat transfer mechanism and structural parameters of solar passive greenhouse at day and night

2.2. Thermal Model Description, Equations and Validation

The most important parameter in greenhouse performance is inside air temperature. Several energy analysis have been done to evaluate greenhouse performance. De Zwart (1996) developed a comprehensive greenhouse climate simulation model that included three sub models: CO_2, water vapor and thermal. The basis of equations was energy and mass balances and was developed for different temperature layers of greenhouse. Chen et al. (2015) developed a greenhouse energy demand model which was based on mass and energy balance considering physiological behavior of plants.

Thermal Model (SGTM) is based on solar collector analysis and trombe wall calculations in buildings (Duan et al. (2016)), it receives hourly climate data (solar radiation, wind speed and ambient temperature) and calculate hourly solar greenhouse inside air temperature during the year. Fig.2 shows how different parameters are connected in SGTM.

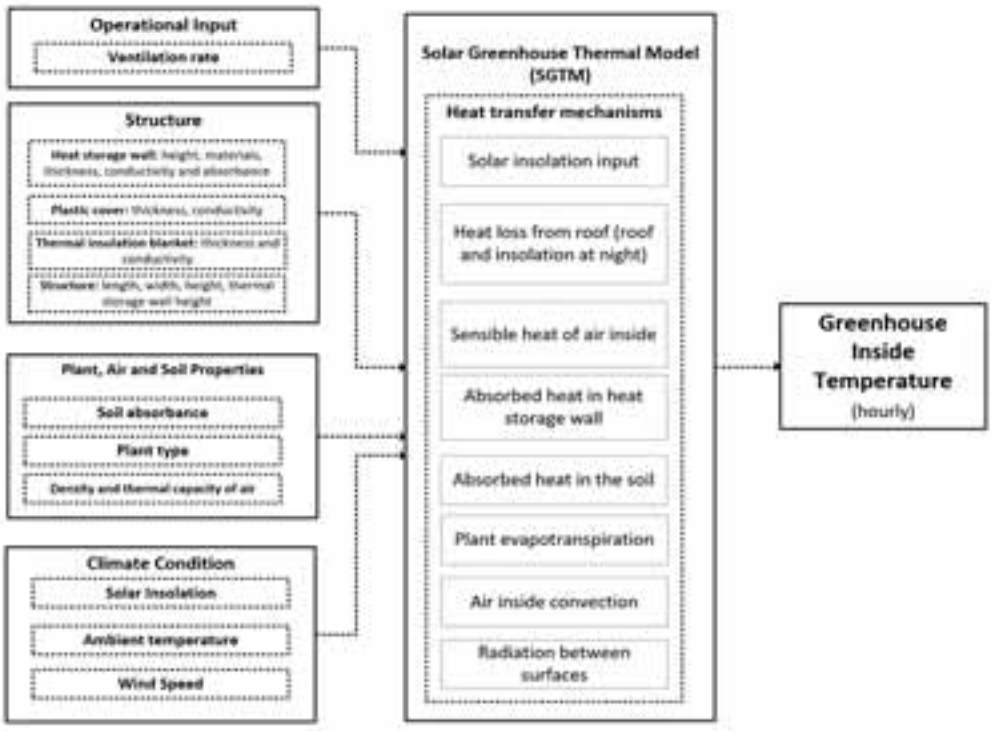

Figure 2: Data circulation diagram of SGTM

Seven surface of temperature has been considered (Fig.3) and for each surface energy balance equation has been developed. It is assumed that there is steady state condition, each surface has a constant temperature and air inside temperature is uniform.

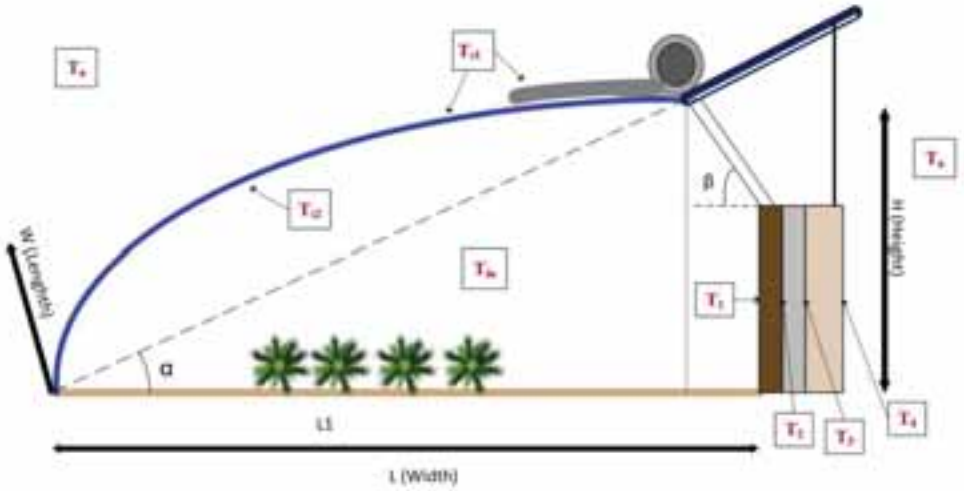

Figure 3: Temperature levels of SGTM

First level of equations belongs to the outer surface of plastic roof, equation 1 indicates the energy balance for it:

$$h_{c,cover-out}A_{cover}(T_{s1}-T_a)+h_{r,cover-out}A_{cover}(T_{s1}-T_a)+\frac{k_{cover}}{L_{cover}}A_{cover}(T_{s1}-T_{s2})=I\alpha_{cover}A_{cover} \quad \text{(eq. 1)}$$

$$h_{c,cover-out}=5.7+3.8u_w \quad \text{(eq. 2)}$$

$$h_{r,cover-out}=\varepsilon_{cover}\sigma(T_{s1}+T_s)(T_{s1}^2+T_s^2) \quad \text{(eq. 3)}$$

$$T_s=0.055T_a^{1.5} \quad \text{(eq. 4)}$$

Where T_{s1}, T_{s2}, T_s and T_a are respectively the temperature of outer surface of plastic roof, inner surface of plastic roof, sky temperature (equation 4) and ambient temperature, $h_{c,\text{ cover-out}}$ refers to convection heat transfer coefficient from plastic roof to out of greenhouse and calculate through equation 2, $h_{r,\text{ cover-out}}$ refers to radiation heat transfer coefficient from plastic roof to sky and calculate with equation 3.

Second level of equations belongs to internal surface of plastic roof and energy balance for it express as equation 5.

$$\left(h_{r,cover-wall}+\frac{k_{air,cover-wall}}{L_{air,cover-wall}}\right)A_{wall}(T_{s2}-T_1)+\frac{k_{cover}}{L_{cover}}A_{cover}(T_{s2}-T_{s1})+h_{c,cover-air}A_{cover}(T_{s2}-T_{in})=0 \quad \text{(eq. 5)}$$

$$h_{r,cover-wall}=\frac{\sigma(T_{s2}^2+T_1^2)(T_{s2}+T_1)}{\frac{1-\varepsilon_{cover}}{\varepsilon_{cover}A_{cover}}+\frac{1}{A_{cover}F_{cover-wall}}+\frac{1-\varepsilon_1}{\varepsilon_1 A_{wall}}} \quad \text{(eq. 6)}$$

$$h_{c,cover-air}=\frac{k_{air,cover-wall}Nu}{L_{air,cover-wall}} \quad \text{(eq. 7)}$$

Where T_1 and T_{in} are respectively temperature of inner surface of heat storage wall and inside air temperature.

Third level of equations belongs to internal surface of heat storage wall and energy balance for it express as eq. 8.

$$h_{c,wall-air}A_{wall}(T_1 - T_{in}) + \left(h_{r,wall-cover} + \frac{k_{air,wall-cover}}{L_{air,wall-cover}}\right)A_{wall}(T_1 - T_{s2}) + \frac{k_1}{L_1}A_{wall}(T_1 - T_2) + h_{r,L_1-L_2}A_{wall}(T_1 - T_2) = I\alpha_{wall}\tau_{cover}A_{wall} \quad \text{(eq. 8)}$$

$$h_{r,L_1-L_2} = \frac{\sigma(T_1^2+T_2^2)(T_1+T_2)}{\frac{1}{\varepsilon_1}+\frac{1}{\varepsilon_2}-1} \quad \text{(eq. 9)}$$

$$h_{c,wall-air} = \frac{k_{air,wall-cover}Nu}{L_{air,wall-cover}} \quad \text{(eq. 10)}$$

Where T_2 refers to the connection of first and second layers of heat storage wall temperature. Energy balance for connecting layers which express with T_2 and T_3 (connection of second and third layers of heat storage wall temperature) express with following equations:

$$\left(h_{r1} + \frac{k_1}{L_1}\right)A_{wall}(T_2 - T_1) + \left(h_{r2} + \frac{k_2}{L_2}\right)A_{wall}(T_2 - T_3) = 0 \quad \text{(eq. 11)}$$

$$h_{r1} = \frac{\sigma(T_1^2+T_2^2)(T_1+T_2)}{\frac{1}{\varepsilon_1}+\frac{1}{\varepsilon_2}-1} \quad \text{(eq. 12)}$$

$$h_{r2} = \frac{\sigma(T_2^2+T_3^2)(T_2+T_3)}{\frac{1}{\varepsilon_1}+\frac{1}{\varepsilon_2}-1} \quad \text{(eq.13)}$$

$$\left(h_{r3} + \frac{k_2}{L_2}\right)A_{wall}(T_3 - T_2) + \left(h_{r4} + \frac{k_3}{L_3}\right)A_{wall}(T_3 - T_4) = 0 \quad \text{(eq. 14)}$$

$$h_{r3} = \frac{\sigma(T_3^2+T_2^2)(T_3+T_2)}{\frac{1}{\varepsilon_3}+\frac{1}{\varepsilon_2}-1} \quad \text{(eq.15)}$$

$$h_{r4} = \frac{\sigma(T_4^2+T_3^2)(T_4+T_3)}{\frac{1}{\varepsilon_3}+\frac{1}{\varepsilon_2}-1} \quad \text{(eq.16)}$$

Sixth layer is outer surface of heat storage wall. Equation 17 refers to energy balance for this surface.

$$h_{c,wall-out}A_{wall}(T_4 - T_a) + \frac{k_3}{L_3}A_{wall}(T_4 - T_3) + h_{r4}A_{wall}(T_4 - T_3) + h_{r,wall-out}A_{wall}(T_4 - T_a) = 0 \quad \text{(eq. 17)}$$

$$h_{r,wall-out} = \varepsilon_3\sigma(T_4 + T_s)(T_4^2 + T_s^2) \quad \text{(eq. 18)}$$

Where T_4 is outer surface of heat storage wall temperature.

Last level is energy balance for greenhouse air inside control volume, assuming there is no temperature distribution and T_{in} as inside air temperature.

$$h_{c,cover-air}A_{cover}(T_{in} - T_{s2}) + h_{c,wall-air}A_{wall}(T_{in} - T_1) + \rho_{air}\dot{V}C_{p,air}(T_{in}(t) - T_{in}(t-1)) + ach\, V_{inside}\rho_{air}C_{p,air}\left(T_{in,h} - T_a\right) + A_{ground}\lambda E(t) + U_{cover}A_{cover}(T_{s2} - T_a) + I\tau_{cover}\alpha_{soil}A_{ground} = I\tau_{cover}A_{cover} \quad \text{(eq.19)}$$

Where λE(t) refers to the crop transpiration and expresses with Penma-Monteith formula (Chen et al. (2014)):

$$\lambda E(t) = \frac{I_a \tau_a \Delta + 2LAI(\frac{\rho c_a}{r_a})(e_s(t) - e_a(t))}{\Delta + \gamma(1 + \frac{r_c}{r_a})} \qquad \text{(eq. 20)}$$

$$\Delta = \frac{2504000}{(T_{in} - 35.6)^2} \exp(\frac{17.27(T_{in} - 273.16)}{T_{in} - 35.86}) \qquad \text{(eq. 21)}$$

Ventilation happens by using of fans which causes force convection. Nusselt number force convection in non-circular ducts can be calculated by circular ducts equations by substitution of hydraulic diameter (Bergman and Incropera (2011)).The distance between the wall and cover is also assumed hydraulic diameter.

$$D_h = \frac{4A_c}{P} \qquad \text{(eq. 22)}$$

Where A_c and P are respectively cross sectional area of duct and wetted environment. Nusselt number is calculated by Colburn equation (Bergman and Incropera (2011)):

$$Nu_D = 0.023 Re_D^{0.8} Pr^{1/3} \qquad \text{(eq. 23)}$$

Equations 1, 5, 8, 11, 14, 17 and 19 form a system of non-linear equations and the output will be temperature of greenhouse levels, the main result is inside air temperature.

In order to predict reliable results with SGTM, a validation has done. The best way to check the accuracy of model results is to compare them with experimental data. Tong et al. (2009) studied a similar solar greenhouse located in Shenyang, China (latitude: 41.8ºN, longitude 123.4ºE, altitude: 42 m). The greenhouse was 60 meter long and 12.6 meter wide with 5.5 meter ridge height, a 0.6 meter layered heat storage wall made of bricks and XPS foam as a thermal insulation material. The plastic roof was made of 0.12 mm PVC film, covered with a 20 mm thick cotton blanket during the night time. Other necessary data like solar insolation, ambient temperature, and physical properties, was reported in this paper as well. The typical weather file of Shenyang downloaded from the U.S. Department of Energy and used for wind speed data.

The highest temperature difference between SGTM model and experimental data is 2.8 Kelvin and the average of differences is 0.89. Figure 4 shows the model results compering to experimental data.

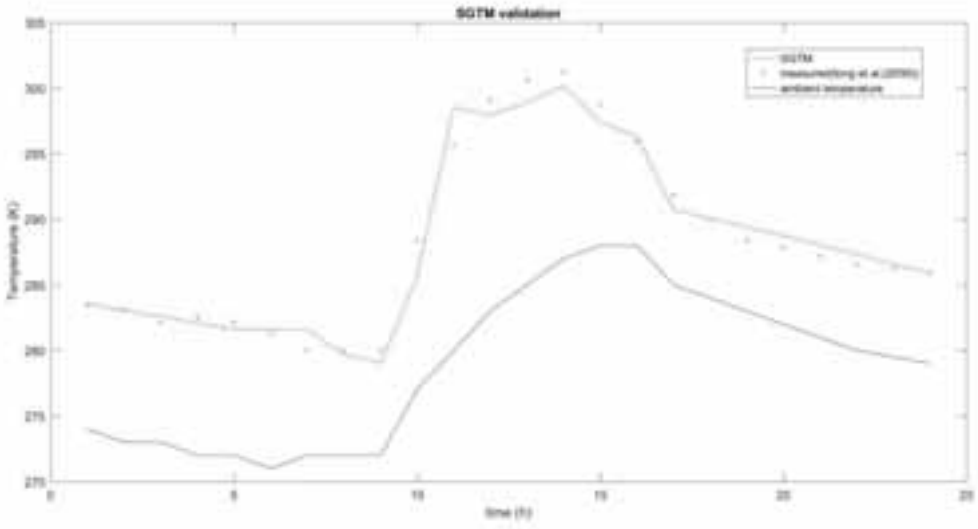

Figure 4: Validation of SGTM model for hourly greenhouse air inside temperature with experimental data in 20 February 2004 in Shenyang, China (Tong et al. (2009))

2.3. Simulation Outline

To investigate solar greenhouse performance in Tehran climate condition, a solar greenhouse is considered with 5.5 meter height, 12 meter width and 100 meter length and the 3 layered heat storage wall is 3 meter high and 0.6 meter thick.

Table 1: Natural and physical properties of solar greenhouse structure

Location	Thickness (m)	Thermal conductivity (W/m.K)	Emissivity ε	Absorptance α	Transmission τ
Plastic cover	0.00012	0.17	0.9	0.03	0.88
Thermal insulation	0.036	0.09	0.9	0.75	0
Heat storage wall inside layer	0.36	0.81	0.93	0.6	0
Heat storage wall middle layer	0.12	0.03	0.9	-	0
Heat storage wall outside layer	0.12	0.81	0.93	0.6	0

3. Results and Discussion

3.1. Solar Greenhouse Performance in Tehran

The aim of using solar greenhouse is to maximize solar energy utilization and minimize using of active energy systems to provide desirable micro-climate for plants. There are two extreme states to investigate greenhouse thermal performance in order to know if it will work properly in a specific climate, hottest and coldest months of the year. July and January are the hottest and coldest months in Tehran based on typical weather file downloaded from the U.S. Department of Energy.

Typical vegetable plants can tolerate temperature range 10 to 32, as it has shown in Figure 5, during the average day of July, greenhouse will be overheated, and it is caused of huge amount of solar radiation and high ambient temperature which means it is necessary to use a cooling system or some energy management solutions like shading and using an optical object to send excessive solar insolation to outside. Figure 6 shows solar greenhouse will work properly in winter and the inside temperature will not be less than 286 Kelvin although the ambient temperature is less than the minimum temperature all the time and it is near to 273 kelvin.

Solar greenhouse can be used in hot climates like Tehran without any auxiliary heating. To prevent overheating in summer a cooling system can be used or can be planned to operate greenhouse only in cold seasons, also some other passive systems can be designed to adjust inside air temperature in a better range like ground to air heat exchanger (Sethi and Sharma (2007 and 2008)).

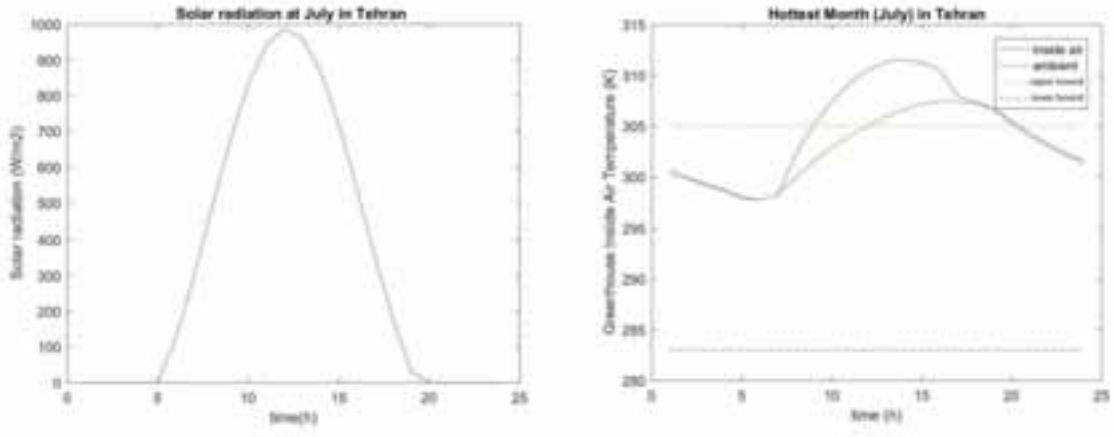

Figure 5: Solar insolation (left) and thermal performance of solar greenhouse (right) at July in Tehran

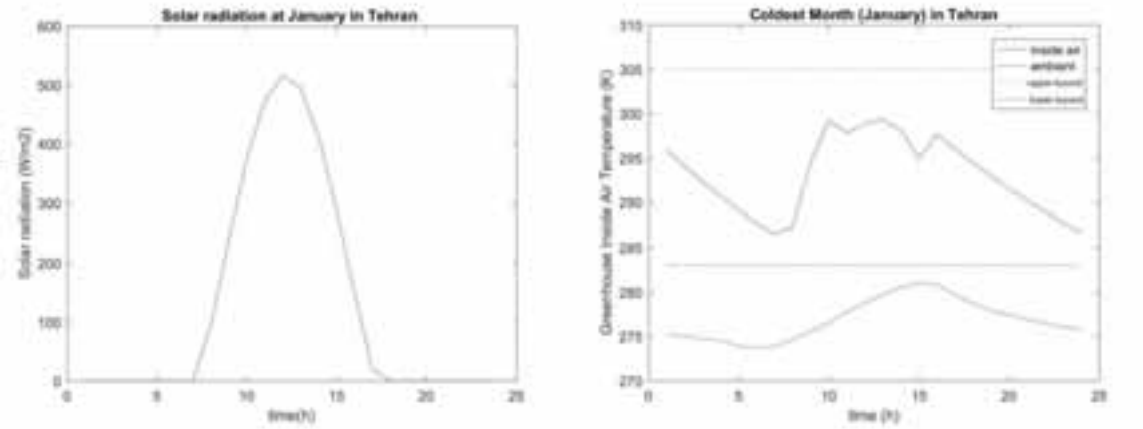

Figure 6: Solar insolation (left) and thermal performance of solar greenhouse (right) at January in Tehran

3.2. Sensitivity analysis

Passive solar greenhouse can be assumed as a solar collector. Like any kind of solar collector its sizing has an essential role in its performance that is determined based on climate condition, to investigate the effect of changing the structural parameters, three cases have been defined and studied. Size parameters of greenhouse structure are α and β which define the ratio of height to width and L and H which define the height and width.

- Case 1
  In this case, α and β remain constant and the total size of greenhouse is changed, which is equal to change the inside air volume. As it has shown in figure 7, the solar greenhouse thermal performance gets better by increasing the size of greenhouse in hottest month of year and it works well in all the cases in coldest month of year, so the bigger solar greenhouse works better in Tehran climate condition. Also bigger greenhouse has a better temperature distribution which is better for crop transpiration.

Table 2: Solar greenhouse structural parameters details for case 1

Number of the case	H (m)	L (m)	α	β
Case 1.1	4.58	10	30	45
Case 1.2	5.5	12	30	45
Case 1.3	6.42	14	30	45
Case 1.4	7.5	16	30	45

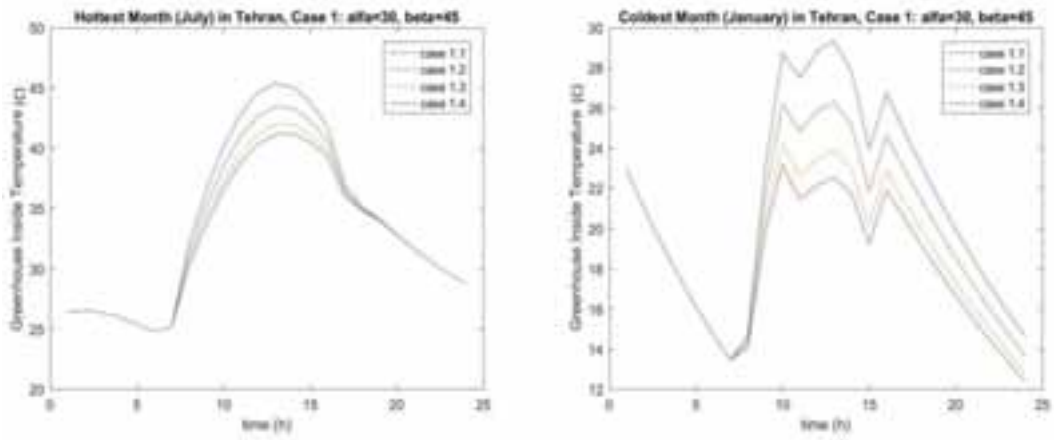

Figure 7: Solar greenhouse thermal performance in case 1

- Case 2

  In this case β and H are constant and α and L are changed to investigate the effect of α angle in thermal performance of solar greenhouse, α angle's function is like tilt angle function in solar collector, but in this case the best tilt angle for winter is important to keep greenhouse warm in winter.

  As it has shown in figure 8, case 2.1 (α=36) has the best performance in hottest month of year and the bigger α angles have better performance in coldest month of year.

Table 3: Solar greenhouse structural parameters details for case 2

Number of the case	H (m)	L (m)	α	β
Case 2.1	5.5	10	36	45
Case 2.2	5.5	12	30	45
Case 2.3	5.5	14	25	45
Case 2.4	5.5	16	22	45
Case 2.5	5.5	9	40	45

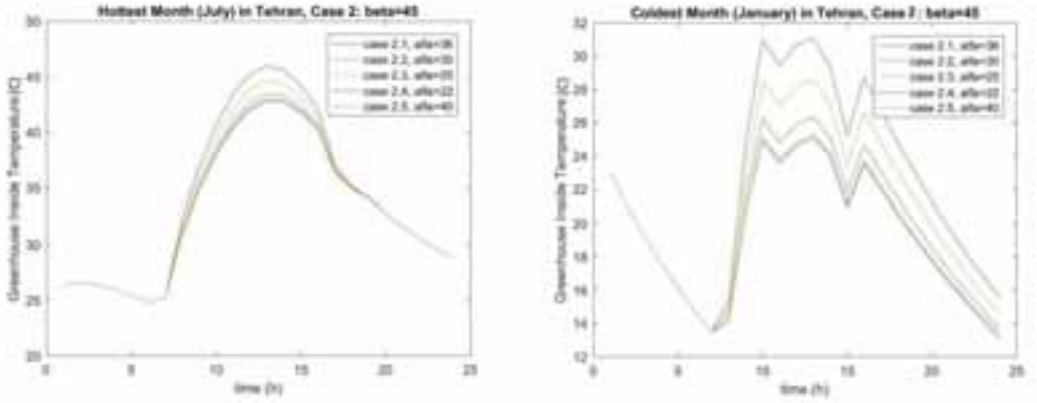

Figure 8: Solar greenhouse thermal performance in case 2

- Case 3

  In this case the effect of β angle and heat storage wall height are investigated. As it has shown in figure 9, bigger β has worse performance not only in summer but also in winter, because bigger beta equals to more area for plastic roof and more area to collect solar energy, in simpler words it leads to a bigger solar collector. The bigger heat storage wall also has overheating in both summer and winter, because of using more thermal mass to store heat.

  Bigger beta and heat storage wall values will effect positively on greenhouse performance in cold climates.

Table 4: Solar greenhouse structural parameters details for case 3

Number of the case	H (m)	L (m)	α	β	Heat storage wall height (m)
Case 3.1	5.5	10	30	45	5
Case 3.2	5.5	10	30	78	3
Case 3.3	5.5	12	30	45	3

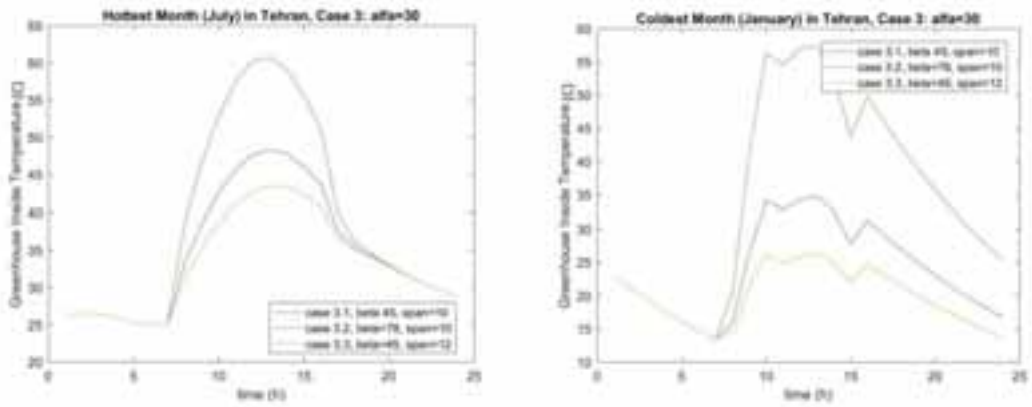

Figure 9: Solar greenhouse thermal performance in case 3

4. Conclusions

In this research a solar greenhouse is designed and its performance is evaluated by developing a thermal model in order to calculate inside air temperature. This study shows that:

- Solar greenhouse thermal model receives climate condition data, plant type, size and materials of structure and operational data and puts them in a system of non-linear equations to predict greenhouse air inside temperature in any region.
- Solar greenhouse can operate without auxiliary heating in winter in hot climates like Tehran, but there is necessary to use an active cooling system (like fan and pad) or use passive systems (shading, ground to air heat exchanger) to cool it in summer. The other solution is to plan greenhouse to operate seasonally.
- The sensitivity analysis has showed that the structural parameters of greenhouse have a great impact on greenhouse thermal performance. It can be concluded that the bigger greenhouse with α angle around 36 and beta angle around 45 is the best structure between the studied cases. It shows that there is an optimum structure for each climate.
- Although greenhouse inside air temperature stays in appropriate range most of the time, there is a specific temperature range for each plant. If the greenhouse keeps in that range, the production performance will be higher, so auxiliary heating and cooling systems can be designed and used. The energy demand of them will be much less than typical greenhouses.

Abstract

The paper analyses the thermal energy requirements of an industrial production line for prefabricated concrete parts using measurements and tests. The goal is to significantly reduce the energy demand and reduce the temperature level in order to be able to integrate solar thermal process heat, and the first-time use of the hydration heat. The final production line, optimized on the basis of the research results, is presented, as well as a simulation study, which shows, that economically interesting solar thermal process heat production costs can be achieved through an optimized overall concept. Regarding the export of this production technology to countries with hot and dry climates it is also aspired, to cover the additional required cooling load by means of solar thermal driven chillers. This option should also be examined by system simulations. These simulations put also emphasis on the development of cost- effective system concepts, which allow the integration of solar thermal process heat and/ or cold.

Keywords: Solar thermal process heat and/ or cold, prefabricated concrete parts, measurements and tests, heat production costs, optimized overall concept, solar thermal driven chillers, polysun system simulations

1. Introduction

The cooling, respectively heating during the production process of precast concrete parts is extremely important regarding quality. In Middle and Northern Europe concrete heating is more relevant, whereas, in Southern countries such as Turkey, United Arab Emirates a production of high quality concrete would hardly be possible without cooling.

The plants operated by the Austrian company Franz Oberndorfer GmbH & Co KG are producing prestressed hollow core slabs in various construction heights at the locations Wöllersdorf, Herzogenburg, Gunskirchen, Grosswilfersdorf, Radfeld and Völkermarkt. Through the restructuring of the production process in the plant Wöllerdorf the energy consumption shall be reduced by 90% in future. This target is a result of an ongoing company internal development process. The final target will be reached through the worldwide first time usage of the so called hydration heat (heat development through chemical reaction of water and cement) and the integration of solarthermal energy in the whole process. The use of hydration heat decreases the energy demand and necessitates changes in the heat distribution system towards lower temperatures. This modification on the other hand, approves the use of solar thermal energy in the production process.

The use of hydration heat insists a long-term comprehensive evaluation of the production data. In the end the heat shall be discharged by means of a heat transfer medium via the mold surface. Based on the results from the evaluation of the production data as well as a series of laboratory tests, the target is to develop a proven hydraulic concept and a control system for the recovery of hydration heat. Hence the achieved production data will be converted to load profiles. These load profiles serve as a basis for dynamic simulations in order to examine the integration of solar thermal energy in the production process. Regarding the export of this production technology to countries with hot and dry climates it is also aspired, to cover the additional required cooling load by means of solar thermal driven chillers. This option is examined also by system simulations.

doi:10.18086/swc.2017.26.05 Available at http://proceedings.ises.org

The project puts emphasis on the development of cost- effective system concepts, which allow the integration of solarthermal process heat and/ or cold. The lessons learned during the long-term comprehensive evaluation of the production data and the lab tests will be incorporated also into the redesign of the other production plants. It is planned to hand over the achieved conclusions to further application areas (precast concrete product range worldwide) by licenses to interested competitors.

2. Production data evaluation

The basis for the planned project objectives is a comprehensive, long-term production data analysis at the demonstration and test facility located in in Wöllersdorf, Austria.

Prestressed hollow core slabs are characterized by low overall height and minimum building material consumption. They belong to the group of full-surface ceilings without subdivision with subsequent grouting and are built according to ÖNORM EN 1168 at heights of 16 cm; 20 cm; 26 cm; 32 cm; 40 cm; 45 cm and 50 cm with a length of up to 22 meters [1]. Up to now, the elements have been produced on up to 150 m long lanes, which are heated by means of a thermo- oil heating system. The corresponding pipe system had to be heated to a temperature of approx. 150 ° C.

In Figure 1, the demonstration (right) system is compared to the previous heating system (left). By increasing the number of tubes, embedding them into a storage medium and connecting it to the steel plate, a better heat transfer is achieved. Therefore, the flow temperatures can be lowered, and water can be used as a heat transfer medium. Due to the novel hardening process, the required surface temperature of the floor panel of 35° C. is achieved with a substantially lower energy input. The temperature of the water circuit is now 50-60 °C.

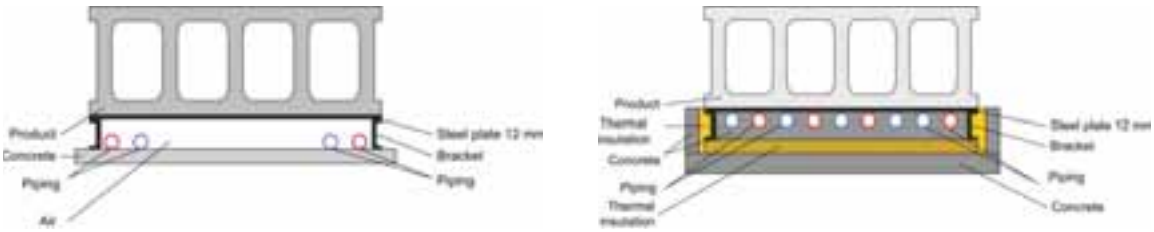

Fig. 1: Comparison old(left) and new (right) product heating system

Three heating circuits are designed hydraulically as parallel circuits with mixing control by three-way valves. A modulating 275 kW gas boiler is the heat source. A control system allows the presetting of a set flow temperature and the definition of heating times per circuit as well as the recording of measured data. The entire production process takes about 24 hours. This production process involves straining the steel ropes, extruding, (applying the concrete on the lane), curing, removing the slab and cleaning the lane.

Irregularities in the internal data collection as well as unexplained temperature gradients along the length of the lane led to the temporary installation of additional data loggers and to the analysis of thermographic images. Control measurements with mobile ultrasonic heat meters confirmed incorrectly closing control valves and showed conversion errors in the internal measurement data acquisition.

The annual energy balance in Figure 2 shows the enormous savings potential that can be achieved by really simple measures. Regarding domestic hot water production and building heating, further measurements are planned.

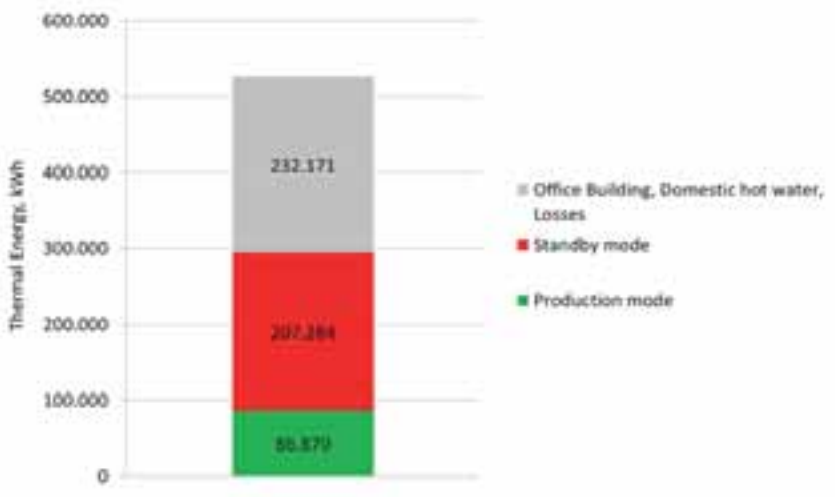

Fig. 2: Annual energy balance of a typical fabrication plant in Austria

3. Use of hydration heat

For the production of concrete, water, binders (e.g. cement), aggregate (e.g. sand/ gravel) and possibly additives (e.g. fluxes) are needed. The chemical- physical reaction of cement with water is called hydration. The heat evolution depends essentially on the amount of cement and the type of cement. The amount of heat developed up to the complete hydration does not differ significantly for the individual types of cement.

Depending on the application, different solutions for the prevention or reduction of hydration heat are sought. On the one hand, attempts are being made to accelerate the curing time of the concrete parts by supplying heat, but on the other hand, the concrete part temperature must not rise too much because of cracking and possible product damaging.

In this project, the heat of hydration is seen as an additional, previously unused energy or heat source, which can help to reduce production costs and increase product quality. The main challenge is posed in the fact that until now there was no way to control the heat of hydration or to offer any technical solutions for removing the heat of hydration. On the basis of temperature measurements and simulations with the software COMSOL® Heat, an attempt was made to document the temperatures occurring during a whole production cycle. Subsequently, a sample was taken to determine tensile and compressive strength. Figure 3 shows one time step of the occurring temperature profile.

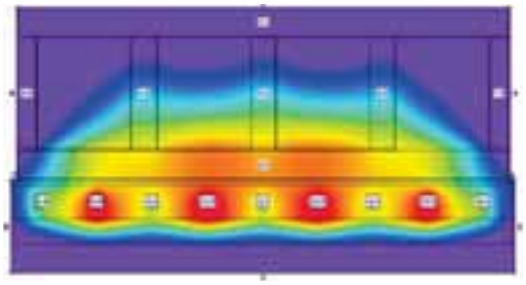

Fig. 3: Temperature profile during production

The high savings potential realized due to the production data analysis relativizes the expected savings of hydration heat recovery. The maximum surface temperature on the bottom side is max 5°C above the current heating return temperature of 45°C. The heat recovery potential is therefore low. For the quality of the products, however, the occurring temperature gradients are important, which should not exceed the maximum 0.3K per hour and 0.7 K/cm slab height.

4. Simulations

4.1 Location Austria, heating energy supply

The data collected during the evaluation over a year were used to create load profiles for the heating of the lanes. From the huge amount of production data and the production plan, the required heating energy quantities were analyzed at different fresh concrete temperatures. The production process consists of 3 parts. The preheating process is used to bring the massive flooring sheet to temperature. A required preheating time of 2 h was selected. The production process is characterized by different thickness of the slabs and therefore different production times. Thus, the thickest slab type is extruded in more than twice the time of the thinnest slab. Finally post heating is used for quality assurance and is necessary to prevent material stresses and to accelerate the hydration. The fresh concrete temperature was approximated with the outside temperature. The resulting energy need equals to 400- 450 kWh for the slight lanes (16-26 cm height) and 600-700 kWh for the massive lanes. (32- 50 cm height). In general, there is only a slight influence caused by the fresh concrete temperature.

The power consumption, the duration and the temperature profile of the production steps results in specific load profiles. These load profiles and the current production plan serves as a basis for the dynamic system simulations using the Vela Solaris software Polysun Designer. This results in a theoretical process heat energy consumption of 248.400 kWh. Figure 4 shows the corresponding plant concept.

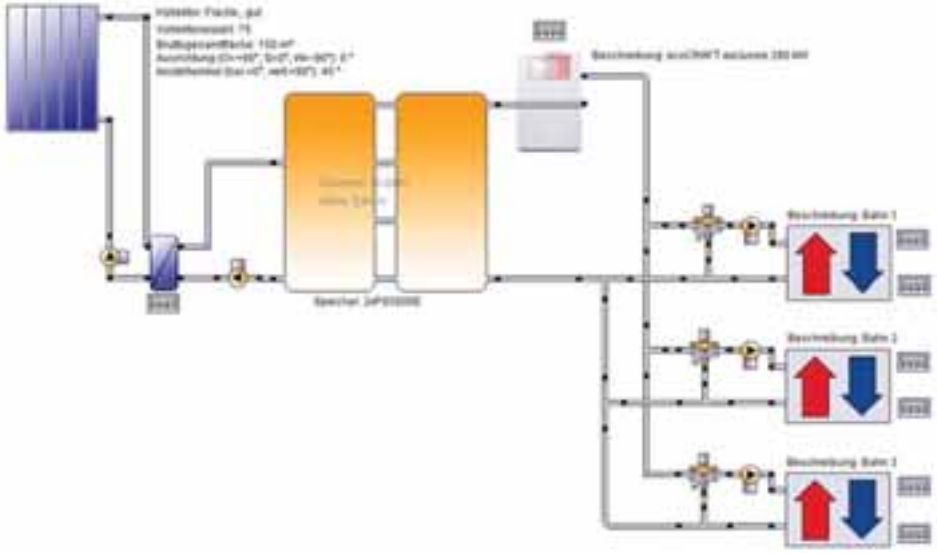

Fig. 4: System concept in the software Polysun Designer

The solar system is designed, that the process heat demand can be covered on a clear summer day. This is to avoid stagnation in summertime. High specific yields are the result, which are important for the profitability of the system. However, the achievable solar fraction is limited. In the industrial sector the aspect of economic efficiency plays an important role [2]. For the design of the hot water storage, it should be noted that the dimensioning depends strongly on the respective load profile. The specific storage volume is calculated by means of the return temperature.

Figure 5 shows the simulation results for flat plate collectors (tilt angle 45°) with optimum azimuth alignment using a 25m³ hot water storage. The plant performance ratio is 29% for a gross collector area of 200m², whereby 25m³ is the minimum storage size. As a result of an increase in the storage volume, the performance ratio increases only slightly.

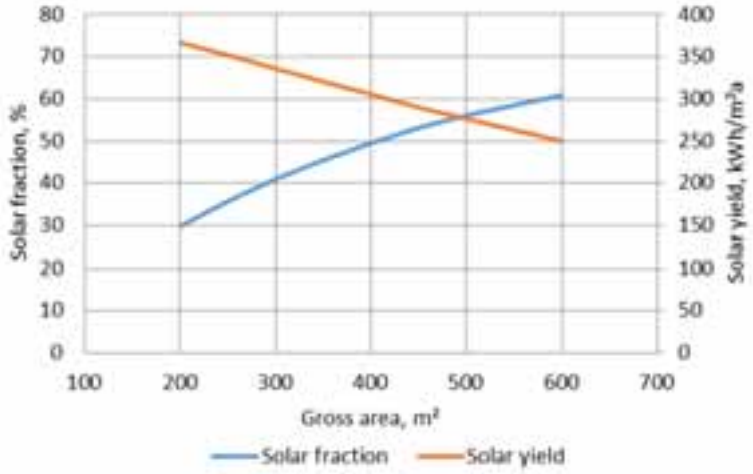

Fig. 5: Solar fraction and solar yield depending on gross area, 25m³ hot water storage

For economic considerations, the costs per kWh heat are used. The investment costs of the plant, an annuity factor, operating costs, consumption costs and the annual solar energy yield influence the costs per kWh heat [2]. For an accurate calculation of the investment costs, functions from a tool developed in IEA SHC Task 48 were used [3]. Since in this case no new additional heat source has to be installed, only the collectors, piping and storage has to be considered. In addition, an Austrian subsidy of 40% of the investment costs was taken into account [4].

At the location Austria,a solar thermal system with a total gross area of 200m² with a 25m² water storage tank for example, can supply 30% of the annual thermal energy demand at a price of 5.6 €cent per kWh heat. This value can be reduced by doubling the storage volume to 4.9 €cent / kWh.

4.2 Location United Arab Emirates, cooling energy supply

Regarding the export of this production technology to countries with hot and dry climates the power consumption load profiles were adapted for the climate in the United Arab Emirates. In these climate the production of high quality concrete is hardly possible without cooling. Therefore a cold supply temperature of 20°C for the lanes was chosen. This results in a theoretical process cold energy consumption of 426.280 kWh.

The system concept includes a single effect absorption chiller with a wet cooling tower, a hot water storage tank which is powered by flat plate solar collectors and a gas backup boiler. A solar thermal driven cooling system with a total gross area of 500m² with a 30m² hot water storage tank, can supply 53% of the annual thermal cooling energy demand. The price per kWh solar generated cold amounts however more than 15 €cent. The investment and operating costs for the backup system are not yet taken into account.

5. Results and conclusion

The detailed investigation of a production line for precast concrete parts in Austria showed that a reduction of the thermal energy requirement to one third is possible. The additional use of the hydration heat (heat development by chemical reaction of water and cement) in order to further reduce the energy requirement has a significant influence on product quality and production time. To ensure a consistent product quality, a massive covering (insulation) of the lanes after the extrusion process, or a heating of the production hall, appears to be more appropriate.

The optimized production line based on these results, was used as a basis to investigate the integration of solar thermal energy generation with simulations. A solar thermal system, located in central Europe, with a total gross area of 200m² with a 25m² water storage tank, can supply 30% of the annual thermal energy demand at a heat price of 5.6 €cent per kWh.

The analysis clearly shows that competitive heat prices can be achieved by the use of solar thermal heat on prefabricated concrete production lines. The precast concrete market or the construction industry represents a promising application for solar thermal process heat integration.

Regarding the export of this production technology to countries with hot and dry climates (e.g. United Arab Emirates), a solar thermal driven cooling system with a total gross area of 500m² with a 30m^3 hot water storage tank, can supply 53% of the annual thermal cooling energy demand. However, costs of 15 €cent/kWh cold must be applied.

Abstract

Two new solar industrial process heat (SIPH) models have been added to the System Advisor Model (SAM) energy simulation tool. The two process heat models were: i) liquid-heat transfer fluid (HTF) parabolic troughs; and ii) direct steam generation (DSG) linear-focus collectors. The DSG model can simulate either DSG parabolic troughs (PT) or DSG Linear Fresnel (LF) fields, based on the optical characteristics supplied. These models help to meet the need for independent, validated tools that reliably simulate the effects of adding a solar field to provide heat for potential IPH applications. During the pre-validation of the liquid-HTF model, operational data was provided and preprocessed by SPF and evaluated at ZAE Bayern. The beta liquid-HTF model provided excellent agreement between the simulations and the operational data for the solar thermal yield generation on a yearly and monthly basis (4.4% difference). The final liquid-HTF process heat model has been further optimized with test users such as ZAE Bayern and SPF. Key improvements in the SIPH models to better model SIPH fields include the use of smaller piping systems and heat capacities, a single collector field, and a higher time-step resolution than for electricity generation (down to 10 minutes). Both the final liquid-HTF and DSG models were successfully validated against operational data for respective solar fields, and showed less than 5% deviation to actual results. A brief application where the liquid-HTF process heat model is used for a brewery in California and the value of reliably simulating a potential SIPH solar field are highlighted.

Keywords: Solar Industrial Process Heat (SIPH), Concentrating Solar Power (CSP), Parabolic Trough (PT), Linear Fresnel (LF), Direct Steam Generation (DSG),), System Advisor Model (SAM), Energy Modelling

1. Introduction

After significant interest during the 1970s, but relatively few deployments, the use of concentrating solar technologies for thermal and industrial applications, including solar enhanced oil recovery (solar EOR), thermally-driven desalination, and industrial process heat (IPH), are again receiving global interest (Kurup and Turchi 2015; IEA 2017; Frank et al. 2014). For larger scale adoption of both non-concentrating and concentrating solar power (CSP) technologies for SIPH, trusted, validated, and readily available thermal energy generation and simulation tools are needed. Free tools that can simulate the use of CSP technologies for SIPH now include the newly modified System Advisor Model (SAM) and the German Aerospace Center's Greenius software packages (NREL 2017b; Deutsches Zentrum für Luft und Raumfahrt (DLR) 2017).

This paper highlights the overall developments and validations to SAM's new process heat models for using concentrated solar thermal energy, made available from the 2017 release of SAM. The paper describes: the need for developing SIPH modules using CSP technologies; detailed model developments for both SIPH models; the differences between the thermal models and SAM's existing electricity generation models; and importantly, the validations of both models to real operational sites where the solar field provides heat. It is worth noting that the SIPH models have focused only on concentrating technologies, but non-concentrating technologies are also very suitable for lower-temperature hot water heating applications, as seen in the Solar Water Heating models in SAM (NREL 2017b). Two models have been developed for SIPH application, the first that utilizes a selectable liquid-HTF with parabolic troughs (e.g., pressurized water, glycol or a synthetic mineral oil), and the second, DSG systems using water in linear-focus collectors. It is important to highlight that the DSG SIPH model can model the parabolic trough (PT) and linear Fresnel (LF) systems, based on changing the optical characteristics, pumping power, and heat loss of the collector. The paper also highlights a utilization of the liquid-HTF model for a brewery in California that could potentially install a new parabolic trough solar field to provide heat.

1.1 Motivation for the developing the SAM SIPH models due to the increasing global interest

Energy-generation and simulation tools such as Greenius and SAM provide a reputable, validated and "consistent framework for analyzing and comparing power system costs and performance across the range of solar technologies and markets" (Wagner and Gilman 2011). SAM's original solar-thermal models were specifically developed for the electricity sector. With growing interest in SIPH, it is important to develop energy-generation modelling tools also able to undertake thermal energy yield analysis. It is straightforward to provide IPH temperatures (e.g., >150°C) using the same CSP technologies as for electricity (e.g., liquid-HTF troughs or DSG collectors). However, there are differences in the solar field modelling used for electricity generation, and a SIPH field used for heat generation. In CSP electricity modelling, the solar field typically is coupled to an integrated steam-Rankine power block used for electricity generation (Wagner and Gilman 2011). It has been shown that when the SAM inputs and the SAM code were changed to minimize the power-cycle impacts (e.g., a constant solar field inlet temperature), the "power cycle caused a 6% underestimation of performance from what should have transpired had the model been freed of the power cycle constraints" (Turchi et al. 2016). Since the outlet of the power block serves as an inlet to the solar field, the state of operation of the power block has a direct impact on the solar field performance. Without the constraints (e.g., a variable solar field inlet temperature) and de-coupling of the power cycle, in attempting to model solar fields used for process heat applications, it was found the performance was underestimated by about 14% (Turchi et al. 2016).

A key project known as Solar Payback was initiated in October 2016 with support from the German Federal Environment Ministry and has partners including the Fraunhofer Institute for Solar Energy and the German bank KFW (German Solar Association 2017). This three-year project funded at nearly €3 million has the purpose of promoting the use of SIPH across four partner countries (Brazil, Mexico, India, and South Africa) to: 1) raise SIPH awareness; 2) highlight the technical merits and economic potential, to then 3) help increase commercial investment in all forms of SIPH (German Solar Association 2017). The first "Solar Heat for Industry" report has highlighted that 74% of the global energy consumed by industry was for heat, with only ~9% of that being provided by renewables rather than by conventional fuels (e.g., coal and natural gas) (German Solar Association 2017). With industrial heat demands expected to increase, SIPH could play an increasingly important role globally, particularly in decarbonizing the industrial sector. Real examples of installed CSP solar fields (e.g., PT or LF) for IPH have highlighted that up to 40% of a large industrial site's heat demand can be met with the CSP solar field. For example, at the Lechera Guadalajara plant the solar field installed in 2016 meets nearly 35% of the heat demand in the pasteurization process. In another example, at Ram Pharma's large pharmaceutical plant, between 30% and 40% of diesel demand is being met with the new solar field (German Solar Association 2017).

Within India, CSP has great potential for SIPH use at the small and industrial scale, with the prospect of fuel displacement in industry and rural areas. The United Nations International Development Organization (UNIDO) has estimated that a market potential of approximately 6.45 GW_{th} for concentrating solar thermal (CST) technologies could exist for Indian industrial applications (MNRE 2017). For example, at the SKF Technologies manufacturing plant in Mysore before solar integration, diesel was the prime fuel burnt to provide heat for the phosphating process. After the integration of the 256.4 m^2 parabolic trough solar field in 2013, the facility now obtains pressurized water from the solar field at 130°C for use in the phosphating processes (PWC India 2017). The solar field, which received a grant for the installation, has been found to reduce diesel consumption by approximately 14,000 liters annually, and the investment had a payback of 5.2 years (PWC India 2017).

India is also increasing investment significantly to meet the potential for SIPH using CST collectors and storage, which provide potential opportunity for technology developers. The SunFocus quarterly report highlights the use of CST (for both electricity and IPH) in India. There is significant developing interest for storage (e.g., phase-change materials [PCMs] and salts) as part of the SIPH integrated solution (MNRE 2017). The Indian Ministry of New and Renewable Energy (MNRE) and UNIDO are also working on a project to provide financial support to concentrating SIPH projects and are helping to create new business models for solar thermal heat to help adoption and deployment (MNRE 2017). With SIPH projects being developed both in the U.S. and globally, the value of independent and validated SIPH modelling tools is clear.

Without such freely available tools, the end-users/beneficiaries of such SIPH solar fields would find it difficult to gauge the value, thermal energy yield, and potential fuel savings from the new solar fields for their applications. The new SAM modules (liquid-HTF and DSG) were created to better understand thermal energy generation and the potential levelized cost of heat (LCOH) at global locations for SIPH applications.

2. Liquid-HTF and DSG Model Development

Various technologies such as non-concentrating collectors and concentrating systems (e.g., sensible liquid-HTF troughs and DSG systems) can be utilized for SIPH applications, depending on the temperatures required by the end-user and the industrial processes (Artic Solar Inc. 2017; IEA 2017). It is important to select the collector technology best suited to the irradiance and land conditions most suitable for the site. This paper considers only the modelling and validation for concentrating collectors, including collectors utilizing either liquid-HTF or DSG, but non-concentrating collectors for SIPH (e.g., flat plate) can also be modeled by SAM (NREL 2017b). Prior to 2017, older versions of SAM already employed robust models for CSP electricity generation systems. The steam power cycle added complexities to extract results relevant for the case where the solar field is only providing thermal energy, i.e., for SIPH. Also, many aspects of the model, such as the solar field layout and piping design, were not optimal for IPH application due to the coupled nature of the solar field and the power cycle. Hence, two new modules were developed to simplify access to SAM's solar thermal collector/receiver models and to simulate solar thermal systems for IPH. Here, we describe some of the development efforts.

2.1 Pre-validation of the liquid-HTF process heat model during model development

In 2016 before the final 2017 development and validation of the liquid-HTF process heat model, a pre-validation was undertaken of a beta SAM version that sought to test the process heat model using liquid-HTF. This work was conducted to isolate the CSP solar field operation, improve the liquid-HTF process heat model, identify bugs, and enhance the user interface. As part of the pre-validation efforts, operational data was provided by the Swiss Institute for Solar Technology (SPF), which highlighted the operations of a 627-m^2 parabolic trough solar field used for a Swiss dairy processing plant (Frank et al. 2014). SPF delivered high-quality operational data and, together with the Bavarian Center for Applied Science (ZAE Bayern), preprocessed and evaluated the operating data; both groups were test users for a beta version of the SAM liquid-HTF model. The Swiss SIPH site is in Saignelégier (northwest of Switzerland), has a 360-kW peak power, and the heat from the solar field is utilized as part of the milk processing. A pressurized water-glycol mixture is used as the HTF, and the required outlet temperature of the solar field is 120°C (Frank et al. 2014). The beta SAM model was used to compare the simulated results of the solar field to one year of operational data from the SIPH site. The SAM weather file for Saignelégier was developed using on-site measured direct normal irradiance (DNI), and ambient temperature.

The beta SAM process heat model already showed good agreement with the operational data from the Saignelégier SIPH site when the solar field was constrained from the power-cycle effects. This was the case especially for the monthly and annual comparison of results for the thermal energy generated. The Saignelégier SIPH site has a designed yearly heat production of 220 MWh. ZAE Bayern utilized beta versions of the SAM liquid-HTF model to validate and compare the modeled thermal output from the solar field to the real yearly experimental thermal yield of 203 MWh. In 2015 NREL provided recommendations for use of the existing CSP Physical Trough model that allowed ZAE Bayern to model the SIPH plant without the specific SAM thermal-application models that are currently available in SAM 2017. Fig. 1 shows the monthly thermal outputs of the simulated SAM Saignelégier solar field compared to the measured or real case. The cumulative yearly thermal energy yield of the solar field simulated through the beta SAM model was 194 MWh, corresponding to an underestimation of only 4.4% compared to the measured thermal output of 203 MWh. On monthly comparisons, the results of the beta version were similarly encouraging, see Fig. 1.

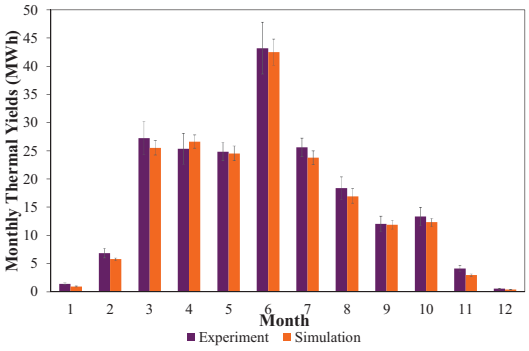

Fig. 1: Monthly comparison between modeled and real thermal outputs at Saignelégier PT-SIPH by ZAE Bayern (Samoli 2016)

The simulated results for the annual thermal energy generation between the real and the beta-version simulated Saignelégier case were within 5% of each other, though deviations in daily simulations could be identified compared to the real operational data. Especially for cloudy days, which do not have a large influence on the total monthly thermal energy generation, an underestimation between the simulated and experimental solar thermal energy generated on an hourly basis showed total daily deviations of up to 15% (Samoli 2016).

It is important to note that SAM typically can handle simulations in one-hour time steps, which were identified as too large for SIPH applications. A key issue in the beta SAM liquid-HTF process heat model was the restriction in using large piping diameters and pipe lengths (suited for power generation), which resulted in large thermal masses. Hence, longer heating periods for the solar field and consequently less thermal energy output was delivered from the solar field in the simulated results compared to the operational data. There were significant differences between the simulated and measured inlet and outlet temperatures, as well as for the volume flow in the main circuit of the solar field. Prior research has identified that the thermal masses play an important role for the prediction of the solar thermal energy generation, particularly for SIPH applications (Möllenkamp et al. 2016). As such, with discussions between NREL and SPF/ZAE Bayern, a more flexible field design as well as a higher time-step resolution (e.g., sub-hourly) was implemented in the beta SAM code, and it allowed a better thermal energy yield prediction than previous, SAM liquid-HTF CSP Physical Trough models.

Moreover, during the pre-validation of the beta SAM liquid-HTF model, standard SI units have been widely introduced and the sensible liquid-HTF trough model has been supplemented by a transient energy balance for the headers and runners. Also, in the pre-validation, the default SAM liquid-HTF case used for the beta version was changed and was more representative of an SIPH application (e.g., 5-MW_{th} facility using pressurized water at 150°C), and some bugs have been removed, which make the beta SAM version more suitable for IPH application. For example, an overnight recirculation of hot fluid that occurred during simulations has been amended. An important real-world implication of SIPH solar fields was the alternating row distances between the rows of collectors (as in Saignelégier), which can lead to errors in the simulated shadowing losses when using fixed row distances. These findings have been incorporated and contributed to support the optimization of the SAM liquid-HTF process heat model. More details of ZAE Bayern's optimizing and pre-validation can be found in work by ZAE Bayern and SPF (Samoli 2016).

2.2 SAM process heat liquid-HTF and DSG model developments and changes

NREL engaged with ZAE Bayern in 2016 and 2017 to address questions and issues found in using the older SAM code for SIPH cases. Review of the ZAE report (Beikircher et al. 2016) helped NREL identify several issues that made the new SAM models more amenable to SIPH applications. NREL has worked to address ZAE Bayern's questions and concerns and to provide feedback and support to this experienced SAM user. The engagement with ZAE Bayern helped the NREL CSP team understand design and operational methodologies for SIPH sites. The work at ZAE Bayern has highlighted key issues such as SIPH sites having smaller piping diameters than the original piping library within SAM, and SIPH solar field layouts that differ from large power plant designs. This type of future engagement will be key to continuing to build and code robust SAM modules for SIPH applications. Working with ZAE Bayern/SPF and understanding how process heat modelling could be changed, the latest version of SAM released in 2017 (NREL 2017b) has the CSP process heat models developed for liquid-HTF and DSG systems. Compared to the previous SAM CSP models for power generation, the solar field model has undergone some significant changes to accommodate the nature of SIPH systems. For example, the solar field from the CSP electricity model had a minimum of two subsections with "H" or "I" configurations common for electrical systems (Wagner and Gilman 2011). This "H" solar field layout is shown in Fig. 2 .

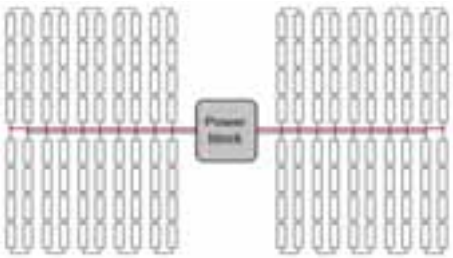

Fig. 2: Typical "H" power block and solar field layout for CSP solar fields for electricity generation (Wagner and Gilman 2011)

Since process heat systems can be much smaller and simpler, the solar fields in the liquid-HTF and DSG process heat models have been developed to utilize a single solar field section (effectively half or one section of the solar field in Fig. 2). In addition, the new models for both liquid-HTF and DSG systems allow for smaller pipe diameters. Also, since the heat sink or process heat exchanger between the solar field and the industrial site can be much closer to the solar field than for power generation sites, the fixed cold and hot header lengths of 50 m has been removed (Wagner and Gilman 2011). In addition, piping through the heat sink can be modeled to allow inclusion of additional thermal capacitance, thermal losses, and pressure drop across the solar-to-process heat exchanger. The DSG model has been developed to allow for modelling either a DSG PT or DSG LF system with a water/steam mixture, where the user can change the optical characteristics of the field. Both process heat models include a simple LCOH calculation and can include financial parameters such as the cost of debt.

3. SAM Model Validations

3.1. Liquid-HTF parabolic trough validation and results

For the final validation of the new liquid-HTF model, having finished the development and optimization, a detailed simulation of an existing parabolic trough solar field was undertaken. This site in Nevada, USA, uses pressurized water in the solar field, and the solar field has a thermal power of 17-MW_{th} (DiMarzio et al. 2015). The parabolic trough solar field was built to provide heat input for a hybrid process, and as such, it was considered a suitable SIPH application. Site operators supplied detailed operational data of the solar field.

The actual solar thermal energy output from the solar field was compared to the SAM simulations (which utilized the final SIPH-model) of the thermal yield generated. The operational data provided included site conditions such as DNI, wind speed, solar field thermal output, and ambient temperature for 58-days of continuous operation between March and April 2015. The validation used 58 days because this was the span of operational data provided, and it was long enough to understand the liquid-HTF model behavior in a variety of DNI conditions. To create the simulation model of the SIPH site, a site-specific weather file was developed, which included the site conditions for the approximate two-month period, and a Typical Meteorological Year (TMY) file was used for the remainder of the year to allow for an annual simulation. While an annual simulation was performed, the modelled simulation of the thermal energy yield was compared to the measured, real solar field thermal output for only the 58 days. This allowed a direct comparison between the simulated and the real thermal outputs and solar field behaviors.

Over the 58-day period, the measured solar field thermal output was recorded to be 4,832 MWh. The SAM model predicted energy output whenever adequate sunlight existed, as well as the cumulative generation that only includes time periods when the actual power plant was operating. Cumulative generation when the plant was operating was calculated by post-processing the SAM data to only sum energy values when the plant had a power output greater than 0 MW_{th}. In the former case, SAM overestimates generation by 1.8%, and in the latter case, SAM underestimates by 1.3%. It is not clear why the plant was idle during certain periods of acceptable sunlight, but the behavior highlights that SAM may need to provide additional user-defined constraints on plant operation. Fig. 3 shows three days of normalized operations data from the SIPH site compared to the simulation.

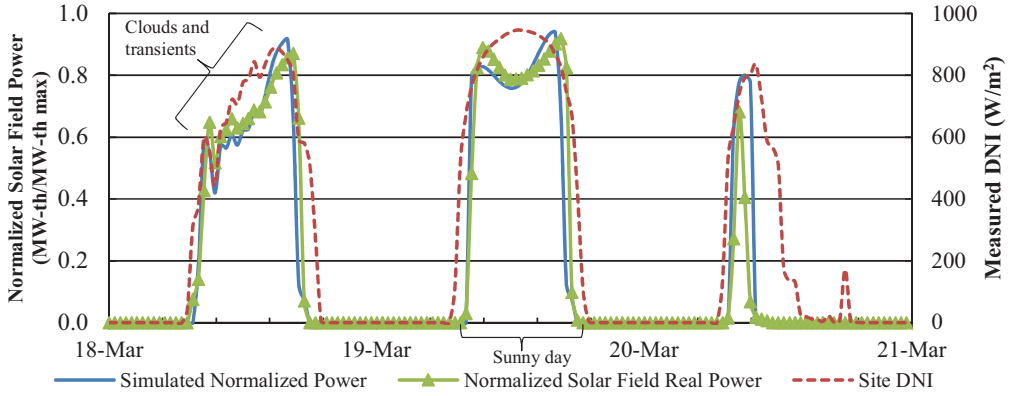

Fig. 3: Comparison of modelled normalized solar field output vs. the normalized solar field actual output for three days

The measured site DNI can also be seen (red dashes); for example, March 19, 2015 was a sunny day, after what was likely a cloudy day on March 18. As can be seen on March 18, the clouds and transients (e.g., the spikes in DNI) led to transient thermal output from both the simulated (green line) and actual operations (blue line). The modelled simulations using the final liquid-HTF model for that day are very similar to the actual site operations. As seen in Fig. 3, on March 20 the SIPH site suddenly stops operations near midday for an unknown reason. The simulated thermal output would normally follow the DNI shape more closely and calculate more thermal energy than the actual site produced on this date. In Fig. 3, an external constraint is applied to the simulation to limit production only to times when the actual plant is operating. Although appropriate for a validation study, such constraints need to be based on plant operation knowledge for a predictive simulation.

3.2. DSG linear-focus collector model validation and results

It has been possible to gain access to operational data for a DSG LF field in Calasparra, Spain. Through collaboration with Tubosol, the plant operators of the 30-MW_e Tubosol Puerto Errado 2 (Tubosol PE2) electricity generation plant, NREL has received and processed operational data for the entire 150-MW_{th} solar field (Novatec Solar 2011) for the month of June 2015. It was determined that the DSG process heat model (which does not include recirculation, but only once-through mode (OTM)), could be used to simulate the Tubosol PE2 solar field. This assumption seemed appropriate because there is no water/steam recirculation in the Tubosol PE2 solar field itself; also, the solar field can be considered to operate as if it were an OTM field, with the steam separation from the water/steam mix occurring after the solar field at the steam drum. The current DSG model would be unsuitable to simulate recirculating DSG fields.

These operational data allow for in-depth observation of the behavior of the solar field, both in normal and transient conditions. The data for the solar field (made up of 28 rows in total) are split into two equal segments (Tubosol PE2.1 and Tubosol PE2.2), where each segment is approximately 75-MW_{th} with 14 collector rows. The reason for the solar field segments is to allow in winter to direct steam from both solar fields to one 15-MW_e turbine. This arrangement ensures maximum electricity generation, rather than generating electricity from both 15-MW_e turbines at part load due to a lack of solar radiation. Each independent solar field segment has the following specification seen in Tab. 1 (Novatec Solar 2011). The data in Tab. 1 has been used for the SAM DSG model validation. It was decided since each segment can be operated independently, that the validation would be done only on one solar field segment. A weather file that uses site data, e.g., the DNI and ambient temperature, has also been created for the validation; again, a TMY file was used for the rest of the year.

Tab. 1: Data used for the SAM DSG validation of the Tubosol PE2 solar field segment

Parameter	Value	Unit
Product name	Nova-1	NA
Number of rows in solar field	14	NA
Solar field length	940	m
Aperture area	151,000	m^2
Operating temperature	270	°C
Operating pressure	55	bar
Peak thermal output	75	MW_{th}

The validation of the DSG process heat model has been done by comparing the predicted thermal energy by the SAM model with the plant data from the Tubosol PE2 segment, although an estimate of the solar thermal power has been made. It is important to note that since Tubosol PE2 has been designed for electricity generation (i.e., 30-MW_e), it was not possible to directly measure the solar thermal power output from the solar field, as the exit of the solar field is a two-phase fluid of steam and water. Unlike the validation of the SAM liquid-HTF process heat model, where the solar field thermal output was directly measured and compared to the SAM simulated solar field thermal output, this was not possible for the DSG validation. While SAM can undertake simulations sub-hourly, the minimum time step for the SAM DSG validation is 10 minutes. Therefore, the sub-minute data from the Tubosol PE2 solar field segment has been averaged to make 10-min time-step intervals, e.g., for the weather file for Calasparra and the estimation of the solar field power output.

Each solar field segment has measurements for pressure, temperature, and mass flow rate of the combined

water/steam fluid. Thus, the enthalpy and the steam quality are unknown at each measured interval at the exit of the solar field segment. Hence, to calculate the solar field thermal output power at each 10-min time step, the steam quality is estimated in two ways (identified as Case 1 and Case 2).

Case 1—where there was a constant steam quality of 0.7485 (i.e., approximately 75% steam in the steam drum). This was determined from the design conditions obtained from the balance of plant process diagram (Novatec Biosol 2011) and thus was used to calculate the enthalpy at each 10-min step.

Case 2—where variable steam quality is estimated from the steam-drum level given in the operations data, then averaged over every 10-min time step. The steam-drum level, as confirmed with Tubosol PE2, is a measure of the steam and water mix in the steam drum, where the steam drum separates the remaining water in the fluid from the steam produced by the solar field. Using the steam-drum level is an estimate of the steam quality produced by the solar field. The calculated enthalpy is multiplied by the mass flow rate to obtain an approximate value of thermal power delivered by the solar field. This estimated thermal power is then compared with the one predicted by the SAM simulation.

However, there are differences between the way the SAM DSG model predicts the solar field operation and the way the actual Tubosol PE2 solar field operates. Therefore, to make a better (and more realistic) comparison, there are a couple of constraints added for Case 2.

Constraint 1: The solar field has hot fluid in the field during the night periods (as well as the day), and the thermal energy can theoretically be calculated during this time. However, as no thermal power from the field is delivered during the night to generate steam, the solar field thermal power output from 9 pm to 6 am is ignored.

Constraint 2: When SAM thermal output is predicted, but the plant itself is for some reason not producing solar thermal power to generate steam for the turbine, this is excluded from the SAM output in a post-processing step.

Fig. 4 shows a plot of such a situation, where the thermal power predicted by the SAM model is shown against the real estimated solar field thermal power output. It can be seen the estimated solar field thermal output was barely present during the day (e.g., the green line), even though there was sufficient DNI for SAM to predict some thermal power generation. The thin blue line represents the SAM simulated power. As seen in Fig. 4, due to the DNI variations (e.g., perhaps due to several clouds that day), the model responded to the spikes in DNI with a considerable power production, whereas the estimated actual output was nearly zero through the day. Hence, the simulated thermal power for days like this was ignored in post-processing, as specific operational decisions such as this made at the site are not accounted for in the DSG model.

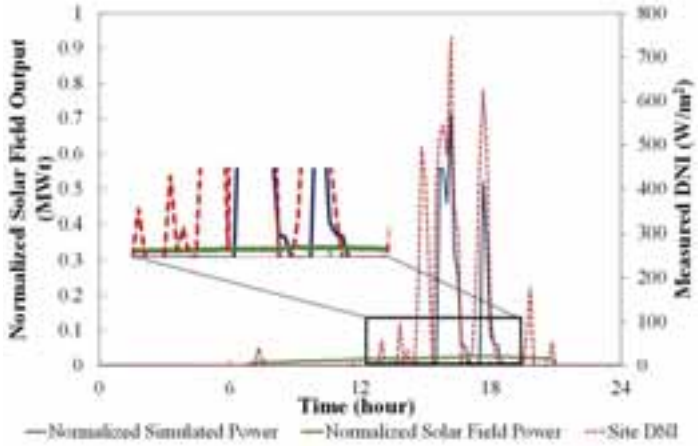

Fig. 4: Comparison of the simulated solar field power output and the estimated actual solar field power output on a day with transients, and showing the need for a constraint to exclude the SAM output when the estimated actual output was minimal

Tab. 2 shows the comparison between thermal energy generation predicted by the SAM DSG model and the calculated estimation using actual field data (for the constant and variable steam quality cases) for June 2015.

Tab. 2: Comparison of the thermal energy generated (MWh) between the actual estimated solar field and the simulated solar field, for the cases of constant and variable steam quality (Case 1 and Case 2, respectively)

Case	Condition	Real estimated thermal energy of solar field (MWh)	SAM thermal energy of solar field (MWh)	Difference in thermal energy (MWh)	Difference (%)
Case 1	Constant steam quality at design conditions	141,105	126,534	14,571	-10.32
Case 2	2.1: Estimated variable steam quality	130,864	126,534	4,330	-3.3
	2:2: Estimated variable steam quality with constraints	127,082	126,128	954	-0.75

As can be seen in Tab. 2, with constant steam quality (Case 1), the actual estimated thermal energy generated for June 2015, was approximately 141.1 GWh, compared to approximately 126.5 GWh from the SAM simulated solar field. In other words, the SAM thermal output was 10.32% less than the real estimated value. Case 1 (i.e., constant steam quality from the solar field) can be considered unrealistic, as there will be a varying steam quality produced by the actual Tubosol PE2 solar field segment. Discussions with the operators at Tubosol PE2 have confirmed that the steam quality can vary from 70% to 80% depending on the DNI conditions. As seen in Case 2 from Tab. 2, when variable steam quality is calculated for the Tubosol PE2 solar field segment, the estimated solar thermal energy generated in June 2015 from the field segment was 130.8 GWh, compared to the simulated output of 126.5 GWh. This is Case 2.1, without further constraints as mentioned being applied. As can be seen, the difference in the energy generated between the simulated solar field and the estimated actual is approximately -3.3%. When the constraints are added, the difference between the actual estimated thermal energy generated and the SAM output drops to 0.75%.

Fig. 5 and Fig. 6 shows the excellent comparison between the normalized simulation (blue) and the normalized estimated actual thermal power output for Case 2. Fig. 5 shows a day that had significant DNI variations (i.e., many clouds throughout the day); Fig. 6 shows a single transient in an otherwise very sunny day.

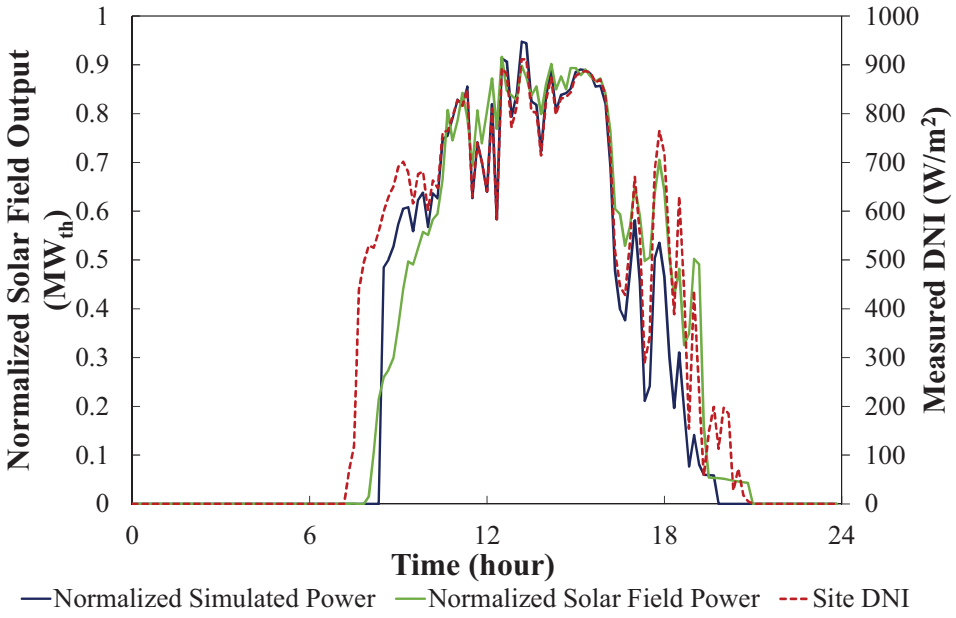

Fig. 5: Comparison of normalized simulated solar field power output and normalized actual estimated output on a day with significant DNI variations

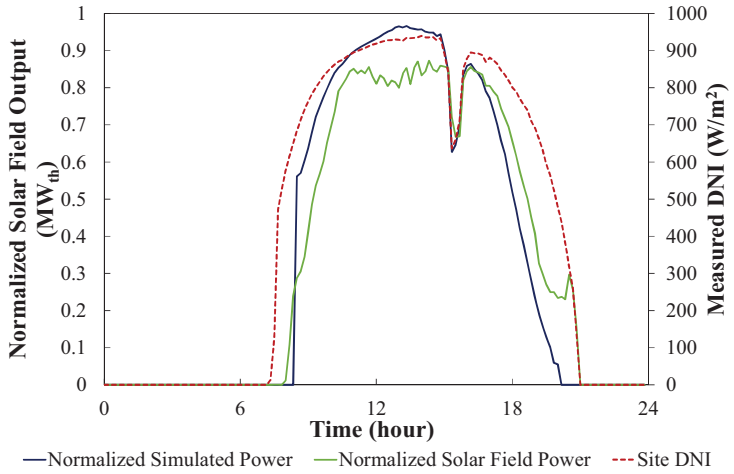

Fig. 6: Comparison of normalized simulated solar field power output and normalized estimated output with one DNI transient

As seen in Fig. 5 and Fig. 6, the simulated power output from the solar field tracks the DNI variations well throughout the day, although the simulated power output, in general, is smoother than the actual estimated solar field output. It is worth noting that near the start of the day, the simulated power compared to the real estimated power is generally slightly overestimating the power output, whereas the reverse is true in the evening. In Fig. 5 and Fig. 6, the simulated power is underestimated relative to the actual estimated amount in the evening. The -3.3% difference between the simulated DSG and the actual estimated energy output for the time period gives confidence that the DSG model is successfully modelling the conditions in the solar field and handling the energy flows. This shows that once the modeled solar field for DSG (at least in this DSG LF case) can be separated from the power generation aspect, the solar field can be well modelled.

4. Utilization of the SAM Liquid-HTF Process Heat Model

The use of both the liquid-HTF and DSG process heat models for potential actual commercial applications would have been ideal. But, it has only been possible to do an initial energy simulation and analysis with the liquid-HTF model. The DSG process heat model could be utilized in future analysis.

The concept of using SIPH for heat addition and integration into breweries is gaining strength, especially in Europe and South Africa, where several studies and operating demonstration SIPH plants for breweries exist (German Solar Association 2017; Mauthner et al. 2014). Either through concentrating or non-concentrating SIPH technologies, breweries that are located in regions having sufficient DNI for solar heat integration could significantly decrease the energy consumed from burning hydrocarbons (Lauterbach et al. 2009; Mauthner et al. 2014).

The newly developed SAM liquid-HTF process heat model has been used for an initial analysis of a brewery in California that is considering implementing a parabolic trough solar field to decrease natural gas usage. An important and potentially valuable financial incentive that currently exists in California is the maximum of up to $800,000 that a project can receive based on being able to show a metered decrease in natural gas due to the addition of a new solar thermal field (California Public Utilities Commission [CPUC] 2017).

The key parameters of the brewery's potential solar field include a design point yield of 1 MW_{th} and the use of unpressurized water as the HTF. The weather file for the site has been created using the National Solar Radiation Data Base, and the brewery site has a daily average DNI of greater than 6.5 kWh/m^2/day (NREL 2017a). The process heat thermal load requirement from the brewery has been highlighted as being approximately constant at 0.3 MW_{th}, 24 hours a day, 365 days a year. The Heat2Hydro solar field and system design also includes a mixed single-tank water storage unit of 50,000 gallons. The storage is expected to be charged fully and maintain an exit temperature to the brewery heat exchanger of 85°C. It is worth noting that SAM version 2017.9.5 has no storage built in. The potential new storage solution for the brewery cannot be directly modelled with the SAM 2017.9.5 version of the process heat model.

The SAM simulation file for the case has been created to model the annual heat input from the solar field to a brewery process heat exchanger. The parameters for the brewery's load (i.e., delivered thermal power to the heat exchanger) have been simulated using collector information provided by Heat2Hydro and Rackam Technologies. At present, since the publicly available SAM 2017.9.5 process heat module is without storage, the initial brewery case has been created whereby all the solar field output in excess of the process load can be absorbed by an ideal storage system. This is a reasonable assumption considering the large storage volume (50,000 gallons) for the Heat2Hydro storage that is charged with the excess thermal energy from the solar field. But this assumption will need to be tested in the future—particularly, how much of the excess energy from the solar field can be absorbed by the single mixed tank.

5. Conclusions

In on-going efforts to improve SAM, the models and use cases for SIPH will continue to be developed. Working with solar developers (e.g., SkyFuel), the SIPH process model developments, particularly for the liquid-HTF model, are likely to include thermal storage and dispatch strategies. With further investigation of the sizing of typical deployed SIPH systems, the default solar field size may be changed, e.g., to 1-MW_{th} for liquid-HTF SIPH fields. The DSG process heat model improvements include developing a recirculation mode to send the remaining water exiting the solar field back to the solar field for further evaporation. This would then allow SAM to better model actual DSG systems, as few DSG systems have been developed as OTM (Feldhoff 2012). Future use of the DSG model could provide a better understanding of the thermal yield generation and steam production for solar EOR.

The highlighted brewery initial case will be important to continue to develop into a case study, to develop both the energy yields and costs of the potential solution, and the financial models to understand economic viability e.g., the net present value (NPV) and the payback period. This will develop the understanding of SIPH applications in California, where the incentive scheme currently in place (e.g., for $800,000 granted to projects that can show a metered decrease in natural gas due to a solar thermal field). As of October 4, 2017, the legislative bill (Bill AB-797 Chapter 473) supporting the CPUC incentive scheme has been extended for two years (California Legislative Information 2017). Further investigation is needed of the financial implications of the extension of Bill AB-797 Chapter 473, particularly on potential projects in California.

The NREL SAM process heat models could help to show thermal energy generation and economic value for known and future applications of SIPH. As global use for SIPH applications continue, modelling tools such as SAM and Greenius can certainly provide an independent method to gauge the potential energy yield at the site. It is possible that the newly developed SAM process heat models could help some users looking to apply for the recently released U.S. Department of Energy (DOE) solar desalination Funding Opportunity Announcement (DOE 2017). The use of the process heat models could help prospects and awardees, better understand thermal energy yield generations and the potential LCOH of CSP process heat solutions, which could then provide heat for desalination activities.

6. Acknowledgements

The authors at NREL would like to thank Jana Möllenkamp, and Thomas Beikircher and Alexia Samoli at the SPF and ZAE Bayern research institutes, respectively, for their diligent and helpful work in the provision of an independent validation effort comparing SAM to operational data, and helping to use and improve the beta version of the SAM liquid-HTF process heat model. Without this type of user interaction, SAM would not be addressing the key issues faced in accurate modelling of end-user needs.

The NREL authors also thank and gratefully acknowledge the efforts and quality of the operational data provided by the operators of the solar fields and partners providing data for these studies. Without these data sets, validations of the SAM models comparing simulations to the real estimated or measured thermal outputs could not have been done. The validations have helped ensure that the SAM process heat models can provide results similar to real operating solar fields where the thermal energy can then be utilized for heat provision. The end-users and industries can put more trust in SAM and other tools such as Greenius, as these are a source of validated and readily available thermal energy generation and simulation tools.

This work was supported by the U.S. Department of Energy under Contract No. DE-AC36-08GO28308 to the National Renewable Energy Laboratory.

INDIA'S QUEST FOR GLOBAL SOLAR THERMAL INDUSTRIAL PROCESS LEADER

- Jaideep N. Malaviya (Secretary General), Solar Thermal Federation of India
info@stfi.org.in, *Phone: +91-9890033399*

INTRODUCTION

Fifty-seven per cent (nearly 240 Metric tons of oil equivalent) of the final energy consumption in India is used for thermal applications. Industrial process heat, residential cooking, and water heating are the main thermal applications accounting for more than 90% of the thermal energy requirement. Presently India's thermal energy demand is primarily being met through coal, biomass, and petroleum fuels. Several areas in India receive good DNI and solar thermal energy has potential to convert this radiant energy to meet the heating needs up to 250 ^{O}C. 15 million tonnes of fuel oil in industries requiring heat up to 250 ^{O}C & 5,000 trillion kWh of electricity (excluding LPG consumption) in various sectors for heating water & air being consumed annually. Even if 1% of this energy requirement is met using concentrated solar thermal (CST) systems the potential estimated is over 2.5 million m^2. However, to achieve these targets there need to be market drivers and one of them suggested is to obligate solar thermal heating in high energy consuming industries and encourage Energy Service Companies (ESCo's).

INDIA'S ACHIEVEMENT IN CST SYSTEMS

More than 200 steam generating systems have been installed so far in the country with a cumulative figure of little over 75,000 m2 of dish area equivalent to about 50 MW. These are largely due to subsidy programmes of Ministry of New and Renewable Energy (MNRE), government of India and programmes under GEF-UNDP and GEF-UNIDO. Most of these have been installed mainly at places where steam generated through conventional boilers for process heating and community based steam cooking besides few demonstration projects for cooling. During the period April 2012 to March 2017 the country witnessed net installation of 44,949 m2 of dish area under the GEF-UNDP Concentrated Solar Thermal Heating programme. Solar Heat for Industrial Process had the lion's share of almost 70%. Table 1 below gives the break-up wise of installation occurred under this programme besides projects supported for revamping.

Sl.	Application	Area (m2)
1	Process Heating	28,188
2	Steam Cooking	9,208
3	Space Cooling	3,826
4	Repair and Maintenance	3,727
	TOTAL	44,949

Table 1: Application wise installations under GEF-UNDP programme

The true market potential of CST technologies in the industrial sectors has been assessed as 6.4 GW in India in a study recently commissioned by UNIDO. Fourteen industry sectors have been identified (Table 2) by UNIDO where CST technologies make economic and technical sense in terms of ready acceptability for their deployment for a variety of process heat applications in the temperature range up to 350°C.

Sl.	Sectors
1	Textiles (Weaving, Finishing)
2	Pharmaceuticals
3	Automobiles
4	Breweries
5	Pulp & paper

doi:10.18086/swc.2017.26.07 Available at http://proceedings.ises.org

6	Electroplating
7	Food processing (including Dairy & Sugar)
8	Rubber
9	Chemical & Fertiliser
10	Petroleum Refineries
11	Desalination
12	Ceramic tile & pottery
13	Plaster of Paris, Steel rerolling, Cement, Mining
14	Tobacco

Table 2: Highest potential sectors for solar thermal process heating

In India mainly 3 types of concentrating solar technologies are presently in promotion:

i) Manually tracked dish solar cookers to cook food for 10-40 people,

ii) Fixed focus E-W automatically tracked elliptical dishes (Scheffler) for direct indoor cooking for about 50-100 people & for steam generation for community cooking, laundry, space cooling etc. of any capacity and

iii) Dual axis fully tracked Fresnel dishes (Arun) for all such applications.

The CST systems can be broadly classified as below

- ★ Fixed Focus Elliptical Solar Dish (Scheffler)
- ★ Fresnel Reflector Based Dish
- ★ Linear Fresnel Reflector Concentrator
- ★ Compound Parabolic Collector
- ★ Parabolic Trough Concentrator
- ★ Paraboloid Dish

There are 22 Manufacturers offering 6 types of CSTs in promotion with varying designs & sizes. Figure 1 gives the technology-wise CST systems. There are couple of solar grade cut mirror glass manufacturers offering international standards quality developed technologies for edge sealing & back coating and state of the art parabolic trough mirrors.

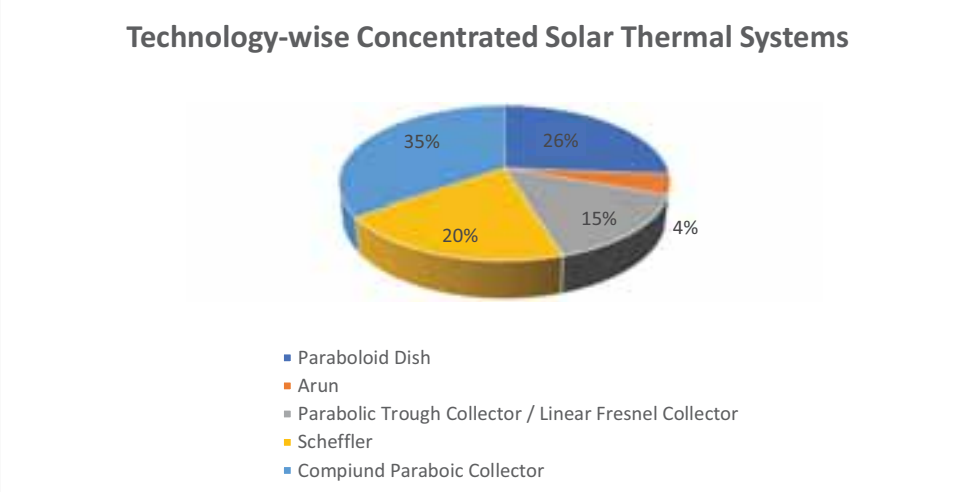

Figure 1: Technology-wise CST systems

DNI MAP OF INDIA

The Direct Normal Irradiation (DNI) in India varies from 4.0 to 6.0 kWh/m²/day as shown in the Figure 2 and is an indicator of the potential regions that can use solar thermal.

Figure 2: DNI Map of India (Geo Model Solargis, EU)

Based on the DNI the potential states with medium to high DNI that facilitate implementation of CST projects are listed in Table 3.

Sl.	Region	Indicative average DNI/ m² / day* (In kWh)	Sunshine days	Fixed focus elliptical dish^ / Non-evacuated heat receiver PTC		Evacuated heat receiver PTC/ LFTR		Fresnel reflector/ Paraboloid based dish	
				Efficiency at 150C**	Heat delivery*** / m²/ year (in million kcal)	Efficiency at 150C**	Heat delivery*** / m²/ year (in million kcal)	Efficiency at 150C**	Heat delivery*** / m²/ year (in million kcal)
1.	Leh Ladakh	6.5	320	35%	0.626	40%	0.715	60%	1.073

2.	Gujarat Rajasthan & western M.P.	6.0	300	40%	0.620	45%	0.697	65%	1.010
3.	Southern & Central	5.0	280	40%	0.482	45%	0.542	65%	0.783
4.	North, West & Himalayas	4.5	250	35%	0.339	40%	0.387	60%	0.581
6.	North – east & Eastern part of Orissa & A. P.	4.0	250	40%	0.344	45%	0.387	65%	0.559

Table 3: Potential states with medium to high DNI

^ Average effective aperture area of 16 m^2 fixed focus elliptical dish for receiving normal radiation during whole year is to be taken as 11 m^2. The heat delivery from a 16 m2 elliptical dish in a year in different regions will, therefore, be 11 multiplied by figures given in above table.
Also, dual axis automatic tracked elliptical dishes may have higher heat delivery by say 5% in comparison to single axis tracked dishes due to avoided errors in manual N-S adjustments.

* Can vary by +/- 10% at a location in the region

** Its average annualized efficiency and is linked with ambient temperature and wind conditions of particular region. It reduces in the regions having lower ambient temperature and high wind velocity. It also reduces marginally for CSTs working at higher temperatures due to higher heat losses, thereby reducing the heat delivery. Temperature range which can be achieved by various CSTs, their salient features, installed cost & payback period are given below.

*** Heat delivery will:

i) increase if the fluid temperature goes down due to less heat losses. Likewise, it will also decrease if working temperature is raised high say up to 350 ^{O}C or so especially in case of Fresnel reflector /Paraboloid dishes which are designed for such temperatures.

ii) decrease by 10% or more if the mirrors are not of solar grade quality.

INTRODUCING SOLAR THERMAL CERTIFICATE SCHEME

Perform Achieve and Trade (PAT) scheme of Bureau of Energy Efficiency, designed to accelerate energy savings in energy intensive and large industries by incentivizing energy savings. The identified industries classified as Designated Consumers (DC's) are aluminum, cement, chlor-alkali, fertilizers, iron and steel pulp and paper, railways, textiles, petroleum processing and refining, sugar, chemicals, commercial buildings and electricity distribution companies. The PAT – Part 1 scheme that ended in March 2015 achieved 8.67 million tonnes of oil equivalent (MTOE) and abated 31 million tons of CO_2. The PAT Part 2 scheme notified on 31st March 2016 has a target reduction of 8.869 MTOE assigned to 621 DC's.

These DC's who achieve reductions in their targets receive ESCerts (energy saving certificates) which can be traded with facilities that are having trouble meeting their targets, or banked for future use.

One tonne of oil equivalent (TOE) is One ESCert is issued.

1 TOE = 1 ESCert = INR 10,968

Each TOE at 890 kgs/m3 density is equivalent to 1,125 litres of fuel oil.

Concentrated Solar Thermal (CST) Technologies can provide a good alternative to reduce their specific energy consumption as shown in Table 4 below:

	Solar PV	Unit	Solar Concentrator (PTC/Dish) >120°C	Solar CPC (NIC) 80-90°C	Unit
Energy (TOE/Year)	1		1	1	
Equivalent Energy	**11,630**	**kWh**	10,000,000	10,000,000	kcal
Capacity	8	kWe	5	5	kWth
Area Required	84	m^2	14	11	m^2
Cost (INR)	6,00,000	INR	283,173	163,929	INR

Table 4: Cost Comparison of energy generation using solar PV, CPC and Parabolic/Dish

Hence for the same amount of TOE, CST technologies offer a viable alternative and hence including it in the reporting structure of PAT will ensure that designated consumers (DCs) will invest in CST technologies.

To encourage these DC to go for CST a scheme of s**olar thermal certificate (STCert)** to be launched by Bureau of Energy Efficiency (BEE). A defined target to be given to potential DC's to generate STCert. The minimum project size to qualify for STCert to be 250m^2 for single axis and 150m^2 for double axis. If the scheme is successful and finds more buyers of STCert, the incentive can be reduced gradually with time. Non-DC's can also apply for STCert and should be an entity consuming at least 5,000 litres/ year of fuel oil annually. Those DC's not able to meet their STCert can buy these STCert from non-DC's.

BARRIERS IN CST'S GROWTH

Major barriers listed in large-scale promotion of CSTs at the start of project were as follows:

- Lack of awareness about the technologies & their benefits.
- Information on successful projects not accessible to public.
- Lack of confidence on technologies. Lacking in trained manpower of technicians.
- No test standards & test set ups for measuring performance exists
- Space constraints for installations to beneficiaries
- Non-availability of solar grade mirrors in required sizes at reasonable prices.
- Non-availability of soft loans to beneficiaries & ESCOs
- Low returns on investments as compared to solar flat plate collectors. Requires higher support, especially for space cooling & standalone systems
- Very few manufacturers. Not much competition.
- Difficulties for cost control measures.

While most of the barriers have been addressed in the last five years however the demand creation has not occurred to a level of commercialisation.

PROJECT SOLAR PAYBACK

The Solar Thermal Federation of India (STFI) and the Indo-German Chamber of Commerce (IGCC) have teamed up for the international 'Solar Payback' project, which aims to increase the use of solar thermal energy in industrial processes. Supported by the German Federal Environment Ministry funded by the International Climate Initiative, the three-year project will be implemented in India, South Africa, Mexico and Brazil. It is coordinated by the German Solar Association BSW-Solar and eleven partner organisations: three German companies, plus each target country's national solar industry association and German Chamber of Commerce. The use of solar heat for cleaning, steam

production, bath heating and surface treatment in manufacturing is still a niche market in India and around the world

The initial study has so far focused on an in-depth analysis of market barriers and drivers by drafting a solar process heat roadmap and making policy recommendations. In addition, it intends to strengthen the industry by offering training for planners and raise awareness by organising an industry conference. The project partners will use a wide range of activities and communication tools to get in touch with the relevant stakeholders in politics, business and financing. Key activity targets include:

- Drafting a National Solar Process Heat Roadmap
- Developing a financing/business tool for planners and investors to offer preliminary analyses of solar process heat plants
- Developing policy recommendations for uptake of solar process heat at national level
- Organising train-the-trainer workshops on planning / designing solar process heat systems
- Implementing an online matchmaking network for investors and technology providers
- Organising a local industry / stakeholder conference

Conclusions:

Looking at the huge heating demand and reducing dependence on imports of fuel oil India has the quest to quest for becoming global leader for deploying solar thermal industrial process heat and meeting the identified target of 6.4 GW. The areas that need to be addressed can be summarised as below:

- MNRE to create demand worth INR 100,000 m^2 in 3 years in food processing industries, automobile and defence etc.
- MNRE to invite manufacturers to develop products and infrastructure to bring down the costs through R&D and have budget for
- Make the available DNI data of various locations to public at no cost.
- Introduce performance based incentive equivalent of MWth or MTOE avoided.
- Output be close to the manufacturer's claim & co-relate to the DNI of that area. Any reduction be suitably penalised. A Renewable Heat Incentive (RHI) policy need to be framed.
- Provide concessional loan to manufacturing industries to scale up operations and business.
- Perform Achieve Trade (PAT) operated by BEE must have a special mention about solar thermal heating in their curriculum.
- Large scale capacity building workshops for skilled personnel for better upkeep and maintenance
- Encourage ESCo model as it ensures proper operation of the installations and can give is the recovery. Easy funding be made available for ESCo projects.

A Comparative Cost Assessment of Low Carbon Process Heat Between Solar Thermal and Heat Pumps

Steven Meyers, Bastian Schmitt and Klaus Vajen

University of Kassel, Kassel, Germany

Abstract

Lower temperature renewable process heat derived from the sun can be generated from solar thermal collectors and a photovoltaic powered heat pump. To determine which can produce lower cost heat under certain technical and financial parameters, a robust methodology was developed to determine the maximum solar thermal project investment for it to remain the lower cost technology. This result can also serve as a target for the solar thermal industry to ensure its role in the future of renewable heat.

The assessment methodology was used in a case study analysis, consisting of typical industrial process heat load and temperature profiles, meteorological conditions, technology costs and performance. Results indicated that for constant energy demand processes when a heat pump can operate the majority of the year, a photovoltaic heat pump system delivers lower cost heat. In a typical five day one shift work week where a heat pump has limited access to a heat source, solar thermal remains the lower cost heat provider. For the same five day one shift case but without a constrained heat source, allowing the heat pump to operate for 2000 hours a year, solar thermal plants must be built for less than 250 €/m^2_{ap} in low irradiation regions like Copenhagen and 525 €/m^2_{ap} in high irradiation regions like Chile or North Africa. For solar thermal to remain a primary renewable heat provider in the future, project investments should consistently be less than 200 €/m^2_{ap}.

The presented results are highly variable based on numerous technical and financial parameters. Therefore the use of the methodology described in this work is critical to quickly determine which technology produces lower cost solar derived renewable heat.

Keywords: process heat, solar thermal, PV, heat pump, techno-economic, renewable heat

1. Introduction

A major result of the climate change conference in Paris was the decision to attempt to limit the rise of Earth's global temperature at century's end to no greater than 1.5 °C. One major sector, Industry, accounted for 28% of global final energy use and 11% of emissions from heat and electricity production (IPCC, 2015). If the 1.5 °C goal is going to be achieved, swift action must be taken to replace all sources of carbon emissions. One such option is the use of the sun to generate renewable industrial process heat typically below 150 °C.

Two main technologies can convert solar irradiance to thermal energy; either directly through solar thermal (ST) collectors or indirectly via photovoltaics (PV) and an electrically driven vapor compression heat pump. Numerous studies have been conducted within the domestic sector which compares and/or utilizes both technologies for hot water production and space heating. In the industrial sector, where load profiles, temperature levels, and project specific costs are drastically different, few studies to date have been conducted to compare these two solar heating technologies. Meyers et al (2015; 2016) have developed a comparison methodology between solar thermal and direct resistance heating photovoltaics, crafting unique terms such as the levelized cost of heat (*LCOH*) ratio and project investment ratio (IR). These terms allow for a quick comparison of technology based on their project turn-key specific capital investments. Pérez-Aparicio et al. (2017) has subsequently undertaken similar methodological approaches, incorporating the use of PV powered heat pump, though is limited in its flexibility to adapt to different meteorological conditions, process temperatures (only 200 °C was tested), technology performance, and future costs. These results were also not supported by energetic simulation. The work presented here has expanded upon the prior Investment Ratio methodology of Meyers et al. (2016) and has incorporated the use of heat pumps to develop a universally applicable method to assess which technology can produce lower cost heat for nearly any possible combination of meteorological, technical, and financial parameters.

2. Methodology

The analysis conducted within this work is an expansion of prior research (Meyers et al., 2015; 2016). Within this publication, detailed solar thermal and PV simulations were conducted and correlations made which determined the lower cost heat provider based on local solar irradiation, process temperature, and technology capital cost. The current work expands upon this methodology to include a PV electricity powered vapor compression heat pump.

2.1 Solar simulations and technical basis

2.1.1 Solar Thermal

The solar thermal (ST) plant design and simulation methodology has been described in Meyers et al. (2016) to calculate solar yields under various process loads, temperatures, and meteorological conditions with different collector types. The ST plant was designed to work in conjunction with an already existing heating facility, serving as a "fuel saver" when solar thermal energy is available, either directly or through a thermal store. In summary, two phases of simulations took place via TRNSYS, with a model that was validated through a currently operating industrial solar heating plant in Germany (Lauterbach, 2014; Schmitt et al., 2015). The first phase were "Infinite Load Case" (ILC) simulations which determined the maximum annual specific ST yield ($q_{sol}^{ST,ILC}$ in $kWh_{th}/(m^2_{ap}\cdot a)$) for 800+ global cities for four non-concentrating collectors (flat plate, flat plate double glazed, evacuated tube, compound parabolic (CPC)) at various mean process temperatures ($T_{P,m}$). The yields were considered as a "maximum" because the process load was constant and had a large heat demand which allowed for the exclusion of a thermal store and second heat exchanger (only the collector field, solar loop heat exchanger and pipes/pumps were modeled). This reduced the mean collector temperature and thus maximized yield.

The second phase consisted of the "Practical Load Case" (PLC) simulations which incorporated more realistic conditions found in industry. These conditions included various process load profiles (one or three shifts, operating five or seven days a week), load magnitude (quantity of daily energy required relative to installed solar field size), and storage volume. Only nine sites were simulated due to the computational intensity, but they represented a wide span of annual solar irradiation (H in kWh/m^2a), annual average daytime temperature ($T_{amb,day}$), with annual specific ST yield results reported ($q_{sol}^{ST,PLC}$) in $kWh_{th}/(m^2_{ap}\cdot a)$. To reduce dimensionality, a differential temperature term was coined, called T_{diff}, which was the difference between the mean process temperature ($T_{P,m}$) and annual average daytime temperature ($T_{amb,day}$). This term highly influenced the annual yield results.

Correction factors (F_{corr}^{PLC}) were calculated to adjust results from the ILC to the nine representative PLC cases, by simply dividing the PLC yield by the ILC yield for the same simulated cities ($F_{corr}^{PLC} = q_{sol}^{ST,PLC}/q_{sol}^{ST,ILC}$).

2.1.2 Photovoltaic Heat Pump

The photovoltaic driven heat pump (PVHP) plant was the combination of a PV plant installed on a factory's roof with a heat pump connected to a heat demanding industrial process. The PV plant was connected to the industry's internal electrical grid. When the PV plant generated electricity, it first went to power the HP and any deficit or excess was "bought" from or "sold" to the internal grid at no cost. This meant that the existing electrical infrastructure on site served as free exchange mechanism. In this light a HP, with a known Coefficient of Performance (COP in units of kW_{th}/kW_{el}), was operated only when needed using "banked" PV generated electricity. The annual thermal energy generated by the PVHP system (q_{sol}^{PVHP}) is shown in eq. 1, with the annual specific PV generated electricity denoted E_{sol}^{PV} in $kWh_e/(kW_p\cdot a)$.

$$q_{sol}^{PVHP}\left(kWh_{th}/\left(kW_p\cdot a\right)\right) = E_{sol}^{PV}\cdot COP \qquad \text{(eq. 1)}$$

This model, while not a true PVHP direct coupled system as seen in the household sector, does better represent typical industrial conditions. The onsite electrical demand of typical industries is often significantly larger than a PV plant could generate on its roof, meaning that all PV electricity would be internally consumed and not fed into the grid. Secondly, a PV plant would never be directly coupled with a HP because factories nearly always have an electrical grid connection and operating an electrically isolated HP directly off PV would require batteries to smooth transient and control HP performance. For both reasons, this design was not investigated.

The peak power or size of the HP relative to the PV plant was scaled to consume every kWh of the annual PV generated electricity. This symbolized that the heat is 100% renewable and zero carbon (ignoring the required carbon to produce the components and refrigerant leakages), thus similar to an ST plant. The HP peak power (P_{peak}^{HP}) was calculated by multiplying the annual solar PV yield (E_{sol}^{PV}) by a known onsite estimated *COP*, then divided by the number of full load operating hours (*FLH*) per year that the HP was expected to operate (eq. 2), in units of Watt thermal (HP) per Watt peak (PV). *FLH* and *COP* can be determined through knowledge of the industrial process and availability of a fitting heat source, often by conducting an energy audit. Through this equation, it is shown that smaller heat pumps are required when operating more hours and larger heat pump for fewer, in order to consume the same annual PV generated electricity.

$$P_{peak}^{HP}\left(kW_{th}/kW_p\right) = E_{sol}^{PV}\left(\frac{kWh_e}{kW_p}\right) \cdot COP\left(\frac{kW_{th}}{kW_e}\right)/FLH\ (h) \qquad \text{(eq. 2)}$$

The heat pumps (HP) used for this assessment were electrical powered vapor compression. An increasing number of industrial grade devices are currently on the market with heating performances well over 100 °C, capacities greater than 100 kW_{th} of heat, and with a *COPs* ranging between 2 and 5, depending on the source and sink temperature (Wolf et al., 2014). These types of HPs are very suitable to deliver similar levels and quantities of heat as ST. For this assessment, annual average HP *COPs* were assumed to be used, taking into account small changes due to part load operation during the year. Through the advent of multiple parallel compressors and variable speed drives currently available for industrial HPs, the variability in COP is quite small through the normal operating range. A small buffer tank was also recommended by HP suppliers to reduce temperature transient in both the source and sink side of the HP. Due to its relatively small size (15 l/kW_{th}), thermal losses were less than 0.5% of the overall HP generated heat and thus ignored.

Solar PV yields were determined through TRNSYS simulations for the same 800+ sites of the ILC using a well-known mono-silicon panel from a global producer, incorporating module temperature and irradiance dependent efficiency modifiers. A correlation between PV solar yield (E_{sol}^{PV}) in kWh_e/kW_p and the local irradiation (*H*) and latitude (φ) was created so an expected PV yield (necessary for heat pump sizing and economic considerations) can be quickly estimated when investigating a solar process heat plant at a specific site (eq. 3).

$$E_{sol}^{PV}(kWh/kWp) = \theta_0 + \theta_1 \cdot H + \theta_2 \cdot \varphi \qquad \text{(eq. 3)}$$

2.2 Solar Heating Project Investment

Specific solar thermal project investment (I_{ST} in €/m^2_{ap}) was the total turn-key cost for all components (collectors, store, pipes, pumps), installation, and process integration to realize a plant, inclusive of any locally available subsidies or financial support mechanisms. The project investment (I_{ST}) varied widely based on technology choice, integration difficulty, thermal store size, and installer expertise. Typical I_{ST} values can range from less than 250 €/m^2_{ap} for 10,000+ m^2_{ap} plants in Denmark to over 800 €/m^2_{ap} for smaller installations with high quality collectors, though typical values are between 300..600 €/m^2_{ap} for projects larger than 500 m^2_{ap} (BAFA, 2016), with subsidy.

Specific PVHP project investment (I_{PVHP} in €/W_p electric) was dependent on three factors, the specific PV field investment (I_{PV} in €/W_p), the specific HP investment (I_{HP} in €/kW_{th}) and the relative HP peak power

(P_{peak}^{HP}) as already discussed in eq. 2. The specific PV investment (I_{PV}) for megawatt scale projects is in the range of 1 €/W_p (Fraunhofer ISE, 2015). The specific HP investment (I_{HP}) is rather application and technology dependent, but values ranging between 200 and 800 €/kW_{th} can be expected (IEA Annex 35, 2014; Wolf et al., 2014). The HP contribution to the overall PVHP investment was determined by multiplying the relative HP peak power by the specific HP investment, shown in eq. 4.

$$I_{HP_{(PV)}}\left(€/W_p\right) = P_{peak}^{HP}\left(\frac{kW_{th}}{kW_p}\right) \cdot I_{HP}\left(\frac{€}{kW_{th}}\right) \quad \text{(eq. 4)}$$

Subsequently, the overall specific PVHP investment per Watt peak (electric) is shown in eq.5.

$$I_{PVHP}\left(€/W_p\right) = I_{HP_{PV}} + I_{PV} \quad \text{(eq. 5)}$$

Expected values of P_{peak}^{HP} and I_{PVHP} are shown in Tab. 1. For the few example cases, the HP investment was typically smaller than PV, which is why values were expressed in units per W_p electric (PV) instead of thermal (HP).

Tab. 1 – Example calculation to determine the overall PVHP investment in relation to the installed PV power

E_{sol}^{pv} ($kW_e h/kW_p$)	COP (kW_{th}/kW_e)	FLH (h)	P_{peak}^{HP} (kW_{th}/kW_p)	I_{HP} (€/kW_{th})	$I_{HP_{(PV)}}$ (€/W_p)	I_{PV} (€/W_p)	I_{PVHP} (€/W_p)
1000	2	4000	0.5	400	0.2	1.25	1.45
1250	3	2000	1.87	400	0.75	1.25	2
1500	4	1000	6	400	2.4	1.25	3.65

2.3 Financial Analysis

By expressing the turn-key PVHP plant investment per W_p electric, a similar methodology can be used from Meyers et al. (2016). In this work, the two technologies were compared by their dividing their installed specific capital investments, called the Investment Ratio (*IR*), a value which was calculated when the Levelized Cost of Heat (*LCOH*) of both were equal (Louvet et al., 2017). This methodology can be altered to fit this comparison by simply replacing the I_{PV} with I_{PVHP} and q_{sol}^{PV} with q_{sol}^{PVHP}.

For each infinite load simulation case (800 cities, 4 ST collectors, 3 process temperatures and 1 PV), ST and PVHP yields were calculated, assuming a known COP. Using the equivalent *LCOH* equation (eq. 6) and parameters in Tab. 2, I_{ST} and I_{PHVP} were iterated until convergence was found.

$$LCOH_{ST} = \frac{\boldsymbol{I_{ST}} + \sum_1^n \frac{OM_{ST}}{(1+DR)^n}}{\sum_1^n \frac{q_{sol}^{ST}\cdot(1-SD)^n}{(1+DR)^n}} = \frac{\boldsymbol{I_{PVHP}} + \sum_1^n \frac{OM_{PVHP}}{(1+DR)^n}}{\sum_1^n \frac{q_{sol}^{PVHP}\cdot(1-SD)^n}{(1+DR)^n}} = LCOH_{PVHP} \quad \text{(eq. 6)}$$

Tab. 2 – The required parameters to calculate the *LCOH*

Parameter	Definition	ST Value	PVHP Value
$\boldsymbol{I_{ST,PV}}$	Investment (/m^2_{ap} , /W_p)	Variable	
$\boldsymbol{OM_{ST,PV}}$	Operation and Maintenance (% of $I_{ST,PVHP}$)	2% (VDI, 2014)	1.75% (VDI, 2012; Shimura et al., 2016)
DR	Discount Rate	6.40% (Ondraczek et al., 2015)	
SD	Degradation Rate	0.4%/a (Fraunhofer ISE, 2016)	0.5%/a (Jordan and Kurtz, 2013)
n	Years of Operation	20 (Duffie and Beckman, 2013)	

Using the iterated I_{ST} and I_{PVHP} per simulation case when their heat costs were equal, the Investment Ratio ($IR^{CPC}_{ILC,local}$) was calculated in eq. 7. The superscript indicates which collector was being assessed and the subscript depicts the Infinite Load Case (ILC). Also in the subscript, the "*local*" denoted the calculated *IR* for that specific case of local meteorological conditions and is a precise value. The resulting "*local*" Investment Ratios were generalized as a function of T_{diff}, H, and COP, determined through linear regression in eq. 8, noted with "*gen*" in the subscript. $IR^{CPC}_{ILC,gen}$ is graphically depicted in section 3.1.1. The subscripts "*local*" and "*gen*" can be interchanged within the other equations in this work, as they approximately equal each other due to the regression analysis. A "*market*" subscript is the site specific known investment for heat pump, PV and solar heating plants to be realized, known by local installers.

$$IR^{CPC}_{ILC,local} = I_{ST}/I_{PVHP} \text{ in units of } (€/m^2_{ap})/(€/W_p) \quad \text{(eq. 7)}$$

$$IR^{CPC}_{ILC,gen} = \theta_0 + \theta_1 \cdot H + \theta_2 \cdot \sqrt{T_{diff}} + \theta_3 \cdot H \cdot T_{diff} \quad \text{(eq. 8)}$$

Using the calculated Investment Ratio for the Infinite Load Cases, one can determine the maximum ST investment required for it to remain the lower cost heating technology. Initially, the $IR^{CPC}_{ILC.local}$ is calculated from the simulation results and regression analysis (eq. 8). Next, a correction factor ($F^{CPC}_{corr,PLC}$) is determined using the simulation results which adjusted the ILC solar yields to a more typical value expect in real solar heating plants under industrial conditions, called "Practical Load Case". The $F^{CPC}_{corr,PLC}$ value typically ranges between 0.7 and 0.95 depending on the load profile, graphically shown in section 3.1.2. By multiplying these together (eq. 9), a more accurate Practical Load Case Investment Ratio ($IR^{CPC}_{PLC.local}$) is calculated which takes into account typical process load conditions and thermal losses.

$$IR^{CPC}_{PLC.local} = IR^{CPC}_{ILC,local} \cdot F^{CPC}_{corr,PLC} \quad \text{(eq. 9)}$$

Next, market insight is required for the known technology costs at a specific location. One must individually calculate the market price for a PVHP plant ($I_{PVHP,market}$) using eq. 2, 4, and 5, and then multiple this by the local PLC Investment Ratio ($IR^{CPC}_{PLC.local}$ in eq. 9) to determine the maximum ST investment ($I_{ST,local}$) a plant can be to remain the lower cost technology again PVHP (eq. 10).

$$I_{ST,local} = I_{PVHP,market} \cdot IR^{CPC}_{PLC.local} \quad \text{(eq. 10)}$$

Quite simply, if the known market investment for solar thermal ($I_{ST,market}$) is less than $I_{ST,local}$, then ST is the lower cost renewable heat producer. If not, PVHP produces heat at a lower price (eq. 11).

$$\begin{cases} ST\ chosen,\ I_{ST,market} < I_{ST,local} \\ PVHP\ chosen,\ I_{ST,market} > I_{ST,local} \end{cases} \quad \text{(eq. 11)}$$

3. Results

The thermal yield simulation results can be viewed in a prior publication (Meyers et al., 2016). The graphical depiction and required equation parameters of the Investment Ratio (*IR*), Correction Factor ($F^{CPC}_{corr,PLC}$), and PV Yield (E^{PV}_{sol}) are shown in section 3.1.1, 3.1.2, and 3.1.3 respectively, all required to for the economic comparison. Section 3.2 provides a short example of how to use the methodology. A focus is given to the CPC collector for this section, but graphs and equations for other cases will be made available in future publications.

3.1 Key Calculation Parameters

3.1.1 Investment Ratio

The generalized form of the ILC Investment Ratio for CPC collectors as a function of solar irradiation (*H*)

and differential between mean process and annual average daytime temperature (T_{diff}) was explained in eq. 8. The resulting parameter coefficients for a CPC collector are shown in Tab. 3. The regression had a root mean squared error (RMSE) of 2.7% and an R^2-adj of 0.982 with all parameters having a p-value less than 0.05, indicating significance.

Tab. 3 – The linear regression derived parameters to calculate the generalized Investment Ratio for Infinite Load Cases using a CPC collector

	$IR_{ILC,gen}^{CPC}$				
COP	1	2	3	4	5
θ_0	1064	532	355	266	213
θ_1	0.066	0.033	0.022	0.016	0.013
θ_2	-83.0	-41.5	-27.7	-20.8	-16.6
θ_3	5.92E-04	2.96E-04	1.97E-04	1.48E-04	1.18E-04

The resulting plot of this regression equation is shown in Fig. 1. The x-axis hosted the site and process dependent T_{diff}, ($T_{p,m}$ – $T_{amb,day}$). The global horizontal irradiation (H) is showed on the y-axis. The intersection of two selected points on the x- and y-axes, defined by its color and contour lines, was the Investment Ratio for various *COPs*, shown on the right hand side. The values on the contour lines of Fig. 1 were for a *COP* of one, essentially an electrical heater. This value helped, along with the color scheme, to orientate oneself to the right hand side table and subsequently determine the $IR_{ILC,gen}^{CPC}$ dependent on the *COP* of a HP.

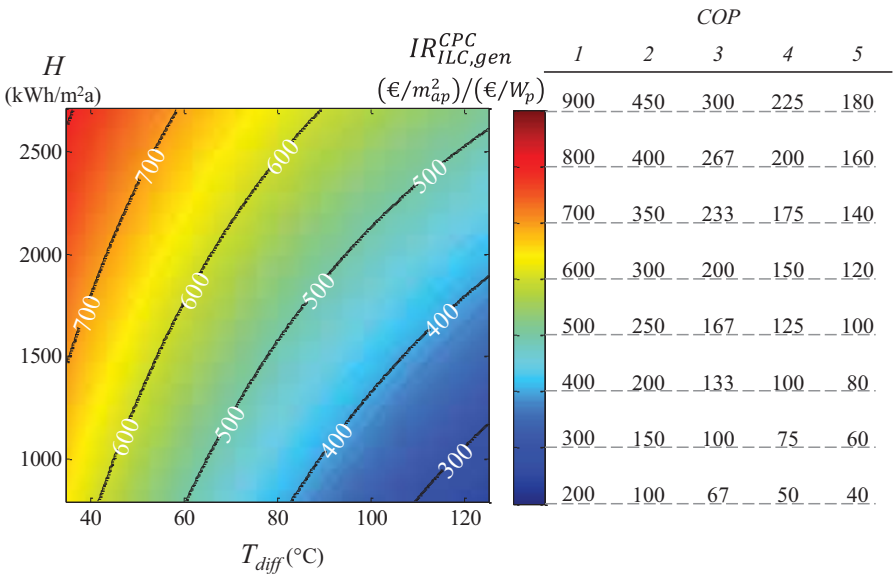

Fig. 1 – The results of a regression analysis from the energetic simulations which depict the Investment Ratio as a function of T_{diff} and H for a CPC collector under an Infinite Load Case

A brief observation of Fig.1 shows that the Investment Ratio increased as a function of global solar irradiation (H) and decreased due to a higher temperature difference between the process and ambient conditions (T_{diff}). This was expected, as this trend is in agreement with the solar collector efficiency equation (ISO, 2013). The performance of a PVHP system (or PV more specifically) was only slightly negatively influenced by higher ambient temperatures (i.e. increasing $IR_{ILC,gen}^{CPC}$).

3.1.2 Correction Factor

An example of a Correction Factor ($F_{corr,PLC}^{CPC}$) curve is shown in Fig. 2, for a seven day constant (three shift) load profile being heated with a CPC collector. The x-axis indicated the temperature difference (T_{diff}) between the mean process temperature ($T_{p,m}$) and the annual daytime average temperature ($T_{amb,day}$). The colored dots in the middle represented the average correction factor of the various locations and process

temperatures, colored by their respective annual solar irradiation (H). The dashed vertical lines per colored dot illustrated the range of correction factors based on various daily specific load requirements and the optimum storage. The upper range of the dashed vertical line represented relatively smaller ST plants relative to the process load achieving higher solar utilization but lower solar fractions. The lower range represented the opposite, relatively large ST plants with higher solar fractions but lower solar utilizations. The black dots within the dashed line indicated the specific simulated cases. A clear decreasing trend of $F_{corr,PLC}^{CPC}$ is shown as T_{diff} increases, nearly independent of annual solar irradiation.

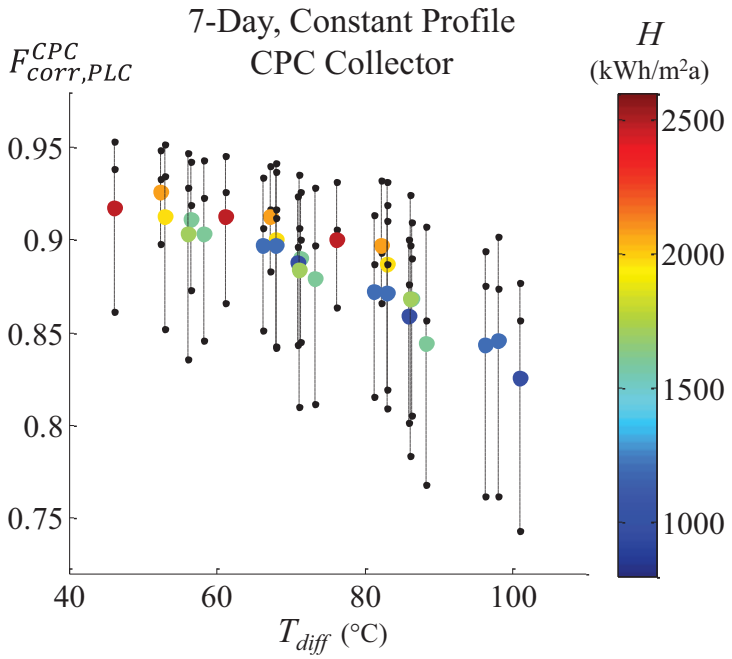

Fig. 2 – An assessment of the PLC correction factor for a 7 day constant load demand being met with a CPC collector

3.1.3 PV Yield

The specific yield of a PV plant in various climates can be calculated with numerous online tools and commercial software packages. While not specifically unique to this research, its presentation in a simple nomogram, calculated through numerous simulations and generalized with linear regression, is helpful for a quick assessment to later determine HP sizing and overall PVHP project investment. The resulting parameters from the linear regression (eq. 3) are show in Tab. 4, which had an RMSE of 2.81% and an R^2-adj of 0.972 with all parameters having a p-value less than 0.05, indicating significance.

Tab. 4 – Model coefficients used to estimate the specific PV yield with the global horizontal irradiation and latitude known for a location of interest

$E_{sol,gen}^{PV}$		
θ_0	θ_1	θ_2
-279.7	0.89	7.52

The results of this linear regression are plotted in Fig. 3. To use, a site's latitude (φ) in degrees was on the x-axis and its global horizontal irradiation (H) on the y-axis. Their intersection point was the estimated annual solar PV yield, in kWh_e/kW_p. The white dots indicate the sites used for the correlation at their specific φ and H. The model's parameter linked to H (θ_1) is 0.89, which is roughly a typical Performance Ratio for PV plants. Built into the latitude model parameter (θ_2) was also a crude ambient temperature correlation, so solar yield benefits not only from collector tilt at higher latitudes but also from lower ambient temperatures often observed there. Collectors were tilted to the site's latitude, minus 15 degrees with a minimum tilt angle of 15 degrees.

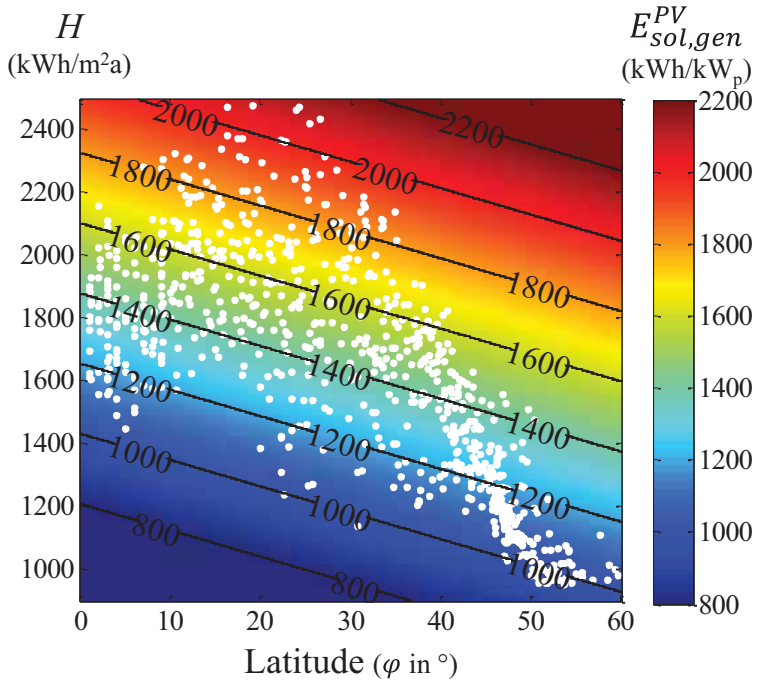

Fig. 3 – A graphical representation of the model used to estimate solar PV yield (E^{PV}_{sol})

3.2 Methodology Demonstration

To determine the use of the methodology, a step by step example is provided:

1 - Determine known process parameters through an energy audit, for example:

- Local meteorological conditions: H: 1250 kWh/m^{2}a, $T_{amb,day}$: 15 °C, φ: 40°
- Industrial process: 70..90 °C ($T_{P,m}$: 80 °C), operates 7 days a week for 3 shifts (Continuous profile)
- T_{diff}: $T_{P,m}$ - $T_{amb,day}$: 65 °C
- Waste Heat: Available 2000 hours per year (FLH: 2000)
- Estimated PV and HP figures – I_{PV} : 1.1 €/W$_p$, COP : 3 and I_{HP} : 500 €/kW

2- Use Fig. 1 or eq. 8 to calculate the Investment Ratio ($IR^{CPC}_{ILC,gen}$) with inputs of H, T_{diff}, and COP

- $IR^{CPC}_{ILC,gen}$= **175** in (€/m$^2_{ap}$)/(€/W$_p$)

3- Use Fig. 2 to estimate a Correction Factor ($F^{CPC}_{corr,PLC}$) with T_{diff} and the known process load profile

- $F^{CPC}_{corr,PLC} \approx$ **0.90**

4- Use Fig. 3 or eq. 3 to calculate E^{PV}_{sol} with inputs of H and φ

- $E^{PV}_{sol,gen}$ = 1133 kWh/kWp

5- Use eq. 2, 4, and 5 to calculate $I_{PVHP,market}$

- Size the Heat Pump: $P^{HP}_{peak}(kW_{th}/kW_p)$ = 1133·3/2000 = 1.7 kW$_{th}$/kW$_p$ (eq. 2)
- Heat Pump Investment: $I_{HP_{(PV)}}(€/W_p)$ = 1.7 · 500 = 0.86 €/W$_p$ (eq. 4)
- $I_{PVHP,market}(€/W_p) = I_{HP_{PV}} + I_{PV}$= 0.86 + 1.1 = **1.96** €/W$_p$ (eq. 5)

6- Use eq. 9 and 10 to determine the maximum ST Investment, $I_{ST,local}$

- $I_{ST,local} = I_{PVHP,market} \cdot IR^{CPC}_{ILC,gen} \cdot F^{CPC}_{corr,PLC}$ = **1.96·175·0.9** = **310** €/m$^2_{ap}$

When a ST plant can be built turn-key at this site ($I_{ST,market}$) for this industrial process for less than 310 €/m$^2_{ap}$, solar thermal is the lower cost renewable heat technology (eq. 11).

4. Case Study

Using the described methodology in this work and the stepwise procedure highlighted in section 3.2, case studies have been performed to estimate the maximum $I_{ST,local}$ under numerous conditions for an industrial process requiring heating from 60..90 °C with a CPC.

4.1 Boundary Conditions

Three site locations were chosen which had different levels of solar irradiation and ambient temperature. The "High" case had an H: 2400 kWh/m^{2}a and $T_{amb,day}$: 29 °C, the "Mid" case H: 1600 kWh/m^{2}a and $T_{amb,day}$:19.5 °C, and the "Low" case H: 1000 kWh/m^{2}a and $T_{amb,day}$: 10.5 °C. By using this range of meteorological parameters, a band of all feasible $I_{ST,local}$ was displayed.

Three process load profiles were selected to represent a range of potential $I_{ST,local}$. The first case, denoted in green, was a constant load profile, requiring heat 7 days a week for three shifts, during which a heat pump can operate continuous at 8000 full load hours (FLH) a year. The correction factor ($F_{corr,PLC}^{CPC}$) was estimated to be 0.90. The second, denoted in blue, was a typical weekly operating process (5 days) for only one daytime shift (8 hours), where a heat pump can operate full time at approximately 2000 hours per year. The third case, in red, was the same as the second, only that the heat source for the heat pump was constrained. This reduced its operating full load hours to 500 per year. The correction factor ($F_{corr,PLC}^{CPC}$) was estimated to be 0.80 for both the second and third case, though the graph is not depicted in this publication.

For the remaining required parameters I_{PV}, COP and I_{HP}, a range was given spanning the current highest and lowest thresholds. From pessimistic to optimistic, the ranges were for 2..0.5 €/W$_p$ (I_{PV}), 2..5 (COP), and 800..200 €/kW (I_{HP}).

4.2 Results

The case study results are displayed in Fig. 4. The x-axis is comprised of the range of pessimistic to optimistic values of I_{PV}, COP, and I_{HP}, from left to right. Each column of values noted on the x-axis were the input parameters to calculate $I_{ST,local}$ for the three process load profiles and three site locations. It was recognized that for real cases these values will not be as orderly but it serves to demonstrate how $I_{ST,local}$ on the y-axis is influenced by the parameters. Three process load cases are represented by their noted colors. The three site locations are identified by their location within each color band. The "High" case was always located on the upper edge, the "Low" case on the lower edge, and the "Mid" case was appropriately in the middle.

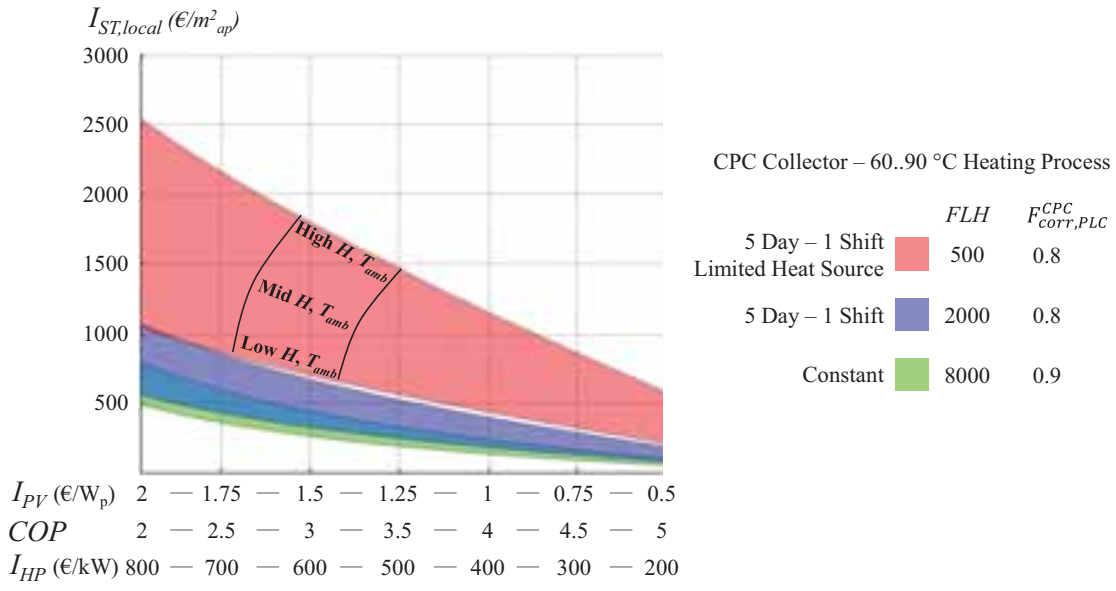

Fig. 4 – The case study results, illustrating the span of potential $I_{ST,local}$ values for numerous process inputs

Fig. 4 shows clear trends which immediately elucidate the sensitivity of certain parameters on $I_{ST,local}$. First and most obvious was that as the main PVHP financial and operating parameters (I_{PV}, *COP*, and I_{HP}) go from pessimistic to optimistic along the x-axis, $I_{ST,local}$ reduces significantly meaning PVHP became more competitive. Second, the process load has a marked influence. The PVHP plant is most competitive against ST (lowest $I_{ST,local}$) during a constant profile in which a heat pump can operate for nearly the whole year, shown in the green band at the bottom of Fig. 4. In turn the PVHP is least competitive (highest $I_{ST,local}$) during a 5 Day – 1 Shift process with limited heat pump operation (500 *FLH*), visible in red at the top of Fig.4. Site location or more specifically the greater available solar irradiation and ambient temperature positively influence $I_{ST,local}$, making ST more competitive when installed in more sunny and warmer regions. The area above an $I_{ST,local}$ of 1000 €/m$^2_{ap}$ should be of little interest because any well-built ST plant can be built for less, making any result above this value automatically in favor of ST over PVHP. To focus on $I_{ST,local}$ values less than 1000 €/m$^2_{ap}$, Fig. 4 was truncated into Fig. 5 by zooming in the region of interest on the y-axis.

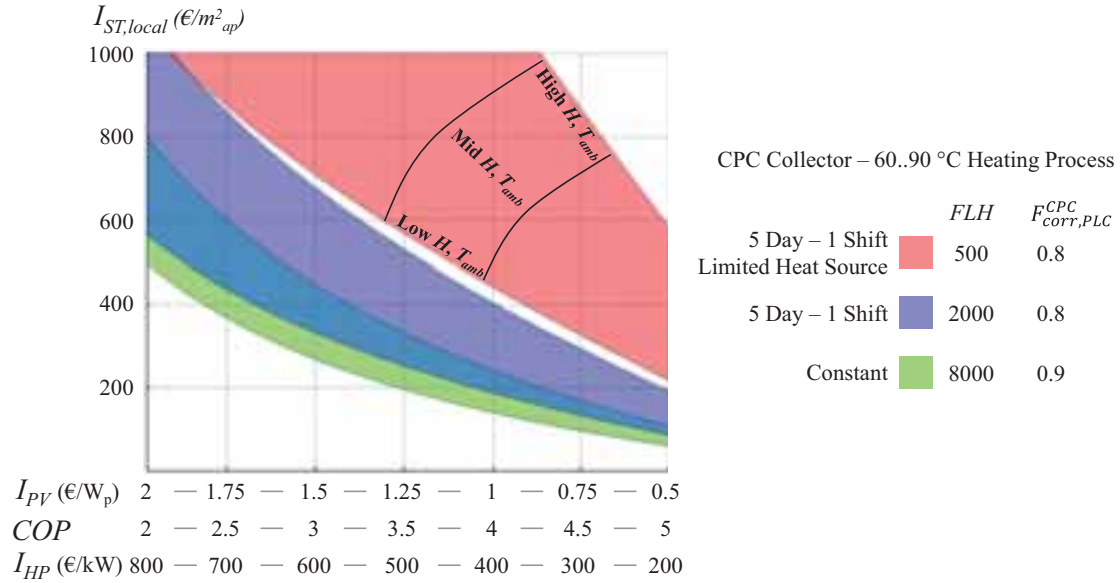

Fig. 5 – The case study results with a focus on $I_{ST,local}$ values less than 1000 €/m$^2_{ap}$

For the 5 Day – 1 Shift case with a limited heat source (red) in Fig. 5, the calculated $I_{ST,local}$ remains above 400 €/m$^2_{ap}$ for nearly every case, meaning that a well-built ST plant will remain the lower cost technology when FLHs are minimal. The opposite case, with a Constant load profile and a heat pump operating 8000 hours a year (green), indicated that for most situations, a PVHP will be the lower cost heat provider as $I_{ST,local}$ must be below 300 €/m$^2_{ap}$. ST can be competitive in cases when both PV and HP technologies are expensive and operate with a low *COP*. The final case, with a 5 Day – 1 Shift load (blue), both technologies could potentially be lower cost depending on the many boundary conditions. At current average PVHP technology costs (I_{PV}: 1.25 €/W$_p$, I_{HP}: 500 €/kW) with a reasonable *COP* of 3.5, $I_{ST,local}$ varied between 250 €/m$^2_{ap}$ to 525 €/m$^2_{ap}$ from the low to high solar irradiation and ambient temperatures locations. This range is the directly in-line with current $I_{ST,market}$ (BAFA, 2016), showing that the comparison between the two technologies is a stalemate, highly dependent on how cost effective can a ST plant be build. In the future, if PV and HP technology investments continue to reduce while HP performance increases, ST must similarly reduce investment below 200 €/m$^2_{ap}$ to remain the clear technology leader in the majority of industrial cases.

5. Conclusions

The quest for zero carbon process heat in industry often pits solar thermal and renewable electricity (by PV) powered heat pumps against each other. While any technology which reduces carbon emissions is welcome in the fight against climate change, industry often requires the lower cost path to reduce fossil fuel consumption and emissions. For the first time, a robust methodology based on numerous techno-economic

simulations is presented which clearly determines which technology is less expensive when primary industrial process and technology parameters are known.

A comprehensive case study analysis was conducted which used the described methodology to determine the maximum specific investment a solar thermal plant can have in order to remain economically competitive against a heat pump operated with PV generated electricity. In cases when thermal energy is constantly required by an industrial process and a heat pump can operate for the majority of the year, PV heat pump plants will likely be the preferred technology. Contrary to this, if a heat pump can only operate 500 hours or less per year, solar thermal will be the lower cost technology in nearly all cases. In between these two, when the process load and heat pump both require/generate heat for 2000 hours per year at current PV and heat pump investments, the maximum ST investment was between 250 €/m^2_{ap} for low irradiation climates to 525 €/m^2_{ap} for high irradiation climates. Depending on how well or cost effective a solar thermal plant can be built, it can be the lower cost technology. For solar thermal to remain a competitive renewable heat technology and "future proof" itself against others, installed projects must achieve investment levels no greater than 200 €/m^2_{ap} to be the lower cost renewable heat technology in most meteorological and process conditions.

Abstract

Two solar process heat plants with liquid heat transfer parabolic trough collectors (PTC, 627 m² and 115 m² aperture) at Swiss dairies have been experimentally investigated in detail. They provide solar thermal heat for a hot water network of 102 °C and a steam network of 135 °C - 150 °C, respectively. Detailed yearly, monthly and daily evaluation with regard to usable solar gains Q_{use} and solar energy necessary for heating–up system components to required temperature T_{set} is presented. Thermal heat capacities of the primary circuit have been analyzed and the change in inner energy ΔU has been calculated and cumulated for periods with no usable heat output below $T_{set.}$ Over the year, the ratio of not usable solar energy required to heat-up the system to overall solar gains in the collectors ($\Delta U / (Q_{use} + \Delta U)$) varies between 14-18 % and 20-22 %, respectively. During winter months ΔU can even exceed Q_{use}. These capacitive losses can be reduced by lower heat capacities or an improved thermal insulation. With intermediate storages, inner energy contained in the hot system could be stored for re-heating after an idle period.

Keywords: solar process heat, parabolic trough collector, concentrating solar thermal, thermal heat capacity, thermal losses, heating-up.

1. Introduction

Nearly 70% of final energy consumption in European industry is required for process heat. Part of this energy could be provided by thermal collectors in order to reduce fossil fuel consumption and CO_2 emissions. Though, to date there is little experience with solar process heat plants (SPHP), especially at temperatures between 100 °C and 250 °C, where thermal losses of system components during stand-still periods play a major role compared to low temperature applications. After periods of non-operation, solar energy is required to heat up the components to operating temperature before solar heat can be delivered to the processes.

The work focuses on experimental analysis of two solar process heat plants with parabolic trough collectors quantifying daily and monthly inner energy ΔU required to heat-up heat transfer fluid and piping system and comparing it to useful solar energy gains Q_{use}. Both plants analyzed provide solar heat for dairies and are located in northwest (Saignelégier) and southeast (Bever) of Switzerland. They operate at different collector temperatures (120 °C/190 °C) and differ in size (627 m^2/115 m^2), integration concept (hot water/steam) and type of heat transfer medium (water-glycol/thermal-oil).

A methodology based on the system configuration in Saignelégier has been developed in order to experimentally quantify the required solar thermal energy during transient heat-up periods of the plant (Möllenkamp et al., 2016). In this work, the methodology has been adapted to the plant configuration of Bever and results of both plants are compared and discussed.

2. Description of analyzed solar process heat plants

Saignelégier

The SPHP in Saignelégier produces thermal energy for a (cheese) dairy operated by Emmi. The collector field comprises of 17 parabolic trough collectors (PTC) PolyTrough 1800 by NEP Solar (SPF 2017) connected in parallel. It is mounted on the roof of a production hall and its orientation follows the roof geometry (north-south with 18 ° deviation counterclockwise). The total aperture area amounts to 627 m^2 and the row distance alternates between 2.98 und 3.84 m. As heat transfer fluid, a 25 vol.% water-glycol mixture with $c_{p(0\text{-}120\ °C)}$=3.9-4.2 kJ/kg/K is used. The primary circuit consists of solar field and return/supply pipes and delivers useful solar heat Q_{use} to the hot water network operated at 102 °C (secondary circuit) via a heat exchanger if a set point of T_{set} = 117 °C is exceeded (Fig. 3 and Fig. 4). Useful solar energy is either stored in a 15 m^3 water storage, used for pre-heating water in two oil-burners or directly delivered to the processes of the dairy (cleaning or thermal treatments of dairy products). Fluid temperatures are measured at inlet and outlet of the collector field and the heat exchanger. Minute mean values of highly resolved (up to 1 secs) measurements are used for the analysis.

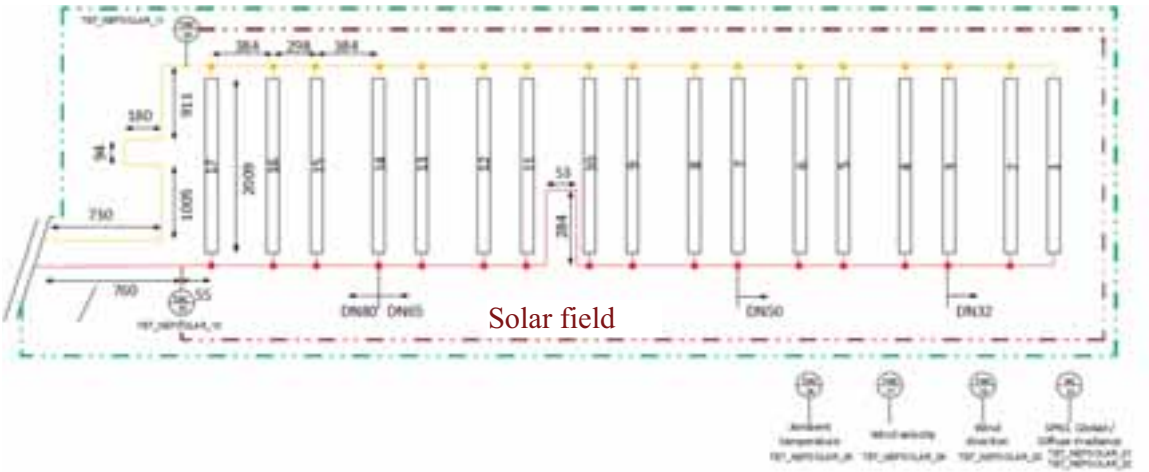

Fig. 3: Hydraulic Scheme of solar field in Saignelégier

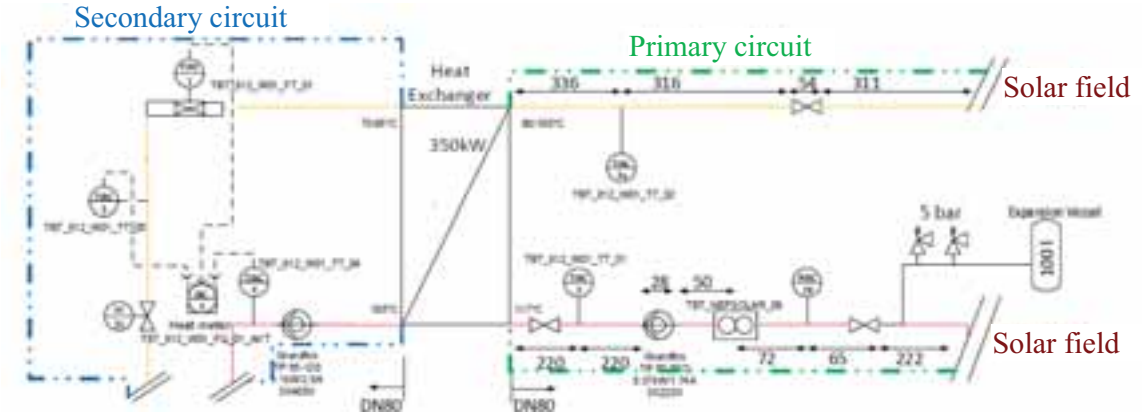

Fig. 4: Hydraulic scheme of SPHP in Saignelégier (solar field not included)

Bever

The second plant is located in Bever and produces thermal energy for a (cheese) dairy operated by Lesa. The collector field comprises of 4 collector rows with a length of 25 m each. Two rows are connected in series and the arising subfields connected in parallel. The solar field consists of parabolic trough collectors PolyTrough 1200 by NEP Solar and is mounted on the rooftop of a production hall. The axis orientation is north-south with 18.8 ° deviation clockwise. The total aperture area is 115 m^2 with and a row distance of 2.45 m (outer rows) and 3.42 m (in the middle). Here, thermal oil is used as heat transfer fluid with $c_{p(0\text{-}190\ °C)}$ = 2-2.7 kJ/kg/K. The solar heat is delivered to a steam network via steam generator. In Fig. 5, the SPHP again is divided into solar field, primary circuit (solar field plus return/supply pipes) and secondary circuit (steam network).Temperatures of the fluid are measured at inlet and outlet of the collector field and evaporator. Instantaneous measurement data with a frequency of one minute was available.

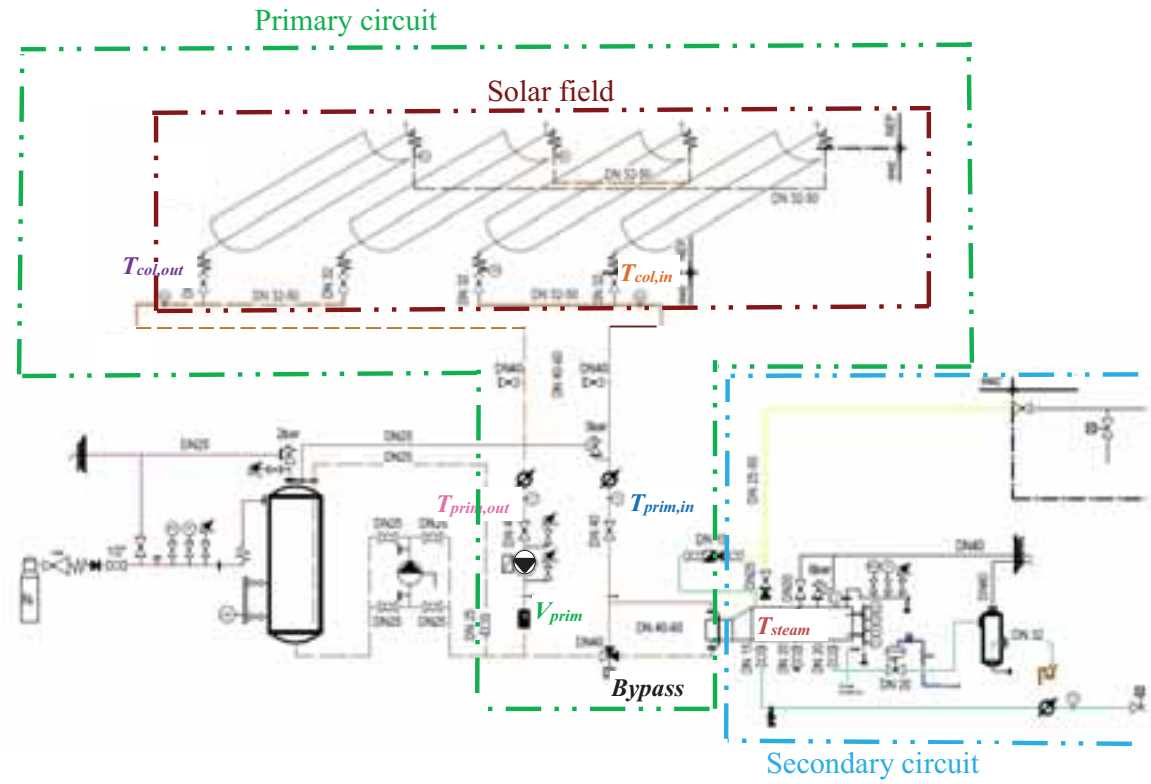

Fig. 5: Hydraulic scheme of SPHP in Bever

In Bever, the presence of a steam generator complicates the evaluation of Q_{use} due to no available information about incoming (feed water) and outgoing (steam) mass flowrates of the steam generator nor from pressure or temperature in the steam network. The steam generator contains 210 l water and is about half filled. Fig. 6 shows a typical operating day for the Bever plant and clarifies the operation modes. If the outlet temperature of the collector field T_{prim_out} exceeds the temperature in the steam generator T_{steam}, the bypass to the internal heat exchanger of the steam generator opens (i.e. at 9:50) and solar energy is used for heating up and evaporating the water in the steam generator. If the steam pressure in the steam generator exceeds the pressure in the steam network plus a certain unknown hysteresis-pressure (e.g. at 11:10 and 12:50), a valve opens their connection and useful solar heat is, driven by pressure forces, delivered to the processes until the pressure in the steam generator has decreased down to the pressure in the steam network (3.1 – 4.8 bar, varying during the day, see Fig. 6). Consequently, a steam temperature of 135 – 150 °C is required to feed useful energy into the steam network calculating T_{steam} from vapor pressure curve. Additionally, the primary circuit has to deliver the necessary temperature difference over the heat exchanger (25 K during operation, see Fig. 6). This leads to a minimal T_{prim_out} of 160 – 175°C (depending on varying steam net pressure) before usable solar heat can be transferred to the process. Though, set temperature for the pump control of the collector field is $T_{col,out}$=190 °C, which can also be seen in Fig. 6.

The dashed lines in Fig. 6 mark two heating up periods converting solar energy in enlargement of inner energy ΔU without providing Q_{use}.

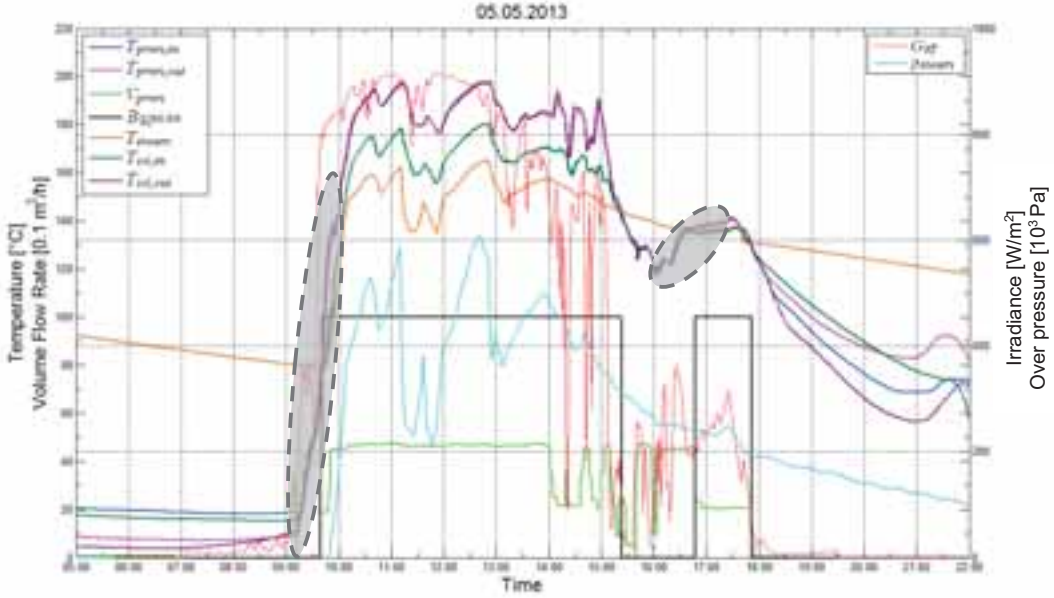

Fig. 6: Exemplary measurement data for the 5th of May 2013 at the SPHP in Bever showing inlet and outlet temperatures of the primary circuit ($T_{prim,in}$ and $T_{prim,out}$), volume flowrates in the primary circuit (V_{prim}), bypass signals (in %), steam temperatures (T_{steam}) and collector field inlet and outlet temperatures ($T_{col,in}$ *and* $T_{col,out}$) as well as direct normal irradiance on the aperture area (G_{bT}) and steam over pressure in the steam generator (p_{steam}).

Comparison of effective thermal capacity

The aperture area specific total thermal capacity C_{eff} [kWh/(Km^2)] of the primary circuit for Saignelegier comprises only of different fluid filled pipe sections (connecting tubes inside and outside the building and collector pipes), see Fig. 5. C_{eff} has been calculated from dimensions, density and specific heat capacities of heat transfer medium and pipe materials. The major part of C_{eff} (80 %) of the primary circuit in the Saignelégier plant is given by the pipes outside connecting the 17 collector rows, see left diagram in Fig. 7.

In contrast, only 50% of C_{eff} of the piping system in Bever (diagram a) Fig. 7, green segments) results from collector connecting pipes due to less collector rows (4), longer collector pipes (5 m longer) and serial connection. Besides the capacity of 198 l thermal oil with $c_{p(0\text{-}190\ °C)}$ = *2-2.7* kJ/kg/K, additionally the thermal capacity of 210 l

water with $c_p = 4.2$ kJ/kg/K in the steam generator (see diagram in Fig. 7, blue section) has to be considered being responsible for two third of the total C_{eff}. Note, that generally the metallic materials of system components like piping, heat exchangers and steam generator account for only about 10% of the total heat capacity, which is mainly determined by the contained fluid.

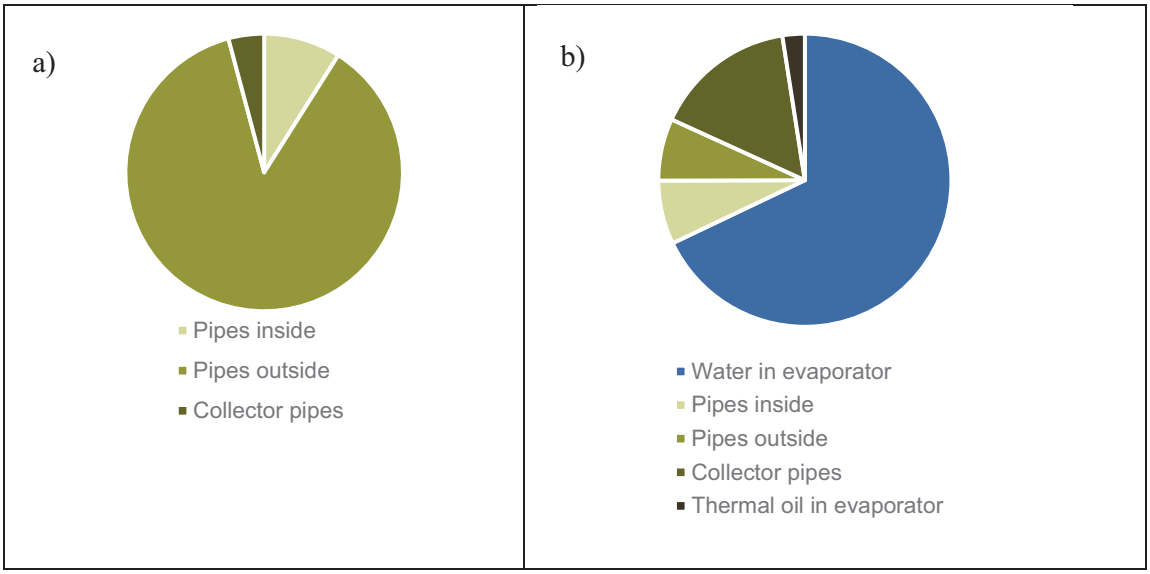

Fig. 7: Distribution of effective thermal capacity C_{eff} in primary circuit of SPHP in a) Saignelégier and b) Bever.

The total thermal capacities C_{eff} (related to the aperture area) for both plants are similar, see Table 1, though the collector fields are differently large by a factor of 6 in aperture area. Regarding only HTF and pipes, C_{eff} in Bever is three times smaller than in Saignelégier. However, in Bever results even a slightly higher total C_{eff}, additionally considering the water in the steam generator. Hence, compared to Saignelégier, the usable part of solar energy in Bever is expected lower, because principally more heat capacity has to be heated to usable temperature level T_{set}, which in Bever (at least 160 °C) is significantly higher than in Saignelégier (117 °C).

Tab. 1: Aperture-specific effective thermal capacity of pipes and HTF in Saignelégier and Bever as well as C_{eff} of water in the steam generator of Bever and the resulting total heat capacities

	C_{eff} [kWh/m²K]	
	Bever	**Saignelégier**
HTF and pipes	0.94	2.73
Water	2.15	
Total	3.09	2.73

3. Methodology for quantification of usable solar energy Q_{use} and solar energy required to heat-up ΔU

Thermal energy required to heat up system components after stand-still periods is calculated by (see Möllenkamp et al. 2016):

$$\Delta U = \sum_{i=1}^{m} \sum_{j=1}^{n} C_{eff,j} \cdot \left(T_{fl,j}\left(t_{2,j}^{i}\right) - T_{fl,j}\left(t_{1,j}^{i}\right) \right) \qquad \text{(eq. 1)}$$

with C_{eff} representing the effective thermal capacity of each capacitive section i and m and n the number of section and heating-up periods, respectively. $T_{fl}(t_1)$ represents the mean temperature of the fluid in each section at the beginning of each heating-up period and $T_{fl}(t_2)$ the temperature at the end, respectively.

Usable solar energy Q_{use} is determined by the energy transferred to the secondary circuit by integrating primary circuit power over periods with an operating pump in the secondary circuit:

$$Q_{use} = \int_{t_2}^{t_3} c_p \cdot \rho \cdot \dot{V}_{prim} \cdot \left(T_{prim,out} - T_{prim,in}\right) dt \qquad \text{(eq. 2)}$$

With t_2 and t_3 defining beginning and end of each period, respectively.

In Bever, the water filled steam generator represents an additional component which has to be considered for the analysis. As derived more above from typical measuring data (Fig. 6), it is simplifying assumed that solar heat is embedded into the steam network (and therefore represents useful energy) if collector outlet temperatures $T_{prim\_out} > T_{set}$. T_{set} corresponds to the minimum steam pressure in the steam network (3.1 bar) and leads to a threshold of $T_{prim\_out} > 160$ °C for useful solar energy. This means, all solar energy below 160° C is used for heating up collector pipes and steam generator. Due to measuring a maximum steam network pressure of 4.8 bar (corresponding to 150°C steam temperature) the evaluation has also been done for this threshold, whereas real conditions meet in between these two limiting cases.

For the evaluation in Bever it was distinguished between thermal energy required to heat up the collector field, the connection pipes inside and outside the building and the water in the steam generator considering different temperatures for each section. For example, the steam generator cools down to 80 °C during night, while the collector field components are at ambient in the morning and differ slightly inside and outside the building (see Fig. 6).

4. Q_{use} and ΔU: Results and discussion

Saignelégier

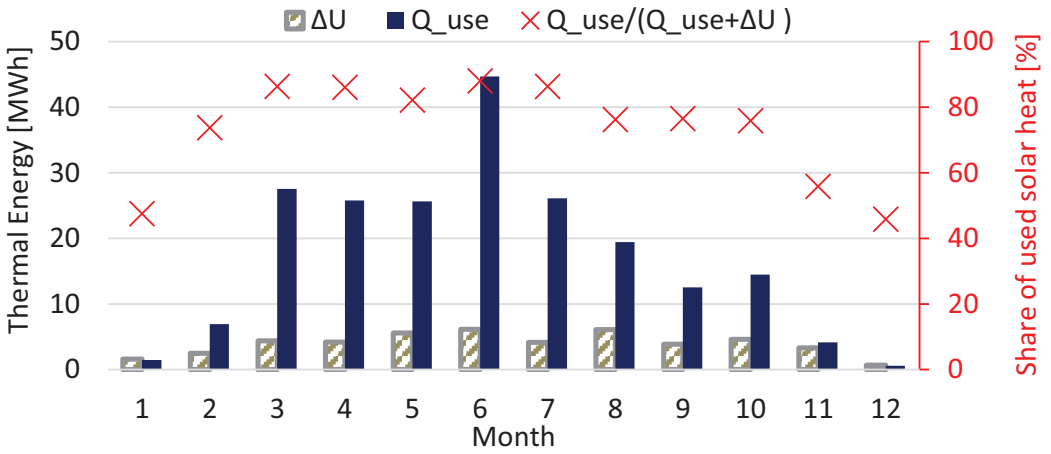

Fig. 8: Solar energy gains required to heat-up system components ΔU, useful solar gains for process heat Q_{use} and share of useful solar heat Q_{use} /(Q_{use} + ΔU) of the SPHP in Saignelégier 2014

According to Fig. 8 between 76 % and 88 % of the total solar gains Q_{tot} with

$$Q_{tot} = Q_{use} + \Delta U \qquad \text{(eq. 3)}$$

has been provided to the hot water network of the dairy between March and October of 2014 in Saignelégier. Here, pipe losses during the operation at $T_{prim\_out} > T_{set}$ have been neglected due to

- having been proven to be totally below 5 % of monthly Q_{tot}, if properly insulated (see Möllenkamp et al., 2016)
- time ratio with $T_{prim\_out} > T_{set}$ is below 20 % during the whole month, reducing part of pipe losses during operation with $T_{prim\_out} > T_{set}$ to less than 1 %

In contrast, the share of useful solar energy decreased down to 46 % in December 2014. This is mainly resulting from less daily direct irradiation on the collector plane and lower ambient temperatures. During the whole year, 18 % (ΔU=47 MWh) of the total thermal solar energy (Q_{tot}=256 MWh) is required for heating-up fluid and pipes of the SPHP in Saignelégier 2014.

In 2015 (see Fig. 9) the annual ratio of required heat for pre-heating is reduced to 14 % (ΔU=37 MWh, Q_{tot}=264 MWh), which is mainly resulting from higher direct irradiation on the aperture area ($H_{bT,2014}$=985 kWh/m² aperture area; $H_{bT,2015}$ =1138 kWh/m² aperture area) and hence higher useful energy gains (Q_{use}=257 MWh). The maximum share of used solar heat is recorded in April 2015 with 93 %. The SPHP was shut down in December 2015 due to snow blocking the tracker. The time of heating-up periods on sunny days in Saignelégier varied between at least 50 min in summer and up to 4.2 hours in winter during 2014 and 2015.

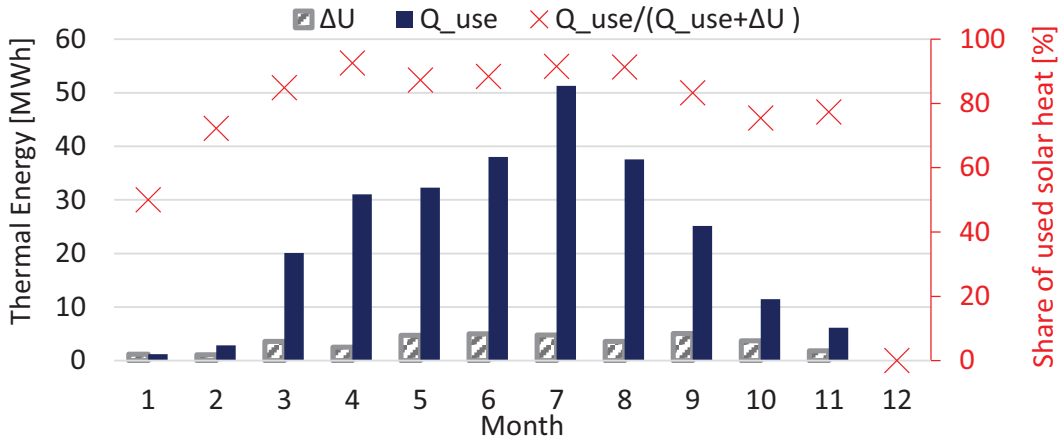

Fig. 9: Solar energy gains required to heat-up system components ΔU, useful solar gains for process Q_{use} and share of useful solar heat $Q_{use}/(Q_{use}+\Delta U)$ of the SPHP in Saignelégier 2015

Thermal losses due to heating-up periods could be reduced by implementation of an additional storage, which collects the heat of fluid and pipes at the beginning of each stand-still period and feeds the solar field with hot fluid before the next start of operation.

Bever

The SPHP in Bever was able to provide 55 % - 89 % of the total solar gains to the steam network from March until October of 2013, whereas in January only 18 % of the total solar thermal energy could be used for industrial processes (see Fig. 10). In 2013, 9 MWh of solar energy gains were used for heating-up system components, which represents 20 % of the total yearly solar gains ($Q_{tot,2013}$ = 44 MWh). Here, it can be distinguished between energy to heat-up water in the steam generator (10 % of Q_{tot}) and energy to heat-up thermal-oil and pipes (10 % of Q_{tot}).

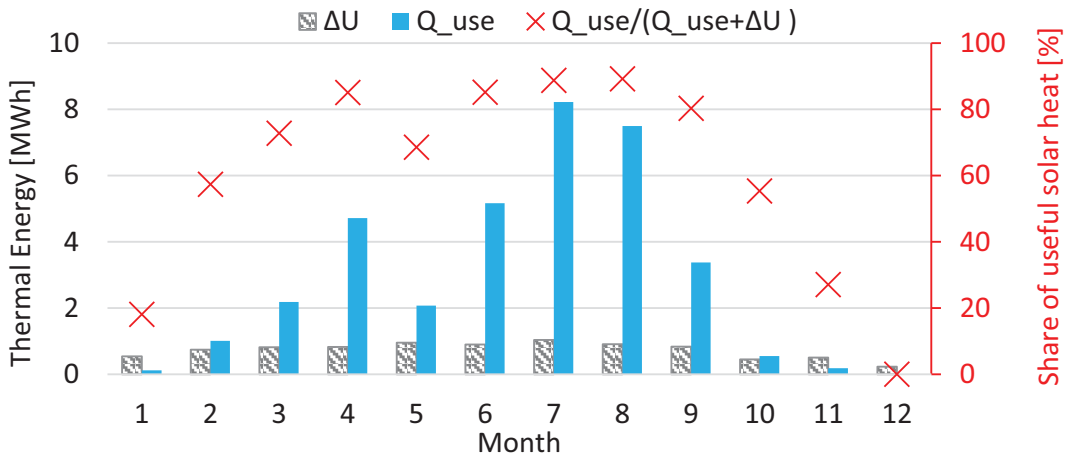

Fig. 10: Solar energy gains required to heat-up system components ΔU, useful solar gains for process heat Q_{use} and share of useful solar heat $Q_{use}/(Q_{use}+\Delta U)$ of the SPHP in Bever 2013

For the maximal pressure of 4.8 bar as measured in the steam network a collector field outlet temperature of 175 °C is required to evaporate the water. Under this assumption, a yearly $\Delta U/Q_{tot}$ =22 % and hence a higher ratio of solar energy used to heat up the system is experimentally obtained. The real value $\Delta U/Q_{tot}$ for Bever is between these two extremal cases (20 % for 160 °C and 22 % for 175 °C). Heating-up times in Bever varied between 1.5 and 2 hours.

For the Bever plant, it is recommended to further improve the insulation of the steam generator, before considering an additional storage for saving thermal energy during stand-still periods.

Comparison between the two plants

The evaluation of measurement data shows that the ratio of required solar energy to heat-up the system compared to overall solar gains do not differ much between both plants analyzed ($\Delta U/Q_{tot}$ 14-18 % in Saignelégier and 20-22 % in Bever) even though minimally acquired collector field temperatures in Bever (>160 °C) are much higher than in Saignelégier (117 °C) and thermal capacities per solar aperture area are comparable.

In spite of a similar total effective thermal capacity C_{eff}, it has to be considered that different temperature differences arise for heating up water and thermal-oil in the Bever plant. Due to its better insulation, the steam generator cools down to only 80°C during night, while the primary circuit cools down to ambient, see Fig. 6. Assuming an ambient temperature of 20 °C inside and outside the building, heating-up in the morning once a day consumes

$$\Delta U_{Bever} \approx C_{eff,water} \cdot (130-80)K + C_{eff,HTF+pipes} \cdot (190-20)K = 267\ kWh/m^2$$

$$\Delta U_{Saignelégier} \approx C_{eff,HTF+pipes} \cdot (120-20)K = 273\ kWh/m^2$$

of solar thermal energy in the morning.

Also the high yearly direct irradiation on the tilted aperture area H_{bT} in Bever (1285 kWh/m² yearly, monthly see Fig. 12) favors a lower $\Delta U/Q_{tot,}$ which can be seen from Fig. 11 showing monthly H_{bT} for the Saignelegier plant comparing the years 2014 and 2015: The yearly share of used solar heat in Saignelégier increases from 82 % to 86 % if yearly H_{bT} grows from 985 kWh/m² to 1138 kWh/m².

Nevertheless, distribution of direct normal irradiance (DNI) over the day also plays a role. For example, five sunny days and five cloudy days show a higher ratio of usable solar energy compared to ten days with fluctuating DNI but same cumulated DNI.

The exact influence of the parameters discussed on the share of usable solar energy Q_{use} and not usable solar energy required to heat-up ΔU can only be determined by dynamic simulations.

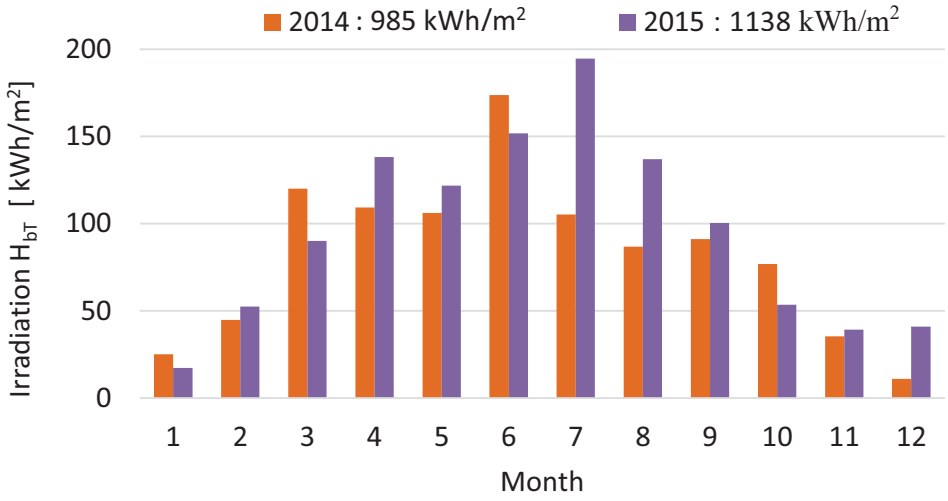

Fig. 11: Monthly direct irradiation on the tilted aperture area of the SPHP in Saignelégier 2014 and 2015

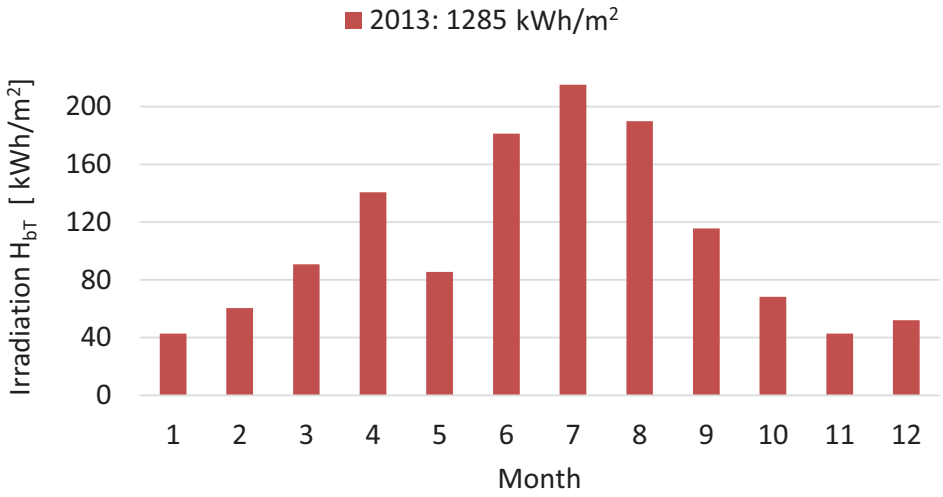

Fig. 12: Monthly direct irradiation on the tilted aperture area of the SPHP in Bever 2013

5. Summary and outlook

For two SPHP in Switzerland with PTC collectors at operating temperatures between 100 °C and 200 °C and collector aperture areas between 115 and 627 m² it could be shown experimentally that 14 to 22 % of potentially usable yearly solar energy, i.e. solar energy transferred to the collector fluid of a SPHP, are lost due to thermal losses in stand still periods which must be balanced by solar heating-up processes. In further studies both plants will be modelled with a dynamic simulation software in order to

- study the exact influence of the different parameters (thermal capacities of components, operating temperatures, integral solar radiation and its distribution, user behaviour) on solar energy required to heat-up ΔU and usable solar energy Q_{use}.
- quantify possible thermal energy savings with the developed optimization methods for each plant, which enlarge Q_{use} reducing ΔU by better thermal insulation and/or saving ΔU at the begin of a stand still period for the next heating up period by means of a thermal storage.

Abstract

Computational fluid dynamics (CFD) was used to simulate the drying process of a Solar-Biomass Hybrid Dryer (SBHD). CFD simulations were set up with the software StarCCM+ for investigating the temperature distribution inside a 5-tonne prototype in a rural community in Ghana. The predicted temperature distributions were compared to the experimental data of temperature distribution in the dryer. The simulated results of Levels 1 and 2 within the dryer were 5–15 K higher than the experimental data. This was due to the introduction of cold air at the bottom of the dryer and also, the absence of the effect of the fans in the dryer during the simulation process. The simulated results fit nearly perfect for Layers 3 and 4 in the dryer with a deviation of not more than 5 K. All in all, the predicted simulation agrees with the experimental data. In order to improve drying conditions in the SBHD, it is suggested that the integration of an automated system which will aid in the controlled introduction of hot air at high air flow at the lower levels of the shelves in the dryer would be required.

Keywords: CFD simulation, Solar-biomass hybrid dryer, performance

1. Introduction

Crop drying has been proven to be an essential process in the preservation of agricultural products (Mastekbayeva, et al., 1999). Being an old technique used for the preservation of food, drying can reduce postharvest loss associated with crops and also make produce lighter, smaller and easier to handle (Green and Schwarz, 2001).

Major drawbacks with open sun drying method as reported by Madholpa et al. (2002) have led to the introduction of enclosed solar structures for drying purposes. Drying of agricultural produce in enclosed solar structures is an attractive way of reducing both the qualitative and quantitative losses of the traditional open-sun drying (Forson et al., 2007). Studies have shown that solar drying techniques lead to a considerable reduction of the drying time and to a significant improvement of the product quality in terms of color, texture and taste as compared to the traditional open sun drying techniques (Fadhel et at., 2014; Srinivasan and Balusamy, 2015; Ajayi et al., 2017).

Solar dryers have a major downside of being weather dependent leading to longer drying times. This has been one of the factors which are impeding the commercialization of such systems in Ghana (Sekyere et. al., 2016). For reaching short drying times, high drying efficiency and product quality, a continuous drying process is targeted. This is the reason why solar biomass hybrid dryers (SBHD) are introduced for reaching constant drying temperatures and a continuous process. With the operation of an external heat source, like a furnace which runs on biomass, the drying process is independent of weather conditions.

The performance in terms of the temperature distribution in the SBHD systems have been studied based on experimental data with little attention geared towards simulated procedures. Carrying out CFD simulations of drying systems can contribute to better design, management and control of such systems. Such studies can help designers analyse spatial temperature and moisture distribution as well as drying time of drying systems prior to scale-up.

doi:10.18086/swc.2017.26.10 Available at http://proceedings.ises.org

The use of CFD modelling for carrying out simulation of drying systems has been proven to be effective and efficient. Such studies help engineers in analysing the performance of drying systems. This goes a long way in the optimization, control and improvement of drying systems in Ghana.

This paper, therefore, sought to study the performance of a 5-tonne capacity SBHD used for drying maize in Ejura, a farming community in Ghana. It was done by using CFD simulated models to validate experimental results.

2. Materials and methods

2.1. Experimental Setup

The 5-tonne capacity Solar Biomass Hybrid Dryer (Fig. 1) is located at Ejura (7° 23′ 0″ N, 1° 22′ 0″ W). It consists of three main parts; the drying chamber, the backup heat generation system and solar photovoltaic system. The dryer has a length of 13 m, the width is 7.85 m and height of 4.6 m. Inside the drying chamber, the shelves have 4 levels with 36 trays on each level.

Fig. 1. 5tonne capacity dryer located in Ejura

2.2. Data Collection of temperature and relative humidity data

Temperature and relative humidity conditions were determined by the use of Tinytag data loggers. The logging date was on 16th October 2016. The logging interval was set at 10 minutes to cater for weather changes at short intervals. During the determination the drying conditions, 5 loggers were placed at each level, 2 on the left and the right side, as well as in the middle, see Fig. 2. The positions of the sensors are implemented in the simulations, to get the temperature variations.

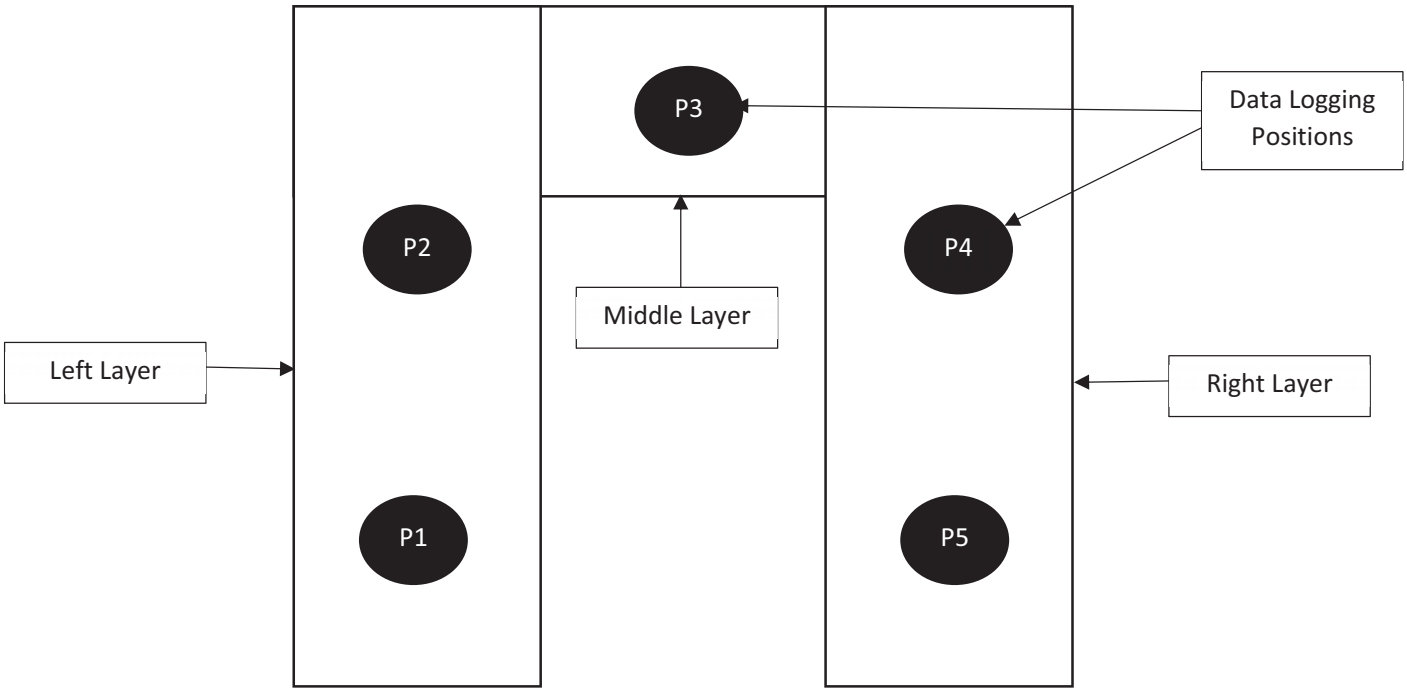

Fig. 2: Layout of shelves and logger positions at each level within the drying chamber

2.3. Physical properties of maize

2.3.1. Heat conductivity and specific heat of maize grain

Heat conductivity and specific heat of maize were determined by Eqn. 1 and Eqn. 2 (Scherer and Kutzbach, 1980; Schwerer and Mühlbauer, 1977)

$$\lambda = 0.108 + (1.80 \times 10^{3} x XM_{H2O}) + (1.79 \times 10^{-4}) \quad \text{(eq. 1)}$$

$$C_{Mp} = 1.294 + (3.44 \times 10^{-2} \times XM_{H2O}) \quad \text{(eq. 2)}$$

Where:

λ is the heat conductivity (W/mK)

XM_{H2O} is the mass water fraction in the maize grain

C_{Mp} is the specific heat capacity of maize (J/ (kg K))

2.3.2. Porosity of maize

The porosity of the maize grains was determined in the laboratory by the use of the water displacement method. Eqn. 3 was used to determine the porosity of the maize grains.

$$\epsilon = \frac{V_V}{V} = 1 - \frac{V_S}{V} \quad \text{(eq. 3)}$$

Where:

V_V is the volume of void

V_S is the volume of solid (maize grains)

V is the total volume of measuring cup

2.3.3. Diameter of maize grain

With the total volume of the maize grains, it was possible to determine the particle volume of a sphere, which is equivalent to the volume of one maize grain. The maize volume was divided by the number of maize grains to get the average volume of one maize grain. The diameter of the maize grain was calculated using Eq. 4.

$$d_p = \sqrt[3]{\frac{6V_g}{\pi}} \quad \text{(Eq. 4)}$$

Where:

d_p is the diameter of a maize grain

V_g is the volume of a maize grain

2.4. Geometry of the SBHD

3D model of the dryer was drawn in the software Autodesk Inventor and exported as a CAD file to StarCCM+ as shown in Fig. 3. In order to set up the simulation, not the original geometry was used, but the geometry in which the fluid flows. The shelves, the maize layers, the inlet, the outlet and the glass are separated in volumes to create single geometry parts for each volume during the import of the CAD file to StarCCM+. Afterwards, a region is created for each geometry part, in order to be able to set individual material properties for each region, e.g. heat conductivity for maize, air and PMMA. The fluid and the porous region are subtracted from the glass shape to get the fluid geometry. Four trays are combined to one maize region to reduce the computational effort, and as a result, each layer is divided into 9 sub-regions.

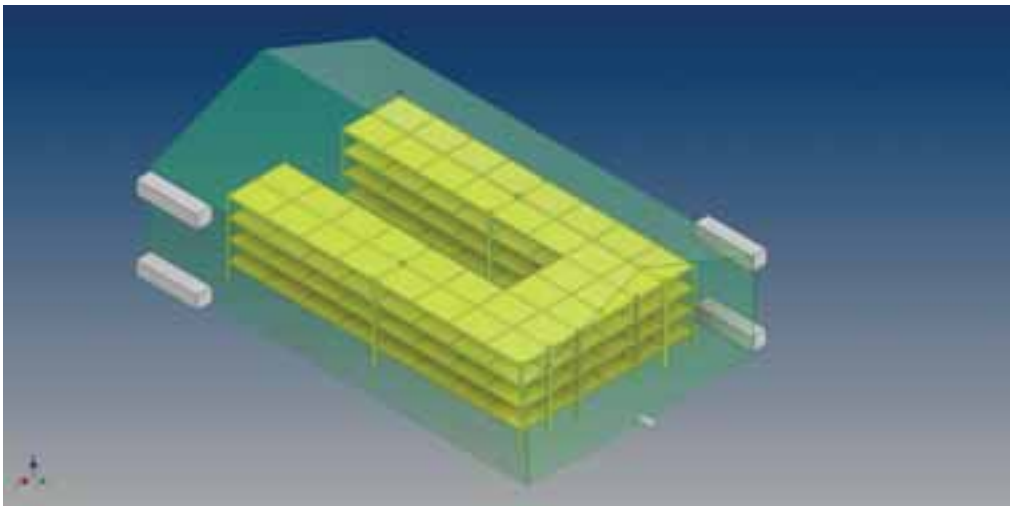

Fig. 3: 3D model of the SBHD

2.5. Boundary conditions

Boundary conditions are set to solve the differential equations. At the pipe, the boundary conditions velocity inlet with 0.25 m/s is defined. Furthermore, the state of the air is given by the data sheets with an average temperature of 305 K and an absolute water mass fraction of 0.025. The relative humidity was transformed into mass fraction xH_2O with Equation 5. The thermodynamic software REFPROP calculates the saturation pressure (REFPROP, 2017).

$$x_{H2O} = \varphi \frac{P_S(t)}{P_M} \quad \text{(Eq. 5)}$$

Where:

P_s is the saturation pressure

P_m is the pressure of the mixture

At the outlet of the drying chamber, a pressure boundary with a relative pressure of 0 Pa is set. The no-slip wall boundary condition is set for the PMMA sheets, the shelve of the maize layers and the floor. For modelling, the solar radiation, the transmissivity, the emissivity and the reflectivity are defined at the interfaces between the fluid and the PMMA region. Table 1 shows the boundary conditions set for the simulation.

Table 1: Boundary conditions for the simulation

Part	Region	Boundary Condition
input	**fluid**	**velocity inlet**
variable	**value**	**entity**
species mass fraction	0.972, 0.028	-
temperature	0.0006.t +296.88	K
emissivity	0.8	-
reflectivity	0.2	-
transmissivity	0.0	-
velocity	0.25	m/s^2
output	**fluid**	**pressure outlet**
pressure	0	P a
PMMA	**glass**	**wall**
emissivity	0.05	-
reflectivity	0.05	-
transmissivity	0.05	-
heat transfer co-efficient	3	$\frac{W}{m^2K}$

2.6. Simulation Procedure

CFD simulations were set up with the software StarCCM+ for investigating the temperature distribution inside the 5-tonne prototype. Before building up the final simulation, the physical phenomena (radiation, fluid flow, heat transfer and species transfer) which occur in the drying process were described by matching numerical models given by StarCCM+. Most important step in describing the drying process was to find an adequate approach for the heat and species transfer. With this approach, the temperature variations in the maize and drying air were calculated. The geometry, through which the fluid flows, was drawn in the software Autodesk Inventor and imported to StarCCM+. Then the given operating parameters (e.g. temperature, relative humidity and velocity at the inlet) and material properties (e.g. transmissivity for the PMMA, maize density) are implemented. Subsequently, the simulation is carried out and the resulting temperature distribution is compared to measurements to evaluate the used models and boundary conditions.

3. Results and discussion

3.1. Dynamics of fluid flow

The simulation of turbulent flow with velocities between $0\ \frac{m}{s}$ and $1.616\ \frac{m}{s}$ are shown in Fig. 4. As expected, the maximum and minimum velocities are close to the inlet and outlet of the dryer. Between the layers, the velocities decrease between $0.323\ \frac{m}{s}$ and $0.646\ \frac{m}{s}$. The velocities at the top of the dryer are approximately $0\ \frac{m}{s}$.

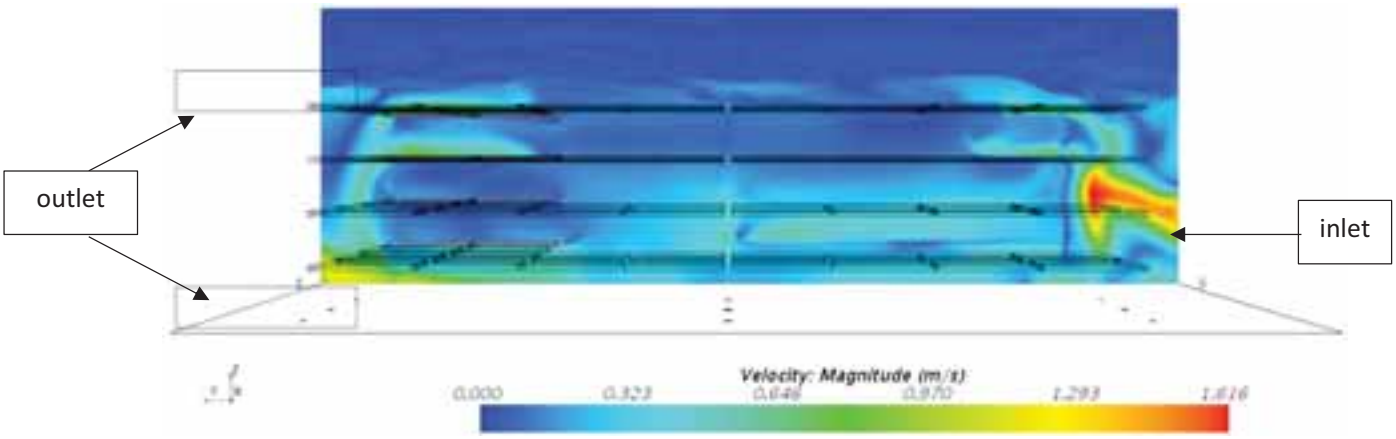

Fig. 4: Velocity field for the unsteady turbulent case

With a closer look at the turbulent viscosity ratio in Fig. 5, the laminar and turbulent flow can be evaluated. The turbulent viscosity ratio between the layers is 600. Hence, the laminar flow cannot be further evaluated, due to the turbulent areas between the layers. With this, the temperature distribution was observed for the turbulent flow.

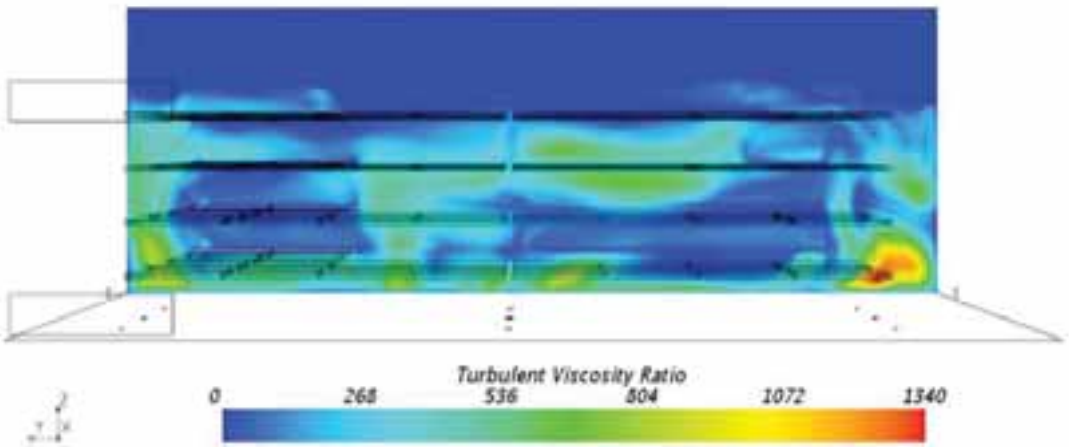

Fig. 5: Scalar Scene for the turbulent viscosity ratio

3.2. Temperature Distribution

Temperature changes are caused by the invading solar radiation and the incoming air; both variables depend on the daytime. The temperature distributions were carried out for a case where the heat transfer coefficient of the Perspex walls was $3\,\frac{W}{m^2K}$. The results for the temperature distribution inside the drying chamber are shown in Fig. 6. Two temperature fronds are developed in Fig. 6. The temperatures close to the roof reached between 340 K and 380 K, and the temperatures around the layers are between 305 K and 330 K. The intruding radiation heats up the drying chamber. This causes hot air to rise due to the density variations, whereas through the pipe at the input, cooler air gets in the drying chamber. The overheating at the top of the drying chamber can result in irregular product quality at the Layer 4 and Layers 1 to 3.

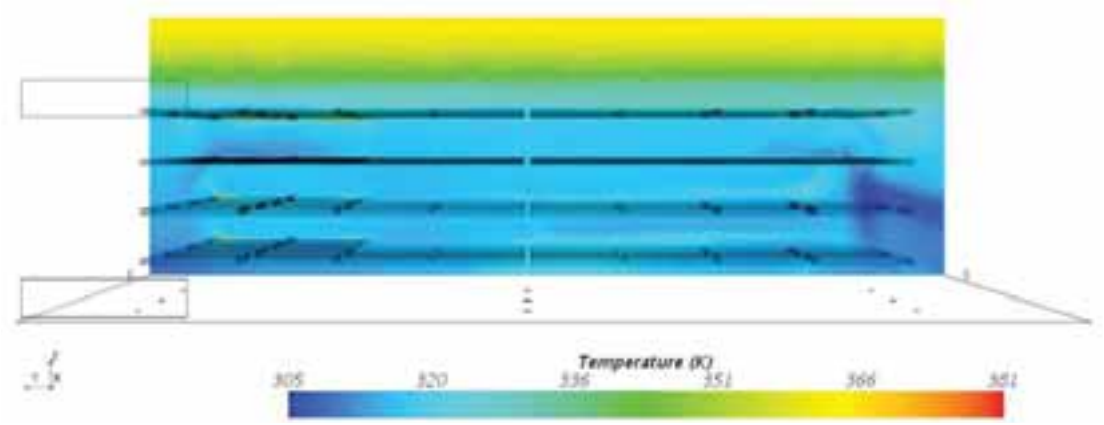

Fig. 6: Scalar Scene for the temperature distribution for the $3\frac{W}{m^2K}$ non-adiabatic wall

The simulation results are compared with experimental data to evaluate the simulations. Temperature distributions for Layers 1, 2, 3 and 4 for the non-adiabatic case are displayed in Fig. 7, 8, 9 and 10 respectively. The temperature function of the simulation results was calculated by Excel to get a smooth distribution and are displayed as dotted lines. The continuous lines display the experimental data. The data from sensor P1 and P2 are averaged to S1. Accordingly, P3 and P4 are averaged to S2. The simulation results for the temperature in Layer 1 (Fig. 7) are up to 15 K higher than the experimental data but the variation decreases in Layer 2 up to 5K (Fig. 8). The simulation results fit nearly perfectly in Layer 3 and Layer 4 (shown in Fig. 9 and 10) for the non-adiabatic case. The high temperatures from the simulation was due to the fact that the dryer was drawn as a continuous shape, but the constructed one in Ejura (Fig. 1) is leaking. Furthermore, temperature differences can be explained by changes in weather, whereas StarCCM+ calculates solar radiation without interruptions. Also, higher temperatures in Layer 1 and Layer 2 in the simulation, can be caused by the missing fans which are installed in the dryer but not considered in the simulations.

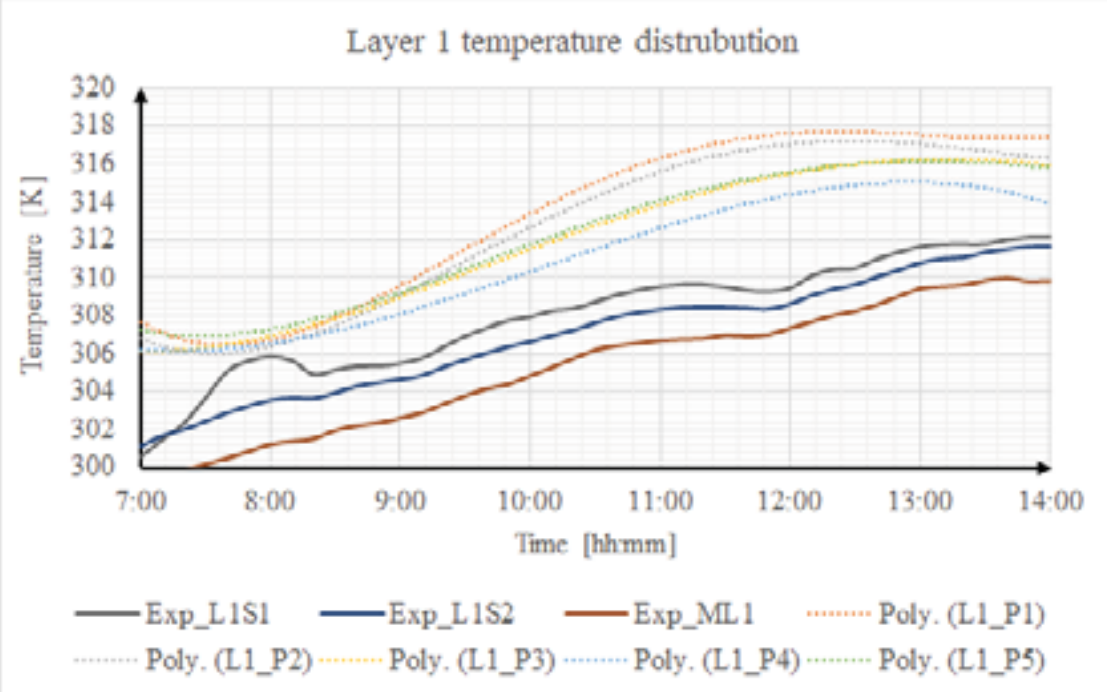

Fig. 7: Temperature distribution for Layer 1

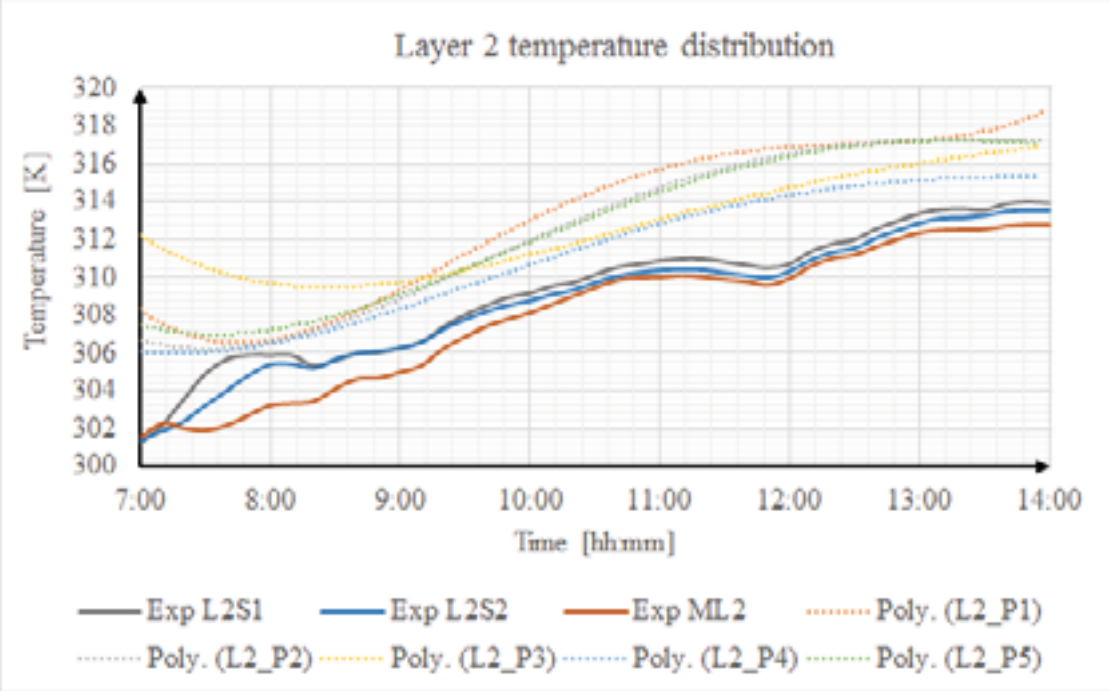

Fig. 8: Temperature distribution for Layer 2

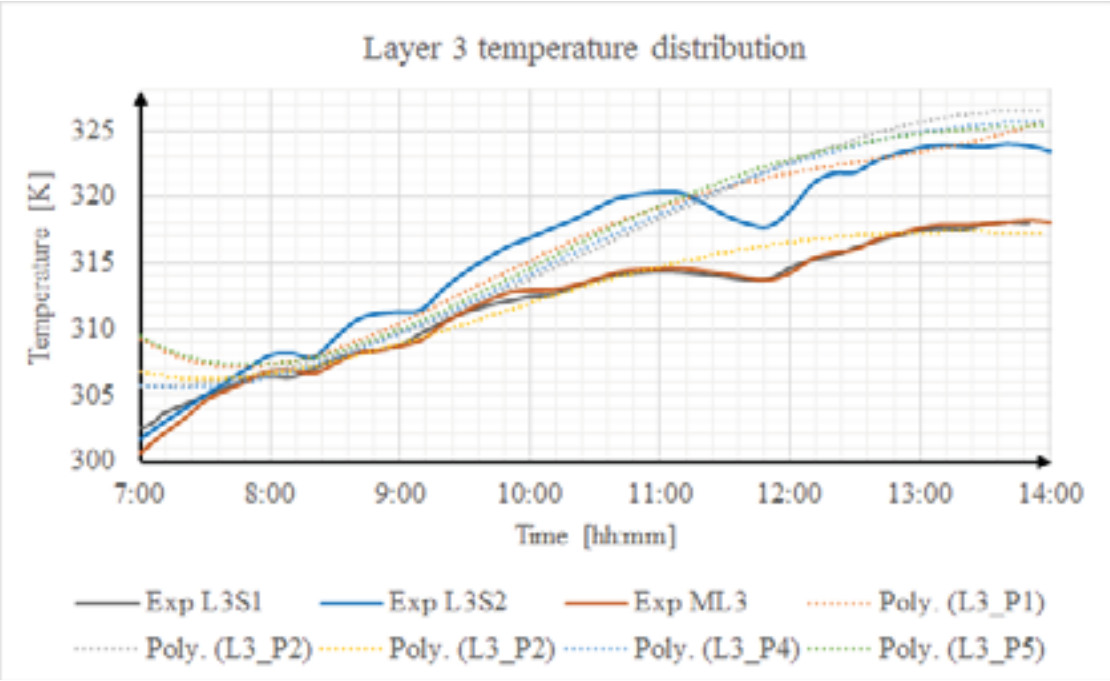

Fig. 9: Temperature distribution for Layer 3

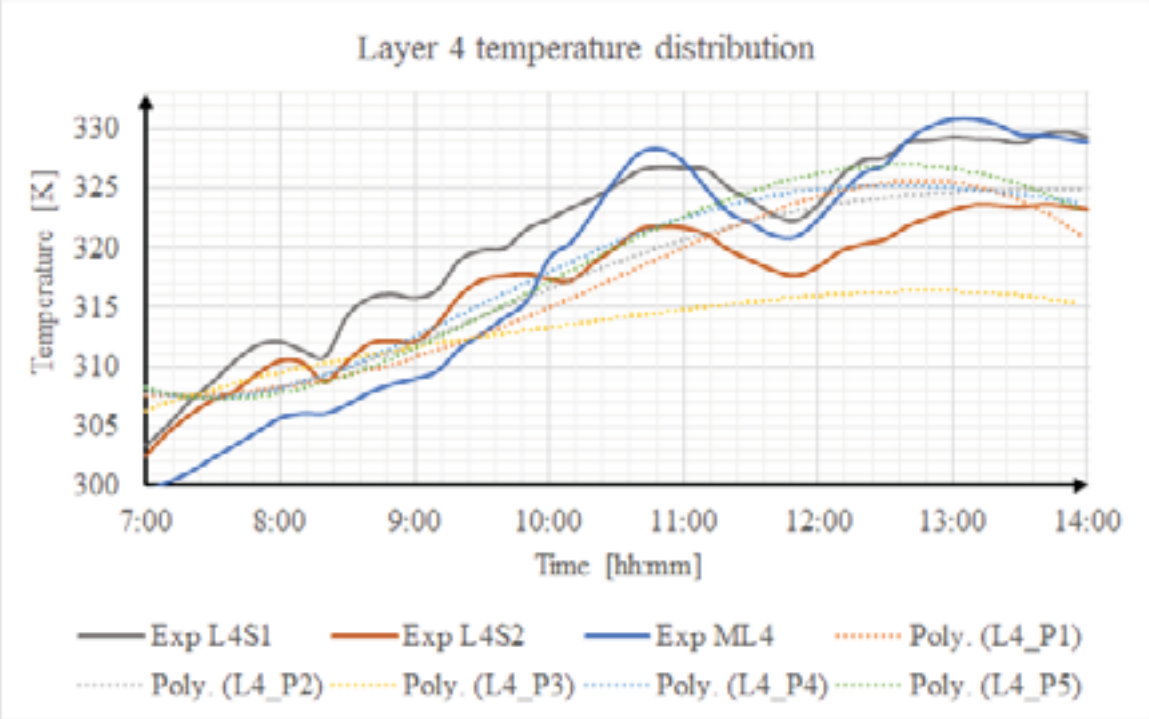

Fig. 10: Temperature distribution for Layer 4

3.3. The automated system

The uneven distribution of temperature in the SBHD could be resolved by the introduction of an automated system. This in addition could also help in the regulation of temperature in the dryer to provide drying conditions which will suit different types of crops.

An electronic circuit consisting of DHT22 temperature and humidity sensors would be designed by the use of Raspberry Pi microcontroller. The Raspberry Pi would be used because of its ability to run Graphic User Interface (GUI) application. The aim of the GUI interface is to enable the users of SBHD to easily interact with the automated system, control and be informed about drying conditions in the dryer. Instead of the conventional keyboard and mouse, an LCD touch screen would be attached to the device to provide a simple interface between the user and the drying system.

Fig. 11 shows the arrangement of the various systems in the automation with the input being the DHT22. The pump and servo motor serve as the outputs of the biomass furnace when the weather and/or drying conditions are not favourable. The DHT22 sensors get signals of temperature and humidity conditions inside the dryer and then relay these signals to the microprocessor. The microprocessor then sends information to the suction pump to either allow or disallow the driving of hot air from the biomass furnace into the dryer. The servo motor acts as the main mechanism to control the movement of shutters at the inlet from the suction pump in to the dryer as shown in Fig. 12. The operations of the suction pump and the servo motor depends on the drying conditions in the dryer. For instance, when temperature in the dryer is lower than the required drying temperature, DHT22 sensor will send signal to the microprocessor for the microprocessor to start the operation of the suction pump.

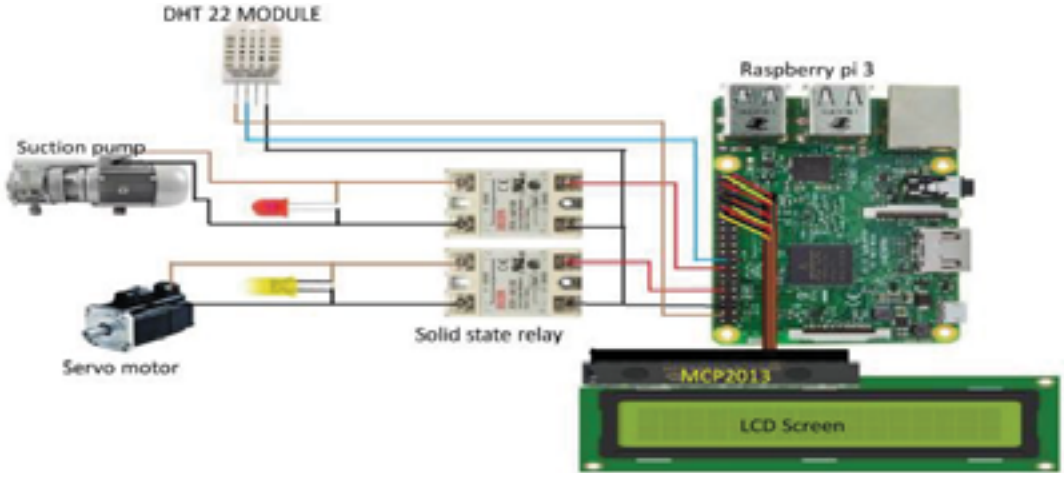

Fig. 11: Schematic circuit of the automated system

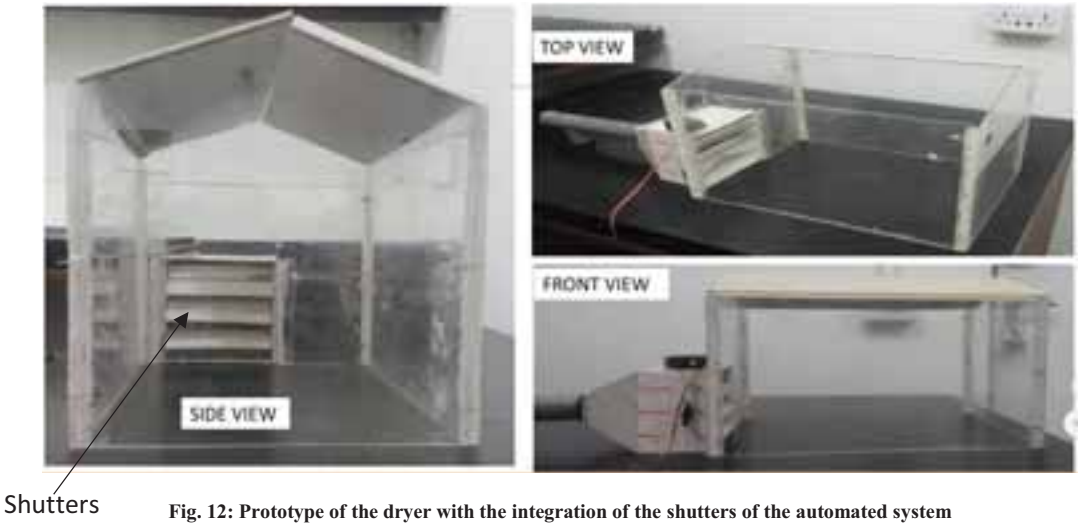

Fig. 12: Prototype of the dryer with the integration of the shutters of the automated system

4. Conclusion

The aim of this work was to develop a CFD model for the Solar Hybrid dryer. The resulting temperature distribution for the heat transfer was compared to experimental data. The comparison showed that the status quo of the dryer was abstracted in a suitable way by the CFD model. Although some deviations between the model and the data exist, they can be explained by the differences between the geometry of the model and the dryer at Ejura. In contrast to the ideal CAD geometry, the physical dryer has several leakages caused by the manufacturing process.

A satisfactory model for describing the status quo of the prototype is compulsory for performing further case studies. For example, case studies can be carried out to investigate the influence of different operation conditions (higher inlet temperature with the furnace, variation of inlet velocities) on the drying process. Furthermore, the dimensions of the shelves (height between the layers, depth of the maize on the layers) can be varied to display effects on the heat and moisture distribution. Again, the integration of an automated system which will aid in the controlled introduction of hot air at high air flow at the lower levels of the shelves in the dryer would help in controlling the temperature of the dryer and then introduce heat from the biomass furnace where weather conditions are not favourable.

Eight Feasibility Studies Demonstrating the Potential of Solar Process Heat in the European Automotive Industry

Felix Pag, Bastian Schmitt and Klaus Vajen

University of Kassel, Institute of Thermal Engineering
Kassel, Germany

Abstract

Solar process heat is an important part of future decarbonised heat supply but has not been able to meet the expectations of the market penetration. The automotive industry is a globally leading industry sector cutting edge research and technical innovation. Together, a large-scale implementation within this sector could bring the much-needed breakthrough for the widespread use of industrial solar process heat. To enable such a reality, several case studies have been carried out within the research project "SolarAutomotive" to detail all relevant industrial heat sinks suitable for solar process heat integration. Within this paper, exemplar results are presented, demonstrating the potential of this application to reduce the CO_2-emissions in industrial heat supply. The collector potential identified in the presented case studies totals to more than 11,000 m^2_{gr} (gross area), which are currently being discussed internally within the companies.

Keywords: Solar process heat, SHIP, Feasibility study, Automotive, Industry, Depreciation, Solar economics

1. Introduction

The automotive industry and their suppliers comprise the most important global industry sectors based on turn-over and employees and have a leading role regarding technical innovations. More than three million people are employed in the European automotive and associated industries representing more than 10 % of the EU manufacturing employment. The sector accounts for about 4 % of the European gross domestic product (GDP). The overall energy consumption (heat and electricity) is 39 TWh and annual CO_2-emissions of 10 million (ACEA, 2017).

Solar heat for industrial processes (SHIP) is a reliable, carbon-free technology for industrial heat supply. Despite hundreds of implementations world-wide, a significant market penetration has not yet been still achieved. If the major automotive players begin to adopt the use of SHIP at their production sites, it can be a strong signal to begin a sustainable and self-reinforcing market uptake. The automotive industry and their suppliers are comprised of 12 sectors, from the OEMs (Original Equipment Manufacturer) themselves to comparably small companies producing textiles, plastics, or electronics. These sectors cover a wide spectrum of production processes required to generalise SHIP projects and eventually transfer the results to other industrial sectors. Therefore, within the research project "SolarAutomotive" several feasibility studies are conducted in the automotive industry. Based on a detailed analysis of various production sites, including heat supply and heat-consuming processes, integration concepts for solar process heat have been technically developed and economically evaluated. Twenty-five case studies in eight European countries have been conducted with eight presented with this paper.

2. Methodology

The case studies are targeted at the complete value chain in the automotive industry and their suppliers. They cover the most relevant heat sinks such as central heating networks, bath heating, drying, and supply of hot water. Very influencing boundary conditions are represented, such as different climatic conditions (irradiation and ambient temperature) and economic parameters (available subsidies, gas prices, internal CO_2-reduction goals and accepted mitigation costs). Within the feasibility assessment all relevant collector technologies such as flat plate collectors (FPC), evacuated tube collectors (ETC), compound parabolic concentrators (CPC) and air collectors (AirC) are considered depending on the respective heat sink and temperature level. The analysed production sites and the relating industry sectors are in Fig. 1.

doi:10.18086/swc.2017.26.11 Available at http://proceedings.ises.org

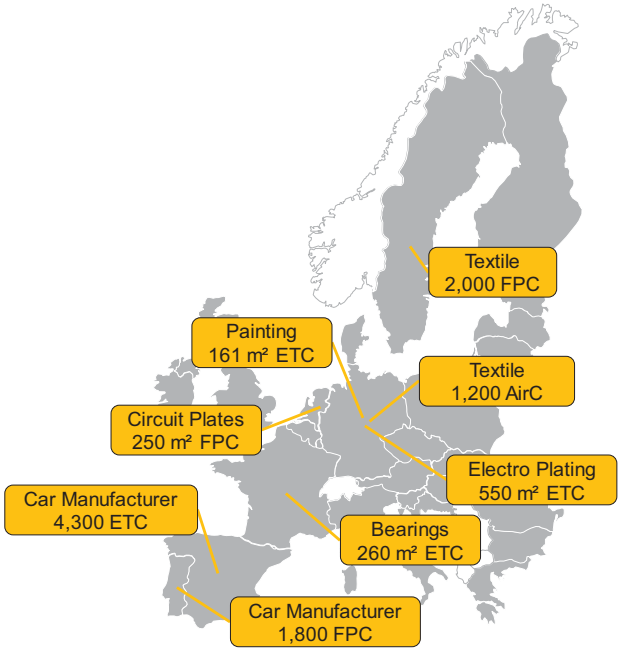

Fig. 1: Analysed production sites within Europe and related industry sectors

2.1 Technical Evaluation

Based on the daily summer heat demand and the heat sink (process) temperature, the maximum potential collector area is calculated. By this design, the solar heating plant produces no excess heat during regular operation and on sunny days the entire heat demand can be covered. This method allows both a relatively high solar specific yield and solar fraction in a highly economical way. Often, the largest solar process heat plant cannot be realised due to site limitations and zoning restrictions. Using Lauterbach (2014), the solar yield and the utilisation ratio of the solar heating plant can be determined for various daily heat demands and installed solar process heat plant size ratios. The energy analysis and solar heating plant performance is then discussed with the company's persons in charge. If there is further interest, a detailed on-site inspection is performed to refine the analysis, which includes suitable roof or ground areas identification and heat sinks as well as heat supply infrastructure. Based on the situation at the production site and the results from the inspection, the collector area of the solar heating plant is reassessed, which often leads to a reduced solar heating plant size and solar fraction. However, an undersized solar heating plant can operate at lower collector temperatures, thus increasing efficiency and utilisation factor. Finally, a detailed simulation with Polysun is performed to calculate the solar yield, utilisation ratio, and the solar fraction, inputs for the economic assessment.

This approach is distilled into a pre-design tool to calculate all relevant parameters within the feasibility assessment. It is based on hundreds of dynamic simulations with different load profiles, process temperatures, geographic locations, and collector technologies (Lauterbach, 2014). The tool uses the production site's latitude to estimate the annual irradiation and peak solar availability in summer for plant sizing purposes. Process flow and return temperatures and an estimated daily load and its profile can be selected by the user. With this information, the tool calculates the potential collector area and storage size, followed in an estimated solar yield and utilisation ratio. If the irradiation at the respective geographic location is known, the solar yield can be recalculated by the product of annual irradiation and utilisation factor for a more accurate result. The tool and its results for those feasibility assessments are validated with Polysun and prove very good compliance. The pre-design tool can be used free of charge (designtool.solar4industry.info).

2.2 Economic Evaluation

Two different economic evaluation approaches are considered. On the one hand, the levelised cost of solar heat are calculated over the life time of the system based on the recommendations of Task 54 (Louvet et al., 2017), comparing solar to conventional heat supply costs over a 25 year lifetime. The conventional heat supply costs are calculated using a gas price and an estimated utilisation factor of the boiler (typically between 75..85 %). On the other hand, the total cost of ownership method is used to determine payback time, internal rate of return and net present value. The solar heating plant investments are estimated by experience and detailed analysis of solar process heat systems in Germany based on size, collector technology, plant location, and integration effort. Other relevant parameters for the economic calculation are in Tab. 1.

Tab. 1: Technical and economic parameters for the calculation of the levelised cost of solar heat and for the total costs of ownership

Parameter	Value
Performance factor[1]	70..100
Price increase of fossil fuels	3 %/a
Inflation	0.8 %
Maintenance, repair, and insurance	0.7 %
Discount rate	4 %
Operation time	25 a

In addition to the natural gas savings, the depreciation of the solar heating plant is considered for a detailed economic assessment. Depreciation is an allocation method that enables a company to reduce the economic value of an asset over a certain time. The depreciated value of the asset reduces to company-wide profit and thus the tax load over the depreciation period. This can significantly decrease the payback time and increase the internal rate of return. Approaches not considering the depreciation of the solar heating plants cannot evaluate the investment correctly.

Assed depreciation is defined by the national tax law and varies between different countries in both number of years and its calculation method. The method of depreciation can either be straight-line or a declined-balanced method. Whereas the straight-line method continuously and equally depreciates the complete investment, the declined-balanced method has an accelerated depreciation in the first years and a decelerated in the final years. Therefore, it is not possible to depreciate the complete investment with the declined-balanced method. The actual additional benefit of a solar heating plant by reducing a company's tax burden is calculated on an annual basis by the product of the depreciation rate per year (DEP in €) and the respective business tax rate (TR in %) shown in eq. 1.

$$Tax\ Benefit = \sum_{i=1}^{Years\ of\ Depreciation} DEP_i \cdot TR \qquad \text{(eq. 1)}$$

In tab. 2**Fehler! Verweisquelle konnte nicht gefunden werden.** different depreciation parameters and tax rates are presented for the analysed countries showing the additional benefit of depreciating a solar heating plant. The depreciation duration plays a significant role regarding the tax benefit of the solar heating plant, most notable for the declined-balanced method within the first four years. Since nearly all companies solely base capital investment on payback time, the first years are most important in reaching a decision in industrial companies.

[1] Ratio of delivered solar heat to used electricity

Tab. 2: Overview of the depreciation methods and rates in the related countries of the EU

Country	Depreciation method	Depreciation factor[1]	Years of depreciation	Depreciated investment in the first 4 years	Corporate tax rates	Additional benefit[2] within the first 4 years
DE	Straight-line	-	10	40 %	29.88 %	12 %
ES	Straight-line	-	14	29 %	25 %	7 %
FR	Declined-balanced	2.25	10	64 %	34.43 %	22 %
NL	Straight-line	-	5	80 %	25 %	20 %
PT	Declined-balanced	2.5	4	98 %	25.5 %	25 %

As an example, the German depreciation method is fixed to the straight-line method with a 10 years depreciation period and the business tax of 29.83 %. In contrast, the Portuguese depreciation period is reduced to four years and applies the declined-balanced method (with an accelerating factor of 2.5). The business tax in Portugal is 25.5 %. Assuming 100,000 € investment, 40,000 € can be depreciated within the first four years in Germany, resulting in an additional economic benefit of 11,932 €. In contrast, the benefit in Portugal is more than double with 24,955 € within four years, nearly depreciating the entire solar heating plant. For a better understanding of the cash flows regarding both depreciation methods, Fig. 2 shows the annual depreciation rates (bars) and the additional benefit (dashed line) of solar heating plants. The Portuguese results for the declined-balanced method with four years depreciation period are in green and the German straight-line method over ten years is shown in red. Exemplarily, a corporate tax rate of 25 % has been assumed for both calculations for a better consistency. As quickly seen, the tax benefit of both methods is the same over ten years. In Portugal, a greater tax benefit is realised within the first years and as such the payback time is significantly reduced.

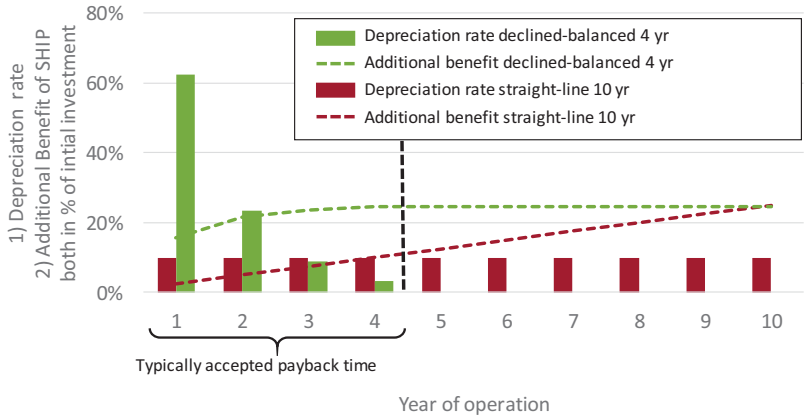

Fig. 2: Comparison between two depreciation methods and duration regarding the depreciation rate and additional tax benefit of a solar heating plant. The depreciation factor for declined-balanced method is 2.5 and the corporate tax rate is 25 %

To conclude, the payback time of solar heating plants in industry is reduced by depreciating capital investments. This boosts the market uptake, already seen in some countries, such as Portugal, France, and also in India. In addition, governmental tax revenue is not affected long term by the inclusion of depreciation and should not be a hinderance in future economic policy.

[2] In relation to the initial investment

3. Results

As already mentioned, numerous feasibility studies including solar heating plant pre-design are carried out within the project "SolarAutomotive". By several case studies in companies specialised in surface treatment, it is seen that this sector in general and electro plating in specific are very promising for the use of solar process heat. In this sector, many baths must be heated and kept at elevated temperatures, easily achievable for solar heating plants. In summer, there is a significant base heat load and any possible heat recovery barely reduces overall heat demand. Solar process heat integration for heated baths is also fairly easy through dimple plates or by external heat exchangers.

Only a few selected case studies are discussed in this work to provide a wide range of examples. For a more detailed assessment on a German electroplating company Pag et al. (2017) details a performed case study and proposes a concept to use of solar process heat in combination with a micro gas turbine.

Tab. 3 shows an overview of the selected feasibility studies, followed by a summarised explanation.

Tab. 3: Overview of the performed feasibility studies
Heating network, supply/return temperature; Heat recovery network, supply/return temperature; Hot water, start..set temperature; Bath heating, bath temperature; Drying, start..set temperature

Country	Sector	Heat sink	Pre-design[1]	Irradiation in kWh/m²a[2]	Specific solar yield in kWh/m²$_{gr}$a	Solar fraction[3]
ESP	Car manufacturing	Heating network, 130/110 °C	4,300 m² ETC	1,670	410	5 %
PT	Car manufacturing	Heating network, 70/40 °C	1,800 m² FPC, 75 m³	1,920	830	34 %
GER	Electro Plating of Plastics	Heating network, 80/70 °C	1,000 m² ETC + 317 kW$_{th}$ CHP,	1,010	350	18 %
NL	Circuit boards	Hot water 15..60 °C	250 m² FPC, 15 m³	1,130	430	5 %
FR	Bearings	Heat recovery network, 80/60 °C	260 m² ETC, 25 m³	1,210	485	5 %
GER	Textile processing	Drying, 10..60 °C	1,200 m² AirC	1,040	480	10 %
SWE	Textile processing	Hot water, 10..60 °C	2,000 m² FPC, 175 m³	1,040	550	23 %
GER	Painting	Bath heating, 43 °C	161 m² ETC, 8 m³	960	390	31 %

3.1 Car manufacturing in Spain

The production site analysis in northern Spain shows that the specific yield does not allow an economic integration of solar heat at the moment, even though there is a good irradiation and significant open land for plant construction. The return and flow temperatures of the central hot water network are unnecessarily high but cannot be lowered due to one single process (wax bath) with a high temperature level. In addition, there are six weeks in summer

[1] If not specified differently, the collector area given refers to the summarised gross area of the collector field
[2] On tilted surface
[3] Solar fraction is given with respect to overall heat consumption (central heating network) or to process heat demand (Hot Water, Bath heating, Drying) if not specified differently.

(two weeks in June and four weeks in August) when the production site is closed completely and the hot water network is shut down. To handle this long period during times of high irradiation without a heat sink, parabolic trough collectors that can be defocused and evacuated tube collectors with a built-in switch-off temperature are considered within the feasibility assessment. The latter concept with 4,300 m² collector area still reaches specific annual yields of more than 400 kWh/m²$_{gr}$. The potential plant site is located more than a kilometre away from the boiler site and complicates the integration. The closest reasonable integration point is 900 m away and still challenging. Due to no subsidy program for solar process heat plants in Spain, an implementation is not realistic and further investigations have been put on hold.

3.2 Car manufacturing in Portugal

Within the production site of a Portuguese car manufacturer, a hot water network is operated with a 70 °C flow and process dependent 40..50 °C return temperature. In addition to heat recovery from the thermal oxidiser in the paint-shop, three gas boilers with an overall capacity of 13 MW provide heat for an annual heat demand of 4.4 GWh. Process heat demand is distributed more or less evenly over the day with a light peak in the morning. Heat demand will be significantly increased due to a doubling of production capacity until the end of 2017. The future designed heat load is estimated to be 7 MWh/d to be served with a flat-plate collector field of 1,800 m². Due to the high local irradiance, a low temperature level and constant load profile, a specific solar yield of 830 kWh/m²a can be achieved. The levelised cost of heat were calculated with 25 €/MWh over 25 years. Despite the four-year declined-balanced deprecation period for solar heating plants in Portugal, the payback time is 15 years due to the low gas price and no other solar process heat plant subsidies.

3.3 Electro plating of plastics in Germany

The analysed electro plating line has a heat demand of 2 GWh/a. Due to a high electrical base load, a combined heat and power plant (CHP) is taken into consideration. In Germany, subsidies for a CHP are paid over a fixed period of full load hours. This opens up the possibility to change the typical dimensioning of a CHP and its operational mode because it is no longer necessary to continually operate the best economic return. To increase the share of heat supplied by CHP in winter, the plant is designed based on the winter load. In return, the CHP is switched off between May and September to avoid inefficient part load behaviour and increased burner cycling. This enables a larger solar heating plant to be integrated, covering a relevant share of the summer heat demand. The residual heat load is covered by a conventional gas boiler. The CHP has a thermal capacity of 318 kW. The collector field is designed with 1,000 m² ETC. This technology coupling covers more than two thirds of the heat demand with low carbon heating technologies (CHP: 50 %, solar: 18 %). The investment is estimated to be 570,000 €, with an internal rate of return of nearly 10 % over 15 years. Using the conventional design rules for CHP (summer load), a CHP with a thermal capacity of only 212 kW could be implemented with no further potential for solar heat due to the reduced heat load during summer that is already covered by CHP.

3.4 Production of circuit boards in the Netherlands

Circuit boards are produced in continuous loop and plunged consecutively into various baths. The company has several production lines with over 500 baths in total (several hundred litres each), with 56 requiring heat up to 60 °C. The baths are electrically heated with an overall nominal capacity of 455 kW. Due to the large number of baths and their small volume, solar process heat integration for direct bath heating would be very complex and expensive. However, the baths are fed with fresh water to compensate evaporation and carryover losses. This is currently done by cold water, which has to be electrically heated. A new concept is developed with a second feed line for fresh water at 60 °C. This enables a simple and cost-efficient possibility to integrate solar heat. The amount of hot water is estimated to be 7 m³/d with a FPC solar process heat potential of up to 250 m². Due to the constant load profile during the week (five days, two to three shifts), a specific yield of 430 kWh/m²a can be achieved (118 MWh/a) and corresponds to a solar fraction of about 5 % with respect to the overall heat demand at the production site. The levelised cost of heat is estimated between 24.5 €/MWh and 37.2 €/MWh depending on the development of the tariffs of the feed-in subsidy scheme.

3.5 Production of bearings in France

The heat for the French production site is currently supplied by a steam boiler. Within 2018, the steam network will be completely replaced by a hot water network with a 70 °C supply and 40 °C return temperature and a condensing gas boiler. Heat recovery from compressed air generation from compression chillers will be implemented and its recovered heat is fed into the network. There is a still a residual heat demand that can partially

be covered by solar heat. A solar heating plant is designed to have 260 m² ETC collectors and includes a storage of 25 m³ generating 126 MWh/a. The levelised cost of solar heat is approximately 20 €/MWh due to an existing national subsidy for solar process heat in France. Following detailed measurements after the implementation of the new heat network, the solar heating plant will be redesigned and built by the end of 2018 if the solar heating plant is still economically feasible.

3.6 Textile processing in Germany

This company with more than 140 employees covers the whole spectrum of product finishing with processes such as sizing, dyeing, and coating of textiles and relating materials. The three-shift operation over five days is very water and energy intensive, constantly needing massive amounts of hot water at different temperature levels up to 90 °C. Due to expansive use of heat recovery from a regenerative thermal oxidiser that purifies exhaust air, the hot water demand is nearly fully covered. The exhaust air originates from several stenters and a dryer that uses fresh air heated to 200 °C. By using all the heat recovery for water (pre-) heating, the fresh air for these applications must be heated internally by internal and external heat exchangers from the central steam network. Solar air collectors can be used to preheat the required air for these heat sinks. Based on the air volumetric flow rates and the set temperatures of the stenters (46,400 m³/h; 200 °C) and the dryer (8,000 m³/h; 140 °C), the heat demand has been estimated by 22.4 MWh/d in summer (ambient air temperature 20 °C), considering a simultaneity factor of 0.5 and 15 hours of operation per day. This results in a yearly heat demand of 5.2 GWh. To cover a relevant share by solar collectors, an air collector system with 1,200 m² is designed and simulated. These collectors preheat the incoming air from ambient temperature to a maximum of 60 °C. The solar heating plant obtains a collector yield of 707 kWh/m²a but only 481 kWh/m²a can be used in the processes due to the lack of storage. Still, a solar fraction of 10 % with respect to the process can be achieved. The estimated investment of 350,000 € including 50,000 € for installation, results in solar heating costs of 12 €/MWh.

3.7 Textile processing in Sweden

The production site is operated 24 hours per day and 6 days per week with a three weeks summer production break. More than 400 m³/d of 60 °C hot water is required for dyeing and washing leading to a daily heat demand of 21 MWh in the summer. The heat demand is met with a steam boiler at 190 °C. To cover the summer daily heat demand, nearly 5,000 m² FPC are theoretically required. A flat roof offers an area of about 10,000 m² but considering roof statics, skylights, and collector spacing the feasible collector area is approximately 2,000 m². Depending on the currently unknown actual hourly load profile the specific solar yield can range between 520 and 580 kWh/m²a and up to 1.2 GWh/a in total. This corresponds to an annual solar fraction of about 22.5 %. A hot water storage of 90 m³ is already installed to ensure the hot water supply during peak demand. This must be complemented with a solar heat storage with up to 175 m³, depending on the load profile and the actual peak loads. During the detailed planning, it will be investigated if the current storage can be used to store the solar heat. Given the size of the collector field, selected technology and integration type, a specific investment of 450 €/m² is estimated. This way, solar heat can be provided with levelised costs of heat of 49 €/MWh, currently below the actual cost of steam.

3.8 Painting process in Germany

This company is specialised in the painting of large scale parts, e.g. of commercial vehicles. In a pre-treatment step, these parts must be removed from rust and debris (pickling). This is done in a 15 m³ acid bath, kept at 43 °C with electrical heaters having a nominal capacity of 42 kW. Measurements show that 28 kW (67 % of the nominal capacity) are constantly required 24 hours per day. The electrical heaters are switched off midday on Saturday until early Monday morning to provide the set temperature for production. This corresponds to a daily heat demand of about 700 kWh in summer and 210 MWh per year.

Based on these data and available roof areas, four solar heating plants with different collector field sizes are designed and simulated with Polysun. Double sided evacuated tube collectors have been chosen due to their low static load when installed. The solar heating heat is integrated with an external heat exchanger into a circulation pipe, which constantly mixes the bath contents. The simulated result are in Fig. 3. The corresponding solar fractions range between 15 % (88 m², no storage) and 58 % (337 m², 32 m³). The company decided for a medium-sized collector field of 161 m² in combination with an 8 m³ storage having a solar fraction of 31 %. Due to expensive electrical energy used to currently heat the bath, a 35 % internal rate of return and a payback time of less than three years can be achieved.

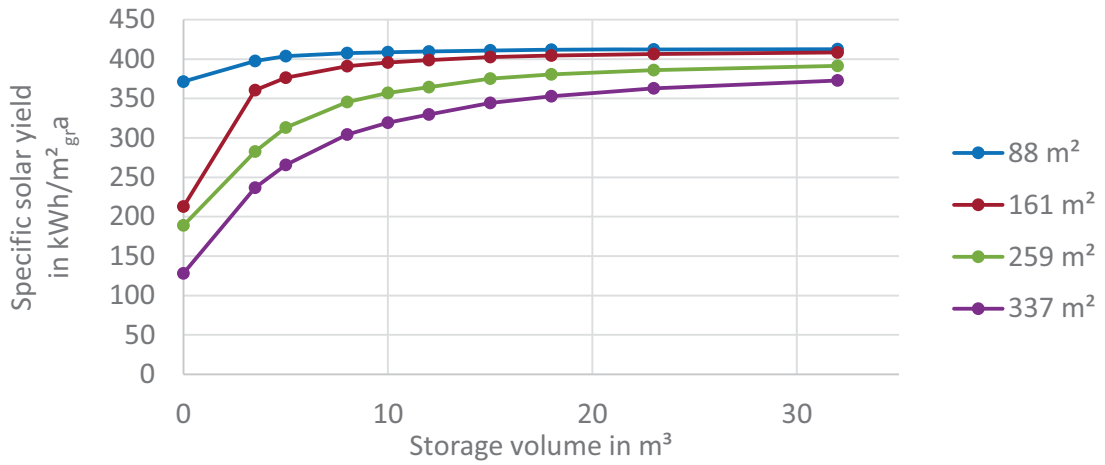

Fig. 3: Specific solar yields for the four different collector field sizes and storage volume variation

The painting hall, where the painting process itself is performed by hand, requires heat that can be covered by solar heat. During the painting process fresh air (74,000 m³/h) must be supplied at 20 °C to guarantee acceptable working conditions. Due to a high load of paint particles, the air cannot be circulated. Afterwards, the painted parts must be dried. Therefore, the hall is heated up to 60 °C with the same air volumetric flow rate as in the painting mode, whereas 67,000 m³/h (90 %) is recirculated and the rest is provided by fresh air. The air volumetric flow rates are provided by an air handling unit that can switch between the painting/drying operational modes and is heated by an air-to-water heat exchanger. A heat recovery system is installed for preheating the fresh air by the exhaust air. By conducting detailed air measurements, it is established that there are either one or two painting cycles per day followed by a drying period during night. Based on these measurements, the heat load profile for the air-handling unit can be calculated and in a further step extrapolated over the year taking into account the seasonal temperature profile of a near-by weather station. The yearly energy demand is estimated to be 270 MWh/a with a daily summer load of 800 kWh/d. By installing an additional heat exchanger, solar heat can be integrated. First simulations recommend a 250 m^2_{gr} ETC solar heating plant. The efficiency of the solar heating plant is increased by varying the supply temperature depending on the actual operation mode (painting vs. drying).

4. Conclusion

The automotive industry and their suppliers have many technical possibilities to integrate solar heat into various processes. In general, central heating networks are available that can be used for solar integration. Depending on the industry sector, there are also individual processes that allow an efficient decentralised use of solar process heat. Generally, companies who specialise in textile and surface treatment, operate multiple baths at a feasible temperature for solar process heat. If there are any restrictions on-site (e.g. space) and solar heat cannot be integrated easily into the baths, the pre-heating of feed-water for carry-over and evaporation loss compensation offers a possibility to cover a small fraction of the overall heat demand with solar heat. Drying for paint-shops, which is comparable to other industries plays a key role with respect to the energy demand. Since fresh air is often needed, the use of solar for air pre-heating can be a cost-effective solution.

Many economically feasible solutions were identified, which were highly dependent on national subsidy programs and on-site boundary conditions. Within the performed case studies, the levelised cost of solar heat ranged between 12 and 49 €/MWh. The most economical concept has an internal rate of return of 35 % and the least economical still has a return of 6 %. Unfortunately, the decision for or against a capital investment in efficiency and renewable energy is still primarily made based on the payback time, regardless of solar process heat's proven long term economic benefit. To help overcome this hurdle, regulations regarding depreciation and corporate tax have a major positive influence on payback time. As such the national tax legislation plays a significant role to obtain the required financial decision metrics by industry.

To date, only a few companies have committed themselves to significantly reduce CO_2-emissions in a way that may conflict with economic decision criteria. Additionally, low natural gas prices currently globally impede further market uptake of solar heating plants. The subsidy programs for solar process heat, if existent, are typically

not sufficient to satisfy the economic targets in industry due to the small difference between the conventional heating costs and the solar heating costs. If some stakeholders in the automotive industry and their suppliers can be encouraged to take the first step, it will be a tipping point for a wider adoption of this reliable, CO_2-free technology. Optimising the depreciation tax legislation for low carbon heat capital investments is a promising possibility to support the necessary market uptake.

Abstract

A solar tunnel dryer system utilizes solar energy to heat up air and to dry any food substance loaded to it, this leads to reduce wastage of agricultural products and prolong their life by natural drying, and has limitations such as, exposure to sunlight, liability pests and rodents, and lack of proper monitoring. The aim of this paper is to design and simulation a solar tunnel dryer for drying of cereal's, fruits and vegetables. In this dryer, the grains have placed directly at absorber and exposed to direct solar radiation. The airflow and associated pressure development in the drying chamber is analyzed with CFD.

The initial and final moisture content considered were 35 and 15 percent for maize, and 94 and 10 percent for tomato. The dryer is designed to dry one-ton of maize in four days, and 250Kg of sliced tomato in two days. The dryer has an integrated fan to drive the moist air, which is powered by energy. The simulation considers Mekelle, weather data as its input.

Keywords: Tunnel dryer; solar dryer; postharvest loss; tomato dryer; simulation of tunnel dryer; Forced dryer

1. Introduction

Food security is a common problem in developing countries that happened not only because of less yields, but also because of poor harvesting and post harvesting management. Proper post-harvest management in developing countries can significantly contribute to the availability of food [2]. Common post-harvest losses are due to improper and/or untimely drying of foodstuffs such as cereal, grains, pulses, tubers, meat, fish, etc…[2]. Traditional drying, which frequently performed on the ground in an open air, is the most widespread method used in developing countries because of its simplicity and does not incur additional cost. Nevertheless, this drying technique has many drawbacks contamination, uneven drying, and uncontrolled moisture content of the products, which in return causes degradation in quality, insect infestation, and attack by animals etc. Traditional dried food items does not fulfil the international quality standards, and it has international market process [4].

To improve the traditional drying techniques, solar dryers have received considerable attentions to improve post-harvest management [1]. Though many developing countries are endowed with higher solar energy potential, unfortunately solar dryers have not well introduced, on these regions the reason for the less technology infiltration includes such as; economically unviable, unsatisfactory technology development and limited knowledge of the technology [3].

Like many developing countries; the, majority of the population of Ethiopia engaged in farming and about 80% the countries food products cultivated by small farmers, these farmers do not use proper postharvest management technologies, but the traditional open air dryer techniques. In this regard, the development and introduction of solar drying as post-harvest technologies are significantly important in improving livelihood development of developing countries [24].

Many solar dryers have been introduced, but accomplishing it is very important performed unsatisfactorily. There is a need to understand the overall operation of the dryer, the interaction between its component parts, the influence of various design and operating parameters on its performance, and the development of systematic design procedures and guidelines. These technical constraints have been limiting the use of natural convection solar dryers. In addition, during drying some materials absorb heat directly from the radiation of the sun and tends to

doi:10.18086/swc.2017.26.12 Available at http://proceedings.ises.org

decolorization of the product, which decrease the quality of the product.

Solar dryers of forced convection type can effectively be used. However, which needs power to drive the fan, and unfortunately many rural areas, do not have power. Because of this forced convection were not introduced widely in many developing countries. In direct driers have low drying rate compare to direct forced dryer, but they have better quality and have potential to access the market as a result it enhances the income of individual farmers [3].

According to FAO report in 2000, Ethiopia produces 115,000Mg from 7,800 hectare and increased to 10,000 ha and 150,000 Mg in 2008(FAO, 2010). Most of the fruits produced in Ethiopia are consumed locally.

Fresh fruits are regarded as highly perishable and bulky commodities as they contain more than 80% moisture. Consequently, their transportation to distant places is costly and their condition on arrival might be less than satisfactory. The best way to maintain the nutritional value of fruit is by keeping the products fresh. On the other hand, its cold chain is difficult to maintain throughout the developing countries. Fruits have an average shelf life of 7 to 36 days [6]. Those losses at fruits could be happen because of thing, poor postharvest handling, and market conditions. For example during the rain season harvesting period of these exist excess, but according many losses happened on the country shortage of supply happens during the other period of the year this cause fluctuation in market.

In this paper crop, fruit and vegetable have considered for drying, Modelling and Simulation of a forced convective solar tunnel dryer has studied. CFD has used to show the flow through the duct and to simulate air pressure and air velocity profiles in the drying chamber.

2. Materials and Methods'

2.1. Solar Tunnel Dryer Construction Material Selection

The construction materials of the solar tunnel dryer based on its quality and suitability. The materials include absorber, metal frame, drying tunnel, rolling bar, concrete block substructure, PV module and fan. Solar absorber is a device that receives solar radiation and converts it into thermal energy. The absorber material is mild steel of thickness 0.9mm or (24.2 × 2 × 0.0009 m). The absorber is black painted metallic in order to increase its absorbance thereby heating the air between it and the cover.

The absorber and the cover have created a triangular shaped tunnel. This tunnel volume of 0.044 m^3 air is heated and the hot air is transported by means of forced convection

The cover plate: of the dryer is transparent sheet used to cover the absorber, to prevent dust and rain entering to the absorber. It permits solar radiation into the system, but hinders reflected radiation from the system. This cover plate is made up of glass with thickness 4 mm or (24.2 × 2.3 ×0.002 m).

Drying Tunnel: is the drying chamber made of a highly polished plywood box (24.2×2 ×0.016 m) held in place by galvanized iron, the material has been chosen because of its poor thermal conductivity , its smooth surface finish, and minimized radiation loss. The cover of the drying chamber is corrugated plastic of thickness of 2-3 mm, or (24.2 ×2.3 × 0.002 m). In order to reduce with radiation and avoid moisture absorption by the wood aluminum foil is wrapped on the inside of the chamber, with Nail and glue fasteners.

Insect net at air inlet and outlet has used to prevent insects from entering into the dryer. The hinges and handle for the dryers door.

Brick block: have used to protect bending of the dryer and collectors structure with dimensions (0.4×0.4 ×0.5 m). The frame has covered by aluminum wire mesh to hold the product to be dried. Axial Fan has selected because of its low static pressure, is required to drive the moist air out of the dryer and the fan has 18 m^3/min with a power of 0.626 Hp (0.46 kW).

Insulators: the insulation material used in this system is fiberglass with 150 mm thickness under the absorber surface, which compromises 48.5 x2 x0.15 m^3 volume of material.

2.2. Methods

The design of the solar tunnel dryer taken into consideration different design criteria and parameters. Some of these were from literature while others were determined by a series of mathematical analysis. The design parameters included environmental conditions of the test location, drying temperature, amount of moisture to be removed, heat energy requirement and airflow required.

The test location is found at a latitude 13° 29′ N and longitude 39° 28′E with elevation of 2084 m. ambient temperature, Ta, of 24℃ and relative humidity 55 %.

Then the following models are applying through the tunnel dryer.

Mathematical

Geometric modelling

Simulation

The mathematical modelling developed for the tunnel dryer is standing form cooling law, and the geometrical modelling is verified using Catia or simply ANSYS software, finally the simulation of the solar tunnel dryer is going on ANSYS Fluent software with version 15.01 the helping of designed and environmental conditions.

3. Analysis

3.1. Input data

The weather condition of Mekelle is obtained from National Metrology Agency

- The average sunshine is 8 hours
- Average temperature is 240C
- Relative humidity 55%
- Drying temperature is 600C
- Solar radiation average 697.8W/m2

3.2. Design

The design analysis sets dimension components of solar tunnel dryer, and the thermal analysis of the tunnel dryer. The total load of the drying is one tone maize to be dried in 8 sunshine hours. The 5000 cobs of maize is required with an average mass 0.2Kg each Maize has fed at once. Referee in the tale shows the design parameter of the solar dryer.

Table 1:

No.	Description	Equation	Result
1.	The mass of water evaporated from the product	$m_w = m_t[(M_i - M_f)/(100 - M_f)]$	235.3Kg
2.	Equilibrium Moisture content	$M_e = \frac{w_m c k a_w}{(1 - k a_w)[1 + (c-1)k a_w]}$	10.33
3.	Water activity	$a_w = 1 - \exp[-\exp(0.914 + 0.5639\ln(M))]$	0.61
4.	Equilibrium relative humidity	$ERH = 100\, a_w$	61%
5.	Initial humidity ratio	$\varnothing_i$	0.012
6.	Final humidity ratio	$\varnothing_f$	0.021
7.	Initial Enthalpy	h_i	50KJ/Kg
8.	Final Enthalpy	$h_f = 1006.9T + \omega[2512131 + 1552.4T]$	115.13KJ/Kg
9.	Mass flow rate	$\dot{M}_a = \rho_a * V_a$	0.24Kg/s
10.	Total Energy	$E = M_a(h_f - h_i)$	1778MJ
11.	Area of collector	$A_c = \frac{E}{I\eta}$	56m^2
12.	Drying area	$A_{dr} = l * b$	48.5m^2
13	Volume flowrate of fan		420.3 CFM
14	Power of fan = $\frac{air\ flowrate(CFM) * static\ pressure}{6320 * fan\ efficiency}$		0.46 KW
15	Pv panel	Three panels	1020 W
16	Page Model $M(t) = (M_o - M_e)e^{-K t^n} + M_e$		K= 0.311 n = 0.873
17	Midilli et al model $M_R = a\, e^{(-K t^n)} + bt$		a = 0-99 K= 0.14 n = 0.711 b = 0.00108

Table 2: The loading rate per batch of the drying products

SN	Name of the drying products.	The loading rate per batch	Loading density in Kg/m2
1	Maize	1000 Kg	30.3
2	Tomato	250 Kg	7.6
3	Potato	330 Kg	10
4	Onions	300 Kg	9
5	Grape	315 Kg	9.5
6	Fish	335 Kg	10
7	Banana	310 Kg	9.4

3.3. fan

Drying depends on airflow rate and the ability of the air to carry moisture. The fan should move air through the grain by overcoming the resistance to flow. This resistance to airflow is the static pressure drop through the grain. Multiply this pressure drop for clean grain by a factor 1.3 to 1.5 to adjust for packing and foreign material in the grain. This value varies depending on the cleanliness and physical properties of the grain. A value of 1.3 is commonly used for wheat and 1.5 for other crops [21].

By considering the specific volume of air from the psychrometric chart, the volume flowrate required to be 731.6 m3/ hr.

3.4. Fan drive

The fan should run under forecasted weather conditions. The PV panel therefore needs to be chosen bigger. A factor of 2.5 is reasonable. If a fan requires 2W it should choose as 5 W panels [22]. It is best to select the PV panel with 340 watt per unit cell, and the solar tunnel dryer needs 3 panels to drive the fan.

3.5. Model preprocessing

Figure 1, shows the placement of Maize cobs inside the tunnel dryer. The cobs have ordered in parallel to the direction of airflow and have a gap of 5 mm each other in order to expose the surface of drying product to the heated air, and creates uniform drying products.

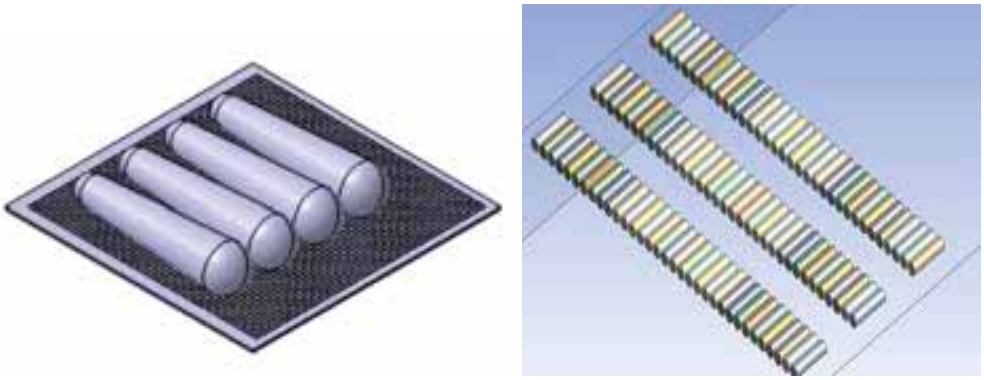

Figure1, Placement of Maize inside a solar tunnel dryer

The geometrical modeling of the dryer is shown in Figure 2 model consists of transparent glass, cob tray, absorber, insulation and the supporting walls.

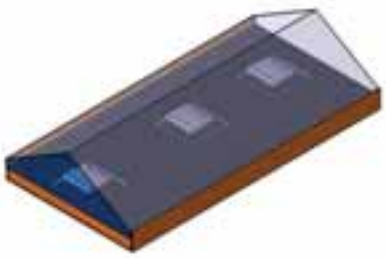

Figure2, Sample geometrical modeling of solar tunnel dryer.

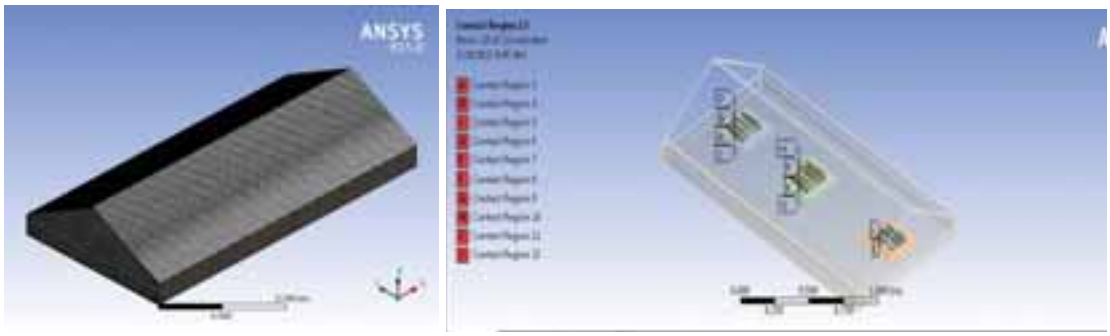
Through this edge two types of meshing for three-dimensional models have applied, Cut cell and tetrahedrons. This study use Cut cell meshing type, because of its convenient for assembly better accuracies of analysing and come up with distributed loads. In additionally, the Cut cell algorithm is suitable for a large range of applications.



(a) (b)

Figure 3: cut cell meshing of the solar tunnel dryer. Figure 4, model contact regions of the product after meshing.

There are five types of zones considering the entire of solar tunnel dryers.

1. Inlet zones: this is the flowing of air in the inlet conditions.
2. Out let zones: this is the properties of air at the exit sides.
3. Absorber: Energy accumulated in the black painted sheets.
4. Insulation: this protects energy losses from absorber.
5. Wall zones: this is considered on both sides of the solar tunnel dryers.

The figure 5, shows the model contact regions of the product after meshing.

This show the continuity and energy equations converge to some constant value after some iterations.

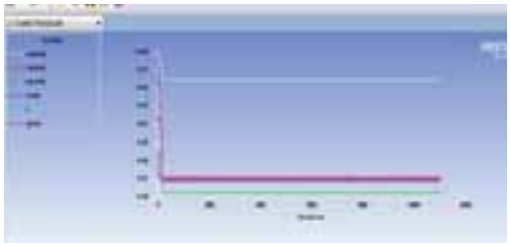


Figure 5, iteration of Maize for a solar tunnel dryer.

4. Results and discussion

4.1. Drying of Maize

Figure 6 and 7 moisture content on dry biases versus the drying time of maize. This model is based on the Midilli et al model since it is more convenient to describe on maize drying. Drying is faster in the first two days then it evaporates its moisture slowly until constant drying happen, there after the maize will reach its minimum moisture content or the equilibrium moisture content of the products.

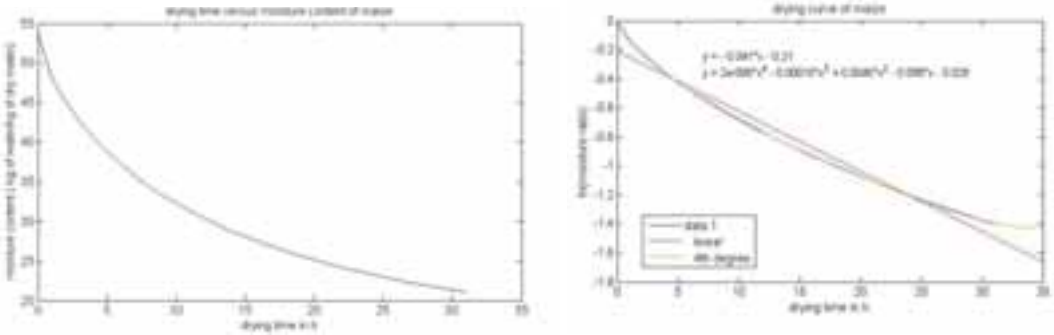

Figure 6, Drying time versus moisture content for Maize Figure 7, Drying curve of Maize

Figure 7, shows the log of moisture ratio versus drying time, which represents the typical characteristic-drying curve of maize during thin-layer drying operation when using solar tunnel dryer. The drying constants are = -0.041 and = 1.233 are the slops and constants of the linear drying curves respectively. The drying curve is above the linear trend for the first five hours and below the linear line up to twenty four hours.

The temperature contour of fluid flow is displayed here at the position of the solar tunnel dryer at different time intervals, then the maize absorbs heat and its moisture releases as the heated air passes over the maize. The flowing air rises up its temperature from the absorber to the upper glass, and reaches the maximum drying temperature.

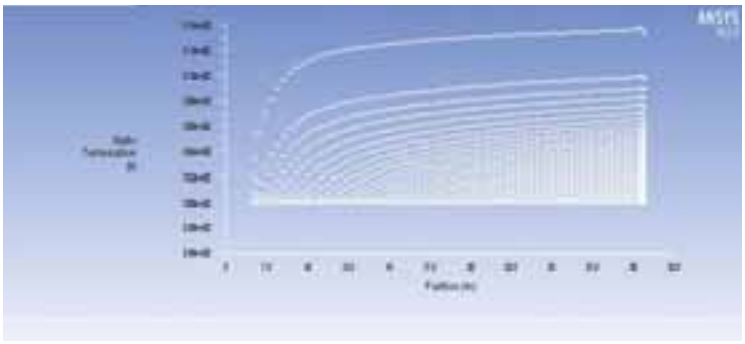

Figure 1, Temperature contour of interior fluid inside a solar tunnel dryer

Pressure contour is defined as the pressure distribution across the length of the tunnel dryer. It helps to define the pressure variation between flowing heated air. The streams of static pressure is maximum at the exit as seen from the figure 9.

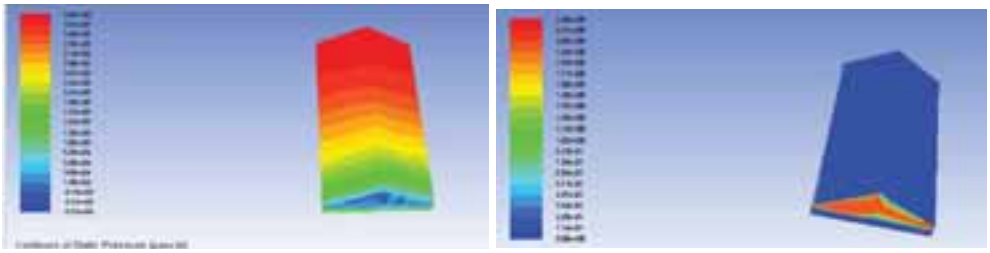

Figure 9, Pressure contour of interior fluid Figure10, Velocity contour of flow ai

Figure 9&10, shows velocity contour, which justifies the velocity distribution across the solar tunnel dryer.as the velocity is maximum at the center, and decreases from center towards the absorber and the cover plate sides. Therefore, grains remove its moisture content when exposure to warm air flow.

The velocity shown is the velocity of the interior fluid that passes through the drying products and the velocity is maximum near the center and drops down when the flow is near the walls. Line 15 which lies in the coordinate x (0, 24.2) and y (1, 1), and line 16 which lies in the coordinate x (0, 24.2) and y (2, 2) shown in the figure describes the velocity throughout the length of the solar tunnel dryer at the center and near the wall side respectively. Therefore, the two flows near the wall have frictional effects and have a zero velocities.

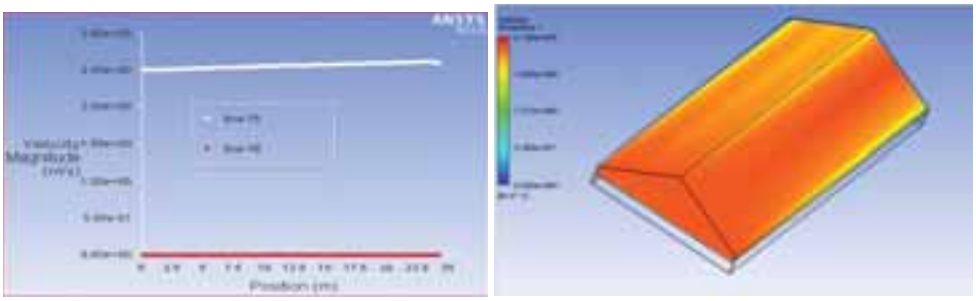

Figure11, Velocity flow interior fluid inside solar tunnel dryer Figure12, Velocity stream line flow

4.2. Modeling of Tomato in solar tunnel drying

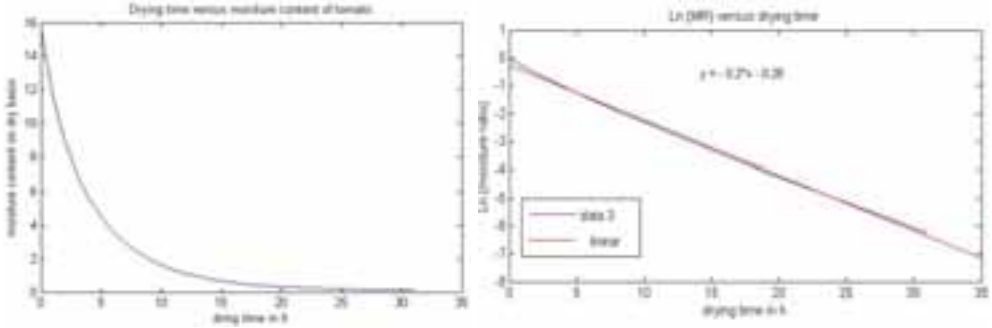

Figure13, Drying time versus moisture content of tomato Figure14, Drying curve of tomato

The figure above shows the moisture ratio versus drying time, which represents the typical characteristic-drying curve of Tomato during thin-layer drying operation. From the Henderson and Pabis model of equation (14) the slope and the constants are k = 0.2 and a = 0.755 respectively.

When we see the drying time characteristics of tomato and maize on same solar tunnel dryer tomato will have a faster drying rate than maize, this tells us products with higher moisture content have higher drying rate than lower moisture content on wet biases.

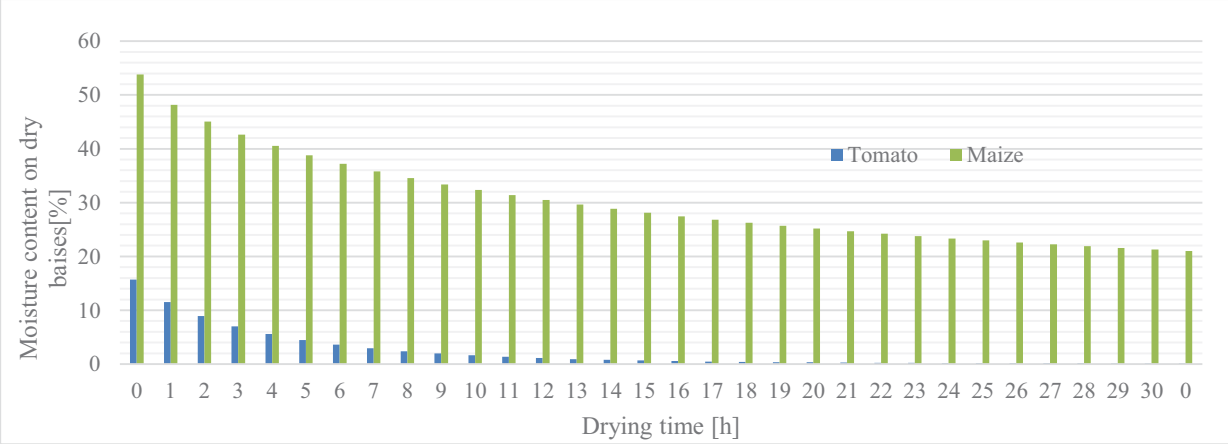

Figure15, Comparison of Tomato and Maize on moisture content versus drying time

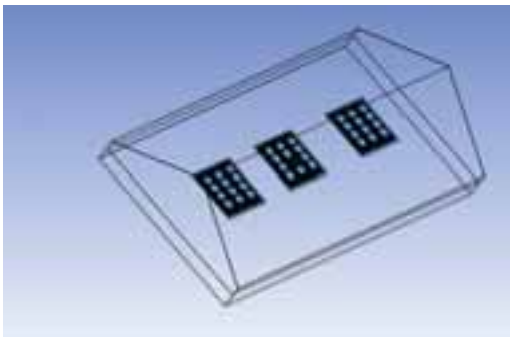

Figure16, This is the arrangement of the Tomato in the solar tunnel dryer

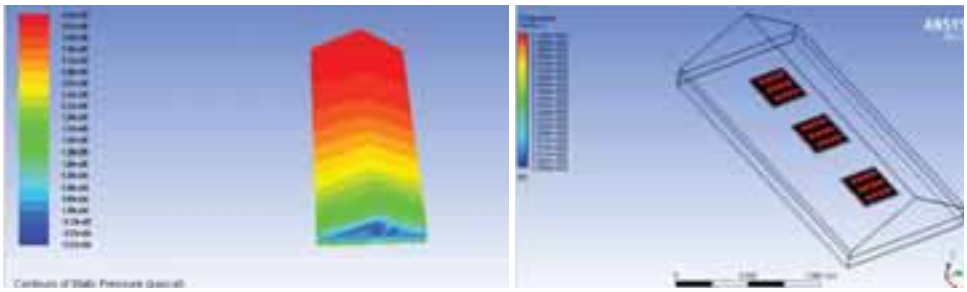

Figure17, Pressure contour of interior fluid. Figure 18, Temperature contour of tomato in side the solar tunnel dryer

The figure shown below is the velocity distribution of the solar tunnel dryer for Tomato, and has a velocity of around 2.4 m/s at the center and 1.12 m/s near the wall.

Figure 19, Velocity contour of tomato Figure20, Velocity of interior fluid flow inside a solar tunnel dryer throughout the length

The figure 20 shows the velocity flow inside a solar tunnel dryer and this velocity is turbulent effect near the walls and flow at the centers are as shown blow. Therefore, the given lines, line 14 or the coordinates of x (0, 24.2) and y (0, 0), line 15 or the coordinates of x (0, 24.2) and y (1,1), line 16 or the coordinates of x (0,24.2) and y (2,2), line17 or the coordinates of x (0, 24.2) and y (1.5) , and line 18 or the coordinates of x (0,24.2), y(0.5)

The figure 21, shown is the velocity stream line of Tomato, hence the flowing hot air is passing over the product which tells us the sliced tomato are in contact with flowing air and, evaporation takes place.

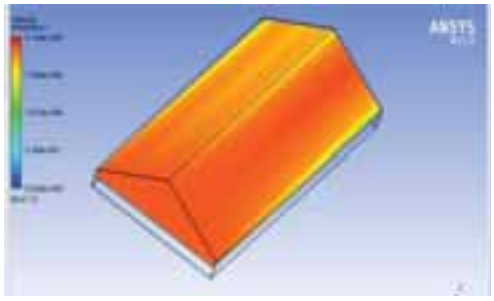

Figure21, Velocity streamline of tomato

5. Conclusion

A solar tunnel dryer was designed and simulated based on Preliminary investigations of maize. The designed solar tunnel dryer to be used to dry maize, tomato, potato and other under controlled conditions. The designed dryer with a collector area of 48 m2 is expecting to dry one-ton maize and 250 Kg of sliced tomato from 35 to15 percent and 94 to 10 percent wet basis in four and two days respectively during harvesting period. A proto type of the solar tunnel dryer was simulated and discussed the results.

Fatigue characterization of potable water certified PA and PPA grades for solar-thermal applications

Patrick R. Bradler[1], Joerg Fischer[1],
Gernot M. Wallner[1] and Reinhold W. Lang[1]

[1] Institute of Polymeric Materials and Testing / Johannes Kepler University, 4040 Linz (Austria)

Abstract

A material screening method for potable water certified plastics for solar-thermal applications based on superimposed cyclic mechanical loading was conducted. One aliphatic polyamide and three semi-aromatic polyphtalamide grades with various glass fiber contents were characterized on specimen level. Therefore, an electro-dynamic testing machine equipped with an in-situ testing device was used to obtain the crack growth kinetics at different temperatures (23°C and 80°C) in different media environments (air and H_2O) . At 80°C in H_2O, specimens revealed a significantly reduced fatigue crack growth resistance compared to tests at the reference conditions of 23°C in air. Comparing all investigated materials at 80°C in water, the polyamide grade and one polyphtalamide grade revealed the best performance. Due to different slopes in their FCG curves, PA-GF30 showed a superior crack growth resistance at low FCG rates.

Keywords: polyamide, polyphthalamide, fatigue crack growth, superimposed loading

1. Introduction

The performance of polymeric materials is strongly dependent on the mechanical and environmental loading conditions (Stern et al., 1998a; Stern et al., 1998b; Lang et al., 2005). Hence, tests are necessary under application relevant conditions. An objective in former research (Schoeffl et al., 2014; Fischer et al., 2016) was to develop and implement advanced testing methods for the evaluation of the long-term behavior of polymeric materials for solar-thermal collectors under service relevant loading conditions (e.g., for an integrated storage collector system). To fulfill the application requirements for pressurized integrated storage collectors maximum internal pressures of 4 bar and maximum application temperatures of 95°C should be considered (Solecrafte, 2017).

While in previous papers, fatigue crack growth kinetics of polyamide under superimposed mechanical loads were described properly (Fischer et al., 2016) and a lifetime prediction approach (Bradler et al., 2016) was presented, this paper deals with the investigation of potable water certified polyamide (PA) and polyphtalamide (PPA) grades with various glass fiber contents under different superimposed mechanical and environmental loads.

2. Background

Polyamides can be classified according to their composition in different polyamide types. Two of them are used in this study, namely (1) the aliphatic polyamides (PA) with an aliphatic main chain including the well known Nylon or PA 6.6 (Gilbert and Brydson, 2017), and (2) the polyphtalamides (PPA) with a semi-aromatic main chain (Wypych, 2016). In single-loop solar-thermal collector systems, potable water is acting as heat carrier fluid (Köhl et al., 2012). Hence, various system components are getting in contact with drinking water. Materials used for such applications should have an adequate drinking water certificate, which is limiting the use of stabilizers. Several studies are describing the negative impact of the lack of stabilizers on the fatigue crack growth (FCG) behavior and thus on the long-term failure (Lang et al., 1997; Pinter and Lang, 2003).

The long-term failure of polymers is usually characterized by the concept of linear elastic fracture mechanics (LEFM) (Hertzberg and Manson, 1980; Lang, 1980). For these tests, some requirements have to be fulfilled (i.e., small plastic zones and a linear-viscoelastic material behavior) (Lang, 1980; Lang et al., 1982). Based on results of fracture mechanics tests, a FCG kinetics curve can be plotted, which is a double logarithmic plot of the fatigue crack growth rate da/dN vs. the stress intensity factor range ΔK_I. The resulting plot can be subdivided into three characteristic regions, where region I describes the threshold, region II describes the stable crack growth which can be described by a power law equation (see eq. 1) (Paris and Erdogan, 1963), and finally region III describes the unstable crack

doi:10.18086/swc.2017.27.01 Available at http://proceedings.ises.org

growth at high plastic deformations. Details and the characteristic plot are described elsewhere (Fischer et al., 2016; Bradler et al., 2017).

$$\frac{da}{dN} = A \cdot \Delta K^m \qquad \text{(eq. 1)}$$

The stress intensity factor range ΔK_I for a cyclic loading (s. eq. 2) describes the difference between the maximum and minimum stress intensity factor ($K_{I,max}$ -$K_{I,min}$) in the loading mode I, which indicates crack opening. "$\Delta\sigma$" describes the difference between maximum and minimum global loading, "a" the crack length and "Y" a geometry and specimen dependent shape factor.

$$\Delta K_I = \Delta\sigma \cdot \sqrt{a} \cdot Y \qquad \text{(eq. 2)}$$

3. Methodology and experimental

Materials and specimens

One aliphatic polyamide (PA) and three different semi-aromatic polyphtalamide (PPA) grades were investigated regarding fatigue crack growth (FCG) resistance. An overview of selected information on these grades is given in Table 1. The grades are varying in chemical composition as well as in glass fiber content.

Tab. 1: Material designation, grade, and glass fiber content.

Material designation	Grade	Glass fiber content
PA-GF30	polyamide 6.6	30 w%
PPA-GF40	polyphthalamide	40 w%
PPA-GF50-1	polyphthalamide	50 w%
PPA-GF50-2	polyphthalamide	50 w%

Fig. 1 depicts a standardized compact type (CT) specimen (E08 Committee, 2000; ISO/TC 156 - Corrosion of metals and alloys, 2011). Specimens were manufactured via milling out of injection molded plaques. According to previous results (Schlaeger, 2015; Fischer et al., 2016), for FCG tests with glass fiber reinforced polyamides and a specimen thickness of 4 mm, specimens with the initial crack in flow direction are most critical.

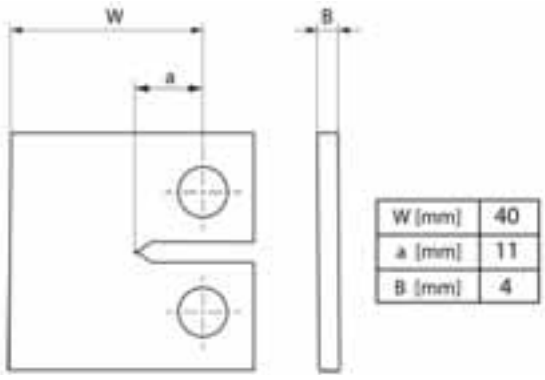

Fig. 1: Compact type (CT) specimen with relevant dimensions for data reduction.

Fatigue tests and data reduction

All FCG experiments were carried out on an electro-dynamic testing machine (Instron ElectroPls E3000; Nordwood, USA). For tests under different environmental conditions, an in-situ testing device was used, which was originally implemented for tests in liquid hydrocarbons by Schoeffl et al. (Schoeffl, 2014; Schoeffl et al., 2014). All tests were conducted with a frequency of 5 Hz and a sinusoidal loading with an R-ratio of 0.1. The R-ratio describes the ratio between the maximum to minimum applied stress intensity factor. The subsequent calculation of the stress intensity factor range "ΔK " was done according to eq. 3 (Gross and Seelig, 2011), where "ΔF" is the difference between maximum and minimum applied force, "B" the thickness of the specimen, "W" the width of the specimen and "f(a/W)" a geometry dependent shape factor.

$$\Delta K = \frac{\Delta F}{B \cdot \sqrt{W}} \cdot f(a/W) \qquad \text{(eq. 3)}$$

4. Results and discussion

The effect of different temperatures and different media on the fatigue crack growth resistance of the grade PPA-GF50-2 is shown in Fig. 2. In terms of temperature, in both media, the material performance was enhanced at the lower temperature of 23°C. At both temperatures, inferior FCG resistances were determined in water. These results are exhibiting hot water as the more critical environment compared to air and are in good agreement with conventional aging data obtained in another research (Geretschlaeger and Wallner, 2016). All further tests were carried out at the best and worst conditions, 23°C in air and 80°C in water, respectively.

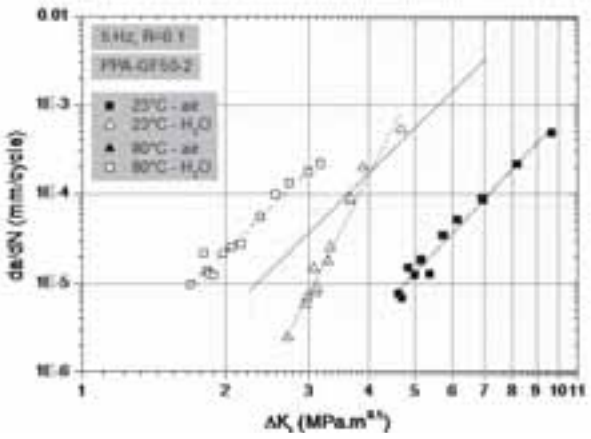

Fig. 2: Fatigue crack growth kinetics for the grade PPA-GF50-2 at various temperatures in various media.

A comparison of the FCG kinetics curves for the two polyphtalamide grades with the same glass fiber content of 50 w% (PPA-GF50-1 and PPA-GF50-2) tested at the best and worst environmental conditions is depicted in Fig. 3. Tests at 23°C in air exhibited a better FCG behavior for both materials compared with tests at 80°C in water, resulting in higher ΔK_I-values at specific fatigue crack growth rates. The material PPA-GF50-1 reveals a better FCG resistance at both conditions. At a comparable rather low crack growth rate of 2E-5 mm/cycle, the difference between the ΔK_I-values of the two materials at 23°C in air is given with a factor of about 1.2 and at 80°C in deionized water with a factor of about 1.6. The results obtained are exhibiting a higher sensitivity of the PA-GF50-2 grade against elevated temperatures and water environment.

Due to the same chemical composition of the matrix material, the grades PPA-GF40 and PPA-GF50-1 are only differing in their glass fiber content. Thus, for these two materials, the effect of glass fiber content on the FCG rates was investigated and is depicted in Fig.4. While the grade PPA-GF40 with the lower glass fiber content of 40 w% shows an inferior FCG resistance, the PPA-GF50-1 with 50 w% of glass fiber reinforcement reveal clearly a higher

FCG resistance.

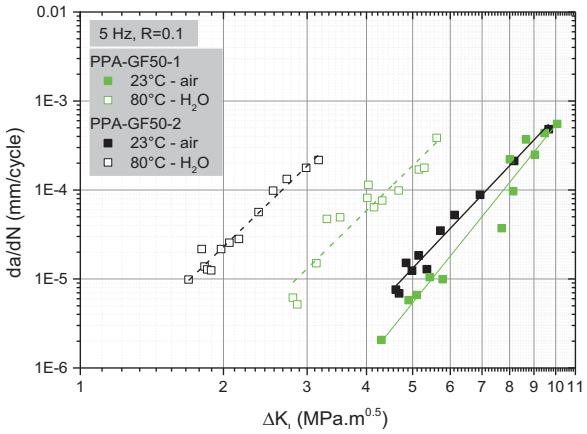

Fig. 3: Fatigue crack growth kinetics for PPA grades with 50 w% glass fiber reinforcement at 23°C in air and at 80°C in water.

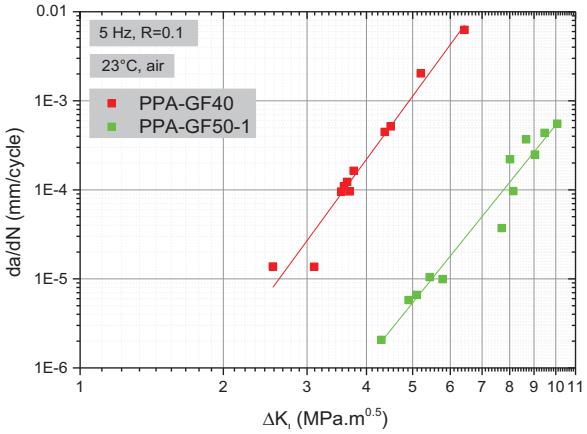

Fig. 4: Effect of glass fiber content on the fatigue crack growth kinetics for the PPA-grades at 23°C in air.

As, in this study, the most critical environmental condition for fatigue crack growth is 80°C in water, all materials were tested at this condition and resulting FCG curves are illustrated in Fig. 5. The grade PPA-GF40 shows a significantly lower FCG resistance, leading to a factor 2.6 lower ΔK_I-value at a crack growth rate of 2E-5 mm/cycle compared with PA-GF30, the best performing material at low crack growth rates. For PPA-GF50-2 and PPA-GF50-1 compared to PA-GF30, lower ΔK_I-values with a factor 1.9 and 1.2, respectively, were obtained. PA-GF30 exhibits a superior crack growth resistance at low crack growth rates. Due to a different slope in the FCG curve, at high FCG rates, PPA-GF50-1 is slightly better.

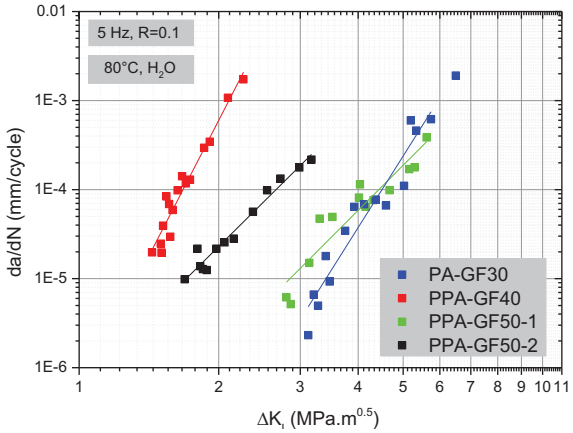

Fig. 5: Fatigue crack growth kinetics for all investigated material grades at 80°C in water.

5. Summary and outlook

The fatigue crack growth (FCG) resistance of one aliphatic polyamide and three semi-aromatic polyphthalamides varying in their glass fiber content was investigated. Due to their certification for the transport of potable water, these materials are of high relevance for solar-thermal applications. Fatigue crack growth measurements were performed at application relevant conditions in two environmental media (air and water) at two temperatures (23°C and 80°C). For the polyphtalamide PPA-GF50-2, tests at all four environmental combinations were conducted resulting in the best performance at 23°C in air and in inferior FCG resistance at 80°C in water. As to the glass fiber content of the polyphthalamides, PPA-GF50-1 showed superior FCG behavior and PPA-GF40 revealed inferior fatigue crack growth resistance. Comparing all investigated materials at 80°C in water, the aliphatic polyamide PA-GF30 and the polyphtalamide PPA-GF50-1 revealed the best performance. Due to different slopes in their FCG curves, PA-GF30 showed a superior crack growth resistance at low FCG rates. Conversely, at high FCG rates, PPA-GF50-1 is slightly better.

In this study, a very fast screening method for materials for solar-thermal applications, especially for reinforced plastics, was introduced. Based on an extension of the test program in terms of testing at different R-ratios, in a further study a lifetime prediction of these materials could be conducted.

Field test results of an innovative PV/T collector for indoor swimming pools

Laetitia Brottier[1,2] and Rachid Bennacer[2]

[1] DualSun, Marseille (France)

[2] LMT /ENS-Cachan/CNRS/Université Paris Saclay, Cachan (France)

Abstract

Hybrid solar PV/T has the potential to become a major player in the renewable energy sector, but one of the most important barriers is the inexistence of a proven track record in terms of reliability and performance. In order to address this issue, a study was conducted to monitor in-field energy performances of two indoor swimming pool installations near Perpignan (France) equipped with an innovative unglazed PV/T collector (1.64m², 250Wp, 912Wth).

With 300m² of PV/T collectors for a 1100m³ indoor swimming pool and 6000L/day of hot water needs, an annual thermal production of 120MWh and an annual photovoltaic production of 64MWh were achieved. Performances were higher than simulated with the TRNSYS study.

Keywords: Photovoltaic thermal (PV/T) collector; Field test; Energy performance

1. PV/T characteristics

A review of PV/T technologies has been done by Zhang et al. (2012) and Good et al. (2015). The PV/T module in the study is based on the unglazed flat-plate liquid design described in these reviews. It has 60 monocrystalline cells for a nominal power of 250Wp. The photovoltaic characteristics are given in table 1.1. The thermal characteristics (table 1.2) were determined by tests conducted at the TÜV Rheinland laboratory following the Solar Keymark certification rules (ISO 9806 : 2013).

Tab. 1: Electrical and thermal characteristics

Electrical characteristics	
Dimensions	1677×990×40 mm³
Number of cells	60
Type of cells	Monocrystalline (6 inches)
Nominal power (P_{mpp})	250 Wp
PV module efficiency (η_{PV})	15.40% (Tolerance : ±3%)
Power loss /°C (βp)	-0.44% / °C

Thermal characteristics	
Heat transfer fluid (HTF)	Water/glycol mix
Absorber surface area	1.58 m²
Conversion factor (η_0)	57.8%
Heat loss coeffiient (b_1)	12.08 W/K/m²
Wind dependency of collector efficiency (b_U)	0.028 s/m
Wind dependency of heat loss coefficient (b_2)	1.842 W.s/K/m³

2. Presentation of the two field tests

Indoor swimming pool systems coupled with PV/T collectors have already been studied by simulation by Buonomano et al. (2015), but few experimental works have confirmed the expected performances with real installations, as has been done in this study.

For the two indoor swimming pools in the study, the PV/T modules are connected to heat exchangers and are used to preheat the water for the showers and to heat the pools. As an auxiliary heat source, a heat pump is connected in series to the solar heat exchanger to heat up the water instantly when needed. In the case that the system does not

doi:10.18086/swc.2017.27.02 Available at http://proceedings.ises.org

provide enough heat, the system is completed if necessary with a natural gas boiler. In order to monitor the system, a calorimeter is placed just before the solar heat exchangers.

Data were recorded every 5 minutes. A diagram of the system and the monitoring is given in Figure 1.

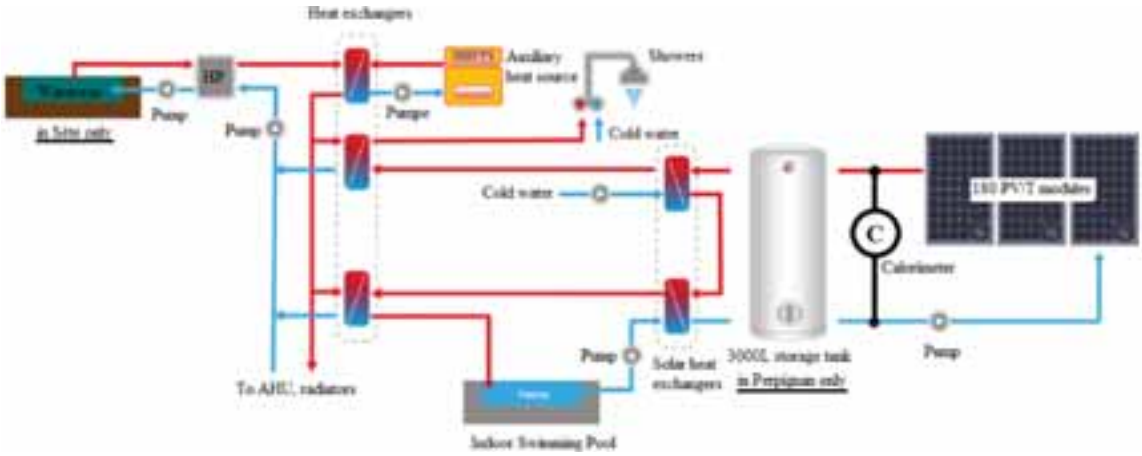

Fig. 1: Simplified hydraulic scheme and monitoring system put in place

In order to verify the in-situ reliability and performance for indoor swimming pools of the innovative hybrid solar PV/T module, two installations were monitored near Perpignan in the South of France (Lat/ Long. 42.6976 / 2.8954). In Perpignan according to Meteonorm, the maximum ambient daily temperature in the day is on average 19.6°C and the maximum daily irradiation in the day is on average 576W/m² over the year.

In Sete (Figure 2) as in Perpignan (Figure 3), 180 PV/T modules were installed as a solar canopy.

Fig. 2: picture of the PV/T canopy for the municipal swimming pool of Sète (France)

Fig. 3: picture of the PV/T canopy for the municipal swimming pool of Perpignan (France)

Key parameters of the two solar installations are provided in Table 2.

Tab. 2: parameter of the 2 installations

	Sète	Perpignan
Swimming pool dimensions	720 m² for 1100 m^3 = 1 056 MWh/an	730 m² for 1095 m^3 = 1 016 MWh/an
Pool temperature setup	28 °C	
Shower needs	~ 6000L/day = ~ 125 MWh/an	
Number of unglazed PV/T	180 (300 m²)	
Integration type	Solar canopy	
Orientation (0° = South)	South-East (-20°)	South (0°)
Slope	10 °	30 °

The solar energy goes to hot water preheating if the temperature of the panels is 6°C higher than the bottom of the sanitary tank or to the pool if it is higher than 30°C. The panels and the technical room, where the heat exchangers and the calorimeter are located, are separated by a distance of 70m. The pipes are buried over this distance.

3. TRNSYS study

A TRNSYS model has been performed, the diagram is given in Figure 4.

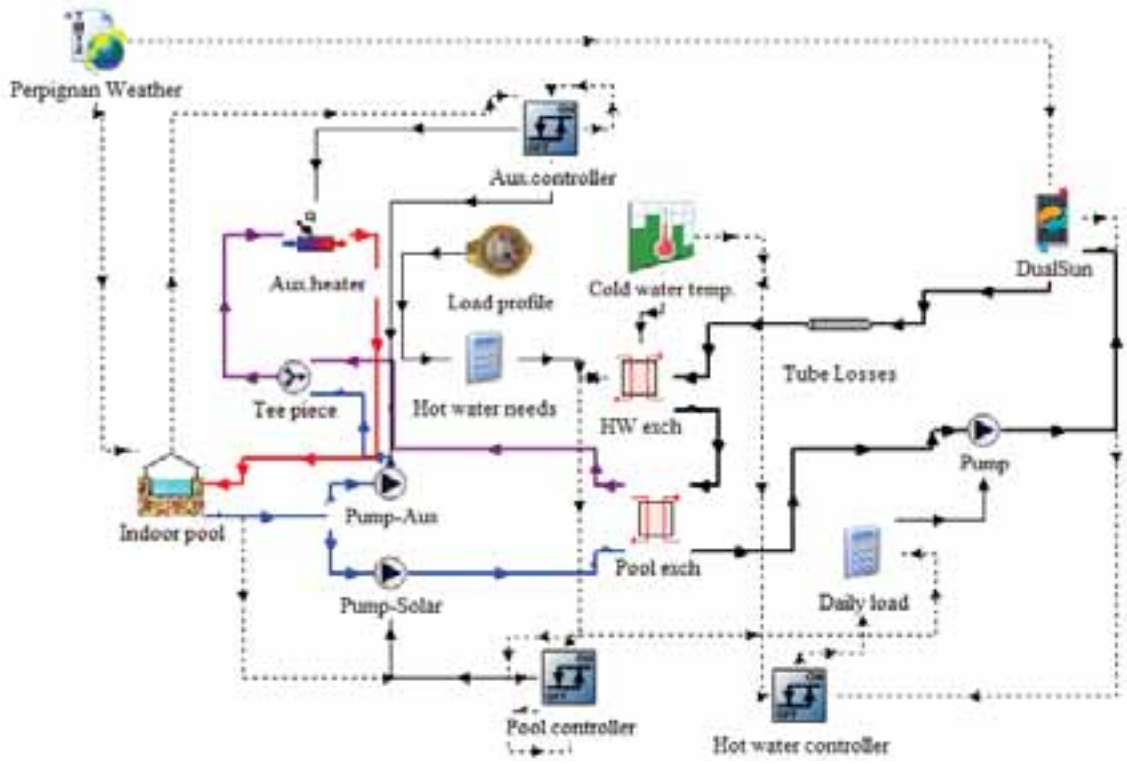

Fig. 4: TRNSYS diagram of the installation

The photovoltaic simulation does not take into account the cooling of the cells, and the storage of the heat for the showers in Perpignan is not included in the model.

The loss coefficient in the 70m buried pipe was taken at 24 W/(m².K).

The hot water profile was built from the scenario for sport facilities in the French thermal regulation method (RT 2012), and the typical day profile is given in Figure 5.

Fig. 5: Hot water need profile in the simulation

The hot water needs are estimated at 1.2GWh/yr, wich seemed very accurate with the 1,27GWh/yr (127 782 m^3 gas volume) consumed in Sète for a year before the solar installation. Recently a monthly detail of the previous gas consumption revealed some significative difference between the monthly distribution of the simulated consumption and the real one before the solar installation as seen in Table 3.

Tab. 3: Real and simulated global heat needs

Month	TRNSYS Heat needs (kWh)	Gas consumption (before solar) (m3)	Energy consumption (before solar) (kWh, η=90%)
January	139 937	16 911	167 727

4. Field test results

The measured results of the PV/T panels are very close to the simulated results for the first year.

At Sète (Table 6), the thermal solar production is 2% higher than simulated, which confirms the accuracy of the model. At Perpignan (Table 7), the production is 23% higher, which proves the good impact of the storage for hot water to improve the solar share covering these needs.

The photovoltaic production measured are respectively 5,9% and 5,6% higher at Sète and at Perpignan, which is to attribute to the cooling of the cells that improves the performances.

Total kWh/yr	**97 077**	**119 870**	**60 535**	**63 942**

The cost of these installations was around 250 k€ (no subsidies taken into account), around 100 k€ for the PV side and 150 k€ for the thermal solar side. If we assume a solar production of 20 years, which seems reasonable, the solar electrical price was around 9c€/kWh and the solar thermal price around 6c€/kWh for the swimming pool at Perpignan (in the South of France). It seems very promising for this innovation, and as the cost reduction potential exists still, the competitivity even with gas may be achieved in the few years.

5. Conclusion

The 300m² PV/T panels provide 30% of the energy for the 6000L/day shower needs and 20% of the heating needs for the 1100m^3 indoor swimming pool during 4 months of the year *(June – September)*.
The measured thermal results of the PV/T panels are very close in this first year, and to add a storage seem to better of 20% the share of solar energy in hot water needs. The positive effect of the cooling of the cells can be estimated around 5.5 and 6% in this type of installation.

With a global cost of energy over 20 years of 7c€/kWh, this promising innovation may be competitive even with natural gas in a few years.

Abstract

By displacing the current heavy use of electricity and gas for domestic hot water applications, solar thermal technologies have significant potential to reduce Australia's fossil fuel emissions. Solar thermal systems prevalent in the current Australian market include a mixture of flat plate and evacuated tube collector types applied in either active or passive style circulation systems. The performance of these systems can vary significantly depending on a number of factors including; the characteristics of the solar collector, storage tank size, hot water load and usage, and climate. As all these factors can vary considerably, particularly the Australian climate, the optimal configuration (considering both performance and economics) of a solar hot water system can also be expected to vary substantially. The purpose of this study is to examine the performance of common solar thermal system designs operating in four climate zones of Australia (Rockhampton, Alice Springs, Sydney, and Melbourne) operating under the load of a four person detached dwelling. A total of six solar hot water systems were designed and simulated using the commercial software package POLYSUN operating in the four Australian climate zones mentioned.

The results showed that solar fractions and payback periods can vary considerably, ranging from 58 to 100 per cent and between 3.8 and 10.1 years respectively. It was found, in this work that, although the evacuated tube collector generally operates with a marginally higher annual thermal efficiency over the selective surface flat plate collector, the overall performance of a system comprising of two selective surface collectors, is greater than a 30 tube evacuated tube system due to its larger absorber area despite taking less roof area. Due to the ratio of absorber to gross collector area, the selective surface flat plate collector was shown, in this study, to yield a higher thermal output per unit area of roof over the evacuated collector making it an ideal choice for domestic hot water projects where roofing area is limited relative to the thermal load. Furthermore, for the regions of high solar irradiance in Australia (Rockhampton and Alice Springs) the cheaper, lower performance flat plate collector was found in this study to operate with very high solar fractions while lowering the stagnation temperature over the selective surface flat plate and evacuated tube collector alternatives and is therefore the preferred solution.

Keywords: solar, thermal, flat plate, evacuated tube, domestic hot water, simulation

1. Introduction

Net energy consumption is increasing steadily in Australia due to a combination of factors including population growth and an increase in living standards (Bush, Harris et al. 1997). A significant portion of the energy consumed within the Australian residential sector is the energy required in meeting domestic hot water needs. Here, Australia is heavily dependent on the use of electric and gas fuelled water heaters responsible for approximately 24% of residential sector greenhouse gas emissions (Ferrari, Guthrie et al. 2012). Solar water heaters have been shown in a number of previous studies to make significant reductions in conventional energy (i.e. electricity and gas) use (Czarnecki 1958, Czarnecki and Read 1978, Morrison, Tran et al. 1984, Crawford 2001, Lloyd 2001, Vieira, Beal et al. 2014) while also demonstrating energy pay back periods of less than two years in some studies (Crawford and Treloar 2004, Hernandez and Kenny 2012).

doi:10.18086/swc.2017.27.03 Available at http://proceedings.ises.org

In order to increase the penetration of solar hot water heaters into the hot water market and reduce greenhouse emissions, a number of incentives have been provided at both state and federal levels resulting in strong growth within the Australian solar hot water industry, particularly within the new housing market such as the Small-Scale Renewable Energy Scheme (CER 2015). In the southern state of Victoria, new homes now require the installation of either a solar hot water system or rainwater tank. This programme alone has resulted in an increase adoption of solar water heaters from approximately 5% in 2004 to over 70% in 2011 (Ferrari, Guthrie et al. 2012).

Although Australia has recently experienced an uptake in the penetration of solar hot water heaters, it is approximated that energy efficient hot water heaters (i.e. solar and heat pump water heaters) constitute only 13% of total current installed water heaters (Shrapnel 2010). With the total number of water heaters sold in Australia to be approximately 700,000 units annually, the future market for solar thermal installations is large, particularly considering the rapid increase in utility costs that is occurring in Australia.

Solar thermal collectors can efficiently convert incident solar energy directly into useful thermal energy. This energy can be utilised by a household and significantly reduce the usage of the traditional fossil fuel powered energy sources.

1.1 Solar hot water systems and components

The typical domestic hot water solar thermal system comprises of the following major components (Kalogirou 2009):

1. Solar thermal collectors
2. Storage tank
3. Energy transfer system
4. Method of providing auxiliary boosting

The principal component of the solar thermal hot water system is the collector. The solar thermal collector is a unique heat exchanger which consists of an absorber, the component which absorbs incident electromagnetic energy radiated from the sun and converts this energy to useful thermal energy via an absorption process. Thermal energy is then transferred to the transport medium (typically water or a water/glycol mixture) which is circulated within the absorber. Thermodynamically, the design of a solar thermal collector aims to maximise the absorption of solar radiation and the heat transfer from the absorber to the transport medium, while minimising heat losses to the environment. A number of collector designs currently exist to achieve these engineering goals, with the stationary non-concentrating type flat plate collector and evacuated tube collector predominant in the Australian solar hot water market.

The typical design of a flat plate collector is shown in Fig 1 with major components forming the assembly identified. Incident solar radiation is attenuated through the glazing, generally high transmission low iron glass, onto the absorber surface. The absorber is made from a material of high thermal conductivity such as steel, aluminium, or copper and coated to increase its absorptivity. As a result of the impinging solar radiation being absorbed the temperature of the absorber will increase. The majority of this energy is then transferred to the transport medium (e.g. water) that is flowing within a series of fluid risers that are placed in thermal contact with the absorber via convection heat transfer.

Analysing the performance of a solar collector can be simplified to highlight the influence of the most important materials. The optical efficiency (η_0) of a solar collector is dependent on the properties of the absorber and glazing. The absorber is a function of two dominant properties: the absorptance of the absorber coating and the collector efficiency factor (F') as shown by Eq. (1) (Frei and Brunold 2000).

$$\eta_o = F'(\alpha\tau)_e \tag{1}$$

Where α is the absorptance, τ is the transmission of the glazing, F' is the collector efficiency factor, and $(\alpha\tau)_e$ is the effective absorption-transmittance product. The efficiency of a collector while in operation is calculated using Eq. (2).

$$\eta = F'(\alpha\tau)_e - F'U_L\left(\frac{T_m - T_a}{G_t}\right) \tag{2}$$

Where U_L is the overall heat loss coefficient, T_m is the mean collector temperature, T_a is the ambient temperature and G_t is the solar insolation on the collector plane.

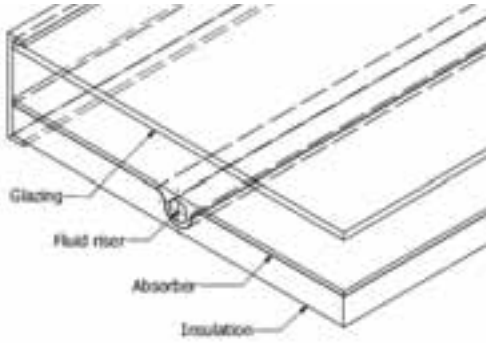

Fig 1: Typical components of a flat plate collector.

Examining Eq. (2), we can see that the thermal efficiency of a solar thermal collector is reduced by the heat loss term which is a factor of the temperature difference between the mean collector temperature (T_m) and the ambient temperature (T_a). As the mean absorber temperature rises above ambient, heat losses will inevitably occur via radiation, convection, and conduction modes reducing the thermal efficiency, and therefore yield of the collector. The characteristic performance of a solar thermal collector is typically expressed using Eq. (3) below.

$$\eta_{th} = a_1 - a_2\frac{(\bar{T} - T_a)}{G_t} - a_3\frac{(\bar{T} - T_a)^2}{G_t} \tag{3}$$

Where a_1, a_2, and a_3 are the collector performance characteristics determined by a laboratory to the local relevant test standard. It is of course ideal to maximise collector efficiency for the range of operating temperatures a solar collector will operate within which is dependent on the application (e.g. domestic hot water or industrial process heat application). For domestic hot water applications, this can range up to 70 degrees C, where a standard flat plate collector can experience significant heat losses reducing the useful energy gained by the transport medium. To minimise this loss, a number of strategies may be employed. One successful method which has been shown in previous studies (Jung 1988, Eisenhammer, Mahr et al. 1997, Schüler, Geng et al. 2000, Roberts 2013) to significantly improve the thermal performance of a collector is the use of spectrally selective absorber coatings onto the absorber substrate. By applying a spectrally selective coating onto the absorber, absorption (α) and emittance (ε) values can be altered and optimised such that thermal radiation losses can be reduced. Heat loss via convection may also be retarded by the evacuation of the air between the absorber and outer glazing reducing heat loss. This is the key feature of the evacuated tube collector (Gao, Fan et al. 2014). By creating a vacuum envelope, the thermal efficiency of the evacuated tube collector is less influenced by ambient conditions (temperature and wind) allowing higher collector operational temperatures.

The performance of a solar hot water system however, is not only dependent on the collector but the design of the whole system. Thermal energy collected from the collector must be stored in a thermally insulated container so that it can be later used by the household. The characteristics of the storage tank (size, heat loss, location of plumbing ports, etc.) will directly influence the collector and the quantity of hot water available to the household. A tank that is undersized for a given collector, application, and climate will lower the efficiency of the collector (due to an elevated mean collector temperature) and increase the likelihood of stagnation and the associated risks. An oversized tank on the other hand will increase the cost of the system and have a detrimental impact on the cost/performance ratio and excessive heat loss.

The manner in which energy is transferred between the collector and tank will have a significant influence on the performance of the system. This can be performed either by active or passive means. An active system is where an electrically driven circulator is used in conjunction with a controller to pump fluid around the collector loop. Alternatively, the passive or thermosiphon system works of the principle of natural convection and flow induced by a density differential and therefore does not need a pump or controller. Of these two methods, the active system will operate with the higher fluid velocity which will improve the heat transfer from the absorber to the transport medium, improving the thermal efficiency of the collector. The passive/thermosiphon system however will operate with reduced electricity consumption and potentially lower annual operational cost.

Finally, when designing a solar hot water system, a means to provide additional heating powered by conventional fuels (e.g. electricity/gas) is generally incorporated to ensure thermal loads are met during periods of insufficient radiation. A number of methods currently exist to achieve this with in-tank electric boosting and in-line continuous gas boosting methods the dominant methods in Australia. The in-tank electric boosting method is where an electric element is immersed in the tank and controlled via a thermostat. Although simple and cheap, a significant pitfall with this method is the addition of energy directly to the fluid being circulated through the collectors. As this will elevate the mean operating temperature of the collector, it will also reduce its operational efficiency. To avoid this issue, a gas booster can be placed between the outlet of the storage tank and the hot water supply line making an 'in-line' configuration. This way, energy is only added to the fluid when required and will not adversely affect the collector performance.

The combination of collector, tank, circulation method, and auxiliary boosting method will all contribute to the performance and cost of a solar hot water system. The optimal configuration will be dependent on a number of factors including the thermal load, installation parameters, and climate.

1.2 Aims of this study

It was discussed in the previous section that a number of collector types and system configurations are typically employed in Australia. When one considers the vast size of Australia, and consequently the vast differences in climate across the continent, the optimal configuration of solar thermal system components can also be expected to vary considerably when both thermodynamics and economics are taken into account.

The aim of this study is to conduct a computational study to determine the thermal performance of a number of solar hot water systems for a typical four-person household in Australia. This study will be limited to stationary, non-concentrating type collectors (i.e. flat plate and evacuated tube collectors only) that are boosted via an in-line continuous gas booster as discussed previously in Section 1.1. One area of focus for this study will be to compare performance and economic metrics between the flat plate and evacuated tube collectors. An emphasis will therefore be placed in this study to examine this specific issue further.

2.0 Method

A computational approach was applied in this work as it has now become common practice to incorporate simulations for the design of a solar thermal systems. Doing so allows the performance to be approximated for a specified system operating under transient environmental conditions. Computer simulations allow a number of system design parameters such as the characteristics of the collector, how it is orientated (azimuth and inclination), climate data, thermal loads, etc. to be varied so that their influence on output can be quantified and then examined and optimised. Although experimental work is the preferred method of acquiring data from an engineered system, it is often not practical and feasible considering time and costs. Such is the case for this study as we wish to investigate a number of system designs operating in different climate zones.

A number of sophisticated off-the-shelf computer simulation programmes for carrying out solar simulations are currently available such as TRNSYS (TRNSYS), T*SOL (T*SOL), and POLYSUN (POLYSUN). POLYSUN software package is used in this study and has also been applied successfully in previous studies (Kalogirou 2009, Bornatico, Pfeiffer et al. 2012, Carbonell, Haller et al. 2014). The accuracy of any computer simulation however, is not only dependent on the software package used but also by the quality of the simulation setup and the input of realistic parameters by the user and the consideration of system uncertainties (Dominguez-Munoz, Cejudo

Lopez et al. 2012). Details of the solar thermal systems and the parameters for the simulation are provided in the next section.

2.1 Simulation setup

In total, six solar thermal domestic hot water systems were investigated in this work operating under four climate zones of Australia. Details of each system configuration are provided in Tab 1. With regards to the types of solar thermal collectors investigated, high and low performance flat plate collectors as well as an evacuated tube type collector were examined in this work. All systems were coupled with a 300 litre storage tank with a daily draw-off of 200 litres per day at 50° Celsius, sufficient for a family dwelling of 4 people (50 litres/person). The energy draw-off pattern shown in Figure 3 was defined and assumed for all simulation studies conducted. All systems were auxiliary boosted via the in-line continuous gas boosted methodology discussed previously in Section 1.1.4. The gas booster chosen in this study was a generic 25kW natural gas fired type operating with a thermal efficiency (η_{th}) of 80 per cent.

The performance characteristics for each of the three solar thermal collectors are provided in Tab 2 below. In all simulations carried out, it was assumed that the collectors were orientated directly north and tilted at 25 degrees in accordance with the Australian standards relevant to the simulation of solar thermal systems (2008). All storage tanks (both active and thermosiphon) were 300 litres in storage capacity, fabricated from stainless steel and insulated with rigid polyurethane (PU). Additionally, piping length between the storage tank and collectors was fixed at 10m for all active systems with loose glass fibre\mineral wool type insulation (ρ = 250 kg/m^3 and k_{th} = 0.045 W/m.k) 20mm in thickness. For active systems, piping length between collectors and tank was fixed at 10m.

Tab 1: Details of the six solar thermal system configurations investigated in this work.

System	Type	Collector	Tank	Auxiliary booster
1	Active	2 x High performance flat plate	300L	25kW in-line gas booster
2	Active	2 x Low performance flat plate	300L	25kW in-line gas booster
3	Thermosiphon	2 x High performance flat plate	300L	25kW in-line gas booster
4	Thermosiphon	2 x Low performance flat plate	300L	25kW in-line gas booster
5	Active	1 x 30 Tube evacuated tube	300L	25kW in-line gas booster
6	Thermosiphon	1 x 30 Tube evacuated tube	300L	25kW in-line gas booster

Tab 2: Performance characteristics of each of the collectors investigated in this work.

Parameter	High performance flat plate (x1)	Low performance collector (x1)	Evacuated collector x 30 tube
$A_{absorber}$ (m^2)	1.62	1.87	2.84
A_{gross} (m^2)	1.8	2.01	4.4
η_0	0.785	0.687	0.71
a_1 (W/m^2/k)	3.35	5.761	1.65
a_2 (W/m^2/k^2)	0.012	0.014	0.008
T_{stag} (°C)	203	124	228

As previously stated, one of the key factors under investigation in this work is the influence of weather on system behaviour. Given the vast size of Australia, four climate zones have been identified in the Australian Standards (2008) to standardise the performance assessment of solar energy systems across the country. These four zones are shown in Fig 2 below. For each climate zone, the meteorological data is taken from a single city. These are Rockhampton, Alice Springs, Sydney, and Melbourne for Zones 1, 2, 3, and 4 highlighted in Fig 2 respectively.

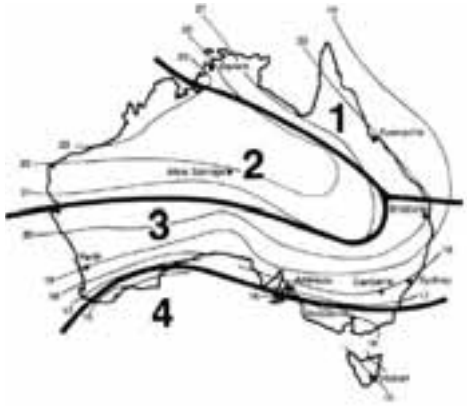

Fig 2: A map of Australia identifying the four climate zones used for simulation studies (2008).

With regard to thermal loading on the hot water system, user profiles will, of course, change considerably based on consumer preferences and seasonal variation. In this work, we will use the thermal load profile specified in the Australian standards (2008). This profile, shown in Fig 3, consists of morning and evening peaks with some usage shouldering the lunch time periods.

In summary, six solar thermal systems (see Tab 1) operating under four weather climates were investigated in this work. Results are presented in the next section.

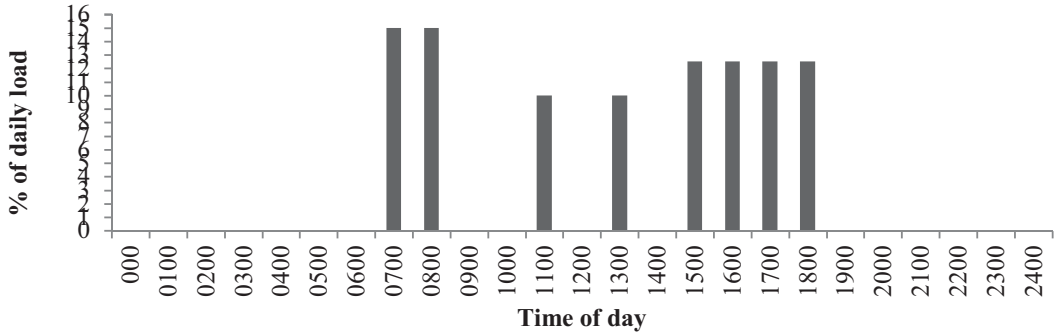

Fig 3: Thermal load profile for all solar hot water systems studied in this work (2008).

3.0 Results and Discussion

The results with respect to energy and economics are presented in this section.

3.1 Energy analysis

Quantitative annual energy results are provided in Tables A.1 to A.6 for Systems 1 through to 6 respectively. The following key performance metrics were taken from the POLYSUN generated results in order to evaluate the overall performance of the systems studied:

a) E_{tot} – the total annual energy that must be purchased by the consumer to operate the booster and if applicable, auxiliary equipment (kWh).
b) *Solar fraction (S_f)* – The POLYSUN total solar fraction is determined by equation Eq. (4).

$$S_f = \frac{Q_{sol}}{Q_{sol} + Q_{aux}} \tag{4}$$

Where Q_{sol} is the collector field yield (kWh) and Q_{aux} is the energy required by the auxiliary booster (kWh).

c) Collector field yield (Q_{sol}) – the total annual energy delivered by the collectors to the loop (kWh).

d) Specific collector field yield – The quotient of the annual collector field yield (Q_{sol}) and the gross collector area (kWh/m^2/year).
e) Collector efficiency ($\eta_{th,col}$) – the quotient of the annual collector field yield ($Qsol$) and the annual global irradiation incident on the collector aperture area.

From the data presented in Tables A.1 to A.6, a number of key findings can be extracted:

1. Comparing System 1 and System 5 we see that the evacuated tube collectors operate with a slightly higher thermal efficiency. However, solar fractions are higher for the flat plate system due to the larger absorber area of the two flat plate collectors resulting in greater collector field yield (Q_{sol}) and reduced auxiliary energy consumption.
2. The specific collector field yield for the high performance flat plate collector system is higher than the evacuated tube collector. This is explained by comparing the ratio of absorber to gross collector areas for both collectors. The flat plate collector has a ratio of A_{abs}/A_{gross} = 0.9 while the evacuated tube collector is 0.65.
3. For Zones 1 and 2, regions of Australia with high solar irradiance, the lower performing flat plate collector is a good choice as high solar fractions can be obtained in both active and thermosiphon systems while reducing the stagnation temperature.
4. Thermosiphon systems operate the minimum E_{tot} values due to the passive or natural circulation of fluid.
5. The difference in solar contribution from a solar hot water system is heavily influenced on its installed location in Australia.

Qualitatively examining the tabulated data presented in Appendix A specifically for Zone 3 (Sydney) we can visually compare the behaviour of each system for a single climate. Fig 4 compares the specific collector field yield and collector efficiencies between all six systems. From this figure we observe that an active system coupled with the high performance flat plate collectors (System 1) offers the maximum specific yield (Q_{sol}/A_{gross}) despite operating with a collector efficiency value slightly lower than the evacuated tube collector (System 5). This result which was similarly found in other work (Budihardjo and Morrison 2009), can be explained by comparing the collector characteristics, specifically the collector area values provided in
Tab 2. The ratios of absorber to gross collector areas are 0.9 and 0.65 for the high performance flat plate and evacuated tube collectors respectively. As the flat plate collector has a much higher ratio of absorber to gross collector area, it is able to compensate for its slightly lower thermal efficiency. This is again highlighted in Fig 5 which plots solar fraction and collector efficiency for each system for weather zone 3. The active system with high performance collectors offers the maximum solar fraction, greater than the 30 tube evacuated tube system. The system with the greatest solar fraction will require the least amount of purchased energy and potentially operate with the lowest annual running cost.

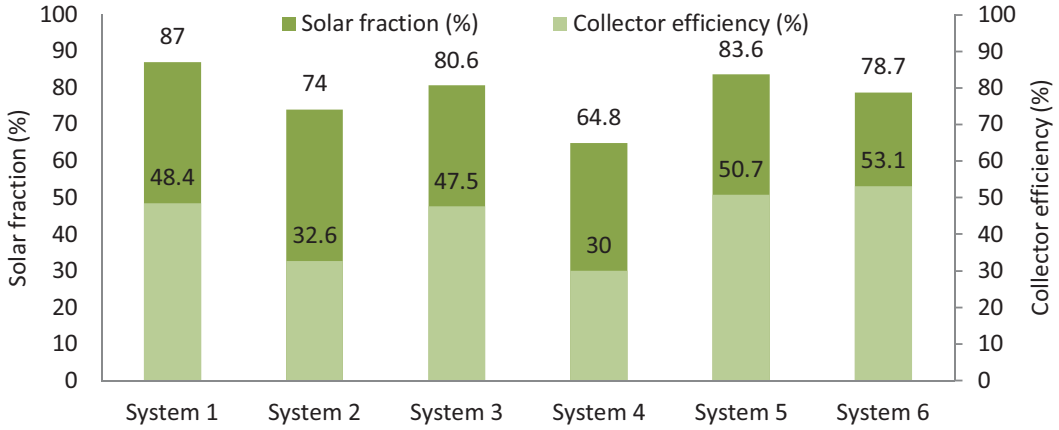

Fig 5: Comparing solar fractions and collector efficiencies for all systems in climate Zone 3.

3.2 *Economic analysis*

An economic analysis of the results was also conducted where the annual energy savings and return on investment (ROI) for each system and weather zone were calculated. System costs for each of the six solar hot water systems used for this step of the analysis are summarised in Tab 3. These figures were determined in consultation with Solimpeks Australia, one of Australia's distributors of solar thermal systems. Installation costs were also included to consider the differences in installing active and passive type solar thermal systems into the analysis. These figures were obtained from Australian Plumbing & Gas Australia Pty Ltd.

Tab 3: Approximate pricing for all six systems investigated in this work including installation. All prices are in Australian dollars.

	System					
	1	2	3	4	5	6
TOTAL (AUD)	$4,210.00	$4,190.00	$3,560.00	$3,540.00	$4,650.00	$4,000.00

Results for the average annual energy savings and ROI are presented in Fig 5 and Fig 6 respectively. Examining these two figures we can extract the following key results:

1. The thermosiphon system comprising of high performance flat plate system offers the maximum annual energy savings and fastest return on investment for all four weather climates investigated followed by a thermosiphon system coupled with an evacuated tube collector.
2. For all active type systems studied, the high performance flat plate collector system offered the greatest energy savings and fastest payback period.
3. A large variation in ROI values was calculated ranging from 3.8 to 10.1 years for the systems studied under the largely varying Australian climate.

The favourable payback period of the flat plate collector system over the evacuated tube system found in this study is supported by the experimental work carried out in a previous study (Chow, Dong et al. 2011). The results of this study highlight the importance of considering the system's holistic performance in its installed location and intended use as opposed to the thermal efficiency of the collector alone. However, under certain circumstances the evacuated tube collector may be the better choice particularly for applications which require higher fluid temperatures (> 70 degrees C) such as industrial process heat applications.

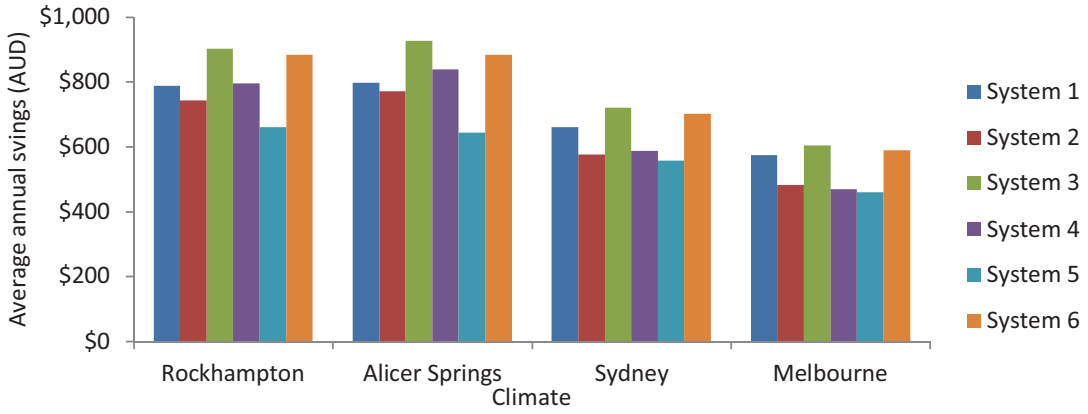

Fig 6: Average annual energy savings for each system in each of the four weather climates investigated.

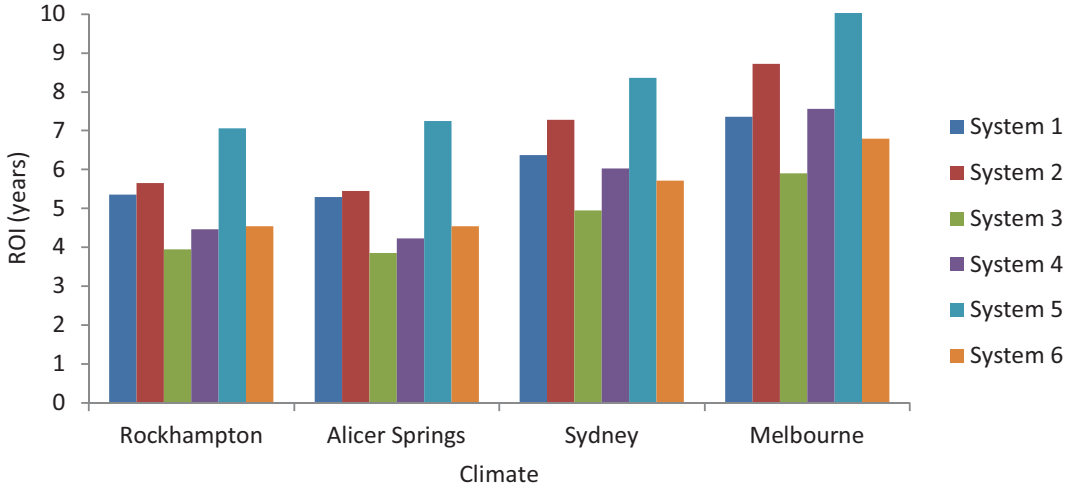

Fig 7: Payback periods for all systems investigated for all four climates in Australia.

4. Conclusions and recommendations

In this study, a number of computational simulations have been carried out on typical solar thermal systems typically deployed in Australia for domestic hot water purposes. Three collector types were investigated including high and low performing flat plate collectors and evacuated tube collectors which were integrated into both active and passive systems. From this work we can make the following conclusions:

1. The high performance flat plate collector operates with a slightly lower thermal efficiency in comparison to the evacuated tube collector, but contributes greater thermal yield per unit area of roof due to its comparatively higher absorber area.
2. The high performance flat plate collector offers the greatest thermal yield per unit area of roof of all collectors studied.
3. For Zones 1 and 2 of Australia, the low performance flat plate collector is a good choice based on its ability to operate with high solar fractions and its reduced cost and operational safety concern which arise from excessively stagnation temperatures.
4. A large variation in payback periods was found in this study highlighting the importance of system design for solar hot water applications in Australia.
5. Thermosiphon systems offer the fastest payback periods due to the lower capital and operational costs despite operating with reduced collector efficiency.

It is common in the solar thermal industry to emphasise the thermal performance of solar thermal collectors as a single component, but other considerations should be taken into account. The results from this study support the claim that the evacuated tube collector do indeed operate with a higher thermal efficiency over the flat plate

collector, however, it is important to assess the performance of the overall system, not just one component forming it. This study has shown for all four weather profiles studied (Rockhampton, Alice Springs, Sydney, and Melbourne) the cheaper high performance flat plate collector operates with a greater solar fraction over the evacuated tube collector and offers the household a faster payback period and lower cost of energy. Furthermore, the high stagnation temperature of evacuated tube collector should always be considered when proposing this technology. With stagnation temperatures over 220°C achievable with the evacuated tube collector, this can stress component materials and create safety concerns for the user.

Appendix A. Results tables

Tab A.1: Energy results for System 1 (active system with 2 x high performance flat plate collectors).

	Zone 1	**Zone 2**	**Zone 3**	**Zone 4**

Solar Refrigeration and Solar Air Conditioning

Monitoring and energy performance assessment of an advanced DEC HVAC system in Morocco

Marco Beccali[a], Pietro Finocchiaro[b], Vincenzo Gentile[c], Matteo Muscherà[d], Mario Motta[d]

[a] University of Palermo - Italy, [b] SolarInvent srl - Italy, [c] Polytechnic of Turin - Italy, [d] Polytechnic of Milan - Italy

Summary

This work addresses the energy performance of a solar Desiccant and Evaporative Cooling (DEC) system working with the freescoo technology. Freescoo is an innovative solar air conditioning concept for ventilation, cooling, dehumidification and heating of buildings in residential and tertiary sectors.
The monitoring of the system started in November 2016 and will continue until the end of 2017. Energy performances are evaluated according to the monitoring procedure for solar cooling systems developed by the Task 38 and 48 of the International Energy Agency experts.
The analysis based on monitoring data shows that, for typical operating conditions in cooling mode, the electricity saving in comparison to conventional HVAC systems can be over 70%.

1. Introduction

Within the agreement between Politecnico di Milano and AMEE (Agence Marocaine pour l'Efficacité Energétique), a solar cooling pilot plant had to be installed at a library in Marrakech. The aim was to develop, test and optimize a robust, low cost, low maintenance solar driven air-conditioning concept, suitable for Northern African climates. At the end of a call for tenders issued by Politecnico di Milano, freescoo by Solarinvent has been selected.

The building is a three-stage structure oriented NE-SW, and the last stage hosts the library. The library stage has a square shape. The roof is plane and presents a square-shaped skylight in the centre with a sloped roof. The skylight height is 1.30 m and his rooftop is 3.50 m above the plane level. The internal ambient is developed around the central space, corresponding to the square skylight. The ambient is composed of two different spaces. The first is assigned to the document shelves, while the other is designated to the hosts' seats. The net internal area is about 300 m^2. The internal ambient temperature is controlled by the pre-existing cooling system, made of four electrical split systems, with a global cooling power of about 18 kW. It has to be noted that only some split units operate properly causing frequent overheating during the summertime and insufficient heating during the wintertime.

Fig. 1: The libray at AMEE

Table 1: Main building data

Description	Data
Internal area	300 m^2
Existing air distribution system	Plaster air ducts
Installed cooling power of split system	18 kW
Existing HVAC system	Ventilation AHU + split system
Occupation pattern	Library 9:00 -16:00

doi:10.18086/swc.2017.28.01 Available at http://proceedings.ises.org

Global radiation on the horizontal on the site of Marrakech reaches 1100 W/m2, whereas global solar irradiation in one year is about 1.9 MWh/m2. Average temperatures vary from about 7°C to 35°C, peak temperature from 4°C to 43°C. Peak humidity ratio is about 16 g/kg in July.

2. Description of the system

The HVAC system is a freescoo AHU integrated with the solar collector; it has a maximum air flowrate of 1000 m^3/h and supplies fresh air to a room of 400 m^3. The max power needed is about 360 W. For driving the cooling process, about 2 litres of water per kWh of cooling energy are needed. In the wintertime, the system can provide also heating to the room when the sun shines and the required air change in the middle seasons.

Fig. 2: Picture of the freescoo system at AMEE

The freescoo concept is based on an innovative and patented DEC (Desiccant and Evaporative Cooling) open cycle technology: by using low enthalpy heat and water evaporation, Freescoo treats directly external hot and wet air to obtain a conditioned stream typically at 18-20°C and 50-60% of relative humidity, reducing drastically electrical demand in comparison to conventional HVAC systems based on vapor compression cycles.

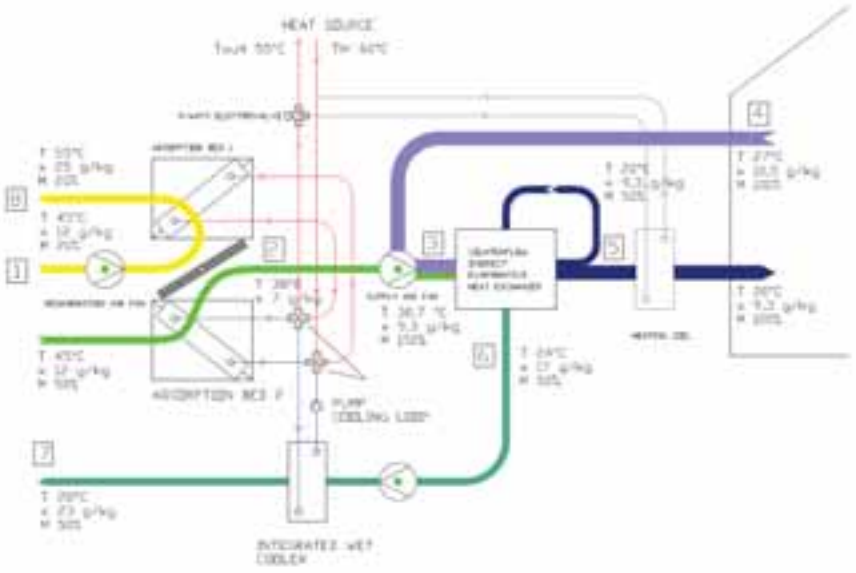

Fig. 3: Scheme of the operation in cooling mode

The innovative Freescoo DEC technology is based on two processes:

- Physical adsorption that reduces moisture content of external air up to the desired humidity rate by using two Cooled Package Beds of silica gel which are operated in a batch process. Each adsorption bed is realized with air to water heat exchanger filled with silica gel grains. The refrigerant used in the process is the water: so the adsorption material is cooled by water flowing through the tubes and a dry cooler is used to reject the adsorption heat generated by the desiccant bed operating in dehumidification mode. After hours of working the adsorption sorbent material reaches the maximum moisture content and it has to be regenerated by heating and drying the sorbent material with hot air.
- Evaporative cooling process takes advantage of advanced double stages indirect evaporative cooler which reduces air temperature up to the supply conditions without increasing the humidity content.

The cooling cycle is described here below. A flow rate of outside air (1) (moderate humidity and high temperature) is drawn through one of the adsorption beds. The moist air is simultaneously dehumidified (passing through the fins filled with silica gel grains) and cooled down (by the water flowing into the heat exchanger tubes). The coupling of dehumidification and cooling steps allows to increase the energy performance of the whole process in comparison to standard desiccant rotor based DEC cycles.

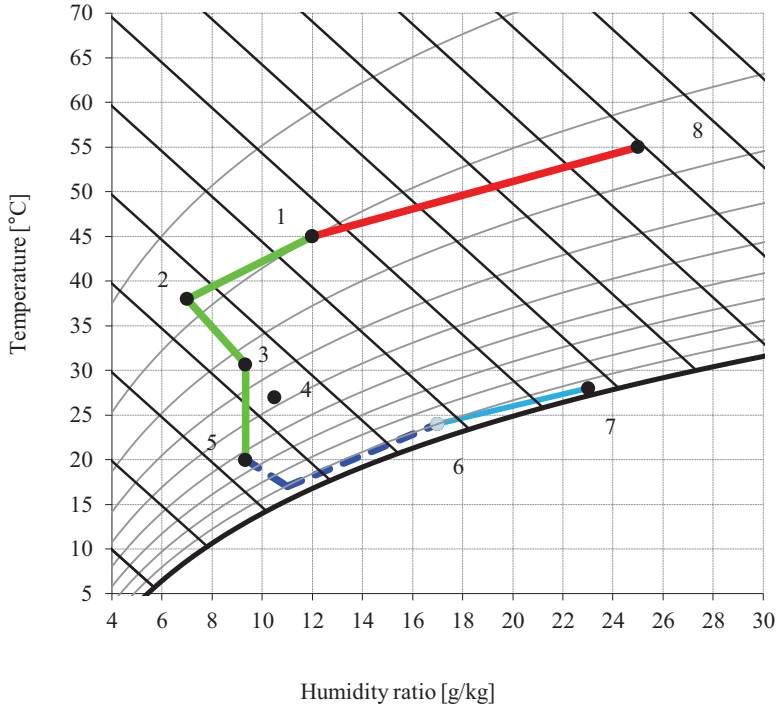

Fig. 4: Thermodynamics of the cooling cycle

Dehumidification process is carried out with a slight temperature decrease (2). Afterwards, dehumidified air is mixed with the return air extracted from the building (4), reaching the conditions of point (3). The mixed air enters the double-stages indirect evaporative cooler allowing to cool down the supply air without increasing its humidity reaching the supply conditions at point (5). In order to produce the cooling effect, a portion of the supply air is drawn to the secondary side (6). The air coming from the secondary side of the indirect evaporative heat exchanger, passes across the wet cooler and receives the adsorption heat caused by the dehumidification process in the adsorption bed (7). When the adsorbent material gets saturated with moisture, this must be reactivated by means of heat supply: outside air (1) is drown into the sorption bed which must be regenerated and receives the moisture released by the desiccant which is now heated up by the hot water (8).

Two adsorbent beds are included in the Freescoo unit to ensure a continuous operation of the system: while the first one is working in order to dehumidify the air, the other one is regenerated using heat from the heat distribution system at temperature > 55°C. A system of air dumpers provides the automatic commutation between the two adsorption beds to guarantee a continuous process.

Tab. 2: Air conditions at inlet and outlet of the internal components at design summer operation (Toutside = 45°C x outside = 10,5 g/kg, T bui = 27°C x bui = 10,5 g/kg)

Description	X	T	h	Position
-	g/kg	°C	kJ/kg	-
Outside air	12	45.0	76.2	1
Outlet ADS bed	7.0	38.0	56.2	2
Mixing	9.3	30.7	54.7	3
Outlet EVA heat exchanger	9.3	20	43.8	5
Building	10.5	27.0	53.9	4
Inlet EVA - secondary side	9.3	20.0	43.8	4
Outlet EVA - secondary side	17	24	67.4	6
Outlet wet cooler	23.0	28.0	86.8	7
Outside air	12.0	45.0	76.2	1
Regeneration	25.0	55.0	120.3	8

The main technical data at the design summer conditions typical for Marrakech are reported in Tab.3.

Tab. 3: Performance at design summer conditions (Toutside = 45°C x outside = 12 g/kg, T bui = 27°C x bui = 10,5 g/kg)

Description	Value	Unit
Supply air flow rate	0-1000	[m^3/h]
Rate of fresh air	50	[%]
Total max cooling power	5800	[W]
Heating power required for the regeneration	3000	[W]
Installed solar collector power	4800	[W]
Power absorbed	360	[W]
Thermal COP	1.9	[-]
EER	16,7	[-]

In addition to the mentioned cooling operation, in the wintertime, the system can provide free solar heat when the sun is shining and can be eventually integrated with different kinds of auxiliary heat sources (heat pump, boiler) in order to guarantee a continuous heating of the building.

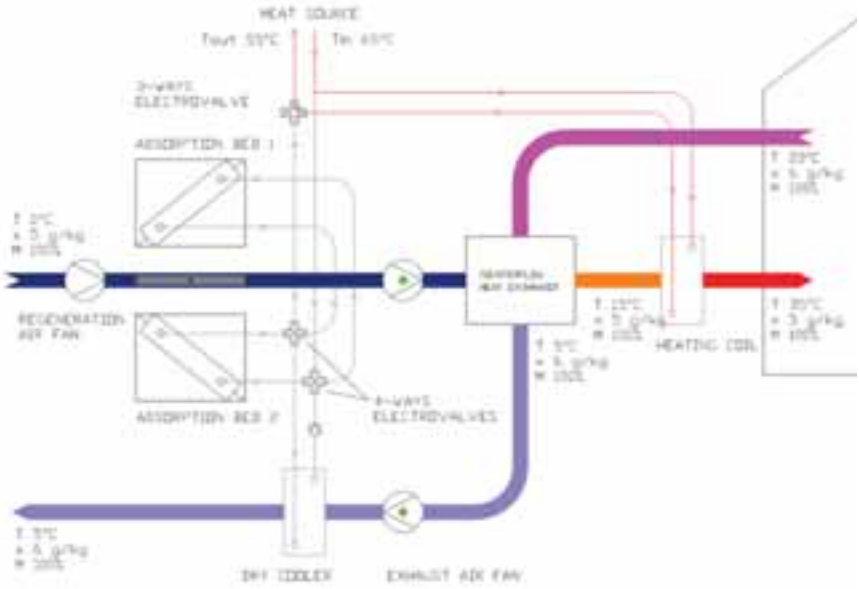

Fig. 5: Scheme of the operation in heating and ventilation mode

Outside air is drown into the counter-flow heat exchanger which is now used as heat recovery unit. Afterwards, the air is heated up in the heating coil which is connected with the heating source, reaching the supply conditions. Simultaneously, an equivalent portion of air is extracted from the building and used for pre-heating the outside air in the counter flow heat exchanger.

3. Results on the energy performance and discussion

In order to assess the energy consumption, an extended monitoring campaign has been performed during the 2017. For the heating mode data presented have been registered in January and February (59 days), whereas for cooling operation from May to September (159 days).

During the wintertime, daily operation hours varied according to the working hours of the solar collectors. In heating mode, being the system solar autonomous, it is operated only when temperature at the solar collectors exceeded 25°C. In summertime, the operation hours varied according to the decision of the users and varied from 10 to 24 hours a day. During the monitoring period, the building was occupied as normally.

Measurements of temperatures (accuracy ± 0.3°C) and humidity (accuracy ± 2.5% of measured value), air velocity (at supply, return, adsorption beds), accuracy of ± (0.5 m/s + 3% of measured value), electricity consumption (accuracy ± 0.5%), solar radiation (2° call accord to ISO9060), and water flowrates (accuracy ± 3%) have been measured at inlet and outlet of main components. Data acquisition has been performed using the GPRS 2 platform from SENECA at 16-bit together with 4 x 8 input analogue modules and 1 digital DI module.

Energy performances have been evaluated according to the monitoring procedure for solar cooling systems developed by the Task 38 and 48 of the International Energy Agency experts.

In the following pages the behaviour of the system will be analysed, and diagrams and instantaneous and long-term energy performances will be presented.

Typical winter operation is depicted in Fig. 5,6,7,8: first two graphs are related to a day of February in which there's a continuous and abundant solar radiation; in Fig. 7 and 8, a day of January with a lower total solar radiation and a discontinuous behaviour is reported. The external temperature has an excursion of 10-15°C between the day and the night time in both cases, instead the building temperature has a quasi-flat behaviour.

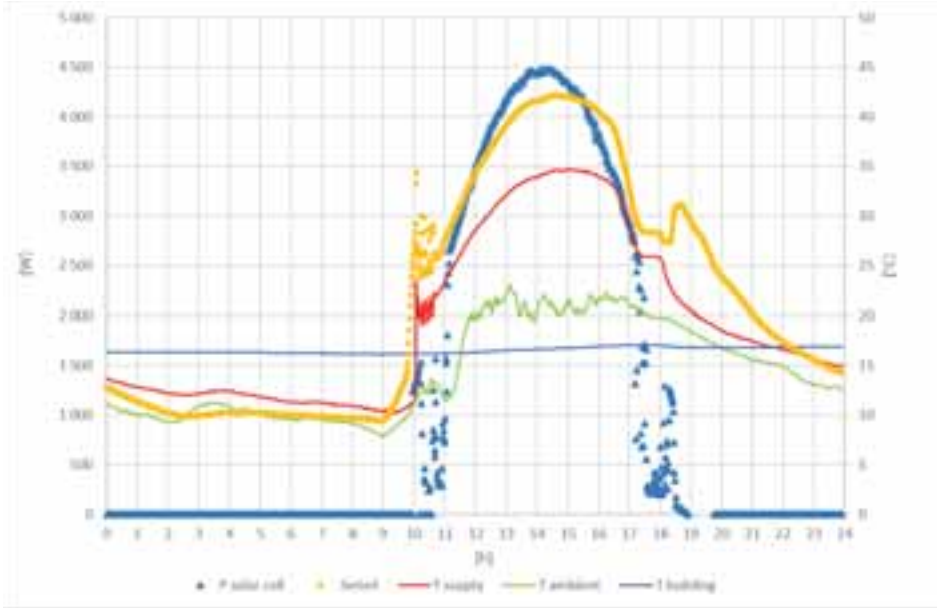

Fig. 5: Thermal performance of the AHU – Day 1, 03.02.2017

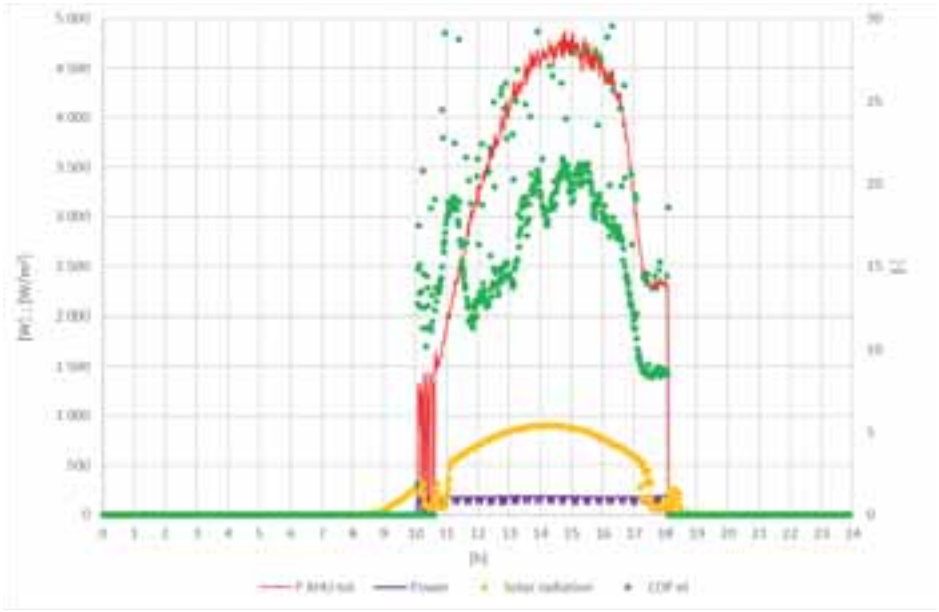

Fig. 6: Electrical performance of the AHU – Day 1, 03.02.2017

For the days considered, the supply temperature of the AHU ranges between 25 and 35°C, with the typical trend that follows the daily solar radiation. Evacuated solar collectors work quite efficiently, between 55-62 %, and the daily COP of the AHU during the winter operation ranged between 11-15. These values are strongly correlated to the total amount of solar radiation that influences directly the energy performances of the AHU. In fact, due to the malfunction of the internal split unit, the temperature of the building is always lower than the supply temperature, therefore the AHU works always at the maximum air flow rate with a constant electrical consumption. As a result, the working operation is quite similar during the winter season, between 6.5 and 8 hours per day. The higher incident solar radiation, the higher thermal power of the AHU, and consequently the higher values of the electrical COP.

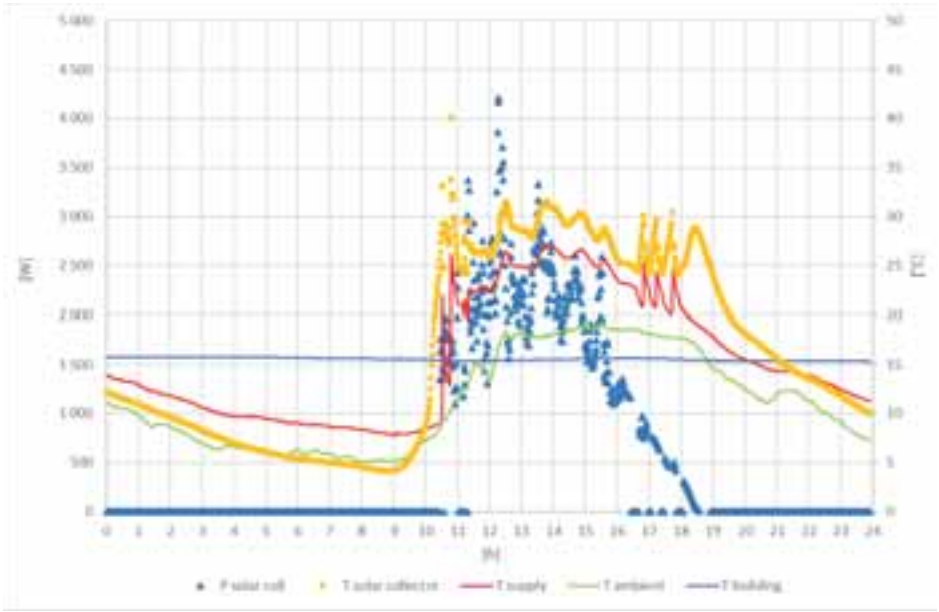

Fig. 7: Thermal performance of the AHU – Day 2, 08.01.2017

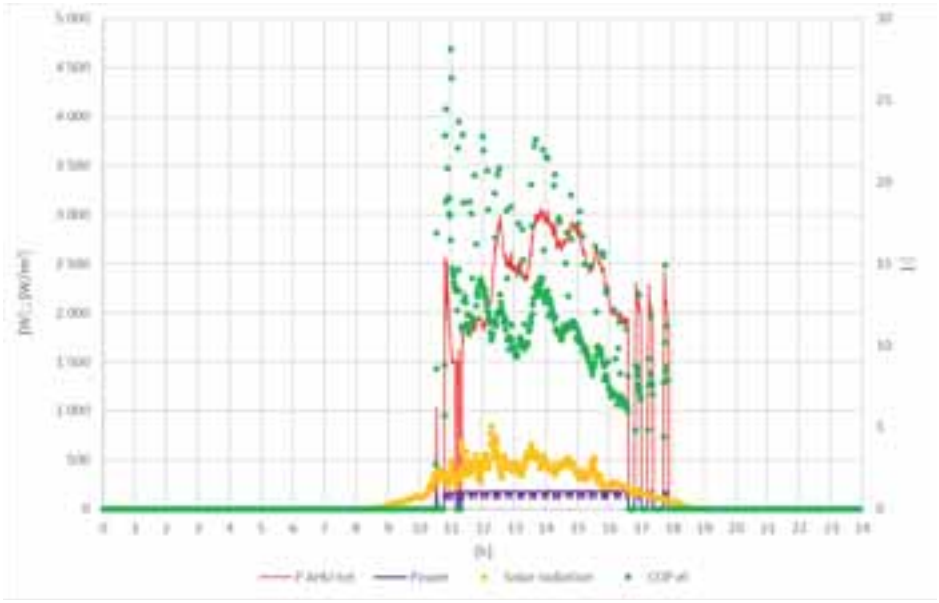

Fig. 8: Electrical performance of the AHU – Day 2, 08.01.2017

Tab. 4: Daily performance of the AHU for the two days considered

Description	Value Day 1	Value Day 2	Unit
Total electricity consumption	1.31	1.04	[kWh]
Incident solar radiation	40.6	21.9	[kWh]
Delivered thermal energy of AHU	22.0	11.9	[kWh]
Delivered thermal energy to the building	27.8	14.7	[kWh]
Solar heat produced	25.3	12.4	[kWh]
Operation hours	7.9	6.4	[h]
COP el	16.8	11.4	[-]
Solar collector efficiency	62%	57%	[-]

With regards of the cooling operation, two days of July are presented here below in Fig. 8 and 9 for the first day and in Fig. 10 and 11 for the second day.

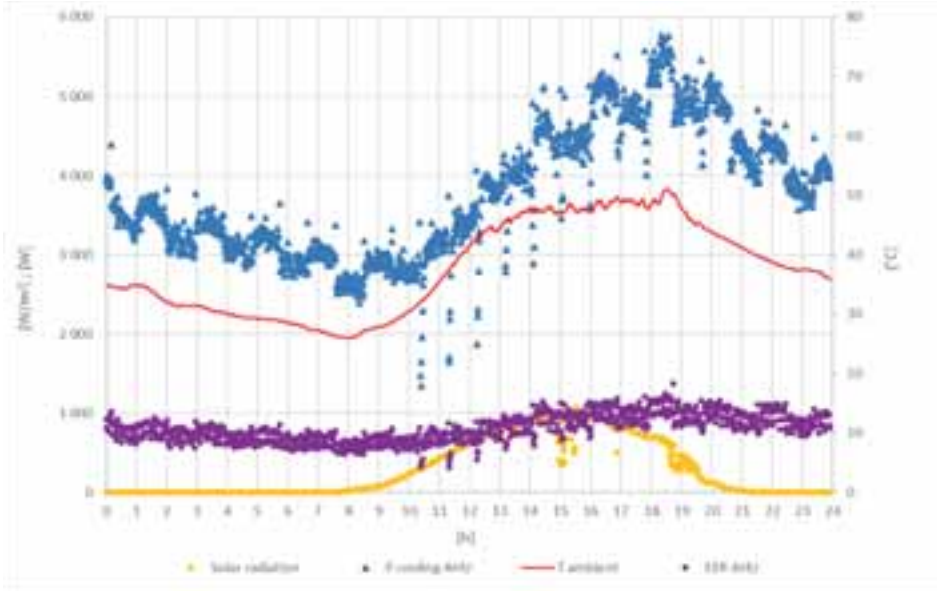

Fig. 8: Energy performance of the AHU – Day 1, 16.07.2017

Fig. 9: Temperature and humidity ratio in the AHU – Day 1, 16.07.2017

The total incident solar radiation ranges between 50-60 kWh/day, and the cooling power produced by the AHU is between 2.5-5.5 kW, with a supply temperature of 19-22°C. First day is characterized by high solar radiation, extreme ambient temperatures (maximum value about 50°C), whereas second day has lower solar radiation and ambient temperatures up to 40°C. System has been operated 24 hours during the first day, and 10 hours during the second day. In the first day, the cooling power of the AHU produced during the night is only due to the indirect evaporative cooling effect.

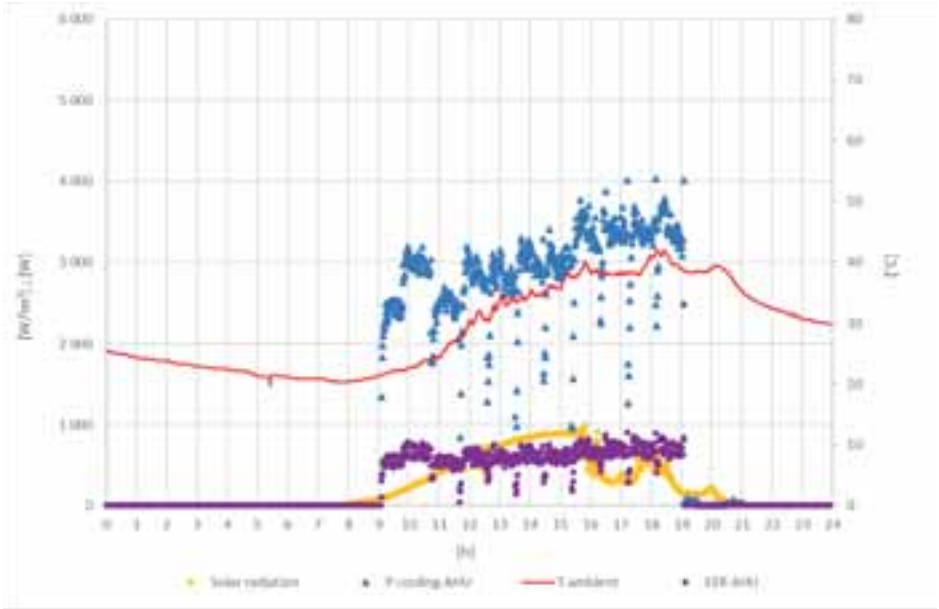

Fig. 10: Cooling performance of the AHU – Day 2, 23.07.2017

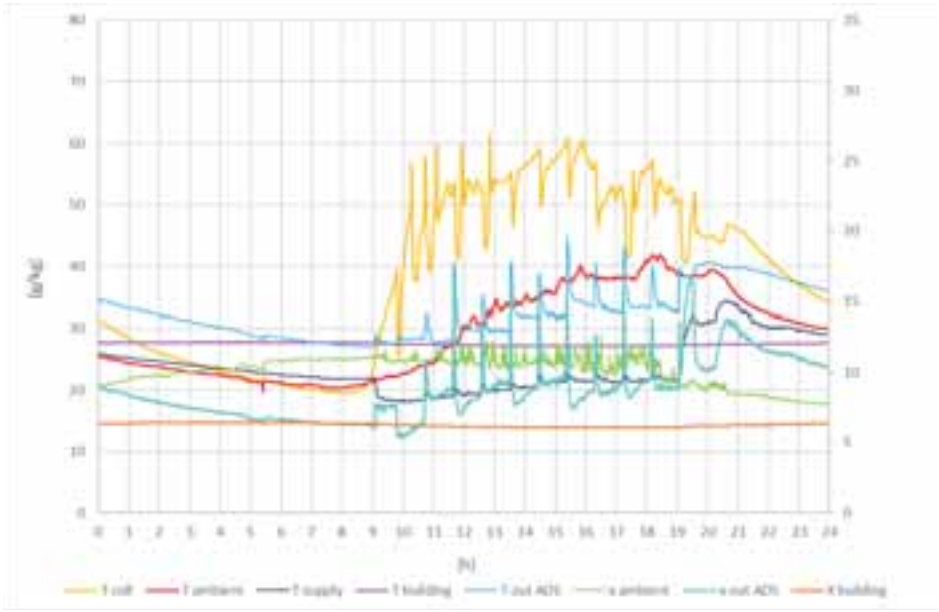

Fig. 11: Temperature and humidity ratio in the AHU – Day 2, 23.07.2017

Tab. 5: Daily performance of the AHU for the two days considered

Description	Value Day 1	Value Day 2	Unit
Cooling energy delivered by the AHU	91	29	[kWh]
Average flow rate	881	376	[m3/h]
Incident solar radiation	52.9	43.3	[kWh]
Solar collector heat	31.9	24.1	[kWh]
Electricity consumed	8.4	3.62	[kWh]
Specific power consumption for ventilation	0.40	0.96	[W/m^3/h]
Hours of operation	24	10	H
EER	10.8	7.92	[-]
COP th	2.88	1.12	[-]
Solar collector efficiency	60%	56%	[-]

In Fig. 12 the daily performances in July are reported. The EER is always higher then 5, with peak values higher then 10, and an average value of about 7. Thanks to the very good performance of the evaporative cooling module of the AHU, the thermal COP of AHU varies between 1 and 2, with a strong influence of the external environmental conditions both in terms of temperature and relative humidity.

In the summer period the air flow rate has a daily modulation, managed by the PID controller since the control strategy implemented uses the building temperature and humidity as input parameters. In Fig. 9, monthly performances of the machine are depicted. The average air flow rate has a minimum value in the month of May, 400 m^3/h and, whereas a maximum value of about 900 m^3/h is reached in the month of August. The electricity consumption varies correspondingly both for the increase of the air flow rate and the daily working hours.

Solar collector efficiency	58%	61%	59%	[-]

According to the results obtained, a comparison with the energy performances of a conventional AHU coupled with a vapor compression reversible heat pump has been assessed. The main hypotheses regarding the conventional system concern the energy efficiency ratio of the chiller/heat pump and the electricity consumption for the ventilation. Results show an electricity saving of 70 % over the year.

Tab. 7: Calculated annual energy performances for a conventional AHU coupled with a vapor compression reversible heat pump

EER for the chiller/HP (assumed)	3	[-]
Electricity consumed by the chiller/HP	2162	[kWh]
Specific power consumption for ventilation (assumed)	0.30	[W/m^3/h]
Electricity consumed by the AHU for ventilation	589	[kWh]
Total electricity consumed	2751	[kWh]
Electricity saving	70	[%]

3. Conclusions

In this work the energy performance of a innovative DEC AHU working with the freescoo concept has been presented. The system has been monitored both in cooling and heating operation and results showed the high energy saving potential of technology.

Summer operation has been characterized by a lower electrical efficiency of the AHU in comparison to the winter operation (6.7 versus 11). The main reason is the dry climate that characterizes the summer season of Marrakech, and the low latent load of the building. As a result, the latent part of the cooling power produced by AHU was much lower than the maximum potentiality of the machine.

Global results can be considered anyway very good, both in terms of instantaneous and long-term behaviour.

The comparison with the energy performances of a conventional AHU coupled with a vapor compression reversible heat pump shows that the freescoo AHU can save 70% of electricity.

Water consumption amounted to about 12 m^3 for the summertime. This is a relevant aspect that can limit the application of the mentioned technology in climates with scarcity of water.

4. Acknowledgements

The mentioned project has been realized with the support of the Italian company Pleion srl which provided the solar collectors and their large experience in the solar thermal area.

Abstract

Typical agro-food value chains use electric refrigeration systems. However, in many non-industrialized countries, the cold chain is often not guaranteed due to lack of electricity access or unreliable electricity grids. In such cases, refrigeration systems must be equipped with electrical backups or other form of energy storage.

This study analyses the use of a commercial available vapour-compression horizontal refrigerator for small-scale cheese processing system. The studied refrigerator of 350 litres capacity is powered by photovoltaic panels, which provide electricity to a DC compressor. Encapsulated phase change materials were incorporated to the system as energy storage option, for a reliable operation at temperature at 11°C. This operating temperature is suitable for the analysed product, but it is also suitable for other agro-food applications, such as the preservation of fruits and vegetables. In particular, this study evaluates the incidence of the incorporation of Phase Change Materials on the stratification temperature inside the refrigerator, the raise temperature time of the refrigerated product, the number of on-off cycles of the compressor, the COP of the system, and the sizing of the conventional storage system with electrical batteries.

Keywords: Solar PV collectors, Compression refrigeration, Thermal energy storage, Phase change materials, Dairy sector

1. Introduction

Proper cold chain management in the agro-food sector is fundamental to preserve the quality of the products, reduce waste products, and also promote their effective commercialization (Gustavsson et al., 2012). Refrigeration systems in this sector typically use vapour-compression systems, powered by electricity, with direct expansion of refrigerant for small applications. In many developing countries, the cold chain cannot be guaranteed due to the lack of electricity supply or the frequent power outages. In such cases, refrigeration systems must be equipped with electrical backups or other form of energy storage.

In this context, several studies have analysed refrigeration systems powered by photovoltaic modules (Deshmukh and Kalbande, 2015; Katic et al., 2010) which use electrical storage and small size Direct Current (DC) compressors, eliminating the losses associated with DC / AC inverters. Energy storage plays a relevant role, especially when the cold production and energy demand are not matching (Dincer and Rosen, 2011; Lott and Kim, 2014). The use of Phase Change Materials (PCM) as a thermal energy storage option in this type of systems, can eliminate or reduce the size of the traditional electrical storage with lead-acid batteries (Pedersen and Katic, 2016). This type of electrical-storage has less useful life, generates a greater environmental impact, and in many cases has higher cost than some thermal storage options.

The integration of PCM into direct-expansion refrigeration systems can be done at the condenser as well as at the evaporator level. The integration at the evaporator level should consider factors such as the type of evaporator, its location within the cooled space, and the air diffusion system. In this regard, different studies have analysed the use of PCM in domestic and commercial refrigerators and freezers (Alzuwaid et al., 2015; Azzouz et al., 2008; Oró et al., 2012; Yusufoglu et al., 2015). In general, the results indicate that PCM provide more stable temperatures, a greater system autonomy and energy savings for refrigerators with non-regulated compressors. Most of these studies have been performed at typical operating temperatures of 4°C and -18°C, for refrigerators and freezers respectively, and in some cases without stored product; so we considered that it is convenient to carry out studies and develop models closer to the real conditions for each type of application.

doi:10.18086/swc.2017.28.02 Available at http://proceedings.ises.org

In this line, the present study analyses the performance of a horizontal refrigerator, of 350 litres of capacity, with a direct-current compressor powered by photovoltaic modules. The refrigerator will be used later in a small-scale cheese processing at an operating temperature of 11°C. This operating temperature is suitable for the analysed product, but also for other agro-food applications, such as preservation of fruits and vegetables. The refrigerator has been adapted for storing the product, as well as for the incorporation of encapsulated PCM, with a phase change temperature between 5 and 6°C. In particular, this study evaluates the incidence of the incorporation of PCM on the stratification and temperature stability inside the refrigerator, the raise temperature time of the refrigerated product, the number of on-off cycles of the compressor, the COP of the system, and the sizing of the conventional storage system with electrical batteries.

2. Methodology

2.1 Description of system and analysed application

The studied system is located in the district of Nyanza (Kenya), with a latitude of 0.08°N, longitude of 35.06°E, and 1914 m of altitude. The system consists of a horizontal refrigerator (Fig.1), which will be installed in a processing room, under controlled temperature between 21 and 25°C. The refrigerator is equipped with a direct current (DC) Compressor, with refrigerant R134a. The system will be powered by a multi-crystalline photovoltaic module, and has two types of energy storage: (1) Electrical storage with conventional lead-acid batteries, with a charge controller, and (2) Thermal energy storage with phase change materials, arranged next to the interior walls of the spaced refrigerated, since the evaporator is embedded in them.

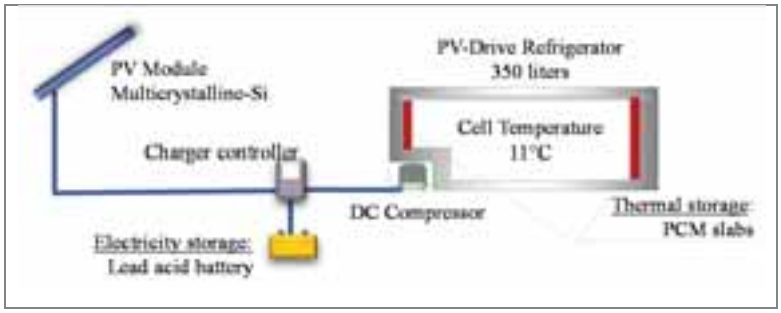

Fig. 1: Scheme of the system

The refrigerator was adapted to store the product (cheeses), incorporating four vertical structures that allow to process up to 16 kg of cheeses, and using forced convection with two small power fans installed in the upper area of the refrigerator.

2.2 Experimental setup for testing refrigeration cell

For performing this study, the refrigerator was tested in a climatic chamber taking measurements before and after installing the PCM. Taking into account that in real conditions the refrigerator will operate in an air-conditioned room, the tests were performed for an ambient temperature of 25°C and a relative humidity between 40 and 60%. During the tests, water was used as a refrigerated product, and in a later stage, a specific mixture will be used to simulate the system in conditions closer to the application.

The experimental setup is shown in Figure 2. The horizontal refrigerator, 350 litters capacity, is equipped with a direct current compressor, Secop BD 35F, with refrigerant R134a and a Danfoss 101N21C controller. The power supply in the test was performed at 12 volts, using a regulated source voltage. The phase change material (PCM) was incorporated in the internal side of the refrigerator, since the evaporator of the refrigerator is embedded in the wall.

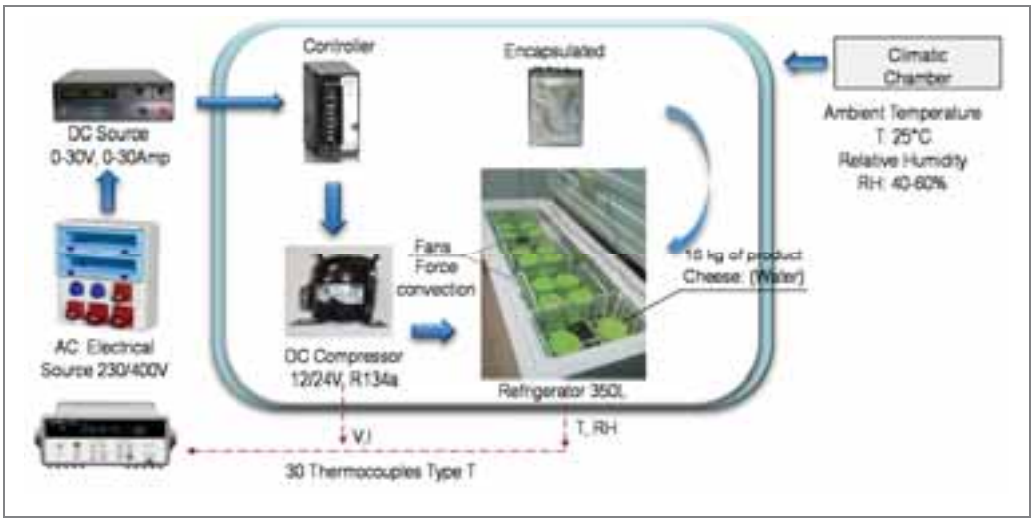

Fig 2: Experimental setup of refrigerator cell

The PCM-encapsulation consists of polyethylene bags with an aluminium layer, placed on a 1mm steel-sheet (Fig 3(a)) attached to the inner side of the refrigerated space (Fig 3(b)), since the evaporator is embedded in the refrigerated space walls. The melting temperature of the PCM, manufactured by Rubitherm, is between 5 and 6 ºC and the operating temperature inside the refrigerator is 11±2°C. The PCM slab has a thickness of 8mm, and the final mass installed was 8.9 kg.

(b) Refrigerator with PCM next to Evaporator-Wall

(c) Refrigerator, inside of the climatic chamber at the laboratory

Fig. 3: Details of the experimental setup of integration of PCM

In total, 30 T-type thermocouples were used to measure the temperatures in the product (cheese), PCM, and refrigerator walls, and ambient temperature. Current and voltage measurements were also taken in order to quantify the electrical consumption, with a measurement interval of 1 minute. Table 1 summarizes the number and types of sensors used in the experimentation.

Tab. 1: Resume of sensors used in the experimental setup of refrigeration cell

Type of sensor		Number of sensors	Location
Temperature sensors	T-type thermocouples	10	Interior walls of refrigerator
		10	Product
		9	Encapsulated PCM
		1	Climatic chamber
Electricity sensors	Voltage: Voltage Regulated Source Output	1	CC Circuits
	Current: Hall effect sensor, Arduino ACS712	2	CC Circuit 1: Compressor, CC Circuit 2: Fans
Humidity sensors	Relative humidity sensor	1	Climatic chamber

2.3 PCM selection and integration

The integration of PCMs in domestic and commercial refrigerators and freezers can be carried out through active and passive solutions. Active solutions are often more effective than passive ones in the heat transfer process; however, passive solutions are simpler for implementation.

Passive integration solutions can be done at the condenser as well as at the evaporator level. The integration at the evaporator level should consider factors such as the type of evaporator, its location within the cooled space, and the air diffusion system.

In relation to this, several previous studies have analysed different options such as: The installation of a PCM slab next to the external side of the evaporator and embedded in the wall of the refrigerator (Azzouz et al., 2008; Yusufoglu et al., 2015); the arrangement of PCM slabs inside freezers with internal evaporator (Oró et al., 2012), the arrangement of PCM next to the condenser, and also the arrangement of PCM in the refrigeration circuit (Cheng et al., 2011). In the case studied, the refrigerator has a wall evaporator, so the integration option adopted consists of placing a slab of the PCM on the inner wall of the refrigerator.

Tab. 2: Main Characteristics of Phase Change Material (PCM) Selected

Description	Value
Manufacturer	Rubitherm
Reference of the substance	RT5HC, Organic
Type of Substance	Paraffin, C5-C20
Phase change Temperature Range [°C]	5 to 6
Thermal storage capacity [kJ/kg]	250 (-2 to 13°C)
Specific heat capacity (solid) [J kg^{-1} K^{-1}]	2000
Specific heat capacity (liquid) [J kg^{-1} K^{-1}]	2000
Density (solid, -15°C) [kg m^{-3}]	880
Density (liquid, 20°C) [kg m^{-3}]	760
Thermal conductivity (solid) [W m^{-1} K^{-1}]	0.2
Thermal conductivity (liquid) [W m^{-1} K^{-1}]	0.2

Since the temperature required for the refrigerated product is 11 ° C, the evaporator temperature should be about 0 ° C, in order to provide a suitable temperature difference for an effective heat transfer process. In this case, the phase change temperature of the PCM should have a value between the evaporator temperature and the required product temperature. This ensures that the PCM material changes phase, without cooling the refrigerated product below the required temperature range.

In this way, the PCM finally selected is the RT5HC manufactured by Rubitherm, with a phase change temperature

between 5 ° C and 6 ° C. Table 2 presents the main characteristics of this material. The material is organic (Paraffin, C5-C20), and does not have a single-phase change temperature, as it happens, in pure substances. The main advantages of this type of PCM compared to the hydrated salts are the greater stability, and that the crystallization process requires less sub cooling of the material.

2.4 Data analysis and simulation

2.4.1 Scenarios considered

The experimental data provide information about the system for two scenarios: (1) Refrigerator without PCM and (2) Refrigerator with PCM. For both scenarios, two types of day were analysed: (1) "Initial day", in which the product is cooled from an initial temperature (25°C) to the required final temperature (11°C) , and (2) "Maintenance day" type, in which the product is only maintained within the required operating temperature range (11±2°C).

Base on the experimental data, two electrical power demand profiles were created for a full month of operation (With PCM and Without PCM). The month selected for analysis was November, since this month has the lowest photovoltaic production. The TRNSYS 16 software was used as a simulation tool for photovoltaic production, and other complementary analysis was carried out by using Matlab.

2.4.2 Total thermal load

Total thermal load (Q_T) was calculated according to ASHRAE (eq.1), which includes: Transmission heat gains or losses through the refrigerator enclosures (Q_{Losses}), the Product thermal load (Q_{Pr}), the heat gains due to internal equipment (Q_{Int}) and the infiltration heat gains (Q_{Inf}).

$$Q_T = Q_{Losses} + Q_{Pr} + Q_{Int} + Q_{Inf} \quad \text{(eq.1)}$$

Transmission heat gains or losses through the refrigerator enclosures (Q_{Losses}) were estimated according to equation 2 (ASHRAE, 2010; Azzouz et al., 2008), where U_{Ref} corresponds to the global heat transfer coefficient of the refrigerator, A_{Ref} corresponds to the refrigerator area, $\Delta T_{Ref,p}$ is the temperature difference between the inside face of the cooler and the outside air at each time interval (p), and the Δt corresponds to the time step of the measurement or simulation.

$$Q_{Losses} = \sum_{p=0}^{P} U_{Ref}.A_{Ref}.\Delta T_{Ref,p}.\Delta t \quad \text{(eq.2)}$$

The overall heat transfer coefficient of the refrigerator was estimated according to equation 3, where x_n and k_n correspond to the thickness and thermal conductivity of the wall layer "n", and h_{int} and h_{ext} correspond to the interior and exterior convection heat transfer coefficients.

$$U_{Ref} = \frac{1}{\frac{1}{h_{ex}} + \frac{x_1}{k_1} + \frac{x_1}{k_1} + .. + \frac{x_n}{k_n} + \frac{1}{h_{in}}} \quad \text{(eq.3)}$$

The layers considered on the refrigerator wall are presented in Table 3. The overall coefficient U_{Ref} is 0.4712 $Wm^{-1}K^{-1}$ without PCM and 0.4623 $Wm^{-1}K^{-1}$ with PCM.

Tab. 3: Properties of the materials of the enclosures of the refrigerator

Layer Number	Material	Thickness [mm]	Thermal Conductivity [$Wm^{-1}K^{-1}$]
1	Steel	1.5	50

2	Polyurethane	60	0.050
3	Aluminium	1	230
4	PE film	0.15	0.33
5	PCM	8	0.2
6	PE film	0.15	0.33
7	Steel	1	50

The heat extracted from the product (Q_{Pr}) includes only sensible heat for this application, since the refrigerated product does not change phase. Q_{Pr} is calculated by applying the basic expression of equation 4, where C_p and m correspond to specific heat and mass of the material, while T_i and T_f are the temperatures corresponding to the initial and final time of the evaluated period.

$$Q = C_p.m.(T_i - T_f) \quad \text{(eq.4)}$$

In relation to the heat gains due to internal equipment (Q_{Int}), the calculation considered two small power fans (1.8W) used for forced convection inside the refrigerated cell. Finally, the infiltration heat gains (Q_{Inf}) were estimated for a full day of operation of the refrigerator, applying equation 5 (ASHRAE, 2010), which includes the transmission heat gains in the enclosures for a stable day of operation ($Q_{Losses,d}$), the door open time factor (D_t), the door flow factor (D_f), and the effectiveness of doorway protective device (E).

$$Q_{Inf} = Q_{losses,d}.D_t.D_f(1 - E) \quad \text{(eq.5)}$$

2.4.3 Power demand profiles

The profiles of the electric power demand were defined based on experimental data for the two scenarios analysed (With PCM and without PCM). To do this, the power was calculated by multiplying the voltage (V) and current (I) measurements at each time step.

2.4.4 Heat transferred in the PCM

The total heat transferred in the PCM (Q_{PCM}) was estimated multiplying the mass of the installed PCM by the variation of enthalpy for each time step, from the initial to the final one, according to the equation 6.

$$Q_{PCM} = \sum_{p=1}^{P} m_{PCM}.\Delta H_{PCM,p} \quad \text{(eq.6)}$$

The specific enthalpy, , was calculated as a function of the temperature of the phase change material, according to equation 7 (Ozisik, 1993), where C_p is the specific heat capacity of the PCM, L is the specific heat of fusion, and the mushy region is between the temperatures T_s and T_l. When the temperature is lower than T_s, the material is in solid state, and when the temperature is higher than T_l, the material is in a liquid state.

$$H = \begin{cases} C_pT & for\ T < T_s\ Solid\ region \\ C_pT + \dfrac{T - T_s}{T_l - T_s}L & for\ T_s \le T \le T_l\ Mushy\ region \\ C_pT + L & for\ T > T_l\ Liquid\ region \end{cases} \quad \text{(eq.7)}$$

2.4.4 PV production

The photovoltaic production profile was calculated by using the component 194 available in the dynamic simulation software TRNSYS 16. This component uses the 5-parameter model (Duffie and Beckman, 2013), that consists of a voltage generator, a diode connected in parallel that represents the semiconductor material, a series resistance, and a parallel resistance.

$$I = I_F - I_{SD}.\left(e^{\frac{V+I.R_S}{a}} - 1\right) - \frac{V + I.R_S}{R_P} \quad \text{(eq.8)}$$

The output current of the photovoltaic module (I) is calculated by applying equation 8, where it is necessary to know the 5 parameters of the model: (1) The series resistance (R_S), (2) parallel Resistance (R_P), (3) the current produced by photovoltaic effect (I_F), (4) the inverse saturation current of the diode (I_{SD}), and finally the factor "a". These parameters can be calculated by using the manufacturer specifications at standard reference conditions according to Eckstein (1990) and De Soto et al (2006).

2.4.5 Electric battery and regulator

The electric battery as well as the load regulator/controller were simulated using the algorithm applied in the "Type 48b", available in the dynamic simulation software TRNSYS 16. In this model, the charging of battery is carried out by applying a global efficiency value (η_b); the regulator charges the battery while the fractional state of charge *(F)*, is between a minimum value (F_d) and a maximum value (F_c). In addition, the battery bank can be discharged when the fractional state of charge is below of a specific value (F_b). On the other hand, a direct current (DC / DC) conversion is performed on the regulator/controller with a global efficiency value (η_r). Table 4 presents the parameters used in the analysed case.

Tab. 4: Values of Fractional state of charge and efficiencies applied in the electric battery and the regulator model

Description	Value
Minimal value of Fractional state of charge (F_d)	0.3
Maximum value of fractional state of charge (F_c)	1.00
Fractional of Fractional state of charge for starting discharging the battery bank (F_b)	0.85
Charging battery efficiency (η_b)	0.85
Regulator efficiency (η_r)	0.95

2.4.6 Performance indicators

The system performance was analysed by reviewing the following variables and indicators: (1) the temperature stratification of the refrigerated product, (2) the number of on-off cycles of the compressor, (3) the rise temperature time and (4) the coefficient of operation of the system (COP). In addition, the process of charging and discharging of PCMs was also studied.

The temperature stratification of the product was revised from the experimental data, using the information of nine thermocouples in the refrigerated product arranged at three different heights and at different points in the refrigerator.

The rise temperature time was measured by turning off the power supply and quantifying the total time in which the temperature of the refrigerated product reaches the maximum permitted value. These measurements were made according the standard EN 62552 for household refrigerating appliances (IEC, 2013).

$$COP = \frac{Q_{Useful}}{W} \quad \text{(eq.9)}$$

The coefficient of operation (COP) of the system was calculated by applying equation 9, where Q_{Useful} corresponds to the effective heat extracted by evaporator, and W corresponds to the electricity consumption of the refrigerator during the period of time evaluated. The effective heat extracted by the evaporator was estimated by adding the heat extracted from the product, the heat gains by transmission through the enclosures, and the infiltration heat gains. In this case, the experimental temperature data measured minute by minute are used and equations 2 to 5 are applied.

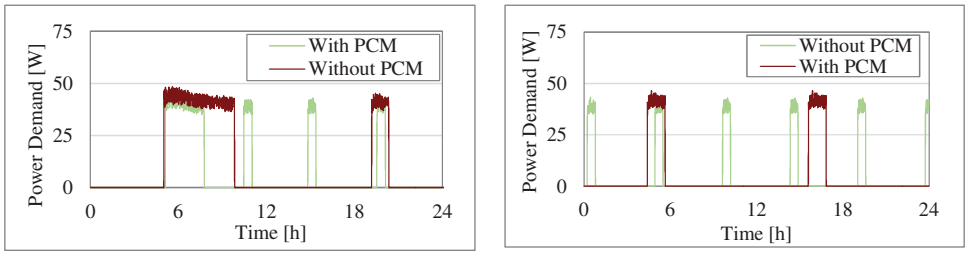
In relation to the charging and discharging processes of the PCM, the transferred heat was also calculated from experimental temperature data and applying equations 6 and 7.

3. Results and discussion

3.1 Power demand

The electric power demand of the refrigerator was measured during 48 hours for the two analysed scenarios (with PCM and without PCM). According to these data, the power demand profile were elaborated for two types of days: (1) "Initial day" (Fig 4a), in which the product is cooled from an initial temperature of 25 ° C to the required final temperature of 11°C, and (2) "Maintenance day" (Fig 4b), in which the product is only maintained within the required operating temperature range (11±2°C).

The average power for the "Without PCM" scenario is 38.7W, with a minimum of 33.2W and a maximum of 45.8W, while the average power for the "With PCM" scenario is 41.6W with a minimum of 35.9W and a maximum of 48.4W. This implies that the incorporation of PCM in the refrigerator increases the average power demanded in 7%.



a) Initial day (b) Maintenance day

Fig. 4: Power demand profile for Initial and Maintenance day, with and without PCM

In relation to the electricity consumption, when the refrigerator does not have PCM, the values obtained are 709 kJ and 410 kJ for the "Initial day" and "Maintenance day" respectively. When the PCMs are incorporated in the refrigerator, these electricity consumption values are 929 and 396 kJ for the "Initial day" and "Maintenance day" respectively. Finally, for the analysed month of operation of the system, there is a slight reduction of 1.5% in the electricity consumption when the PCM are installed.

3.2 PV Production

Taking into account the daily demand for electrical energy, the proposed photovoltaic installation consists of a single multi-crystalline type module, 50Wp in STC (37WP in NOTC). The azimuth of the module is 0°, and the slope is 15°, this value is slightly higher than the latitude in order to improve the maintenance conditions. Fig 5 shows the production of the photovoltaic module, simulated in TRNSYS 16, for the month analysed (November). The average daily production of electricity is 870 kJ, with a minimum of 692 kJ on the 30th of the month, and a maximum of 1024 on the 3rd of the month.

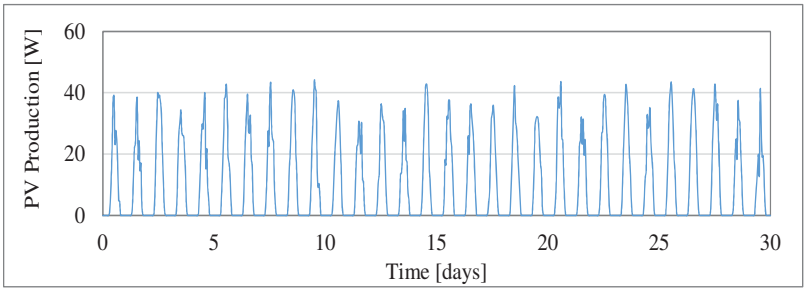


Fig. 5: Electricity production of the photovoltaic installation for analysed month

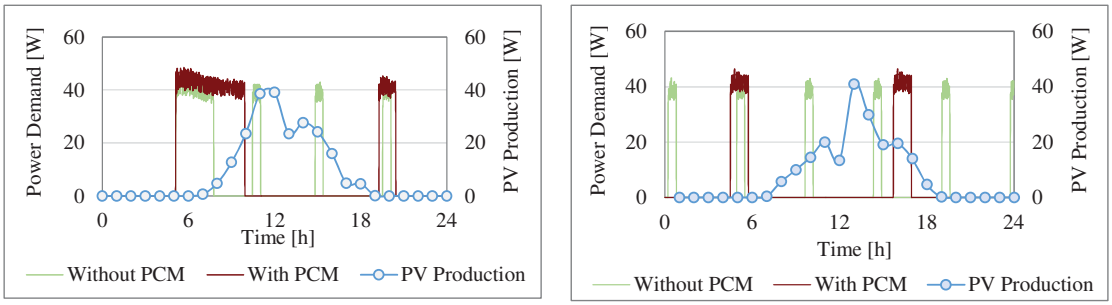
The electricity production does not match the demand, as shown in Figures 6a and 6b for the “Initial day” and the "Maintenance day" type respectively. Therefore, the installation must incorporate energy storage (thermal or electric) as is usually for the off-grid photovoltaic installations.

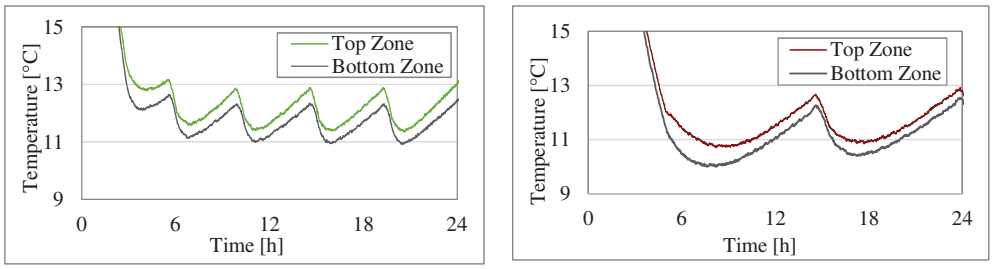


a) Initial day (b) Maintenance day

Fig. 6: Mismatch between electric production and power demand for initial and maintenance day

3.3 Evolution and stratification of product temperature

Figure 7 shows the evolution of the temperature in the top zone of the refrigerator as well as in the bottom zone, for the analysed scenarios (With PCM and without PCM). According to this information, the product temperatures in both refrigerator zones (top and bottom) are maintained within the required operating range (11 ± 2 ° C). The maxim temperature difference between the top and bottom zones is 5% for the "Without PCM" scenario and 6% for the "With PCM" scenario for the Maintenance cycles.



a) Without PCM (b) With PCM

Fig. 7: Product temperature evolution for Initial day

The data allow concluding that the influence of PCMs on stratification of product temperature is low. However, the temperature of the refrigerated product in the "With PCM" scenario is lower than the temperature in the "Without PCM" scenario. This difference of temperature between both scenarios reaches a value of 1.5°C.

The lower temperature of the "PCM" scenario is because the PCM is at a lower temperature than the product, so when the compressor stops, the heat transfer process continues until the equilibrium is reached. Therefore, it is advisable to take into account this behaviour in order to improve the control of the product temperature in the Scenario "With PCM".

3.4 Number of on-off cycles of the compressor

There are two types of operating cycles In the operation of the refrigerator: The "Initial Cycle" in which the product is cooled from the initial temperature (25 ° C) to set temperature (11 ° C); and the "Maintenance Cycle" in which the product is maintained in the required temperature range (11 ± 2 ° C). In both cycles, the compressor is "on" until the set-point temperature is reached, and then it continues "off" until the product temperature reaches the maximum allowed value.

According to the power demand profiles presented item 3.1, it is possible to verify that the number of off-on operations of the compressor are reduced from 4 to 2 for the "Initial Day" of operation, and from 5 to 2 for the "Maintenance Day" type. This implies that during the studied month, the number of off-on operations of the compressor decrease 59.7%, from 149 to 60 operations. This fact has a positive impact in the useful life of the compressor.

3.4 COP of the system

The COP was calculated according to 2.4.6, when the useful heat extracted by the evaporator was estimated by adding the heat extracted from the product, the heat gains by transmission through the enclosures, and the infiltration heat gains. The calculations were carried out for the "Initial" and "Maintenance" cycles, and for the two analysed scenarios (With PCM and Without PCM). Table 5 summarizes the results for the two analysed scenarios.

Tab. 5: COP of System

Cycle	COP Without PCM	COP With PCM
Initial cycle	2.19	1.90
Maintenance cycle	1.83	1.99

We can see that the scenario “With PCM” has a lower COP than the scenario “Without PCM” for the Initial cycle. However, the result is just the opposite when the maintenance cycle is analysed. This is because the smaller number of off-on operations of the compressor finally have a positive impact on the efficiency of the system, as some previous studies have verified.

3.5 Charging/discharging process in PCM

The charging and discharging process of PCMs can be analysed by monitoring the temperature in the encapsulation bags of PCM. Figure.8 shows the evolution of the average temperature of the PCMs located in the top, middle, and bottom zones of the refrigerator wall.

This information indicates that the PCMs located in the top and middle zones of the refrigerator wall reach the temperature required to change the phase (less than 5°C), and can storage sensible and latent thermal energy. However, the PCMs located in the bottom zone of the refrigerator wall do not reach the required temperature and only storage sensible thermal energy. This result makes necessary to adjust the integration solution of the PCMs in the bottom zone of refrigerator wall; one option can be to install insulation material in this part instead of the PCMs, and another option can be to use a PCM with a different phase change temperature.

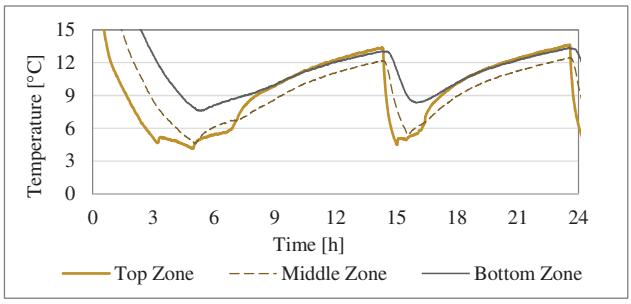


Fig. 8: Temperature evolution in the PCM

In relation to the energy rate transferred during the charging /discharging process of the PCM, the values obtained for the maintenance cycle were 177 W for charging process, and 44 W for the discharging process. These values can also be improved by other actions, such as the use of materials with better thermal conductivity to carry out the integration of PCMs.

3.6 Raise temperature time

The raise temperature time, correspond to the time from the compressor stops (off), until the refrigerated product reaches the maximum allowable temperature. The measurements were made according to “The Rise Temperature Test” included in the standards EN 62552 for household refrigerating appliances (IEC, 2013). Table 6 presents the duration of the different cycles (“Initial” and “Maintenance”), according to the state of the compressor ("on" and "off") and for each analysed scenario ("With PCM" and "Without PCM").

Tab. 6: Cycle duration time and raise temperature time

Description	Without PCM [h]			With PCM [h]		
	On	Off	Total	On	Off	Total
Duration of Initial Cycle	2.63	2.72	5.35	4.78	9.38	14.16
Duration of Maintenance Cycle	0.55	4.07	4.62	1.18	8.08	9.26
Raise Temperature Time		5.01	5.01		11.31	11.31

In general, the incorporation of the PCM in the internal side of the refrigerator increases the duration of the different cycles as well as the raise temperature time of the refrigerated product. According to these data, the raise temperature time changes from 5.01 h to 11.31 h; that means an increase of 126%. Thanks to this, the size of the energy storage with the electric batteries can be reduced as item 3.7 exposes.

3.7 Sizing of electrical battery

In order to sizing the electric storage with lead-acid batteries, we first consider the results of daily electrical consumption, presented in 3.1, and secondly we select a four-day autonomy for the system. According to this, for the “Without PCM” scenario, a battery bank should have a capacity 2345kJ, which correspond to 51Ah C20 for a voltage of 12V and a discharging time of 13.1h.

On the other hand, for the "With PCM" scenario, the initial capacity of the battery bank would be 2263kJ, which can be adjusted, taking into account the increase of the raise temperature time of the refrigerated product in this scenario. In this way, the capacity of battery bank can be reduced to 1996 kJ, which correspond to 46 Ah C20, for a voltage of 12V and a discharging time of 18.5h.

The result means a decrease of 10% in the size of the electric battery bank when the “With PCM” scenario is compared with the “Without PCM scenario”. This reduction is low, and the system should be optimized in order to improve the performance of the thermal storage with PCM.

Because of this, the experimental results will be used for validating a model and analysed different parameters in the system, such us the thickness of the PCM slab, the thickness of the insulation, and the velocity of the fans for the force convection.

4. Conclusions

This study analysed the performance of a commercial horizontal refrigerator, of 350 litres of capacity, with a direct-current compressor powered by a photovoltaic module. The refrigerator will be used later in a small-scale cheese processing at an operating temperature of 11°C. The system has an electrical storage with a lead-acid batteries and also the refrigerator incorporates a thermal storage with an inner slab of PCM, next to evaporator-wall, with a thickness of 8mm and phase change temperature between 5 and 6°C.

The analysis considers two scenarios, one is the refrigerator “Without PCM” and the other is the refrigerator “With PCM”. From the experimental data, two electrical power demand profiles have been created for a full month of operation (With PCM and Without PCM). The month selected for analysis was November, since this month has the lowest photovoltaic production throughout the year.

The incorporation of PCM, does not have a high impact in the stratification of product temperature, nevertheless the temperature of the refrigerated product is lower when the Refrigerator has the PCM slab. This is because the discharging process of the PCM continues once the compressor stops in each cycle. Taking into account, this behaviour the control system of product temperature can be improved.

Regarding to charging process of PCM, it was possible to verify that the PCM located in the top and middle zone of the refrigerator wall reach the temperature required for the freezing and took advantage of the latent energy storage; however, the PCM located in the lower do not reach the required temperature. This result makes necessary to adjust the integration solution of the PCMs in the bottom zone of refrigerator wall in order to improve the analysed thermal storage option.

The PCM gives more inertia to the system, since the number of daily on-off cycles of the compressor, has a reduction of 59.7% for an analysed month. This fact has an indirect positive impact in the useful life of the compressor and in the electricity consumption. With regard to this electricity consumption there is an increase of 31.0% in the "Initial cycle" and a decrease of 3.5% in the "Maintenance cycle". Finally, for the full-analysed month, there is a slight reduction of 1.5% in the electricity consumption.

As far the raise temperature time concern, this value increases 126%, going from 5.01h to 11.31h. This implies that conventional energy storage with electric batteries can be reduced about 10% for the analysed application. This reduction is low, and the system should be optimized.

Efficient Solar Cooling by Using Variable-Effect LiBr-H_2O Absorption Chiller and Linear Fresnel Solar Collector with Cavity Receiver

Yanjun Dai, Jishuai Ma

Institute of Refrigeration and Cryogenic Engineering, Shanghai Jiao Tong University, Shanghai (China)

Abstract

A solar cooling system, which mainly consists of a variable-effect LiBr-H_2O absorption chiller and arrays of linear Fresnel solar collector, has been investigated and analyzed by experiment. The 50 kW variable-effect absorption chiller, which can work from single to double effect mode continuously, depending on the temperature level of the linear Fresnel solar collector array, can obtain a COP span of 0.6–1.15. Compared to the conventional single- and double-effect solar absorption cooling, the solar variable-effect cooling is capable of operating for a longer time, leading to more cooling output. Such solar cooling plant has been tested and analyzed in depth. The experimental results show that thermal efficiency of the linear Fresnel solar collector is approximately 58.8%, and the operation temperature is as high as 147 °C. Thermal COP of the variable-effect LiBr-H_2O absorption chiller varies between 0.84–1.05 depending on the solar collector temperature. The solar cooling plant can convert solar radiation to cooling output accompanied by a solar COP span of 0.41–0.53 under given conditions.

Keywords: Solar cooling, variable effect, absorption chiller, Linear Fresnel solar collector, performance evaluation.

1. Introduction

Solar cooling is a promising approach to shift the peak of power grid due to its ability of converting effective solar radiation to cooling production which reducing the energy demand of city power grid. So far, it has been recognized as one of the best substitutes of conventional cooling, and is attracting more and more attention worldwide, especially in the regions with the hot and humid climate (Winston et al., 2014). Conventionally, a solar cooling plant is configured by single-effect LiBr-H_2O absorption chiller driven by stationary solar collectors (e.g. non-tracking flat plate or evacuated tubular solar collectors), or by double-effect LiBr-H_2O absorption chiller driven by concentrated solar collectors (e.g. trough or linear Fresnel solar collectors). For the first option, the conversion efficiency from solar radiation to cooling production (i.e. solar COP) is lower than 0.3. For the second option, the solar COP can be greatly upgraded due to the higher COP of double-effect chiller and high flux contributed by concentrated solar collector, however, the operation time of cooling output is limited because of a high driving temperature required by double-effect absorption chiller. To reach the target of high efficiency and longer time of solar cooling, it is urgent to develop a novel absorption chiller and the corresponding concentrated solar collector.

The predominant merit of linear Fresnel reflector (LFR) solar collector is the decrement manufacturing, operation and maintenance costs (Gharbi et al., 2011). LFR solar collector is becoming a potential method for solar thermal cooling and mid-temperature industrial utilization due to its simplicity in structural design and low investment cost. Chemisana et al. (2011, 2013) carried out a solar cooling system driven by LFR solar collector which provided thermal energy to a double effect LiBr-H_2O absorption chiller, where the rated COP of 1.35 and 150-170 °C driving temperature of chiller can be observed. The results showed that the LFR solar thermal cooling system has advantages and disadvantages. The advantageous is that a higher solar cooling COP can be realized with LFR solar collector under good conditions of solar irradiance. However, the disadvantageous in the system may be somewhat complex and expensive compared with the non-tracking solar cooling system. When comparing to evacuated tubular LFR collector, cavity receiver has its merits in cost benefit, and thermal stability, especially for pressure water cycle. Zhou et al., 2017 assessed

doi:10.18086/swc.2017.28.03 Available at http://proceedings.ises.org

the performance of a single/double hybrid effect absorption cooling system driven by linear Fresnel solar collectors with latent thermal storage, based on the parametric optimization. The variable-effect absorption refrigeration cycle previously proposed by Xu et al. (2013) indicates the COP of variable effect cycle increases with driving temperature. Based on the concept design, a 50 kW prototype of variable effect LiBr-H_2O absorption chiller was built and tested (Xu and Wang, 2016).

To date few reports of such similar detailed analysis of the performance in LFR solar thermal cooling system combined with the variable-effect absorption chiller has been produced. In this paper, an integrated LFR solar thermal cooling system with a variable-effect absorption chiller is introduced and studied experimentally. The individual test was carried out for major components including LFR solar collector arrays, and the variable-effect chiller. Finally, the solar COP of the entire cooling system was evaluated by dynamic test.

2. Description of the solar cooling system

The solar cooling system investigated in this paper is composed of a 50 kW variable-effect absorption chiller and LFR solar collector arrays with total aperture area of 144 m^2. In fact, the solar cooling system is originally a small part of a solar tri-generation system, for heating, cooling and power generation by using an ORC generator, shown in Fig. 1. Specifically, LFR solar collector arrays convert effective solar radiation to intermediate temperature heat, and then the heat is charged into a steam manifold that produces steam for the variable-effect absorption chiller (cooling), the ORC generator (power), and the domestic water (hot water). In this paper, the authors only focus on performance of the variable-effect absorption chiller driven by high-temperature steam heated by LFR solar collector arrays, outlined in Fig. 1.

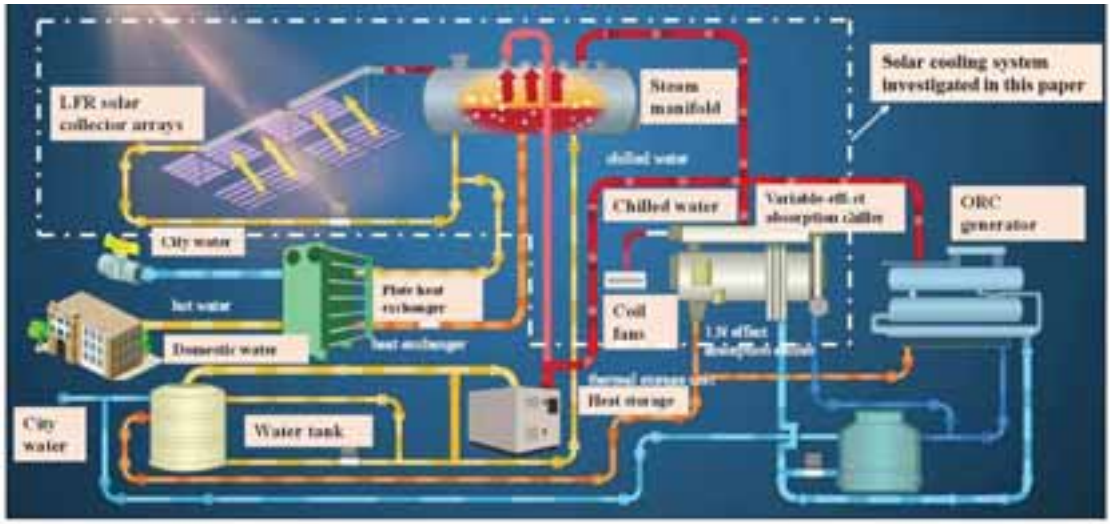

Fig. 1: Schematic diagram of the solar cooling plant with a variable-effect absorption chiller and LFR solar collectors

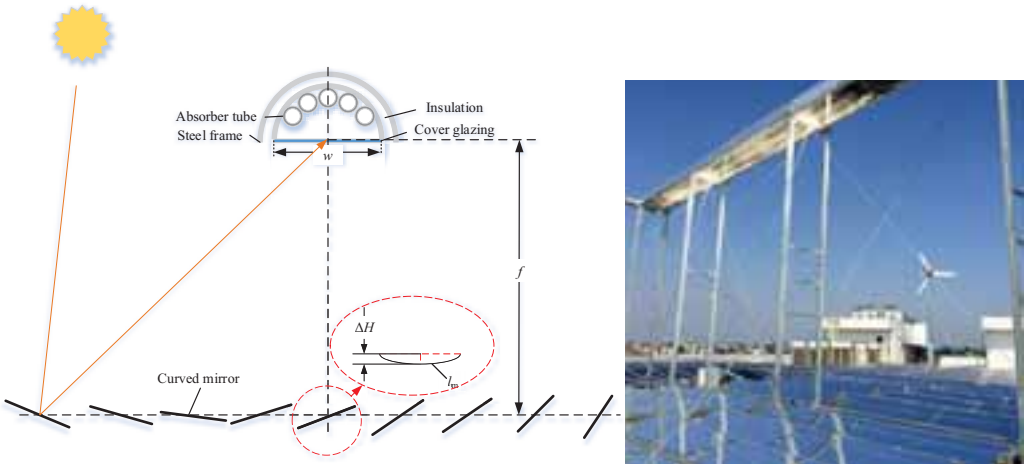
2.1. LFR solar collectors

A prototype of LFR solar collector employed steel tubular absorbers coated with selective absorption film was developed and serves as the thermal source. The schematic and prototype of LFR solar collectors are shown in Fig. 2.

The array of LFR collector consists of 8 individual LFR collector units, where each unit contains 12 rows of curved mirrors. The curved mirror was designed with an arch height of ΔH = 3 mm. To reduce the effect of shading and blocking caused by adjacent mirrors on the optical efficiency of LFR collector, the distance

between adjacent rows was set to be 7 cm based on the model proposed by Mathur et al. (1991). The semi-circle cavity receiver with reasonable optical efficiency, relatively low investment, operation, and maintenance costs (Xie et al., 2012) was located at the latitude of 4 m, where the semi-circle receiver is comprised of five copper pipes with the inner diameter of 38 mm. Selective black chromium coating was covered on the surface of absorber pipes with a ultra-white glass of 3 mm thickness. Besides, phenolic foam serves as the insulation material between absorber and steel frame to minimize the conductive heat loss. The structure and other main parameters of LFR collector are shown in Table.1.



(a) (b)

Fig. 2: The schematic and photograph of LFR solar collectors: (a) schematic of the LFR solar collector, and (b) the prototype

Table 1: The geometric and thermos-physical properties of the LFR solar collector array

Component	Parameters	Value
Mirror array	Number of units	8
	Collector area of each unit	18 m^2
Curved mirror	Arch height	3 mm
	Mirror length	3 m
	Mirror width	50 cm
	Distance of the adjacent mirrors	7 cm
Cavity receiver	Altitude	4 m
	Inner diameter (D_i) of absorber tube	38 mm
	Aperture width (w)	53 cm
	Aperture area	1.59 m^2 (each LFR unit)
	Thickness of the cover glazing	3 mm
	Absorptivity	0.85
	Emissivity (at 353 K)	0.5

2.2. Variable-effect absorption chiller

The variable effect absorption chiller, which is configured by adding an additional low pressure generator for

harvesting the absorption heat, is the main section to improve the solar cooling efficiency. As is shown in Fig. 3, the main components of the chiller are presented. Fig. 3a (Xu et al., 2016) shows the thermodynamic cycle of the variable-effect absorption cooling. The variable absorption cooling works in three processes: (1) if the temperature of heat resource is enough high (> 140 °C), it works in double effect mode, and the chiller is a double effect absorption chiller; (2) if the temperature of heat resource is less than 100 °C, it works in single effect mode; (3) if the temperature level is in the range of 100-140 °C, the chiller works in the 1.N effect mode, namely, it can work almost linearly from single to double effect depending on the temperature level, thus the cooling output can be increased, in comparison with the normal single effect or double effect chiller, especially for solar cooling application. The key for realizing variable-effect absorption cooling is that the internal absorption heat recovery in the high pressure absorber, even when the temperature level can not effect complete operation of high pressure generator, it can still contribute some for cooling production by using the heat from the high pressure absorber to the additional low pressure generator. The detailed thermodynamic process of the solar energy conversion and the cooling production is investigated. The prototype of the variable-effect absorption chiller is shown in Fig. 3b. The detailed parameters of the 50 kW variable-effect absorption chiller were reported by Xu et al., 2015.

3. Performance indexes

3.1. LFR solar collector

Optical efficiency η_o of LFR solar collector can be introduced with respect to cosine efficiency, end loss, reflectivity of mirror, and absorptivity of the absorber. The similar theoretical models (Morin et al., 2012) are used to predict the solar-to-thermal performance of the proposed LFR solar collectors. According to energy balance, the heat absorbed by cavity receiver is equal to the difference of the heat reflected to cavity surface by mirrors and heat loss of cavity, which is shown as the following relationship:

$$\eta_{th} = F_R\left[\eta_0 - \frac{U_L(T_{i,LFR} - T_{amb})}{CI_b}\right] \quad \text{(eq. 1)}$$

where F_R is the heat removal factor of the solar collector. $T_{i,LFR}$ is inlet temperature of pressure hot water. I_b is direct normal irradiance (DNI). U_L is heat loss coefficient between HTF and ambience. T_{amb} is ambient temperature. Geometric concentration ratio C of the LFR collector is defined as the ratio of collecting area A_c and absorber area A_a of the receiver.

Thermal efficiency represents the ratio between absorbed energy by cavity receiver and total energy received by mirror fields in steady state or sufficiently good quasi steady state condition. Thermal efficiency can be calculated by

$$\eta_{\mathrm{th}} = \frac{\dot{m}c_p\left(T_{\mathrm{o,LFR}} - T_{\mathrm{i,LFR}}\right)}{I_{\mathrm{b}}A_{\mathrm{c}}} \quad \text{(eq. 2)}$$

where $\dot{m}$ is mass flow rate of pressure water. c_p is specific heat of HTF. $T_{\mathrm{o,LFR}}$ represents the outlet temperature of the LFR collector array.

The heat loss coefficient of LFR solar collector can be expressed as

$$F_R U_L = \frac{Q_{\mathrm{loss}}}{A_{\mathrm{a}}\left(T_{\mathrm{i,LFR}} - T_{\mathrm{amb}}\right)} = \frac{\dot{m}c_p\left(T_{\mathrm{i,LFR}} - T_{\mathrm{o,LFR}}\right)}{A_{\mathrm{a}}\left(T_{\mathrm{i,LFR}} - T_{\mathrm{amb}}\right)} \quad \text{(eq. 3)}$$

3.2. Variable-effect absorption chiller

Cooling capacity is calculated by

$$Q_{\mathrm{chw}} = \dot{m}_{\mathrm{chw}} c_{p\mathrm{chw}} (T_{\mathrm{chw,in}} - T_{\mathrm{chw,out}}) \quad \text{(eq. 4)}$$

where $\dot{m}_{\mathrm{chw}}$ is defined as the flow rate of chilled water. $c_{p\mathrm{chw}}$ denotes specific heat of chilled water. $T_{\mathrm{chw,in}}$ and $T_{\mathrm{chw,out}}$ are the inlet and outlet temperatures of chilled water.

Input power of the pressure hot water is calculated in terms of flow rate of hot water ($\dot{m}_{\mathrm{hw}}$), specific heat of hot water ($c_{p\mathrm{hw}}$), inlet and outlet temperatures ($T_{\mathrm{hw,in}}$ and $T_{\mathrm{hw,out}}$) of hot water. The equation can be expressed by

$$Q_{\mathrm{hw}} = \dot{m}_{\mathrm{hw}} c_{p\mathrm{hw}} (T_{\mathrm{hw,in}} - T_{\mathrm{hw,out}}) \quad \text{(eq. 5)}$$

Based on the cooling capacity and input power of pressure hot water, COP of the variable-effect absorption chiller can be expressed by

$$\mathrm{COP} = \frac{Q_{\mathrm{chw}}}{Q_{\mathrm{hw}}} \quad \text{(eq. 6)}$$

Considering the conversion performance from solar radiation to cooling production, the solar COP is defined as

$$\mathrm{COP}_{\mathrm{s}} = \frac{Q_{\mathrm{chw}}}{I_{\mathrm{b}}A_{\mathrm{c}}} \quad \text{(eq. 7)}$$

4. Results and discussion

Thermal performance of the solar cooling system was tested under outdoor field conditions on the roof of a building in Guangzhou. In order to conduct a practical assessment, the variable-effect absorption chiller and the LFR solar collector array were experimented under dynamic conditions. In the testing system, physical measurement parameters should include all temperatures at the inlet and the outlet of all units, circulating volume flow rates, ambient temperature, and DNI. Platinum resistance thermometers (PT100) were used to measure all temperatures. All temperature sensors were calibrated to an absolute measuring error of 0.1 K and a relative deviation between each other less than 0.05 K. To minimize temperature measurement error, two temperature sensors were located as close as possible to the inlet and outlet locations. A pyrheliometer with the measuring error less than 5% were employed to measure DNI. The ambient temperature sensor was housed in a well-ventilated instrumentation shelter above the ground and with its door facing north in order to shield from direct irradiation. A set of Keithley 2700 served as the data logger, which collects and records the data of sensors with a time interval of 10 s.

Fig. 5 shows the variations of DNI and ambient temperature as a function of local time in the test day. As seen, it was typical cloudy day. The DNI varied in a span of 100-650 W/m^2 due to the cloudy weather condition and the mean ambient temperature is about 32 °C.

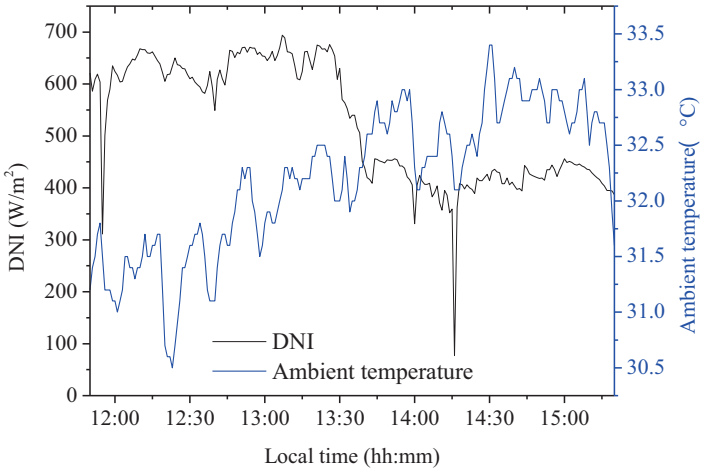

Fig. 5: DNI and ambient temperature as a function of local time

Fig. 6 shows the thermal performance of the LFR solar collector array including inlet and outlet temperatures, and thermal efficiency. The test results indicated that the peak temperature of the LFR solar collector array with cavity receiver can reach 150 °C under weather conditions shown in Fig. 5. It should be noted that the inlet and outlet temperatures of pressure hot water gradually increased, however, the DNI decreased hugely after 13:30. It is mainly contributed by the heat capacity of the steam manifold like storage tank. Thermal efficiency gradually decreased with the increasing temperature of hot water mainly due to the increasing heat loss of the cavity receiver.

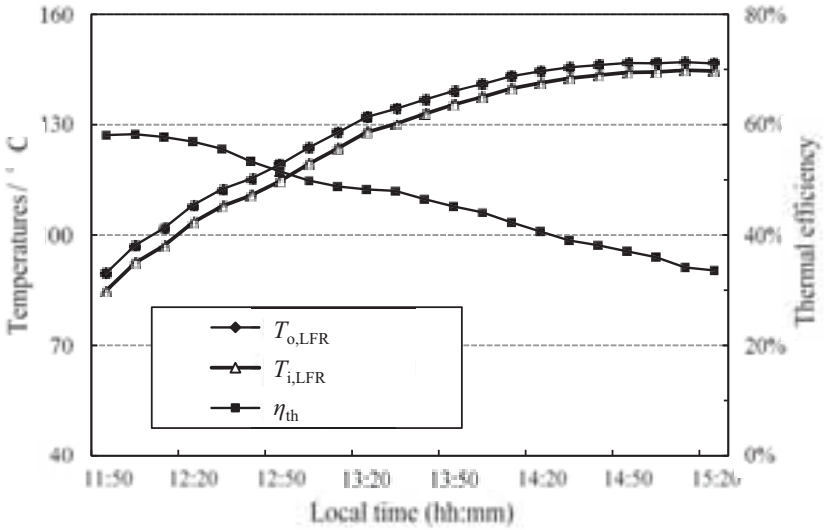

Fig. 6: Thermal performance of the LFR solar collector array

The details of performance of the variable-effect absorption chiller are depicted in Fig. 7. The cooling capacity of the variable-effect absorption chiller is around 50 kW, and the thermal COP of the chiller is about 1.05 during the operation period. During a typical cloudy day, the chiller COP varies from 0.84-1.05, much higher than the solar single effect absorption cooling system. It is found that the solar cooling system works well and the chiller COP is always above 0.8 during the given period. Fig. 8 further shows the variations of the system COP, indicating that 36-53% of solar radiation can be converted to cooling output. Also found is

that the solar thermal efficiency for the Fresnel solar collector varies from 36-58% during the operation period, and the operation temperature is within the range of 90-147°C. The cooling output changes (Q_{chw}) from 28-65.8 kW accordingly. It is important that the COP and the cooling output are almost linearly changing instead of step changing from single effect mode to double effect mode, and the operation time is also extended.

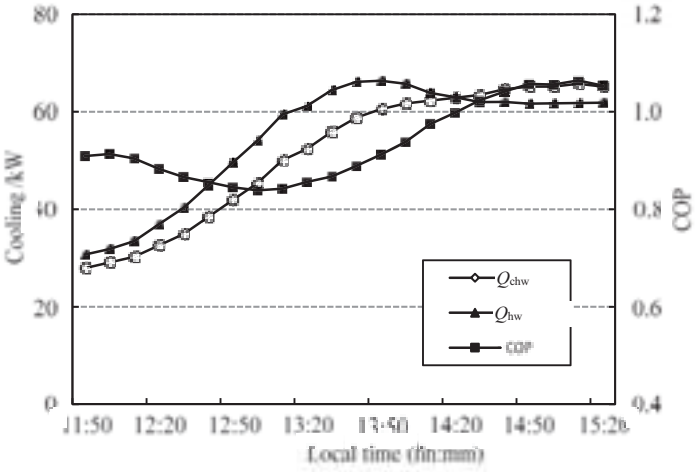

Fig. 7: Cooling output and chiller COP as a function of local time

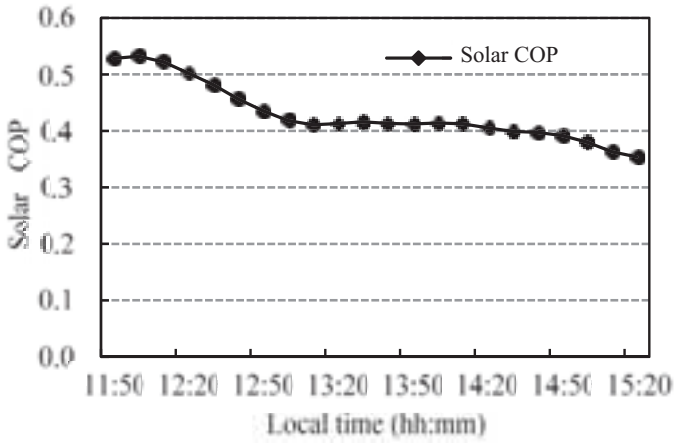

Fig. 8: Solar COP as a function of local time

5. Conclusions and Future work

A solar cooling system, composed of linear Fresnel reflector (LFR) solar collectors, a variable-effect absorption chiller and assistant components was established and investigated experimentally in this paper. A typical cloudy day test was conducted. The corresponding conclusions can be drawn:

(1) Thermal efficiency for the LFR solar collector varied from 36-58% during the operation period, and the operation temperature was in a temperature span of 90–147 °C.

(2) The solar cooling system COP is about 0.4–0.5, indicating that this design and configuration for solar cooling can convert 40-50% of solar radiation to cooling output. The results show that the variable-effect absorption chiller is one of the best choices for improving solar cooling output and efficiency.

Future work will be focused on detailed whole day and entire summer season test, parametric optimization of

such kind of solar cooling system, and cost benefit analysis.

Abstract

This paper presents a smart design named PV COOLING to produce solar cooling using low GWP heat pump system coupled with a standard photovoltaic plant. A maximum of self-consumption is promoted by means of a light bank of batteries and chilled water tank. For this, a test bench has been installed on the building roof in the south of France with the originality to be entirely controllable in terms of building load injected. Thereafter, this new system aims to be used for air-conditioning and/or dehumidification in the tertiary sector and positive cold storage in the industrial sector in countries where climatic, regulatory and technical conditions are suitable. PV COOLING potential is developed within a market study. The aim of this study is to assess the thermal / electrical performances of our test bench with the purpose to air-conditioning a building by means of several sensors and meters.

Keywords: solar air conditioning, photovoltaic, heat pump, self-consumption, batteries, inverter, thermal tank, glycol water, propane, R290, low GWP, air-conditioning, cold storage

1. Introduction

Until now, traditional PV economic model was based on feed-in tariff. However this trend is currently moving toward on-site self-consumption. PV self-consumption can be used in a straightforward manner for domestic purposes: lighting, heating, domestic hot water heating (DHW), cooking, domestic appliances, etc.

An example of application consists in using solar power to directly drive a thermodynamic device with a target to produce cooling or refrigeration. It can be noted that PV production perfectly matches cooling needs during the day. Besides, in many countries all over the world, the summer comfort in buildings becomes necessary in order to allow employees to work in good condition.

The use of renewable energy for powering heat pumps can solve environmental problems due to the ways of producing energy (e.g. CO2 emissions by coal thermal plants in China). Even if the energy problem is settled, it remains the issue of refrigerant fluid leakage which represents a non-negligible share of the greenhouse effect. Therefore, the use of low global warming potential (GWP) fluid in thermodynamic system allows to reduce the device carbon footprint.

2. The adopted strategy

At first glance, compressor power shall be adapted with PV output power. This may work within a certain range until a minimum threshold where chiller compressor has to be stopped. When PV output power is back, the main issue is to be sure that power remains sufficiently stable and reliable to start compressor again and avoid short-cycle. Indeed, the problem of driving a chiller compressor with PV lies in the fact that it may happen that irradiation may be temporary obstructed by some peculiar clouds.

doi:10.18086/swc.2017.28.04 Available at http://proceedings.ises.org

Using variable-frequency drive can solve the problem of high inrush current during compressor run-up. For the intermittent energy problem, storage using batteries or other electricity supply can easily sort this problem out. It's also possible to mix with thermal storage system which is a shorter-term storage mode. Both electricity and thermal storage allow to store a sufficient energy when the PV production exceeds and use it when the need becomes higher than the PV production.

To contribute to an environmentally friendly device, propane (R290) has been chosen as refrigerant for this project. This very low GWP refrigerant (GWP < 10) combined with an original configuration allows a significant reduction of refrigerant amount. To maximize the self-consumption, the inverter has to allow both electric powers issued from PV and batteries.

This research aims to study a test bench using PV cooling, installed on the building roof in the south of France. For a better understanding of the system behaviour, instead of cooling the building, cooling is distributed into a chilled water tank in which is fitted a power controlled heating resistor which simulated all sorts of building thermal load configurations.

3. Promoting solar photovoltaic on new market segments

3.1. Air-conditioning for the tertiary sector

To avoid an unfair competition with cheap traditional heat pump produced at ten millions samples yearly, PV cooling will be suitable for medium / high power in the tertiary sector and according to certain criteria. The criteria to lead the market study are classified into three main contextual families (climatic, economic and regulatory) and are summarized through a "bubble chart" (Fig. 1). These criteria are expressed inside the chart as:

- The cooling demand expressed in cooling degree days (CDD) on the x-axis.
- The annual global horizontal irradiation (GHI) per square meter on the y-axis.
- The market size of mid-sized / large heat pump in the tertiary sector is expressed by the percentage of the worldwide unit demand through the surface size of the bubble.
- The electricity price in the tertiary sector as a driver of renewable investment is expressed by the colour of the country, with cheap costs in light and high costs in black.
- Finally, self-consumption policy and fiscal incentives which are positive for renewables (e.g. feed-in-tariffs, subsidies, solar obligations) are marked with (+); others with (-) and unclear situation with (?).

Figure 1 shows only the final result of an ambitious market study. Indeed, several countries have been removed from previous "bubble charts" because of following weaknesses. First of all, many countries in Europe have an insufficient radiation like Germany and even if the radiation is enough like in South Europe, the cooling needs are only present during summer. Among countries which gather good natural conditions (both radiation and cooling needs), the low electricity price doesn't allow for photovoltaic to be profitable (e.g. Saudi Arabia).

Countries that appear qualitatively as the most mature to accommodate a short-term photovoltaic air-conditioning system according to Figure 1 are mainly countries with a tropical climate. Indeed, under this kind of climate, the cooling needs are constant during the full year. Electricity price appears as an important criterion which participates to have a return on investment the most quickly possible.

The market size is not an essential criterion because PV COOLING can find its place in a market niche where the tertiary sector is not developed like high-income countries. For instance, the air-conditioning for a cybercafe in Africa which doesn't have access to a reliable electrical grid. Indeed, more and more African cities have the means to propose services moving towards European standard for a category of population which are increasingly financially secure.

The self-consumption policy and fiscal incentives are the last criterion which may help PV solutions to be more attractive especially the right to self-consume. But it is difficult to be entirely exhaustive in each country because the PV policy changes quickly. PV outlooks show that each government will pass laws to tend towards a smarter way to consume photovoltaic which is self-consumption model. Besides, a lot of PV self-consumption projects take place in countries where no PV policy exists particularly in Western Africa. That means PV policy is not a necessary criterion to have the right to self-consume.

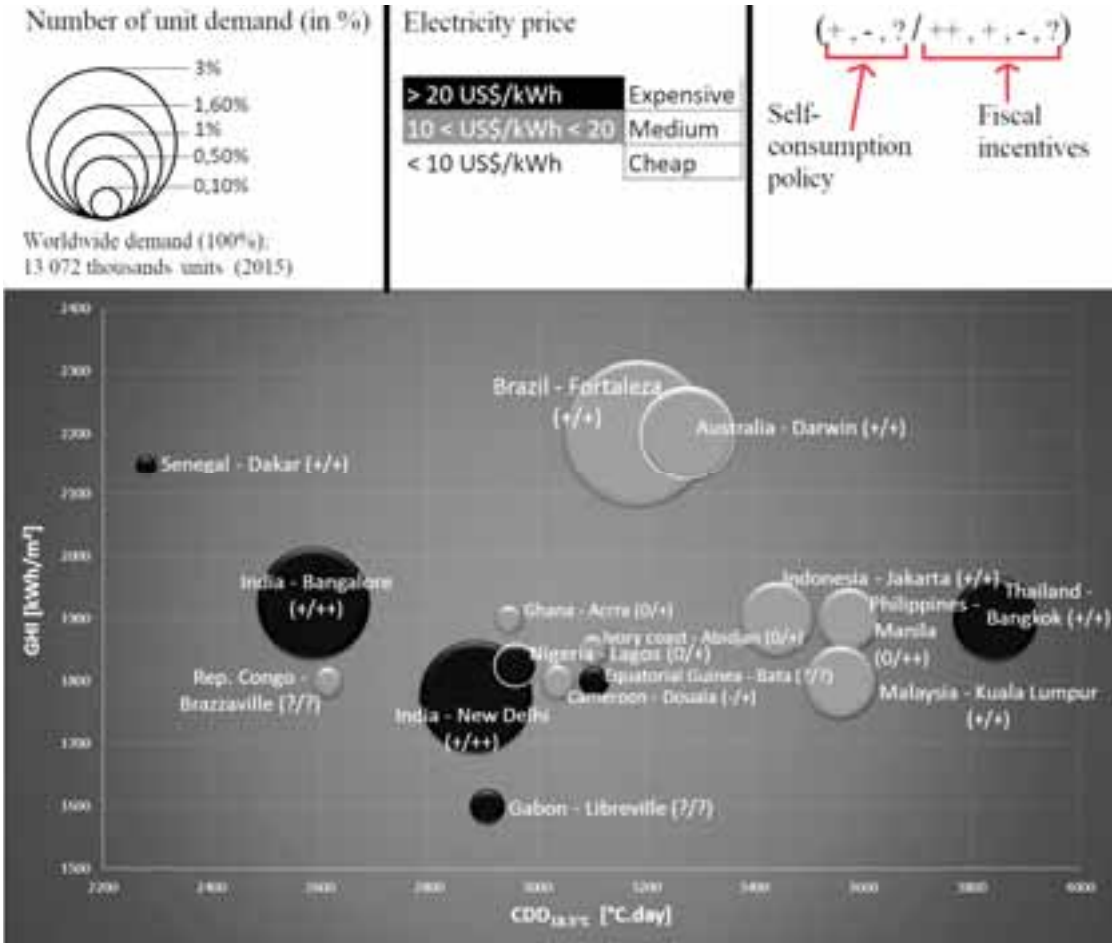

Fig. 1: Graph illustrating the attractiveness of cooling markets for PV COOLING

3.2. Cold room for perishables foods in industrial sector

The industrial sector which matches quite well with the natural condition is agri-food industry and more specifically storage for perishable food items with positive cold storage or refrigerated warehouse. The perishable foodstuffs which require positive cold storage to maintain a longer lifetime are mostly fruits & vegetables and roots & tubers. Countries with tropical climate appear to be regions where food harvest are significant and represent a considerable share of GDP. The majority of countries with tropical climate are low or middle-income, so the food cold chain is not developed as high-income countries. This is why due to

economic and climate problems (hot and damp), tropical climate regions have a significant food losses share caused by a lack of cold storage (Jenny Gustavsson et al., 2011).

As the air-conditioning study market, the “bubble chart” underlines the fact that tropical countries appear to be the most attractive for PV COOLING usage for positive cold storage food.

We can notice all the same a slight difference, with the apparition of very low-income countries in Africa in the “bubble chart” owing to the fact that agriculture is the only source of revenue.

4. R&D carried out for a properly sized system

Actual PV COOLING innovation mainly consists of setting together in a clever way, components which actually are highly improved, but never have been set together in a single goal system: PV plant dedicated to driving a thermodynamic fluid chiller as shown in Figure 2.

This is the fruit of two years co-operation with four French companies, with several decades’ expertise in solar energy (Tecsol), heat exchangers technology & design (NeoTherm Consulting), designing special thermodynamic equipment (EED) and designing & implementing innovative systems (Atisys).

Besides, the R&D project has also an academic dimension in France with an expert in cold industry from the Conservatoire National des Arts & Métiers (CNAM-Paris).

4.1. Overall PV COOLING architecture

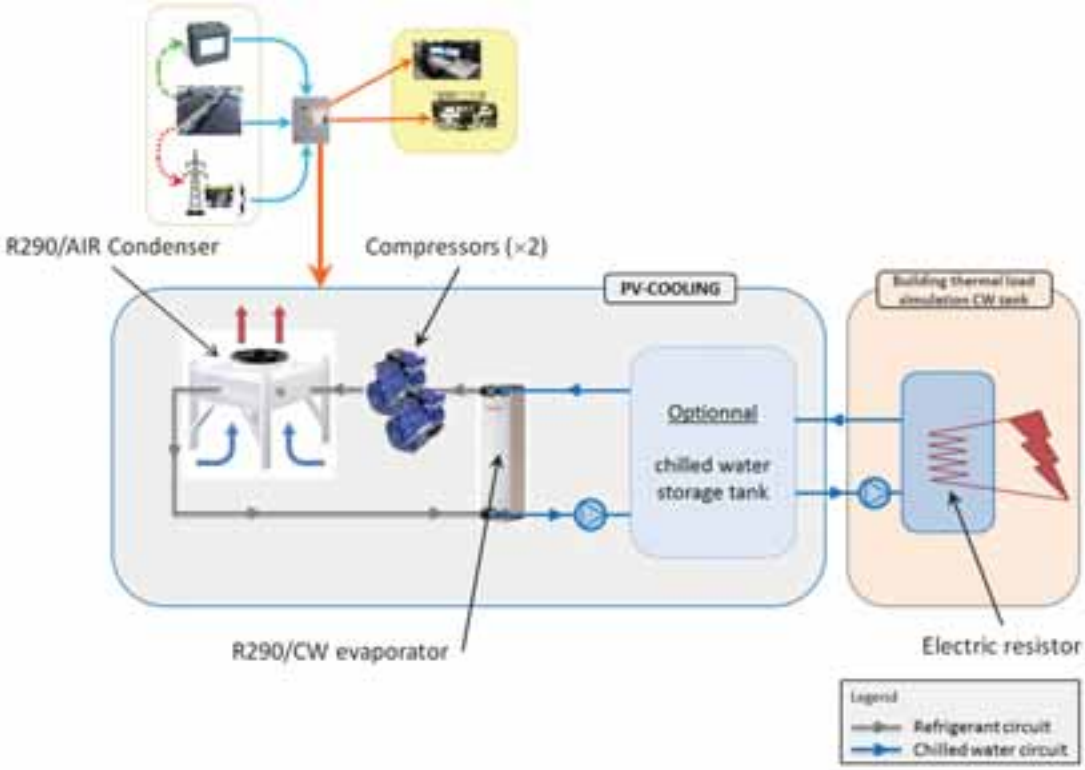

Fig. 2: Schematic architecture of PV-COOLING system

4.2. Layout description

The first test bench, installed on the Atisys head-office roof-top, is located in Toulon area (South East of France, lovely site in French Riviera).

Fig. 3: Picture of 19 mono-crystalline photovoltaic modules (280 Watts peak (Wp) for each module) on the Atisys roof top

Fig. 4: PV COOLING control and management system

In the pilot testing system, electrical production is delivered by 18 mono-crystalline photovoltaic modules (280 Watts peak (Wp) for each module) as illustrated on Figure 3, which represents a total power of 5.0 kWp. This power is quite enough for driving chiller compressors and all ancillary equipment dimensioned for 10 kW_{th} chilling power (condenser fan and chilled water circulation pump).

These photovoltaic panels are connected to a three-phase wired inverter along with batteries bank. The four selected 12-Volt batteries are connected in series to obtain a voltage of 48V. Their 150Ah capacity each with a 50% depth of discharge (DOD) allows to obtain a useful electrical storage energy about 3.6kWh. This is enough to drive the full load power installation at least for one hour.

For a real operational system, battery capacity may be chosen according to actual need.

In order to limit the inrush current during compressor run-up, a variable-frequency drive has been installed downstream from the inverter which makes possible to divide the inrush current by 6.

Figure 4 presents the complete electrical setting.

Two parallel-mounted semi-hermetic compressors were selected and adapted for propane. Each compressor can provide from 2.4 to 5.4 kW of cooling by varying its rotation frequency from 30 to 70 Hz. This allows a cooling capacity between 2.4 and 10.8 kW. For the future, commercial PV cooling systems will be able to reach high cooling power till 300 kW using bigger compressors. It is enough to size the other equipment accordingly.

Fig. 5: Picture of the Two parallel-mounted semi-hermetically compressors

The condenser is an air/R290 type heat exchanger, also called air-cooled condenser. In order to reduce refrigerant load, a microchannel type condenser has been chosen.

The evaporator selected for the project is brazed plate heat exchangers, also suitable for propane.

The major innovation regarding the heat pump system lies in the use of low Global Warming Potential (GWP) refrigerant.

The choice fell on propane (R290) with (<10) GWP, which is considerably low compared to a common refrigerant (e.g. 1300 GWP for R134a).

The only drawback with using propane is the necessity of additional security due to propane flammability. In our case and according with French safety regulation, setting the chiller outdoor (see Fig. 6) is considered as sufficient. Thus, no additional security is necessary.

The fluid that transports the refrigerating capacity from the cold unit to the chilled water tank is water/methyl propylene glycol (MPG) mixture, so as to avoid any freezing risk.

Fig. 6: Picture of the global chiller installation installed on the Atisys top roof

For this test bench, the chilled water tank is representative of a typical building whose thermal load is simulated with an electrical resistor heating the 180L chilled water tank (see heater on Fig. 6). That gives the advantage to fully control the building loads and consequently simulate several conditions which correspond to different building utilization/insulation and climate conditions.

A monitoring system has been set up with a view to monitoring performances of the system according to the needs throughout the year. Monitoring is powered by PV-COOLING itself.

4.3. PV COOLING management

Building thermal load is estimated as follows:

$$P_{Build-Load}(t) = G \times V \times \left[T_{ext}(t) - T_{set}(t)\right] + K \times S_{Build} P_{Sol.Ir}(t) * \delta(t-\tau) \qquad \text{(eq. 1)}$$

With:
- T_{ext} : outdoor temperature
- T_{set} : indoor setpoint temperature
- G : volume heat loss coefficient [W/m^3.°C] choosen as G=2.5 (poorly insulated building in our case)
- V: the cooled volume. V=325 m^3
- $P_{Sol.Ir}$: Power of solar irradiation [W/m^2]
- S_{Build} : time average wall surface of building exposed to solar irradiation (chosen to 40 m^2)
- K: solar power absorption sensitivity of building walls [non-dimensional, $0 \leq K \leq 1$], chosen to 0.20
- $\delta(t-\tau)$: delay function (Dirac), corresponds to thermal inertia of building to solar irradiation (τ = 1 hour)

For the automatic control of heat pump management, several approaches are tested between two main paradigms.

The first one is the **economy mode** (also designated as **"eco" mode**) in which compressor driving power is adapted to PV output power.

The second one is the **comfort mode** in which setpoint value consists in keeping constant chilled water feedback temperature (12°C) and if necessary take complementary power from the grid when both PV and batteries power are insufficient.

5. Results and discussion

PV COOLING test bench has been tested during several months with monitoring sequences of several days from June to September 2017. The electrical resistance of the heater has been controlled to model a 325 m^3 building (i.e. 125m^2 with a high ceiling of 2.60m). To correspond to reality, an outside temperature sensor has been installed.

PV COOLING major monitoring data and performance results are presented hereby, for both **"eco"** and **"comfort"** modes, and under both **sunny** and **intermittently disrupted sunny/cloudy** conditions.

On graphical displays of fig. 7 to 11, negative values of grid electric powers means that power in injected by PV system into the grid (red curve). For battery (black curve), it is the opposite (this was done for lisibility).

Data and performances results are obtained on a daily basis, from 8 a.m. up to 7 p.m. Those data may permit one to appreciating PV COOLING efficiency (fig. 12), especially EER (ratio of thermal energy produced to grid energy consumption, from 8 a.m. up to 7 p.m.).

5.1. "eco" mode

Figure 7 below shows PV COOLING monitoring data captured on Sept 5th. Although this was a very sunny day, weather was quite windy due to a northern dry and cold wind, designated as "Mistral" (quite typical of south of France) : Mistral blows clouds away and also pushes Mediterranean sea thermocline offshore, such that sometimes even in summer, swimming on the French Riviera is a matter of bravery !

That explains why despite of sunny conditions, thermal load is far below classical figure in this period of the year. Therefore, PV-COOLING power remains far below PV power until late afternoon (5:30 p.m.) and no any external source is required.

This case gives **EER = 106.3** ! (see fig. 12).

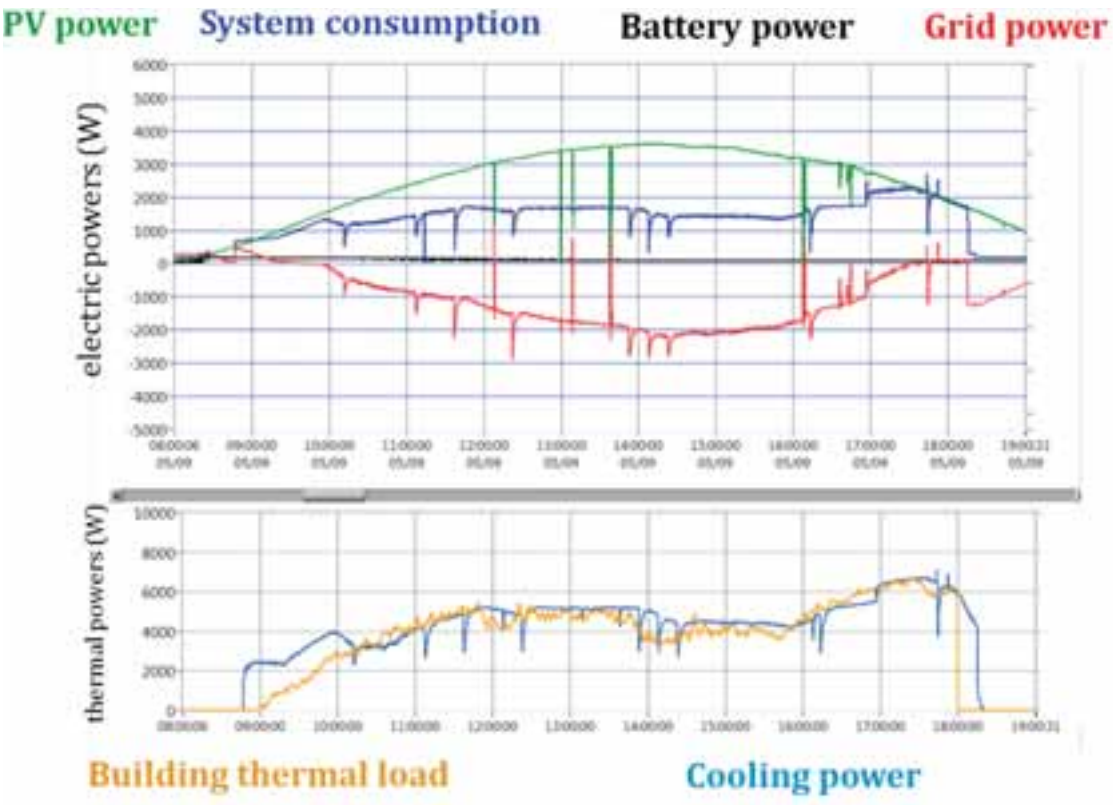

Fig. 7: Electric and thermal powers time history (Sept 5th 2017 – TOULON) – "eco" mode

It can be noticed that if PV-COOLING manager was configured as “comfort” mode, results would have been identical.

Figure 8 displays a much more significant case of ”eco” mode efficiency : Sept 6th was quite a disrupted sunny/cloudy day until 4:00 p.m. and in can be seen that system consumption (and thus cooling power) is limited by both PV power and thermal load.

One can notice that despite disrupted conditions, Sept 6th conditions show a much higher building thermal load than eve, and even in “eco” mode, cooling power matches quite well thermal load history.

This case gives **EER = 44** (see fig. 12).

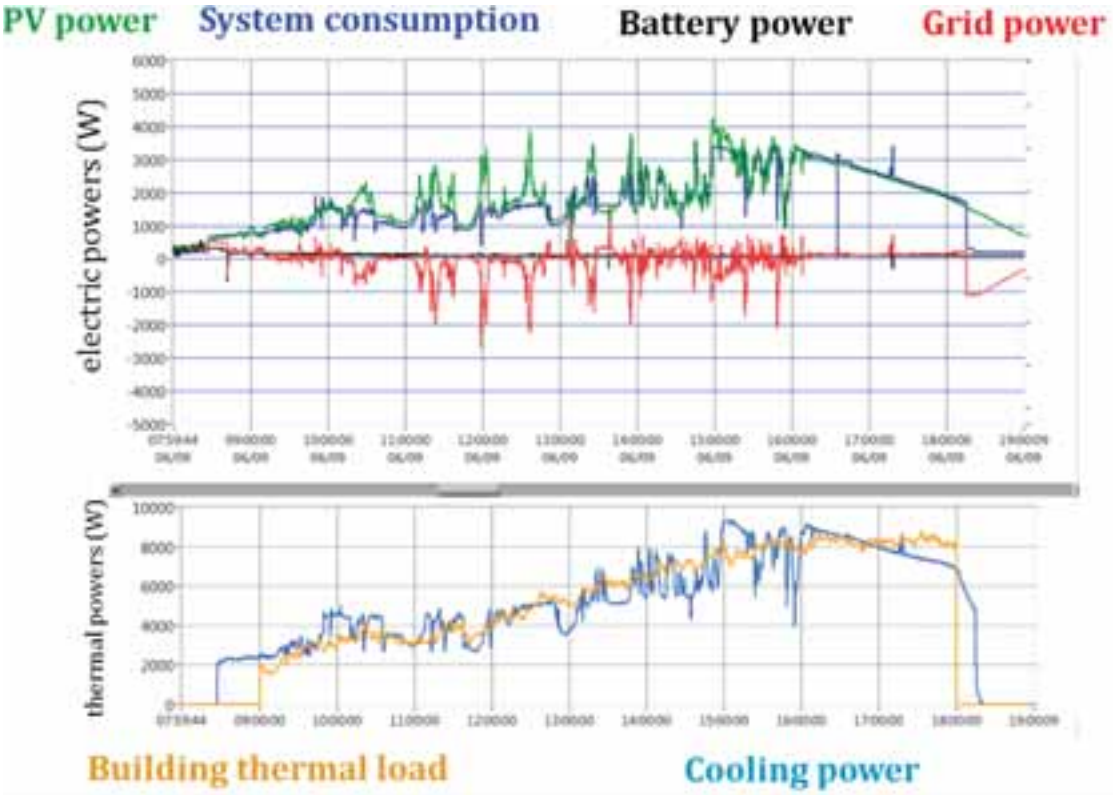

Fig. 8: Electric and thermal powers time history (Sept 6th 2017 – TOULON) – “eco” mode

5.1.”comfort" mode

Figure 9 displays PV-COOLING results obtained on Aug. 28th 2017, quite a sunny day and with high thermal load (71.15 kWh), a high cooling production (75.46 kWh) and a low grid consumption (0.47 kWh) which yields to **EER = 161.93** (see fig. 12).

Figure 10 displays following day (Aug 29th) which much more disrupted than previous example and still exhibits high thermal load (72.04 kWh) a high cooling production (75.14 kWh) and a low grid consumption (0.78 kWh). Here **EER = 95.82** (see fig. 12).

Similar comments can be done regarding Aug. 30st (fig. 11) where cooling power matches quite well building thermal load history. One may notice that battery power was limited to 1.5 kW as a security barrier set up to save battery lifetime, which yields to grid consumption (3.15 kWh) and consequently degrades performances to **EER = 24.71** (see fig. 12).

On all those examples, one can see that priority is given to battery as external supply (at the condition that battery charge level is sufficient).

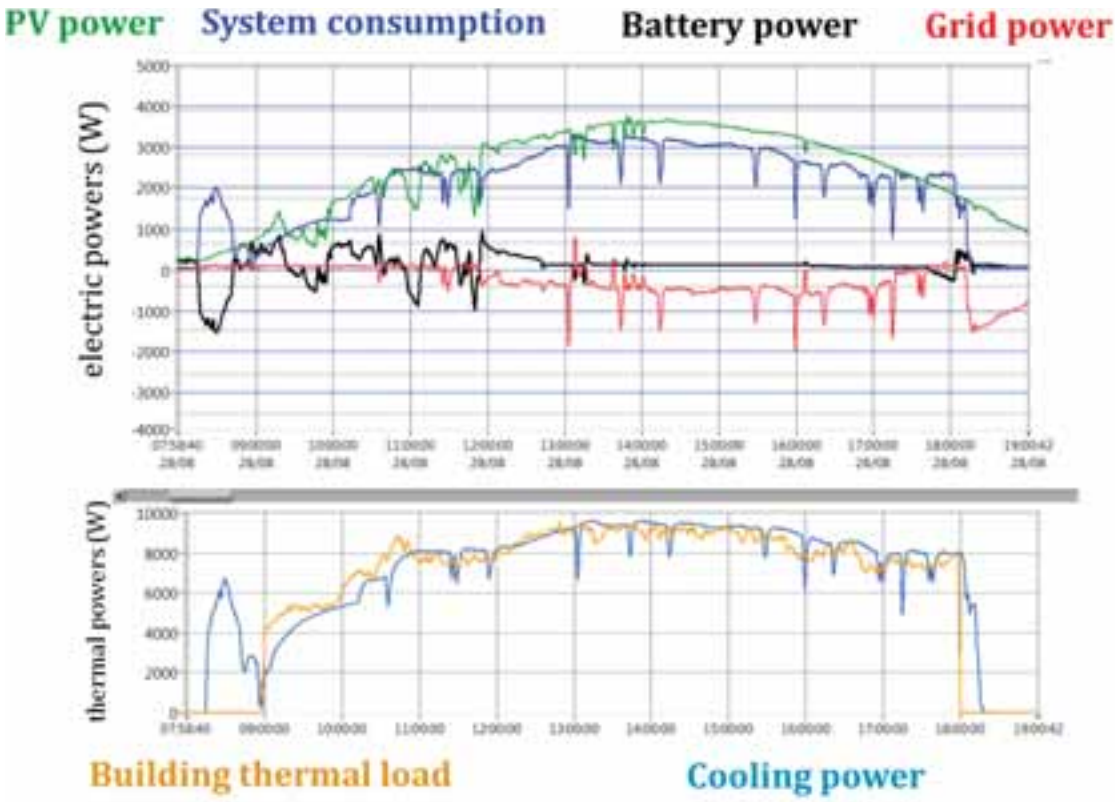

Fig. 9: Electric and thermal powers time history (Aug. 28th 2017 – TOULON) – "comfort" mode

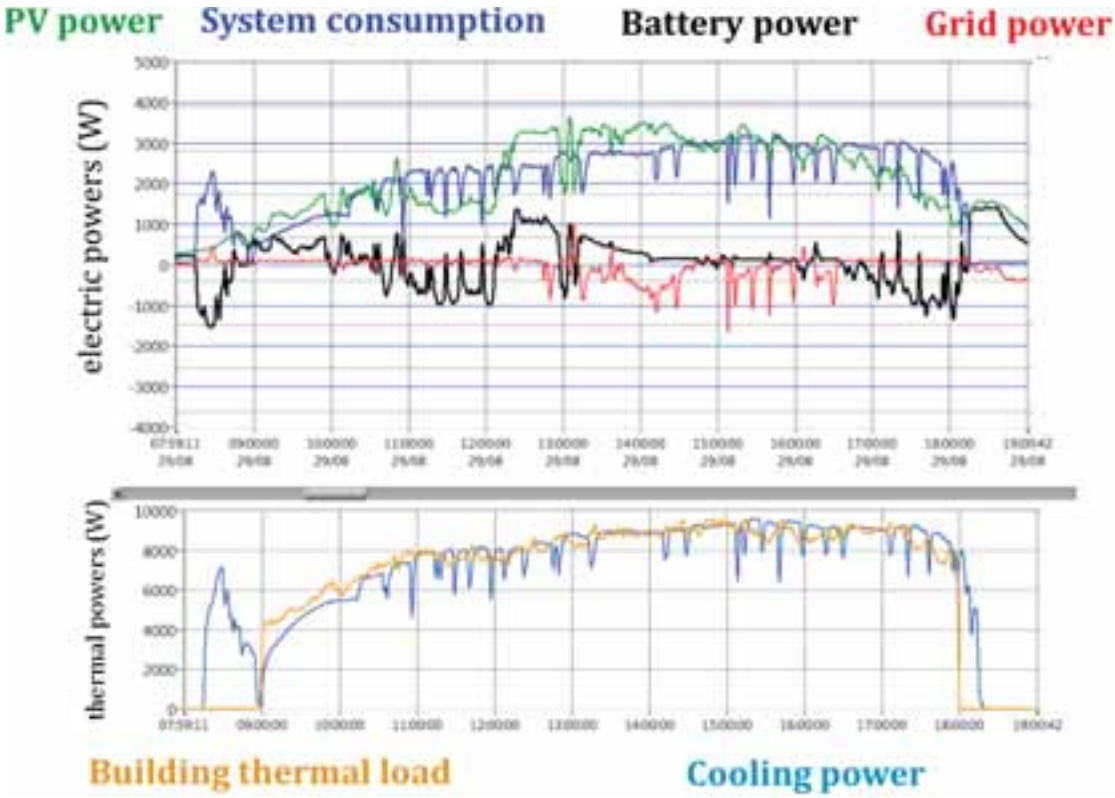

Fig. 10: Electric and thermal powers time history (Aug. 29th 2017 – TOULON) – "comfort" mode

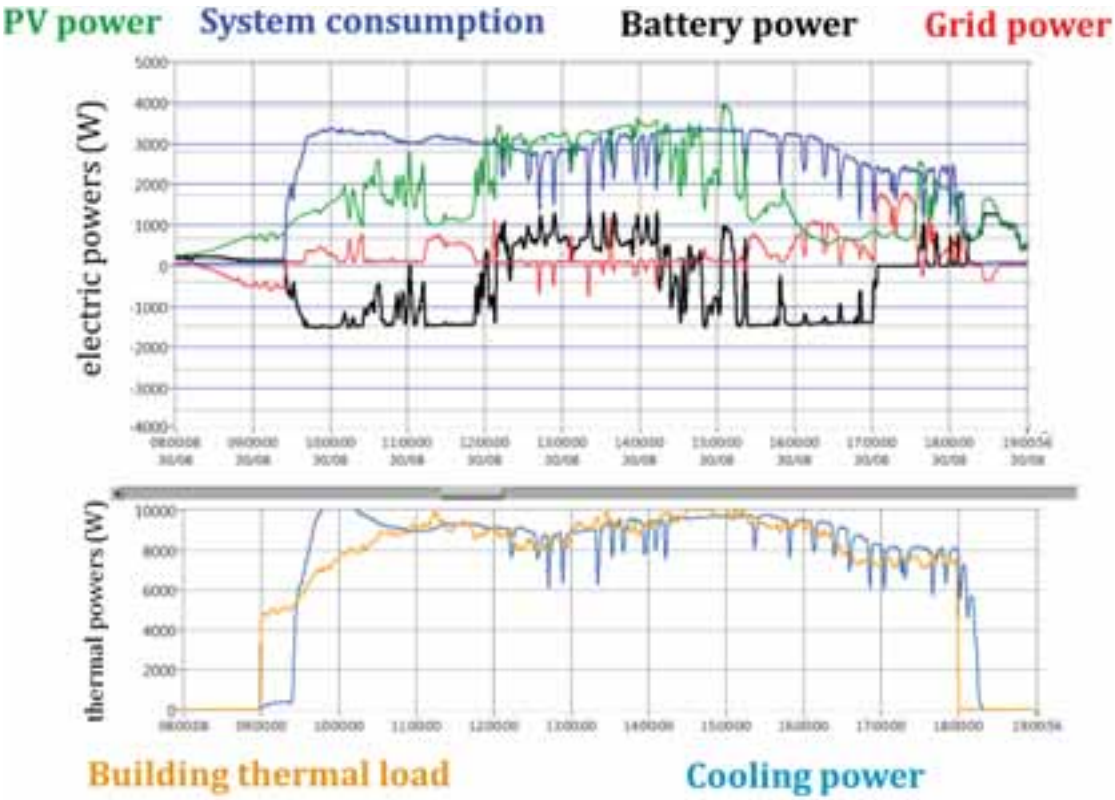

Fig. 11: Electric and thermal powers time history (Aug. 30th 2017 – TOULON) – "comfort" mode

Fig. 12 below is a synthetic table of significant values which permit one to appreciating PV-COOLING performances.
Surprisingly high values of EER are the result of very low grid consumption and have to be interpreted with humility: in fact, comparing EERs on Aug. 8th and 9th (respt. 162 and 96) is only du to 0.31 kWh difference in 11 hours !

	"ECO" mode		"COMFORT" mode		
data	**sept 5th**	**sept 6th**	**Aug. 8th**	**Aug. 29th**	**Aug. th**
overall electric PV-COOLING consumption (kWh)	14,52	17,87	22,62	22,22	25,24
PV-COOLING PV consumption (kWh)	14,11	16,64	21,29	19,26	15,95
PV energy production (kWh)	26,56	19,94	25,88	22,94	18,72
Battery consumption (kWh)	0,00	0,01	0,87	2,18	6,13
Grid consumption (kWh)	0,40	1,22	0,47	0,78	3,15
building thermal load (kWh)	38,64	51,74	71,15	72,04	75,99
Cooling production (kWh)	43,03	53,87	75,46	75,14	77,89
Compressor COP	**3,40**	**3,36**	**2,91**	**2,96**	**2,82**
PV-COOLING COP	2,96	3,02	2,72	2,76	2,64
PV-COOLING EER (Q_{th}/Q_{grid})	**106,34**	**44,11**	**161,93**	**95,82**	**24,71**

Fig. 12: Summary off significant values for different weather and management conditions

However, as a result of those examples, it may be concluded that PV-COOLING concept can be considered as efficient and quite acceptable values of EER were obtained which demonstrate possibility to run PV-COOLING independently from grid.

6. Conclusion

To conclude, the developed and tested PV-COOLING concept allows bringing following conclusions:

- PV-COOLING demonstrates that it is possible to combine improved technologies which are photovoltaic (PV) power plant to drive vapor compression thermodynamic system for the sake of producing cooling energy ;
- Securing PV plant with external power supply to drive thermodynamic system was successfully demonstrated ;
- Part of efficiency results in possibility to real-time adapting cooling power to solar irradiation ;
- EER obtained values shows that only a limited amount of grid supply is necessary and consequently, external generator may efficiently be substituted to grid ;
- Proper management permits one to consider fully autonomous systems disconnected from grid ;

Technically, existing system is planned to further investigate clever ways of using PV excessive power. This concerns mainly investigating cold storage (as shown on fig.2), but also electric storage and compare which is better to improve autonomy of PV-COOLING.

The marketing plans carried out target PV COOLING as a development tool in sunny and/or tropical regions for both air-conditioning system and positive food storage. Eventually, PV-COOLING concept open wide perspective for insulated areas and may constitute a tool for land-use planning, and especially in the developing world.

Abstract

The scope of this paper is to give a short overview of the state of the art regarding control strategies, identify the role of different operating conditions, and provide useful suggestions for the design and operation of a solar assisted absorption cooling system, in line to the European regulation as well as its directly related directives.
The operation of a solar absorption cooling system under real conditions is subjected to various limitations regarding its ability to satisfy the required cooling demand, as well as to avoid certain internal conditions which would lead to problematic situations and jeopardize the smooth operation of the system - such as solution crystallization and water freezing. Thus, it is very important to define and refine new control operating strategies, from an internal and external perspective. Several control strategies are discussed, altogether with a new fuzzy logic approach, which shall be experimentally validated as future actions, due to its highly promising capability.

Keywords: *Air-cooled, numerical simulation, LiBr-Water, object-oriented, transient, single-effect, absorption, fuzzy logic, control.*

1. Introduction

In 2005, the Ecodesign Directive 2005/32/EC established a framework aimed at setting the ecodesign requirements for energy-using products. In 2009, the Ecodesign Directive was extended (Directive 2009/125/EC) to all energy-related products (ErPs). Thus, also products which do not necessarily use energy, but have an impact on energy consumption and can therefore contribute to save energy were included.
The most common available technologies that increase the energy efficiency of chillers, and thus help to comply with the normative, are: i) Electronic expansion valves (EEV), ii) Variable capacity compressors, iii) Variable frequency drives (VFD), iv) Evaporative cooling, v) Electronic fans and pumps, vi) Controllers and supervisory systems with energy-efficiency functionalities, and vii) High efficiency heat exchangers (e.g. micro-channels, flooded).
In this paper an extended discussion over the potential use of variable frequency drives is included, aiming to achieve a great performance of the chiller under different operating challenges. In fact, an intelligent operation of the absorption chiller may result in an adequate performance, together with a minimization of operating interruptions (freezing, crystallization, etc.).
Internal and external controls must be focused on the operation of air-cooled absorption chillers. In this work internal chiller processes are addressed by reviewing several control strategies present at the scientific literature and also from the industry. External control deals with external parameters of the chiller, such as the ones concerning low, medium and hot circuitry.
Controlling hot and cooling water is one of the most promising approaches but in a direct air-cooled machine is highly complicate, at least at the medium focus. Nevertheless, an optimal control of the chiller concerns on defining a good strategy for the whole system, including heating and cooling components (hot and cold storage, solar circuit, etc.).
The principal controlled parameters of a solar cooling system may be inner hot water temperature and mass flow, cooling air or inner water temperature and mass flow, and chilled water outer temperature and mass flow. Chilled water must be kept in certain limits to allow satisfactory operation (Kohlenbach and Ziegler, 2008). At

doi:10.18086/swc.2017.28.05 Available at http://proceedings.ises.org

the same time differential on/off operation of the external circuits should be avoided (Bong et al., 1987) (Yeung et al., 1992) (Labus et al., 2012).

Directly focusing on the direct air-cooled absorption chillers, these are attractive due to it is not necessary both cooling tower either the associated installation. However, the key technical barrier to operate an air-cooled absorption chiller using LiBr-Water as working fluid is crystallization because of high temperatures achieved inside the absorber which derives in a concentrated solution. It is the main difference towards water cooled absorption chillers. As air is used as coolant, low heat transfer characteristics must be taken into consideration because operational concentrations of the solution are very close to the crystallization limit. Therefore, not always the evaporator temperature can be maintained as low as it would be necessary to overcome the absorption pressure increase. LiBr begins to crystallize when the temperature solution is reduced under the crystallization limit or when concentration ratio is increased.
When high condensation temperature is required due to high ambient temperature (Florides et al., 2003) (Izquierdo et al., 2004), high temperature at the desorber is needed, with a possible overloading power to the desorber. Therefore, a high concentrated solution has to return to the absorber through the solution heat exchanger. On the other hand, for condensation temperatures over 40C, single-stage air-cooled absorption chillers cannot be operated by single glaze flat plate collectors (McNeely, 1979).
Other causes which allow the creation of slush are low ambient temperature and full load, electrical failure (shutdown dilution process) and when the chilled temperature is set too low (Liao and Radermacher, 2007). The presence of non-absorbable gases (air and hydrogen) which may vary according to the power input at the desorber and their effect on the performance of the absorption process phenomena have previously been studied at a basic research level (Garcia-Rivera et al, 2008, 2011, 2012, 2016). The effect on the performance of the chiller will be discussed in future works on the performance of the air-cooled absorption prototype.
Air leaks into the system raise the evaporating temperature and the chilled water leaving temperature. A higher temperature increases the heat input and the solution concentration to the point of crystallization. When the system is operated at full load, if the temperature of the cooling water is too low, the diluted solution temperature may fall low enough to reduce the temperature of the concentrated solution to the point of crystallization. If the electric power is interrupted, the system ceases to operate. The temperature of the concentrated solution in the heat exchanger starts to drop and may fall below the crystallization line.

Because of the particular operating principle of absorption chillers, novel and imaginative integration strategies have been proposed in the literature and shortly reviewed next. Several devices have been developed in order to minimize the possibility of crystallization. Moreover, several approaches can be found on the scientific literature as self-decrystallisation technique (DeVuono et al., 1991) by driving high temperature secondary fluid through the solution heat exchanger. It is only possible if high temperature drives the desorption process. Other techniques as controlling the absorbed mass by monitoring the fluid level at the evaporator or boosting the absorber pressure have also been studied by different authors (Zogg and Westphalen, 2006), (Xie et al., 2012). These approaches and an overview of control strategies can be found at Labus PhD dissertation, (J. Labus, 2011), where a new Artificial Neural Network (ANN) modeling and optimization approach is described. Another focus is to define a control strategy based on minimizing specific costs or the price for generation of cold (J. Albers, 2014).
A J-tube technology or by-passing the solution from the desorber to the absorber in order to avoid crystallization is widely applied on the industry [18], (Wang et al, 2011). When crystallization phenomena appear, a connection between the desorber and the absorber, which by-passes the solution heat exchanger, is opened. Therefore, immediately the concentrated solution is diluted and its temperature decreases, warming the low concentrated solution. At the same time, the mass flow over the solution heat exchanger will allow to avoid crystallization at the concentrated solution which is at low temperature.
Summarizing, regulation and control of the cycle is quiet challenging due to crystallization phenomena and environmental temperature dependence. In fact, mass flow driven from the generator to the absorber depends on the pressure gradient, which at the same time depends on the geometrical configuration. Therefore, it is important the mechanical design in order to define correctly all the input parameters at the numerical simulation. Transient numerical modeling helps to define an optimum control strategy.
Therefore, switch-on, standard operation and shut-down process must be aware not only of delivering cooling to overcome the cooling demand but on the protection of the components, i.e. the solution pump, to avoid

unexpected interruption of the machine and possible warnings (i.e. freezing). Several potential internal and external control strategies must be analyzed, and the authors have implemented different control strategies at the numerical platform tool called NEST (in-house developed object-oriented numerical tool) (López et al, 2012). The readiness of the chiller to deliver cooling demand is also considered, depending on the load demand and operating boundary conditions of the chiller. Operational data of a small capacity single-effect air-cooled LiBr-Water absorption chiller has been obtained and presented in this paper.

2. Numerical approach of the control strategy

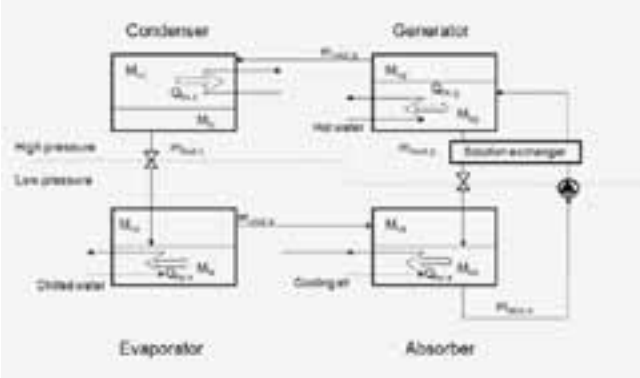

Fig. 1. Basic diagram of a single effect LiBr-H_2O absorption chiller based on parallel configuration

For performing the simulations a modular object-oriented simulation platform named NEST has been used, allowing the link among different components (solar field, pumps, tanks, heat exchangers, absorption chiller, etc.). In this numerical platform each component is an object, which can be an empirical-based model (e. g. heat exchangers, solar collector), lumped capacity models or a more detailed calculation if necessary. With this numerical platform, parallel computing is allowed. This model plant is capable to simulate the thermal and fluid dynamical behavior of the whole air-cooled absorption chiller (Farnós et al., 2017a, 2017b).

Numerical control strategy has been implemented considering a wide variety of causes which may interrupt the operation, basically in terms of crystallization and freezing. In fact, internal and external controls must be focused on the operation of air-cooled absorption chillers. External control deals with external parameters of the chiller, such as the ones concerning low, medium and hot secondary circuits.

Controlling hot and cooling water is one of the most promising approaches, but in air-cooled machines it is not possible, at least at the medium focus. However, an optimal control of the chiller is based on defining a good strategy for the whole system, including heating and cooling components (hot and cold storage, solar circuit, etc.). A multivariable approach presents a high performance control capability. The main controlled parameters of a solar cooling system may be water inlet temperature and mass flow at low, medium and high source.

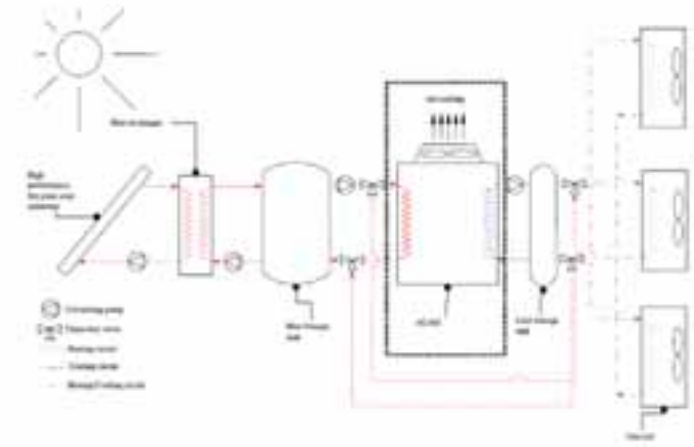

Fig.2. Solar cooling facility implemented in a virtual facility

Regarding the main technical characteristics of the secondary ciruitry, the total considered solar area is 30m^2 with flat plate collectors with an efficiency of: $\varepsilon = 0.803 - 2.4\frac{Tin-Tm}{G} - 0.0058\frac{(Tin-Tm)^2}{G}$. The cold water tank has a capacity of 1000 liters, and the hot water tank 5000 liters. Finally, the auxiliary source has a thermal power of 20 kW.

3. Technical Characteristics of a direct air-cooled absorption machine

A small, compact and cost-effective single-effect LiBr-Water absorption chiller has been designed, prototyped and commissioned not only from a scientific perspective but from an end-user perspective at the Heat and Mass Transfer Technological Center from the Technical University of Catalonia (UPC-BarcelonaTech). The use of standard components and procedures from the whole assembly has been mandatory during the whole development. The arrangement between the air-cooled heat exchangers is in parallel flow. The absorber takes more than the 50% the total air flow, the same proportion as the frontal area. All the heat exchangers have been divided in two parts in order to keep the design as compact as possible. On the other hand, and based on the EU regulation control approaches must also be focused and discussed.

Table 1. Equipment specifications and main results of the cycle simulation (* output value)

	Units		**Specification**	
Nominal capacity	kW		7.0

Hot water stream	ºC	kg h^{-1}	88	1730
Cooling air stream	ºC	m^3 h^{-1}	35	16500
Chilled water stream	ºC	kg h^{-1}	9	1200

4. Analysis of the performance of the chiller under different control strategies

Data obtained from numerical simulation is used to manage the regulation based in a transient analysis, taking into account several heat and mass transfer phenomena like absorption, desorption, evaporation condensation etc., aiming to assure an acceptable performance of the chiller under different operating conditions, etc. Therefore, a great effort was done by obtaining mass transfer coefficients, which feed the transient numerical simulation, by solving the falling film phenomena in detail. Furthermore, thermal size of the components is not fixed but obtained in each time step (Farnós et al., 2017a, 2017b). Monitoring the performance focusing on heat rejection temperature dependency and crystallization phenomena is a very valuable data to reconsider state of-the-art strategies where air is not the most common used coolant.

In order to regulate the cooling capacity of the chiller according to the cooling demand, different strategies can be attended. The first one may be the regulation of the mass flow of the secondary stream at the desorber. Nevertheless, figure 2 demonstrates that the regulation of the cooling capacity becomes a challenge using this strategy because the delivered cooling mainly depends on the rate of the mass flow on the interval 0-25% of nominal mass flow. Between 25-75% of nominal flow the variation of cooling capacity is around 7-9% only. It agrees perfectly with scientific literature (Zamora et al, 2015).

On the other hand, and based on temperature regulation of the secondary source of the desorber, an other control strategy has been focused (Figure 3). Even though it shows a great potential, in a real solar cooling facility is not easy to implement due to the thermal inertia of the heat storage tank (a tank is used to storage heat when the solar circuit is not activated and to use as minimum as it would be possible the auxiliar heat source; a gas boiler). Therefore, temperature variation can not be reached in a short time in order to follow the cooling demand.
Finally, a third strategy is attended with the aim of following the cooling demand varying the air mass flow of the secondary sources at the absorbers and condensers. An accurate fuzzy logic control shows enough potential to analyze the chiller performance within different operational conditions of the chiller and improve the capabilities of the system, avoiding internal failures and reducing electricity consumption.

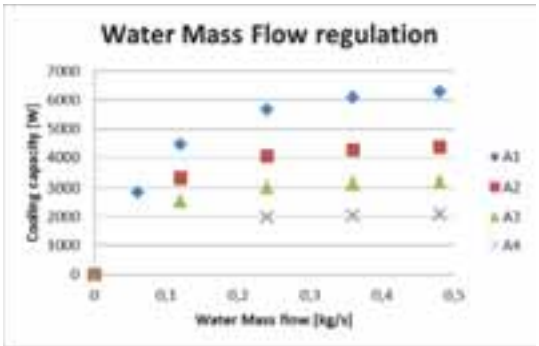

Fig. 3 Water mass flow regulation (*)

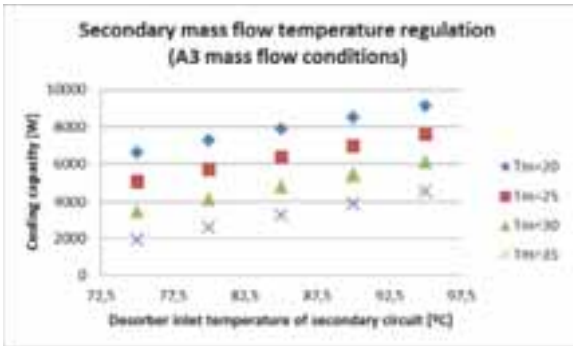

Fig. 4 Secondary mass flow temperature (Desorber) (*)

(*) Secondary nominal mass flows are:
A1: i) Desorber 0.48 kg s^{-1}, ii) Absorber 2.5 kg s^{-1}, iii) Condenser 1.5 kg s^{-1}, and iv) Evaporator 0.334 kg s^{-1}.
A2: i) Desorber 0.48 kg s^{-1}, ii) Absorber 1 kg s^{-1}, iii) Condenser 0.6 kg s^{-1}, and iv) Evaporator 0.334 kg s^{-1}.
A3: i) Desorber 0.48 kg s^{-1}, ii) Absorber 0.6 kg s^{-1}, iii) Condenser 0.36 kg s^{-1}, and iv) Evaporator 0.334 kg s^{-1}
A4: i) Desorber 0.48 kg s^{-1}, ii) Absorber 0.36 kg s^{-1} iii) Condenser 0.216 kg s^{-1}, and iv) Evaporator 0.334 kg s^{-1}

4.1 Air mass flow regulation

Here in this section are presented the results of a parametric analysis of the chiller (Figure 4). Secondary air mass flow streams have been varied from A1 to A4 conditions. Furthermore, a variation of the inner hot water temperature at the generator altogether with the environmental temperature is also presented. Different cooling capacities under different boundary conditions are obtained. Analyzing plotted results it is obvious the necessity of a well-performing control approach, which should be aligned with the EU regulations.

A first basic approach based on switching the operation of the secondary impellers has been considered and presented in Section 5. Nevertheless, it is important to match the cooling load with the cooling capacity, maintaining the internal and external conditions inside the working range and avoiding operating failures. It is the reason why a new fuzzy logic control strategy approach is described in Section 6 of this paper, as well as some examples for a transient operation of the chiller in Section 7.

Table 2: Parametric study: range of operation

Inlet T conditions secondary circuit [ºC]	Desorber	Absorber and condenser	Evaporator
Range	75-95	20-35	14

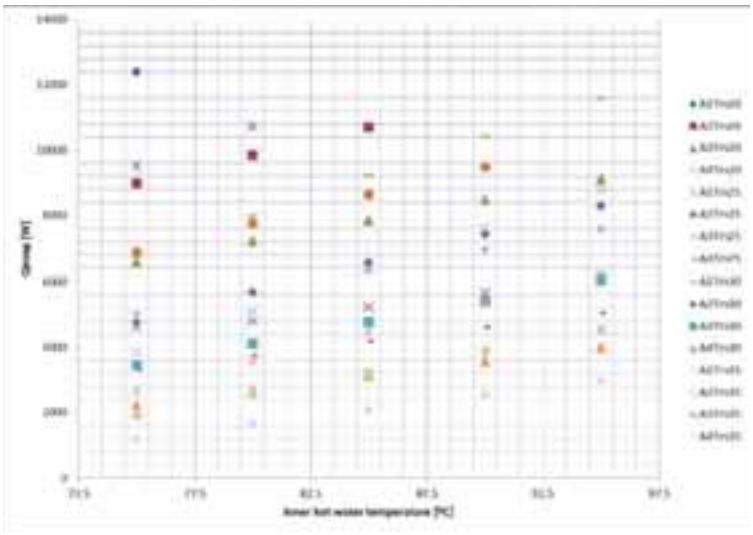

Fig. 5. Parametric study of the cooling capacity of the chiller under different mass flows and temperatures

An other interesting aspect is to analyze the performance of the chiller under different air flow regimes and temperatures, but for a fixed inner hot water temperature. In Figure 5 the cooling capacity over the frequency variation of the fan is presented, showing the wide range that the chiller can overcome under different cooling demands under different medium focus boundary conditions.

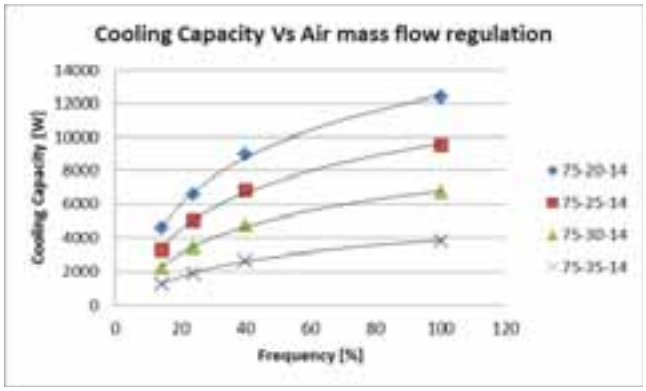

Fig. 6 Cooling capacity under frequency impeller variation

5. Basic control regulation: On/Off approach

Next it is shown the basic control diagram for an On/Off control approach. It is based on the WFC10 from Yazaki [25] and modified according to the direct air-cooled chiller necessities. Nevertheless, a basic On/Off control approach would lead into internal problems and cause failure operating conditions, and is not possible to achieve a high value of the electrical COP.

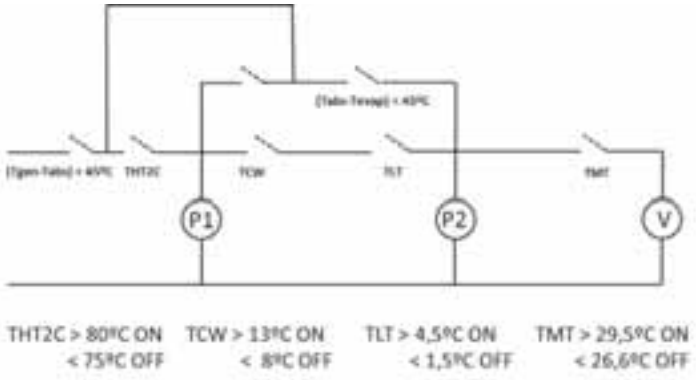

Fig. 7. Basic electric control diagram of the secondary circuitry

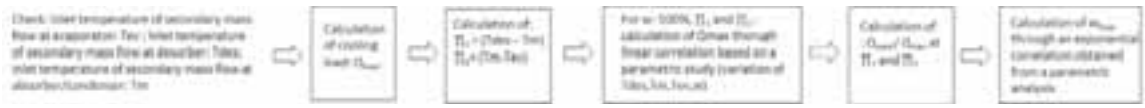
6. Basic fuzzy logic control strategy

A new fuzzy logic control of the cooling capacity of the chiller is based on the impossibility to modify the inlet secondary temperatures but having different cooling demands to satisfy. Therefore, in order to avoid processes of freezing or crystallization is important to know which is the maximum capacity of the chiller for each boundary conditions, aiming to change its capacity among the whole frequency range of the air impeller. This basic control strategy is compared to that widely used in other types of chillers based on switching the solution pump between ON and OFF operation (C.P. Underwood, 2015), and presented in Section 7.

A basic algorithm is presented next in order to achieve a high quality cost-competitive control strategy based on a basic sampling temperatures at the secondary circuits.



Equations related to obtain the output value of the fan frequency (w_{out}) are detailed next:

$$\pi_1 = T_h - T_m \quad (1)$$

$$\pi_2 = T_m - T_l \quad (2)$$

$$\dot{Q}_{max} = f(\pi_1, \pi_2, w_{max}) \text{ (Linear correlation)} \quad (3a)$$

Equation (3) is obtained by defining secondary mass flows and keep them constant. Then cooling capacity is obtained for different temperature conditions (a parametric numerical analysis has been carried varying inner hot water temperature from 75ºC to 95ºC and environmental temperature from 20ºC to 35ºC).

Once the cooling capacity has been calculated, eq. 1 and eq. 2 are used to calculate temperature differences. Finally, a relation between cooling capacity for arbitrary temperature conditions and the maximum cooling capacity obtained from the parametric study allows to obtain the value of the cooling ratio (Q/Qmax) for arbitrary conditions. Finally a correlation between π_1 and π_2 and Q/Qmax is obtained. The maximum error between the correlation and the Q/Qmax values obtained from the numerical simulation is lower than 2%, allowing to move forward on this control strategy approach.

$$Q_{wmax} = (0{,}059226879 + 0{,}019855119\pi_1 - 0{,}025693839\pi_2)\, Q_{ref} \quad (3b)$$

$$w_{out} = f(\dot{Q}_{demand}, \pi_1, \pi_2) \quad \text{(Exponential correlation)} \quad (4a)$$

Equation (4) has also been obtained by means of a parametric study of the prediction of the performance of the chiller under different boundary conditions (See Fig. 4).

$$w = 5.3145e^{2.9126(Q_{demand}/Q_{max})} \quad (4b)$$

The inner hot water temperature range varies between 75-95ºC and the environmental temperature oscillates among 20-35ºC. Then, for fixed mass flows over the secondary circuitry (Block A1,A2,A3 and A4) the cooling capacity is calculated for the whole temperature range defined. Then, defining Th,Tm and Tl the cooling capacity per block is obtained . Moreover, the maximum cooling capacity is referenced to the A1 block, but this Qref can also be either the nominal expected cooling capacity (7kW) or correspond to the maximum cooling capacity that the chiller is capable to deliver for a fixed Th,Tm,Tl. Then, the cooling ratio is calculated (Q/Q_{max}). Q/Qmax ratio is almost the same for all the same temperature case (fixing Th,Tm,Tl); varying the frequency of the air impeller.

Finally Figure 7 plots the cooling ratio versus the frequency of the impeller. Defined temperature conditions altogether with a variation of the air mass flow can oscillate the cooling capacity of the chiller, which will allow to follow the cooling demand, reducing the electricity consumption and avoiding internal challenges.

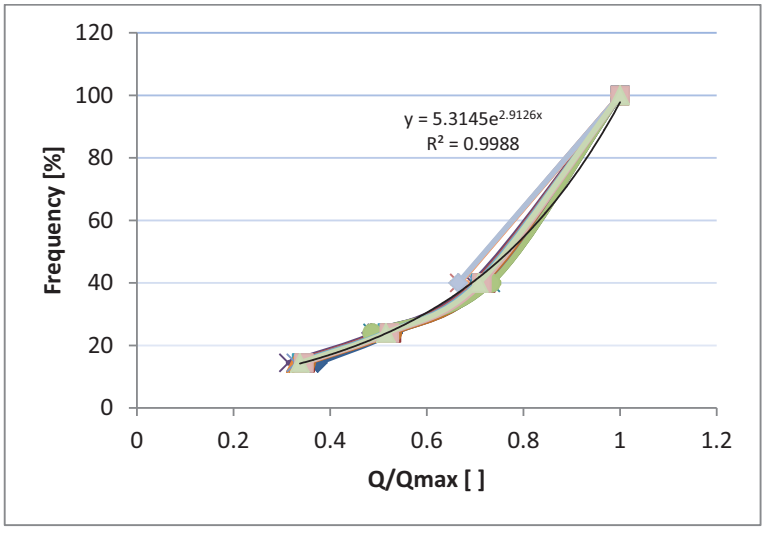


Fig. 8 Normalised exponential function (eq. 4)

7. Control demonstration: application, basic, fuzzy logic, and no control approach

A virtual laboratory has been created in order to analyze a solar cooling facility. Evaporator and generator secondary stream inlet temperatures are determined by two sinks, which are used as a buffer, in order to avoid oscillations on the driving temperature. Temperature inside the tanks is controlled so that the high temperature circuit (solar circuit) is activated only when is required. Hysteresis of the tanks is considered when the high temperature source is activated or deactivated. Moreover, there is an auxiliary circuit if solar circuit is not available to overcome heating demand. The low temperature circuit is controlled in order to avoid freezing at the chiller. In the figure 8 it is described:

7.1 Transient numerical simulation using a basic control strategy of the chiller

A characteristic day (8th July) in Barcelona (Spain) has been simulated in order to understand the performance of the chiller under different control approaches. In Fig. 8 the basic control described in Section 5 has been applied, and thermal power along 24h is plotted, according to a variable cooling demand of a house. It is observed that there are many switches which do not allow the system to operate in the best conditions, and achieve high energy savings. Nevertheless, it permits a very easy implementation on the electrical control device.

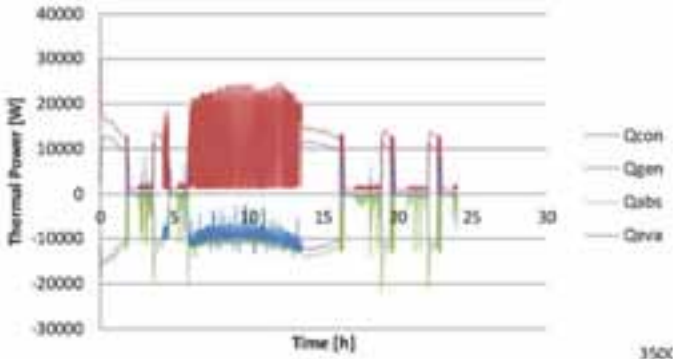

Fig. 9. 24h simulation based on a basic control strategy

7.2 Fuzzy logic control strategy of the chiller (application example):

In this section an example of how the fuzzy logic is applied is shown. Linear and exponential correlations described above are used.

Table 3: Example of a control strategy application

Qdemand [W]	Th [ºC]	Tm [ºC]	T [ºC]	(Th-Tm) [ºC]	(Tm-Tl) [ºC]	Qmax[W] (w=100%)	Qload/Qmax (w=100%)	Wout [%]	Qdelivered [W]
7000	90	30	14	60	16	10404	0,67	37,41	7000

7.3 Transient numerical simulation using a fuzzy logic control strategy

The fuzzy logic approach described above allows the system to reduce dramatically the energy consumption as well as to follow the cooling demand in an optimal way. Thus, internal challenges are reduced drastically and mean electrical COP is quite larger than the one obtained by using a basic control approach. In future works these values will be presented and compared.

For the same case presented in section 7.1, the performance of thermal power are smoother than using the implemented basic approach. It means that the operation of the chiller becomes easier as well as its potential to avoid internal and external failures. Nevertheless, all these control strategies must be improved and experimentally validated.

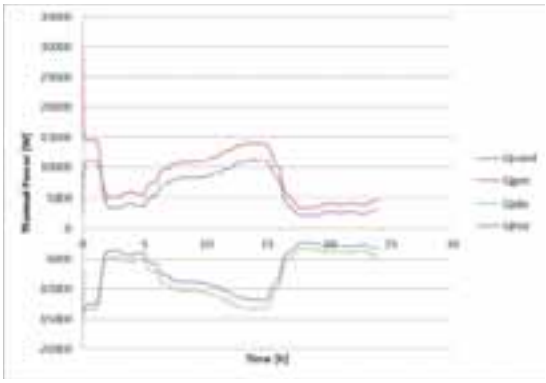

Fig. 10. 24h simulation based on a novel fuzzy logic control strategy

7.4 Comparison between a basic and a fuzzy logic control strategy

In figure 11 the evolution of the electrical COP is presented (same case than in Section7.1 and 7.3). It is clear that using a fuzzy logic approach the COPel is higher than the one achieved by means of a basic control strategy. Large electricity consumption would be expected to be saved by means of this novel approach.

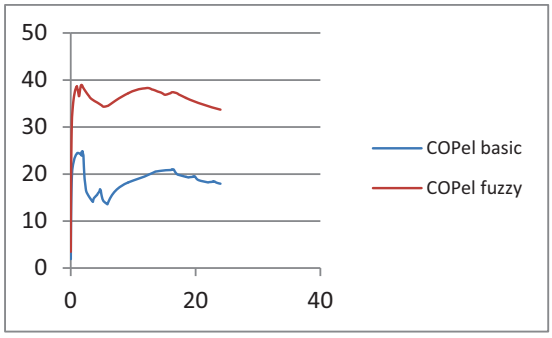

Fig.11 24h COPel evolution

7.5 No control approach

Based on a numerical simulation carried in May for half a day (12h), from 8 am to 8 pm, after 5 hours of a control-based operation (1pm), control is switched-off. Initial basic and fuzzly logic control both have been plotted before switching-off the control device. Then it is shown what would happen regarding freezing and crystallization after basic and fuzzy logic control during the first 5 hours of operation. In the first case we can observe in Fig. 12 the evolution of the primary evaporator temperature after the control is switched off. On the other hand, in Fig. 13 it is described the evolution of the concentration of the LiBr-Water solution inside the desorber vessel. Freezing and crystallization phenomena appear as internal failures. These may damage the absorption chiller operation, being impossible to avoid and leading to operating interruptions if no control strategies are considered, at least in a direct air-cooled absorption chiller.

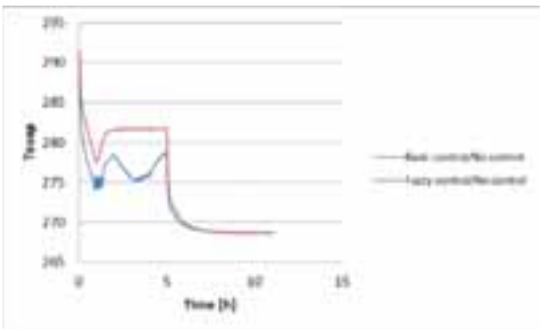

Fig.12 Internal failure if no control is considered (freezing)

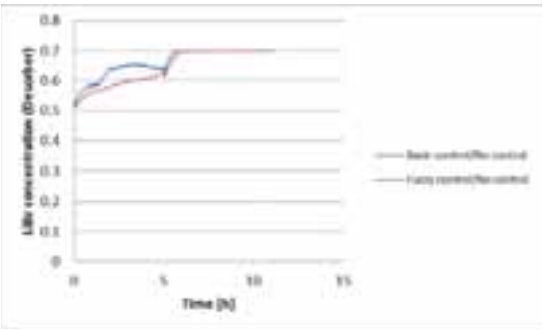

Fig. 13 Internal failure if no control is considered (crystallization)

8. Conclusions

In this work a dynamic model for an air-cooled H_2O-LiBr absorption machine has been used as the basis to implement different kind of control strategies. The model is based in the use of heat & mass transfer empirical correlations of the scientific literature, to avoid ad-hoc adjusts of the main parameters of the absorption refrigeration cycle.
Targeted end users of the absorption chiller must be enlarged in order to go further than domestic applications if an acceptable Return of Investment (ROI) wants to be achieved. In that sense several actions should be performed: increase of the temperature lifts to allow its operation as a heat pump, active/ passive improvements for heat & mass transfer, optimization of transient response, reduction of the total circulating mass flow, and new control strategies to optimize the performance of the chiller and the whole solar cooling facility. Based on this issue and taking into consideration EU regulation, different control approaches of the absorption chiller are herein presented and discussed: i) Inner hot water mass flow regulation, ii) Inner hot water temperature regulation, iii) Basic control regulation, and iv) A novel fuzzy logic control strategy applied to direct air-cooled absorption chillers.

A fuzzy logic approach seems to be the most valuable control strategy, keeping in mind that a multivariable approach, considering inner hot water mass flow regulation, should be focused in the near future. As it has been shown in Fig. 11 the obained COPel based on the fuzzy logic control strategy is clearly higer than the one obtained by means of a basic control strategy. Internal and external behavior are also smoother than a basic control, which help to avoid operation failures such as freezing or crystallization.Therefore, this tool is recommended to be numerically assumed and experimentally validated in further works, quantifying the total energy savings in terms of thermal load and electricity consumption.

Performance Analysis Of a Solar-Powered Air-Conditioning System Using Absorption Refrigeration Cycle And High Efficiency Cooling Technologies Installed In Colombia

Caterina Fella[1], Paolo Silva [2] and Cesar I. A. Rolán [3]

[1] Politecnico di Milano, Milan (Italy)

[2] Politecnico di Milano, Milan (Italy)

[3] Universidad Pontificia Bolivariana, Medellín (Colombia)

Abstract

In this work an analysis of the performance of solar absorption air-cooling system installed to a building office of the Bolivarian Pontifical University (UPB) of Medellín in Colombia is presented. The solar powered, single-effect Li-Br absorption cooling system using evacuated heat pipe collectors, has a nominal capacity of 11,5 kW and it is implemented with a 17,6 kW indirect evaporative cooler (iec), responsible to improve the energy efficiency and to renovate the air in the building, for a total cooling capacity of more than 29 kW (more than 8 refrigeration tons). A system of chilled water capillary mats is implemented for air conditioning, where the heat transfer takes place through a radiant ceiling, reducing recirculation airflow and increasing the temperature of chilled water supplied, allowing a reduction in energy consumption by airflow and an improvement in energy efficiency of the solar-powered absorption cooling system. The performance is evaluated for three main subsystems composing the air conditioning system the absorption chiller, the heat pipe evacuated tube collectors and the indirect evaporative cooler. A series of test-measurements (TMs) are carried out varying the value of one or more particular parameters that affects the performance. Some indicators, which describe the performance, are calculated and compared, so an evaluation of the different TMs is provided. In more is presented an economic comparison with a conventional scheme in order to assess the potential energy savings of the system, the simple payback period of the investment is calculated for different size and cooling demand for Colombian and Italian case.

Keywords: Solar Cooling system, absorption chiller, heat pipe evacuated tube collectors, indirect evaporative cooler, performance analysis, experimental test-measurements, simple payback period

1. Introduction

Buildings produce high CO2 emissions as they consume almost 40% of worldwide energy, and a remarkable percentage of this energy is used for achieving thermal comfort conditions, both in heating and cooling. Thermal comfort is one of the first priorities, as it represents around 65% of building energy consumption [1]. Solar energy is the most widely renewable energy all over the World [2]. Solar power is sufficient to cover the thermal comfort demands in medium and low latitude regions [1] and it is not a fortuity that a solar-powered absorption cooling system was projected in Medellín, whose latitude is 6° 15' 6 N. Among the various solar air-conditioning alternatives, the absorption cooling system appears to be one of the most promising methods[3], because of the fact that the pick concentration of solar energy coincides with the hours when the cooling is required, in more as no chlorofluorocarbons (CFCs) are used, the system is presented as environmentally friendly. The project presented is the 7th out of 8 projects belonging to the National Strategic Plan of Energy Management that includes 4 years last projects in order to implement energy efficiency of Colombia's electric and thermal energy production systems, reduce the emissions and the environment resources depletion. This project was born as implementation of air-conditioning system for a building office, called Building 24, of UPB by Li-Br solar absorption cooling system with evacuated tube collectors. The office selected hosts about 50-80 persons and has an area of 239 m^2, for improving the energy efficiency of the air conditioning system, an indirect-evaporative air cooler (iec) responsible in

doi:10.18086/swc.2017.28.06 Available at http://proceedings.ises.org

renovation of the air, was installed, resulting that the air entering is provided at lower temperature than the temperature outside. Employing both system the thermal capacity needed for the office building is satisfied. The peculiarity of this air-conditioning system consists on the use of chilled water capillary mats instead of conventional fun coils. The heat transfer takes place through a radiant ceiling, reducing recirculation airflow and increasing the temperature of chilled water supplied, allowing a reduction in energy consumption by airflow and an improvement in energy efficiency of the solar-powered absorption cooling system.

2. System description

Medellín is also known as the city of eternal spring, presenting full year mostly sunny weather, with diurnal temperature which oscillate between 22°C and 35°C and a relative humidity between 40% and 75%. For this reason, it suits the solar powered air conditioning system very well. The figure below shows a schematic picture of the system with its principal component by the control screen of the engineering software used in order to test, measure and control its data. The picture with typical values from operation of 5th TM during chilled water production is shown below. For a good understanding, a brief description of the most important sub-system that characterize this configuration of Li-Br solar absorption air conditioning system, in order to justify the technologic choices that have been taken and focus on the specifications needed for proceed to a performance analysis is presented.

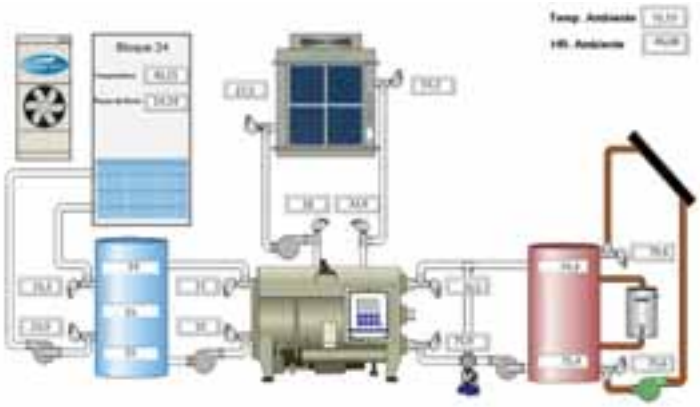

Fig. 1: LabView Control screen of the system

1. Evacuated heat pipe tube collectors (ETCs). The operating temperature of the hot water supplied to the generator of the LiBr-water absorption refrigeration system is about 70°C and 90°C. The lower temperature limit is imposed from the fact that hot water must be at a temperature sufficiently high to be effective for boiling the water off the solution in the generator[4]. For a number of 20 tubes for 10 collectors, the effective lighting area installed resulted of 20.4 m^2. The ETCs are connected directly to the hot water storage tank. Because no evaporation or condensation above the phase-change temperature is possible, the heat pipe offers inherent protection from freezing and overheating. The collectors were installed on the roof of the building chosen. Although it is recommended to incline the collector according to the latitude in order to catching the most direct radiation of the sun, it resulted that didn't permit the natural cleaning of the collectors by the rain and for this reason an inclination of 10° was chosen, and being installed in north hemisphere, they are directed to the south.

2. The absorption chiller constitute the core of the configuration: the refrigerant steam enter into condenser and is cooled down by cooling water flowing in the pipes, that passes from about 35°C to about 25°C, and the refrigerant water gathered in condenser enter into the evaporator by throttling. Because of low pressure (0,6 kPa) in the evaporator, obtained thanks to a vacuum pump, the refrigerant water will be evaporated by absorbing the heat of chilled water flowing in pipes, so that to lower the temperature of chilled water and realize the refrigeration; it is possible to obtain chilled water from 20°C until 7°C (in the picture the temperature in the evaporator are higher

because the screen shot is taken when chilled water production is still not started). In order to work, the temperature out of the tank could not be lower than 65°C and the cooling capacity increases with increase of this temperature.

3. Due to the intermittent nature of available solar energy, hot and chilled water storage tanks of a capacity of 1000 L are needed. They are carbon steel inertia buffer tanks, characterized of a high thermal inertia and insulation, allowing correct management of energy, ideals for the closed cooling circuit, because they act as the installation energy regulation[5]. Because of natural thermal stratification, the top zone of the tank is kept at the maximum temperature, and the bottom one at the lowest.

4. An auxiliary gas heater, of 40 kW of nominal power, directly connected to the tank, activated whenever the heat pipe collectors outlet temperature is less than the temperature required in the generator of the chiller, so that the temperature out of the chiller is not enough to assure the system functioning.

5. Since in an absorption-refrigeration cycle heat must be rejected from the absorber and the condenser, a cooling water system must be employed in the cycle. Because the absorber requires a lower temperature than the condenser, the cool water from the cooling tower is fist directed to the absorber and then to the condenser[4]. It has been chosen a particular closed circuit cooling tower because it is necessary that the water does not present problems of contamination and encrustation. The closed-circuit evaporative cooler is composed by wet panel type adiabatic cooler, in order to decrease the air temperature at the inlet of the coils, two coils of copper tubes and aluminum fins installed in V with an axial fan of variable volume installed on its top, so the air is cooled by ventilator and by adiabatic cooling, to assure high efficiency. The closed-circuit assure to minimize energy consumption and water consumption (the nominal power at maximum capacity is at 1,9 kW) and to avoid contamination problem.

6. Water capillary mats were chosen instead of conventional fun coils, because they result more efficient, exchanging heat by radiation. For this reason, they need a higher minimum temperature for being effective (about 7°C or even until 18°C water temperature, against the fun coil's temperature of 5°C), reducing recirculation airflow and increasing the temperature of chilled water supplied, allowing a reduction in energy consumption by airflow and an improvement in energy efficiency of the solar-powered absorption cooling system. This system is installed in a superimposed form on the "false ceiling", of the top of building 24, required in order to avoid to damage the ceiling in case of condensation of the water inside the tube.

7. Five pipe sections are identified in the system. The tabled below shows, at the sections considered, the diameter of the pipeline and the nominal parameters of the pumps selected (the head, the number of step-speed that could be selected and the power with respect to the working speed):

Tab. 1: Water Pipeline specifications

Section	Diameter internal	Head max	Speeds	Max power input
1 Hot water storage tank - Collectors	0.032 m	10 m	1	245 W
2 Hot water storage tank - Absorption chiller	0.032 m	10 m	1	245 W
3 Chilled water storage tank - Absorption chiller	0.032 m	9 m	3	150-179-196 W
4 Chilled water storage tank - capillary mats	0.063 m	8,5 m	Adapta ble	9..144 W
5 Cooling tower - Absorption Chiller	0.04 m	27 m	1	740 W

8. In order to improve the energy efficiency, to renovate the air in the building, a 17,6 kW indirect evaporative cooler (iec), called Coolerado, was installed, therefore the air entering is at lower temperature than outside; the system draws a maximum of 750 watts of power at full flow[6]. Coolerado system is based on Maisotsenko cycle, a particular case of indirect adiabatic (evaporative) cooling air conditioning system. Humid working air, that constitute about half of the air that enters the heat and mass exchanger is released back into the atmosphere, carrying energy removed from the conditioned air. Chilled fresh air with no added humidity is supplied.

9. Auxiliary and measurement components.

In order to evaluate the performance of the solar cooling system a performance analysis for the three main subsystem that characterised the air conditioning in the Building 24 is carried out: the absorption chiller, the solar collector and the Coolerado.

3. Absorption chiller performance analysis

In order to test the performance of the equipment a series of test measurements (TMs) in different conditions are carried out.

In order to describe and compare the performance of the absorption chiller in different TMs done the performance indicators are estimated by an overall steady-state energy balance on the absorption chiller, neglecting net losses that may occur to the surroundings. Being possible to experimentally calculate the flow rate into the cooling tower ($\dot{m}_{c\,tower}$) from the manifacture's pump flow rate delivered/ power supply curve [12], the power removed by the cooling tower, from the the absorber to the condenser, was calculate as

$$\dot{Q}_{c\,tower} = \dot{m}_{c\,tower} * (T_{cooling,out} - T_{cooling}) \quad \text{(eq.1)}$$

Where

$\dot{m}_{c\,tower} = 1{,}389$ kg/s

$T_{cooling}$ ($T_{c\,tower,out}$) is the temperature of condensation or "Cooling water inlet temperature" to the condenser, coming from the cooling tower.

$T_{cooling,out}$ ($T_{c\,tower,in}$) is the outlet temperature at the condenser, entering the cooling tower.Starting from the nominal performance curve of the equipment[11], furnished by the constructor, with respect to the chilled water outlet, cooling water inlet and hot water inlet temperature respectively, the equation curves of the cooling capacity were extrapolated. In particular, for each measure the cooling capacity ($\dot{Q}_{eva}$) with respect to the following parameter was calculated:

- Temperature of evaporation (T_{evap}) that is "Chilled water outlet temperature" at the evaporator, going to the chilled water tank, according to eq. 2

$$\dot{Q}_{eva} = 0{,}2698 * T_{evap} + 9{,}3811 \quad \text{(eq 2.) [11]}$$

- Temperature of condensation ($T_{cooling}$) according to equation 3

$$\dot{Q}_{eva} = -0{,}889 * T_{cooling} + 37{,}681 \quad \text{(eq.3) [11]}$$

- Temperature of generation (T_{hot}) that is "Hot water inlet temperature" to the generator, coming from the hot water tank), according to equation 4

$$\dot{Q}_{eva} = 0{,}3197 * T_{hot} - 17{,}482 \quad \text{(eq.4) [11]}$$

Indeed for each TM three cooling capacities were found and the correction factor calculated as

$$f_1(T_{evap}) = \frac{\dot{Q}_{eva}(T_{evap})}{\dot{Q}_{nom,evap}} \quad \text{(eq.5)}$$

$$f_2(T_{cooling}) = \frac{\dot{Q}_{eva}(T_{cooling})}{\dot{Q}_{nom,evap}} \quad \text{(eq.6)}$$

$$f_3(T_{hot}) = \frac{\dot{Q}_{eva}(T_{hot})}{\dot{Q}_{nom,eva}} \quad \text{(eq.7)}$$

Where

$\dot{Q}_{nom,eva}$ is the nominal capacity of the absorption chiller equal to 11,5 kW

Assuming valid the overlap of the effect the Coefficient of Performance was find for each TM ($COP_{i,TM}$) as

$$COP_{i,TM} = COP_{nom} * f_1(T_{evap}) * f_2(T_{cooling}) * f_3(T_{hot}) \quad \text{(eq. 8)}$$

Where:

COP_{nom} is the norminal Coefficient of Performance of the machine equal to 0,69.

f_1 is the correction factor of the cooling capacity due to the influence of the chilled water outlet temperature.

f_2 is the correction factor of the cooling capacity due to the influence of the cooling water inlet temperature.

f_3 is the correction factor of the cooling capacity due to the influence of the hot water inlet temperature.

The indicators of performance ($COP_{i,TM}$ and $\dot{Q}_{eva}$) were analyzed during a period in which the air-conditioning supplied by the transient operation of the chiller could be approximated to idealized steady-state operational conditions (the transient operation of the chiller leads to approximately 8% lower COP than would be expected if transients would neglected[7]). In order to compare the performance between each test measurement was chosen an equal period of 45 minutes.

Finally, knowing $COP_{i,TM}$ and $\dot{Q}_{i,c\,tower}$ for each TM, following parameters that characterize the system performance are calculated as:

$$COP_{i,TM} = \frac{\dot{Q}_{eva}}{\dot{Q}_{gen}} \quad \text{(eq. 9)}$$

$$\dot{Q}_{c\,tower} = \dot{Q}_{eva} + \dot{Q}_{gen} \quad \text{(eq. 10)}$$

$$COP_{i,TM} = \frac{\dot{Q}_{eva}}{\dot{Q}_{gen}} \quad \text{(eq. 11)}$$

$$\dot{Q}_{c\,tower} = \dot{Q}_{gen} * (COP_{i,TM} + 1) \quad \text{(eq. 12)}$$

$$\dot{Q}_{gen} = \frac{\dot{Q}_{c\,tower}}{(COP_{i,TM}+1)} \quad \text{(eq. 13)}$$

$$\dot{Q}_{eva} = \dot{Q}_{c\,tower} - \dot{Q}_{gen} \quad \text{(eq.14)}$$

Where

$\dot{Q}_{gen}$ is the heat consumption from the generator.

The results are shown in term of average in the table below:

Tab. 2: Performance results of the absorption cooling system during the five TMs.

	1st TM	2nd TM	3rd TM	4th TM	5thTM
Average during 45 minutes of air conditioning (stable period)					
$\overline{T_{hot}}$ [°C]	72,690	77,320	75,950	79,140	69,930
$\overline{\Delta T_{gen}}$ [°C]	3,484	3,28	3,166	3,380	4,560
$\overline{\dot{Q}_{gen}}$ [kW]	10,589	9,112	8,706	8,713	17,673
$\overline{T_{evap}}$ [°C]	15,330	13,670	16,150	14,140	13,560
$\overline{\Delta T_{evap}}$	2,648	2,308	2,697	2,652	4,030
$\overline{\dot{Q}_{eva}}$[kW]	**4,273**	**4,473**	**4,240**	**4,698**	**6,699**

$\overline{T_{cooling}}$ [°C]	29,530	29,520	29,460	29,430	27,600
$\overline{\Delta T_{cooling}}$ [°C]	2,56	2,340	2,230	2,310	4,198
$\overline{\dot{Q}_{c\ tower}}$[kW]	14,862	13,585	12,946	12,830	24,372
$\overline{COP}_{i,th}$	**0,404**	**0,491**	**0,487**	**0,539**	**0,379**
$\overline{P}_{\substack{air\ cond \\ entire\ period}}$ [kW]	2,8	2,65	2,5	2,4	3,4

Where

$\overline{\Delta T_{gen}}$, $\overline{\Delta T_{cooling}}$, $\overline{\Delta T_{evap}}$ are the average temperature difference inlet and outlet from the generator, the evaporator and the condenser respectively

$\overline{P}_{\substack{air\ cond \\ entire\ period}}$ is the average of total power required by the system.

During all the TMs was never reach the nominal cooling capacity of 11,5 kW, that because of an intrinsic limit of the system that never allows to work with a temperature in the generator (T_{hot}) equal to 90°C . During the start up period, indeed the period in which no vapor would have been involved, the generator consumes a lot of power, as initial and final temperature shown in Table 3. This behavior is more remarked during the 5th TM when working with a cooling temperature lower, and less remarked when working at partial load, during 3rd and 4th TMs.

Tab. 3: Start up period of TMs.

	1st TM	2nd TM	3rd TM	4th TM	5thTM
Start up period [min]	8	7	7	5	5
Lost in temperature [°C]	5,8	7,5	6,5	6,5	8,2

Passing from 1st TM to 2nd TM could be noticed that increasing the inlet temperature of the generator of an average of 5°C (it was necessary to heat the hot water storage tank of 13°C mores, from 79°C to 92°C) the COP increase of 17,7 %. Also the cooling capacity increase of 4% and the time employed in chilled water production decrease of about 48 minutes.

The 3rd TM and 4th TM are characterized by a reduction in evaporator's flow rate, working with the second speed of the pump. It brings to an improvement in the effectiveness of the heat exchange that could be reflected also in an improvement of the COP.

If compare the indicators of the 3rd TM with which were obtained in the 1st TM, that are characterized by more similar generator temperature, the COP passed from to be the 58,6 % of the nominal in the 1st TM to the 70,6 % in the 3rd TM. During 3rd TM, for almost the same cooling capacity, the machine exploit much less thermal power than in the 1st TM (8,7 kW versus 10,6 kW), indeed a better COP is reached allowing the machine to work longer. The air conditioning last 25 minutes more respect to the 1st TM: the machine worked longer, because the minimum conditions required in the generator are guaranteed longer.

The best COP is registered during the 4th TM that is characterized to high temperature in the generator (the thermal storage temperature arrived to 98,4 °C) and better heat exchange effectiveness (the highest difference in chilled temperature, due to reduction of the mass flow rate in the evaporator). In this measurement, it was capable in reaching the 78% of the nominal COP and the cooling capacity improve of 5% with respect to the 2nd TM and the lowest time in production of chilled water was registered.

The 5th TM presented the highest cooling capacity, about equal to the 60% of nominal, but presented the lowest COP registered (about the 55% of the nominal one). That is because in order to provide about 7kW of cooling power ($\dot{Q}_{evap}$) consume about 17 kW of thermal power stored. Such situation provoke that the minimum condition requested from the chiller are extinguished very quickly.

4. Collectors performance analysis

The performance of the collectors are described by the efficiency in term of useful energy delivered in joules: a solar collector receives solar radiation $\dot{Q}_s$ from the sun [product of the surface area, $A_c(m^2)$ and the solar radiation perpendicular to the surface I_p (kW/m^2)] and supplies $\dot{Q}_g$ to a heat engine at the temperature T_H. The ratio of supply heat $\dot{Q}_g$ to the radiation $\dot{Q}_s$ is defined as the thermal efficiency of a solar thermal collector[8]:

$$\eta_{coll} = \frac{\dot{Q}_g}{I_p * A_c} = \frac{\dot{m} c_p (T_O - T_i)}{A_c * I_p} = \frac{\dot{Q}_g}{\dot{Q}_s} \qquad \text{(eq.15)}$$

In order to calculate the flow rate $\dot{m}$ circulating into the collectors were assumed negligible energy loss into the hot water tank and the average flow rate came out from the energy balance was assumed as real constant flow rate delivered by the collectors' pump. The table below resume the collector's performance registered during 3rd TM, 4th TM and 5th TM (measurement for which was possible to measure the solar radiation I by means of the use of pyrometer). In the table below $\overline{\eta_{coll}}$ is the average efficiency of the solar collectors during the whole period of operation; $\bar{I}$ is the average solar radiation registered during the period of operation; P_{peak} is the maximum power output from the collectors registered; $\overline{P_{coll,inst}}$ is the average power output from the collectors; E_{tot} is the total amout of energy provided by the collectors.

Tab. 4: Results of performance analysis of solar collector installed in the Building 24.

	3rd TM (27/03/2017)	4th TM (28/03/2017)	5th TM (25/05/2017)	Weighted Average
$\overline{T_{amb}}$ [°C]	31,40	29,50	30,90	
$\bar{I}$ [W/m^2]	746,50 (725,08*)	723,20 (668,17*)	655,70 (775,6*)	
Collectors ON	11:29 (11:53*)	10:06 (11:23*)	11:12	
Collectors OFF	16:00	15:13	16:00 (13:30*)	
$\overline{\eta_{coll}}$	0,56 (0,57*)	0,50 (0,53*)	0,38 (0,50*)	0,53*
P_{peak}	14,91	15,60	11,08	13,86*
$\overline{P_{coll,inst}}$[kW]	9,82 (9,88*)	9,34(9,79*)	6,14 (8,30*)	9,50*
E_{tot}[kWh/day]	44,34 (40,65*)	47,82 (37,48*)	29,5 (21,9*)	40,97

*The value is referred to the average calculated during the period in which operate also the absorption chiller

The values remarked by the asterisk in the table, resulted higher because when the chiller works and exploit thermal power stored, the collectors' contribution is much more remarkable. Because the generator of the chiller is consuming the power collected into the tank, the temperature entering the collector is lower; indeed the collectors are much more effective, being the difference between temperatures in and out of the collectors higher. This is the condition C of the figure below that point out the performance of the collectors by the temperature difference in and out of the collector in orange related to the radiation incident on the collectors in blue, during the 4th TM. In particular collector efficiency, referring also to the system condition, is affected by the auxiliary heater contribution, that heating the water inside the tank increase its temperature inlet to the collector, so to make inefficient the collector contribution in case the radiation is not enough or the temperature inlet is too high (see Condition D in the figure). This phenomenon is even worse in case the chiller does not work and the auxiliary heater is switched on in order to heat the storage faster. When the Chiller is starting up, a not stable state persists (see Condition B) that addresses an appropriate control behavior; the same happens when the hot water pump is switched on in order to make the temperature into the tank homogenous (see Condition A).

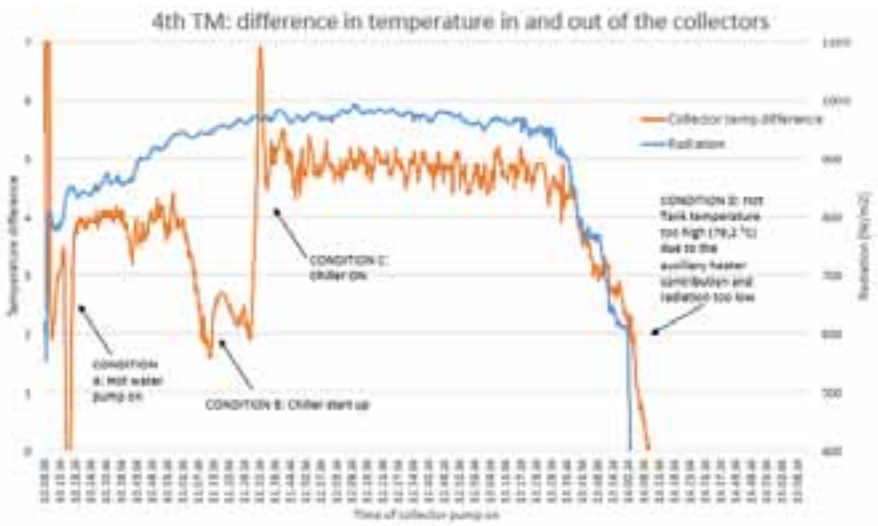

Fig. 2: Collector performance analysis during 4th TM

The 3rd TM registered the best value of global efficiency, instant power output and energy output because presented an higher average radiation and low generator temperature (see Table 4) indeed the condition D happen later. It is the longest measurement in which the collectors works simultaneously with the absorption chiller and the difference in temperature in and out from the collectors was higher (Condition C).

The 5th TM was the measurement in which the Condition C lasts less (only 2h 36min with respect to 3h 50min of the 4th TM and 4h 22 min of the 3rd TM) and indeed the global efficiency is lower. In more, the chiller during its operation required much more thermal power in order to produce a bigger cooling capacity: the collectors could only partially provide to it. This, in fact, suppose that the average temperature difference in and out of the collector, and so the global efficiency and the power output, during absorption chiller operation was lower than in the previous cases because the chiller faster consumes the power provided by them, together with the auxiliary heater.

5. Indirect Evaporative Cooler (iec) performance analysis

Being the IEC performance depending on temperature and relative humidity two different cases were simulated, assuming a constant volume air flow equal to $\dot{V}$= 0,76 m^3/s (maximum value registered in the measurement, assuming the ventilator of the iecworks always at the same speed). Were chosen two favorable weather condition typical of the city of Medellín: relative humidity (r.h.)equal to 30% and dry bulb temperature equal to 33°C. The product air temperature ($T_{product\ air\ flow}$) was calculated through equations furnished by the constructor: with respect to the external static pressure of Medellín the air product temperature should approach at 94% to the wet bulb temperature(T_{wb}). In equation is also considered an about of 2,5% of worsening in performance because of the height of Medellín of 1538 meters [13] :

$$(T_{amb} - T_{wb}) * 0{,}94 * (1 - 0{,}005 * 1538/305) = X \quad \text{(eq.16)}$$

$$(T_{amb} - X) = \text{Design } T_{wb} \quad \text{(eq.17)}$$

$$T_{product\ air\ flow} = \text{Design } T_{wb} + 1{,}1 \quad \text{(eq.18)}$$

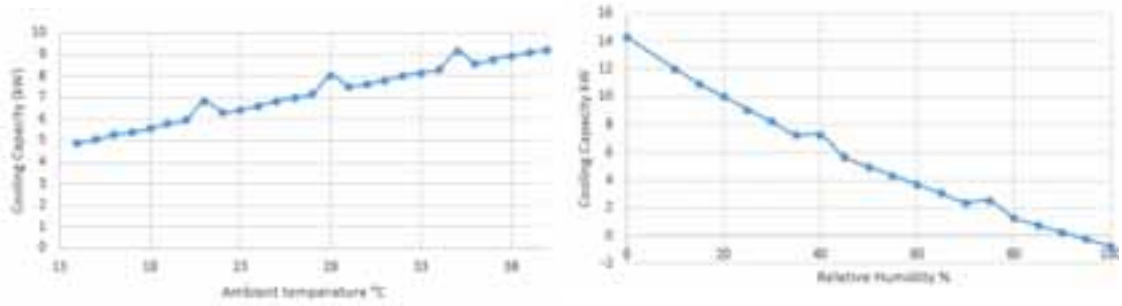

Fig. 3: Iec Performance at a defined relative humidity (r.h.=30%) and dry bulb temperature ($T_{amb} = 33\ °C$)

By these plots it could be seen that in these conditions it is never reach the maximum nominal capacity (17,6 kW): in the first simulation (at r.h.=30%) about 9,2 kW of cooling power is reach at the temperature equal to 40 °C and at temperature under 35°C the capacity is halved. At the ambient temperature of 21, 28 and 35 °C the capacity improve because the difference in wet and ambient temperature registered[9] is higher. Instead, in the second case (at T=33°C) the cooling capacity reaches a maximum of 14,3 kW but decrease really rapidly at relative humidity few lower (reaching negative values at high relative humidity, because the outlet temperature resulted even higher than inlet temperature).

Considering all the tests measurement done so far, it could be said that the air conditioning with the use of iec at Building 24 happens when the temperature oscillates between 33 °C to 23°C and relative humidity between 30% to 72% (without take in account the day in which rain, because in that case is not convenient to work with theiec). Indeed taking into account these ambient condition, and the maximum flow rate registered experimentally, the maximum cooling capacity of the iec is more than 8 kW (a cooling capacity of 8,2 kW was obtained at the best ambient conditions of the air cooling, T=33°C, r.h.= 30%) and an energy consumption of maximum 681,3 W (the maximum experimentally registered).

6. Economic analysis

In order to analyze the economic effort and justify the initial capital cost of the system a comparison with an air cooler Chiller, the most used conventional refrigeration system is done. An analysis of fixed and annual cost was done, taking in account only the purchased equipment costs (PEC) in the fixed capital investment (FCI). The simple payback period was calculated as [10]:

$$Simple\ Payback[years] = \frac{Cost}{Benefit} \qquad \text{(eq. 19)}$$

Where

the $Cost$ are represent by the fixed cost difference between solar and conventional [€]

the $Benefit$ are represented by the variable (annual) cost savings, in primary energy consumption and Operational and Maintenance (O&M) costs, represented by the variable cost difference between conventional and solar systems [€/year]. The analysis was carried on for different size of the system (indeed for different cooling capacity), from the actual case (about 30 kW_{fr}) up to 1300kW_{fr} , and assuming that the expenditure is justified over a long period of cooling demand, the analysis was also done for different operational hours ($t_{op\ hours,year}$) from 3000 h/year up to 1000 h/year. Two different cases were analyzed: Colombian and Italian case, differentiating only for the specific cost of Electrical Energy (EE). For both variable and fixed cost the following assumption were made:

- Specific costs decrease with the increase of the size of the equipment (exchange rate of June20th 2017)
- The sizing of the collectors installed was estimated accounting for cooling capacity and the thermal storage.
- For the equipment which was not possible to provide the specific costs the relationship between the size and the actual cost with a coefficient equal to 0,6 was used.

- The Balance of Plant (BOP) account for a 10% and a 30% of the PEC of the solar and conventional respectively.
- $\bar{P}_{\substack{air\ cond \\ period}} = 2{,}5\ kW$, whose 40% does not depend on the size of the cooling system.
- $COP_{\substack{air\ cooled \\ Chiller}} = 3 \div 4$ variable with respect to the size
- Renewable system works for the half time of its operational hours by thermal energy coming from the auxiliary heater
- $\eta_{auxiliary\ heater} = 0{,}92$
- The O&M costs equal to 4% of the equipment cost of the conventional cooling system and the middle for the solar one.
- $\dot{c}_{natural\ gas} = 0{,}3$ €/Smc (tax free)
- $\dot{c}_{EE,\,Colombia} = 0{,}16$ €/kWh for Colombian case, $\dot{c}_{EE,\,Italy} = 0{,}21$ €/kWh for Italian case (tax free).

The Figures below show the results of the analysis for the Colombian and Italian case.

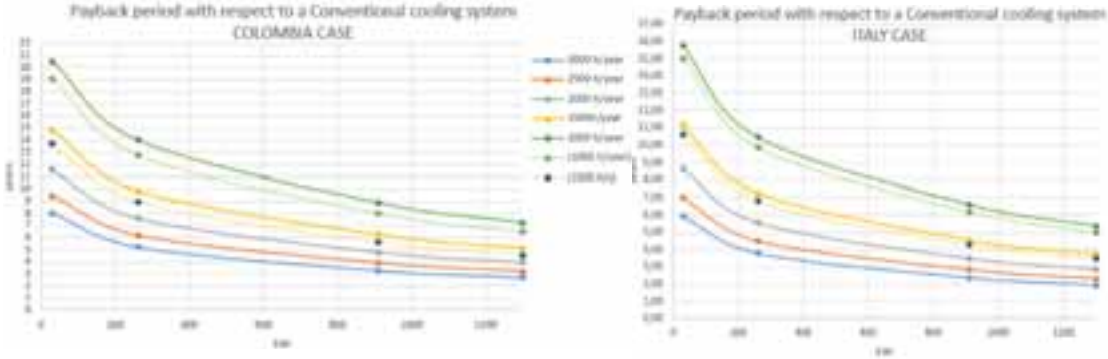

Fig. 4: Results of the payback period between Solar and Conventional cooling system

It is very clear the dependence in size of the equipment: the benefit, indeed the annual primary energy savings in term of money increase so that the ratio to the benefit over the cost decrease exponentially, increasing the size of the system. In Colombia, because of the very low cost of electric energy (0,16 €/kWh), this technology resulted economically convenient (payback period less than 6 years) from capacity few lower than 200 kW if the cooling demand is minimum of 3000 h/years. The situation seems much more convenient for Italy, where the price of electrical energy is 25% higher. The dotted lines represents the payback period for different size of the solar cooling system in case in which it operates 2/3 of the operational hours by sun radiation and 1/3 by thermal energy given by the auxiliary heater, indeed at different share in primary energy consumption. This assumption is done only when the operational hours are lower and indeed is enough to suppose that are present these conditions (1000 and 1500 h/year). For both cases a remarkable improvement could be seen passing from 1000 to 1500 h/year. That because the electric energy consumption has much more heavy contribution for high cooling demand, and the savings are more remarkable with respect to the cost of the investment: it might be not justifiable if the electric energy consumption is not so elevated. In more, should also be noticed that for the electrical energy consumption of the conventional system was assumed a COP that improves with the size; it is not always verified as true, even more if considered that over time the machine is affected by a drop in performance due to wear. Therefore, the payback period curve with respect to the size could present an even more inclined trend, that is traduced with the fact that even shorter period in return of the investment could be expected.

7. Conclusions

The absorption chiller evidenced a cooling capacity lowered of more than the 50 % of the nominal capacity, essentially due to impossibility of the system to maintain a high temperature in the generator. The machine, in fact cannot exploit the nominal thermal power required by the generator (that should be equal to 16,7 kW). Starting from the performance curve provided by the constructor and assuming a linear overlapping of the effects of the generator, evaporator and condenser temperature in the performance of the machine, a lower power furnished by the generator

was registered, (values between 10,5 to 8,7 kW). The problem could be solved doing some modification of the layout:

• The pump that goes from the hot water storage tank to the absorption chiller takes water from the bottom of the tank; indeed, it affects negatively the generator operation due to the thermal stratification inside the tank. It is appropriate to connect the pump to the top of the hot water storage tank, in order to bring into the generator always the hottest water stored.

• The auxiliary heater input is located directly to the hot water tank. A future simulation could be to connect the auxiliary heater in series with the thermal storage. It could lead to provide always the nominal temperature required by the machine, and to avoid the stoppage of the machine, assuring the minimum temperature required in the absorption chiller.

• The pump that goes from the chilled water storage tank to the absorption chiller takes water from the bottom of the tank; indeed, it always sent the coolest water to the evaporator, affecting negatively the heat exchange effectiveness in the evaporator. Move the downstream handle of the chilled water pump to the top part of the tank will increase the difference between inlet and outlet temperature of the heat exchange of the evaporator, increasing the cooling capacity.

With the actual layout, two different operational conditions of the system could be preferred: the one, which could lead to highest COP registered so far, and another that, provides the highest cooling capacity, at a cost of higher energy consumption. These two different configuration are obtained by the lasts two TMs, the 4th and the 5th, proving indeed that during the experimental tests, the right directions in varying operational conditions has being followed. The operational conditions, which lead to optimize the COP, have been reached at 4th TM. Working with the second speeds of the chilled water pump to the evaporator and at the highest temperature that actually could be possible to maintain in the generator, heating the thermal storage up to the limit that avoid the boiling (about 98°C), the effectiveness of the heat exchange in the evaporator improves and the machine produce chilled water exploiting less thermal power in the generator, indeed obtaining the highest values of COP so far registered, equal to 0,54 that is only 20% less of the nominal value. This configuration assure the longest period of work of the chiller because consumes less instantaneous power from the generator. In more, it is assure the lowest value of energy consumption, because both the cooling tower and the pump required less power input. This configuration could be more suitable in case is needed only to maintain the same temperature in the building, and indeed when the cooling demand is lower.

The operational conditions, which lead to optimize the Cooling capacity, have been reach at 5th TM. As the performance curves of the absorption unit shows, lowering the condensation temperature up to the limit that avoid crystallization of the refrigerant flow, increase the cooling capacity of the machine. In particular, it was working with a Tset in the cooling tower equal to 28°C and at maximum capacity in the evaporator, indeed with the third speed of the chilled water pump. It was possible to reach the 60% of the nominal cooling capacity, once have heated the thermal storage up to the boiling limit. This configuration is very useful in case the cooling demand is imminent and big.

The average maximum collectors capacity registered during the TMs done, resulted equal to 13,86 kW, indeed the actual capacity of the collectors does not resulted enough in order to furnished the nominal thermal power required by the absorption chiller. This justify the use of the auxiliary heater during the whole test measurements. Is evidenced an inappropriate control behavior is registered during start up period of the Chiller. In order to improve the capacity of the collectors some improvement have been proposed.

• The actual arrangement of solar collectors sees a series of 5 manifolds in parallel with the same series. In this way the flow rate provided by the pump is separated into two flux. Neglecting the heat loss from the hot tank, the flow rate resulted by the energy balance into the hot tank, is equal to 972 L/h per manifold. Reducing the flow rate, that referring to the datasheet of similar collectors could be even three times lower, the ΔT of the collectors and indeed the power output could improve. Positioning the collectors in series of two, indeed five in parallel could increase them performance.

• The actual arrangement of the auxiliary heater provoke that in case the radiation is low and the temperature inside the storage tank already high (due to the auxiliary heater contribution) the collectors contribution is not effective. The problem could be solved arranging the auxiliary heater in series with the hot water storage tank, so that the

thermal storage is completely depended by the solar energy contribution.

• The actual position of the collectors does not permit to exploit the solar radiation after 4 pm, because the collectors resulted covered by trees' shadows. Very recommended is to move the collector to a different point of the roof of the building.

In order to cover the nominal thermal power required by the absorption unit, dimensioning the capacity of the collectors assuming to receive always an instant power equal to 13, 86 kW, a total of 4,2 m^2 of absorption area of collectors should be added. This corresponds to 4 collectors more (each collectors has 10 tube and each tubes 0,102 m^2 of absorbed area).

From the iec performance analysis, responsible in renovate the air in the building, is evinced that the machine in Medellin condition, and at the actual state of cleaning of filters could furnish a cooling capacity about equal to 8 kW.

From the economic analysis, is evinced the very strong dependence of the simple payback period on the size of the solar cooling system. Increasing the size of the system the benefit, indeed the annual primary energy savings in term of money, increase, so that the ratio of the benefit over the cost decrease exponentially, also due to the lower specific cost of the machine. The payback period is strongly reduced passing from the solar cooling system of a capacity of 30kW to a system of 250 kW. For installed capacity higher than the system analyzed, the technology resulted very convenient not only for a typical Colombian cooling demand (3000 h /year) but also for demand halved, indeed also for an Italian case. Actually in Italy, where the electric energy cost is very high the payback period of the investment resulted in general, much reduced than in Colombia, where the electric energy costs 35% less, due to the wealth of rivers that allows low-cost hydroelectric power production. Considering a cooling demand that could be realistic for Italian weather, equal to 1500 h/year, the technologies proposed resulted convenient (payback period of 6 years) already for system with cooling capacity equal to 500 kW in Italy (the same capacity for Colombian cooling demand has a payback period about of 3years).

Should also be noticed that the economic analysis was carried out considering for the electrical energy consumption of the conventional system a COP that improves with the size; it is not always verified as true, even more considering that over time the machine is affected by a drop in performance due to wear. Therefore, even shorter period in return of the investment could be expected. Anyway, the very good news is that installing an air conditioning system that uses these technologies could make the user richer not only in term of money but also in term of sustainability, because the conditioned ambient in which he will live won't be responsible in remarkable CO2 emissions and won't use any type of refrigerant that impacts the ozone. The user will live not only on a cheap air-conditioned but also environmental-friendly room.

Abstract

Solar cooling technologies have the potential to improve crop and vaccine supply chain management in areas with unreliable access to an electricity distribution network. The diffusion absorption refrigeration (DAR) cycle is a technology of interest for cooling in rural areas and developing countries due to its low capital cost, low maintenance requirements, and unique design in which the requirement for electrically-driven components are fully omitted. The main feature of DAR systems is a thermally driven bubble pump that is used to circulate the refrigerant and absorbent fluid components around the system. In this paper, we present results from a laboratory DAR system operating over a range of pressures and heat input rates with ammonia-water-hydrogen as the working fluid. By reducing the system pressure from 21 bar to 14 bar, a 17% increase in maximum coefficient of performance (COP) is reported, and the system start-up time is reduced by up to 58%. The results are used to calibrate a thermal model of a solar-DAR system, which is then used to determine the optimal system pressure and solar collector array configuration for summer operation in the location of Chennai, India.

Keywords: Solar cooling, diffusion absorption refrigeration, cold chain, solar thermal collectors

1. Introduction

The DAR cycle was patented by von Platen and Munters in 1928. Its principle of operation differs from that of absorption refrigeration systems based on dual-pressure cycles and binary fluid mixtures in that it is designed for "single-pressure" operation enabled by a third component, which imposes different partial pressures on the refrigerant. The basic design has changed little since the early systems, which use ammonia-water-hydrogen as the working fluid at system pressures of 20-25 bar to utilize thermal energy typically at temperatures of 180-250 °C.

A DAR system schematic is shown in Fig. 1. An ammonia-water solution is heated in the generator (1-2), and boils so that the depleted liquid solution (3) is lifted by the ammonia-rich vapour (4) to the top of the bubble pump. The vapour rises to the rectifier, where most of the remaining water is separated out (5), leaving a near-pure ammonia vapour (6). The ammonia returns to the liquid phase in the condenser (6-7a) and is precooled (7a-9) before entering the evaporator, where it evaporates and diffuses into a reduced partial pressure hydrogen environment, extracting heat from the evaporator's surroundings (9-10). Any uncondensed vapour leaving the condenser bypasses the evaporator entirely (7b-10). Saturated-vapour ammonia mixed with hydrogen exits the bottom of the evaporator and enters the reservoir, then rises through the absorber column where it is absorbed by the downwards flowing weak solution introduced at the top (8a). The hydrogen meanwhile is not absorbed and rises back to the evaporator (8b) via a gas heat exchanger where it is pre-cooled by the downward flowing refrigerant. The liquid solution, having absorbed the ammonia from the upward-flowing gas, settles in the bottom of the reservoir before proceeding to the generator via the liquid heat exchanger (11-1).

Recent research has considered how the DAR cycle can be adapted for use in a lower temperature range with solar thermal collectors. Approaches considered include the use of alternative working fluids (Zohar *et al*. 2009, Ben Ezzine *et* al. 2010, Acuña *et al*., 2013) and the configuration of the generator and bubble pump (Zohar *et al*. 2008, Damak *et al*., 2010). The UK company Solar-Polar has recently developed a solar-DAR system for use in rural cold chain applications. A field-test of the system is currently in preparation at Anna University in Chennai, India (see Fig. 2), where fifteen modular roof-top units will be used to provide cooling to a 34 m^3 insulated cold store. Each unit provides a nominal 60-70 W of cooling from a 0.72 m^2 array of solar heat pipe collectors. A one-year monitoring study will be undertaken in order to assess the seasonal performance of the system.

To ensure that the units in the pilot study are configured to provide maximum cooling output in Chennai conditions, a predictive model that can capture the performance of the system over diurnal and seasonal time-scales is an invaluable tool. The processes of the DAR cycle are well understood, however many of the models presented in the literature (Zohar *et al*. 2005, Starace and De Pascalis 2012, Taieb *et al*. 2016) use restrictive assumptions about the state of the system that are based on a limited range of operating conditions. In particular, there is a lack of experimentally-validated models for the ammonia-water-hydrogen DAR cycle operating over a wide range of system pressures and solution concentrations. The system pressure is an essential parameter for optimization in solar thermal applications, which represents a trade-off between the operating temperature and efficiency of the solar collector array, and the ability to reject heat from the cycle to the ambient air.

Fig. 2: Solar-Polar DAR demonstration system with heat pipe solar collector array, installed at Anna University campus, Chennai.

In this paper, the Solar-Polar DAR system will be used as the basis for a laboratory study in which the performance of the system will be characterized over a range of operating conditions. The experimental data will be used to calibrate a thermodynamic model of the system developed in earlier work (Freeman *et al*. 2016), and a whole-system solar-DAR model will then be used to simulate performance in the Chennai climate over a range of operating pressures and with various solar collector configurations.

2. Experimental methods

Steady-state tests were performed on the laboratory DAR units over a range of generator heat input powers ($\dot{Q}_{\mathrm{gen}}$) and system charge pressures (p_{ch}). In this paper, results will mostly be presented for a cooling delivery temperature (T_{cool}) of 5 ˚C. The main performance parameter of interest is the cooling power delivered by the DAR evaporator ($\dot{Q}_{\mathrm{evap}}$) and the coefficient of performance (COP), which is defined as the ratio of the cooling output delivered at the evaporator to the heat input provided to the generator. Therefore accurate measurements of both the heat input and cooling output from the system are required.

Heat was provided by five 9.5-mm diameter cartridge heaters, of similar dimensions to the condenser end of the heat pipe collectors used in the solar-DAR setup. The cartridge heaters were fitted into sockets welded to the outer surface of the generator tube. The full length of the bubble pump was insulated with 50 mm of rockwool insulation, while a larger thickness of 100 mm was used to insulate the generator and cartridge heaters. During each steady-state test, the electrical power to the cartridge heaters was maintained at a fixed value, set using an AC autotransformer (variac). The heater power was varied between 0-500 W at intervals of 50 W for each pressure level. Three system charge pressure settings were chosen for the experiments: (i) 14 bar; (ii) 17 bar; and (iii) 21 bar (absolute pressure, measured while the system was at rest under ambient temperature conditions).

Fig. 3: Layout of the laboratory DAR system showing major components and numbered state points representing the locations of temperature measurements on the system.

In order to measure the cooling power $\dot{Q}_{\mathrm{evap}}$, a box was constructed around the evaporator using 100 mm thick layers of rigid polyurethane insulation. The internal dimensions of the cold box were 710 × 360 × 110 mm, giving an internal volume of 0.0281 m^3. Sealant was applied around all pipe penetrations in order to minimize air leakage to or from the surroundings. A small electric fan heater placed inside the box was used to control the temperature of the air delivered across the surface of the evaporator. Air was delivered in a downward direction via an insulated channel running along the edge of the box and was distributed between parallel aluminium fins attached to the outer surface of the steel evaporator tubing. The power delivered by the fan heater was controlled so that the "air off" temperature measured at the bottom of the evaporator was maintained at a constant value of 5 °C. Heat losses from the box were estimated in the final COP calculations by assuming a U-value of 0.24 W m^{-2} K^{-1} and an air leakage rate of 0.2 air changes per hour from the cold box.

Detailed temperature measurements were taken on each system sub-component in order to evaluate assumptions used in the thermodynamic model of the cycle (see Section 3.1). For some of the locations, measurement of fluid temperatures was challenging, for example in the concentric tube (pipe-in-pipe) heat exchangers in the evaporator and bubble pump. The apparatus was modified to include thermowells welded into the pipework so that fluid temperatures in the inner tube of the bubble pump could be measured more accurately at locations 2 and 3. Elsewhere in the system, most fluid temperatures were estimated from measurements in contact with the outer surfaces of the steel tubes. A direct measurement of system pressure during the tests was also provided by a pressure transducer located at the fluid reservoir. For each run, the system was operated under steady-state

conditions for a period of one hour while temperatures, pressure and electrical input power to the cartridge heaters and fan heater were measured at intervals of 1 second. Air temperature in the laboratory was maintained at approximately 25 ºC, although some variation of ± 2 ºC was found to occur between the tests.

Previous experimental studies by Mazouz *et al.* (2014) and Ben Jemaa *et al.* (2016), among others, have noted that the starting characteristic of DAR systems varies significantly with heat input rate. During the start-up process, the solution in the generator is heated until it transitions from nucleate boiling to a state where significant bubble coalescence takes place to provide lifting of the liquid solution through the entire length of the bubble pump. Shelton and White (2002) and Hanafizadeh *et al.* (2014) have discussed the conditions under which the bubble pump processes are dominated by slug flow or churn flow regimes. It is important to consider the dynamic behaviour of the system in any situation where the heat source is intermittent (such as solar applications), and therefore in the present work the temperature profiles of the generator during start-up will be used to determine the thermal capacity and minimum starting temperature under various operational settings.

3. Modelling methodology

A model of the solar-DAR system was developed to evaluate its performance under realistic climatic conditions and to select the most appropriate operational settings for the chosen location. In this paper, the model is used to investigate the optimal system pressure and solar collector array configuration for summer operation in Chennai. The sub-models of the DAR cycle and the solar collector sub-systems are described in the following sections.

3.1. DAR system sub-model

The thermodynamic model of the DAR cycle is based on the equations of Starace and De Pascalis (2012), and consists of 6 lumped sub-component models: (i) generator and bubble pump; (ii) rectifier; (iii) condenser; (iv) evaporator; (v) absorber; and (vi) liquid-solution heat exchanger. The energy balances for each component are shown in Eqs. 1-6, where $\dot{m}$ is mass flow rate in kg s^{-1}, $\dot{Q}$ is heat flow rate in W, h is specific enthalpy in J kg^{-1}, and "ig" denotes hydrogen (inert gas). The numbered state points correspond to those shown in Figs. 1 and 3.

$$\dot{Q}_{\mathrm{gen}} = \dot{m}_3 h_3 + \dot{m}_4 h_4 - \dot{m}_1 h_1 + \dot{Q}_{\mathrm{bp,loss}}, \quad \text{(eq. 1a)}$$

$$\dot{Q}_{\mathrm{bp,loss}} = \dot{m}_3[h_3 - h_{\mathrm{l}}(T_2)] + \dot{m}_4[h_4 - h_v(T_2)], \quad \text{(eq. 1b)}$$

$$\dot{Q}_{\mathrm{rect}} = \dot{m}_5 h_5 + \dot{m}_6 h_6 - \dot{m}_4 h_4, \quad \text{(eq. 2)}$$

$$\dot{Q}_{\mathrm{cond}} = \dot{m}_6(h_7 - h_6), \quad \text{(eq. 3)}$$

$$\dot{Q}_{\mathrm{evap}} = \dot{m}_9(h_{10} - h_{7\mathrm{a}}) + \dot{m}_{\mathrm{ig}}\left(h_{10,\mathrm{ig}} - h_{8\mathrm{b,ig}}\right), \quad \text{(eq. 4)}$$

$$\dot{Q}_{\mathrm{abs}} = \dot{m}_{11} h_{11} - \dot{m}_{10} h_{10} - \dot{m}_{8\mathrm{a}} h_{8\mathrm{a}} + \dot{m}_{\mathrm{ig}} h_{8\mathrm{b}} - \dot{m}_{\mathrm{ig}} h_{10,\mathrm{ig}} - \dot{m}_{7\mathrm{b}} h_{7\mathrm{b}}, \quad \text{(eq. 5)}$$

$$\dot{m}_3 h_3 + \dot{m}_5 h_5 - \dot{m}_{8\mathrm{a}} h_{8\mathrm{a}} = \dot{m}_1(h_1 - h_{11}). \quad \text{(eq. 6)}$$

The thermodynamic properties of the ammonia-water mixtures were calculated using the correlations of Patek and Klomfar (1995), and REFPROP was used to calculate the properties of hydrogen. The DAR system models presented in Zohar *et al*. (2005) and Starace and De Pacalis (2012) require temperatures to be specified as inputs at several points in the cycle, including the inlet and/or outlet of the generator, condenser, evaporator and reservoir. The aim in the present work is to predict DAR performance using only the local climatic conditions, and information on the system charge pressure and thermal input provided from the solar collector array. Thus the experiments in this study will be used to characterize the performance of the various system components, and the following additional relations will be formulated for the bubble pump, rectifier and condenser:

$$T_2 = f(p, \dot{Q}_{\mathrm{gen}}), \quad \text{(eq. 7)}$$

$$T_6 = T_4 - \varepsilon_{\mathrm{rect}}(T_4 - T_{\mathrm{a}}), \quad \text{(eq. 8)}$$

$$\dot{Q}_{\mathrm{cond}} = UA_{\mathrm{cond}}\Delta T_{\mathrm{LMTD}}. \quad \text{(eq. 8)}$$

The following assumptions were also used: (i) the mass fraction of the rich ammonia-water solution entering the generator from the reservoir is fixed at 30% NH_3, with no hydrogen present; (ii) the preheated solution enters the generator as a saturated liquid; (iii) the refrigerant enters the condenser as a saturated vapour.

3.2. Solar collector sub-model

Two types of solar heat-pipe collector will be investigated for use with the DAR system. Collector 1, shown on the left in Fig. 2a, is a classic low-cost design consisting of a heat pipe with an aluminium fin inside an all-glass tube formed of two concentric layers. The annulus is evacuated, and a solar absorbing coating is applied to the inner glazed layer. Collector 2, shown on the right in Fig. 2a consists of a single-glazed tube with a fully evacuated core that contains a copper tube with a textured fin. The heat pipe is inserted inside the copper tube, and the solar absorbing coating is applied directly onto the surface of the metal fin. The former type of collector is easily mass-produced and available at very low costs in bulk quantities, while the latter tends to be more expensive due to the high-quality glass-to-metal seal required at the copper tube penetration point.

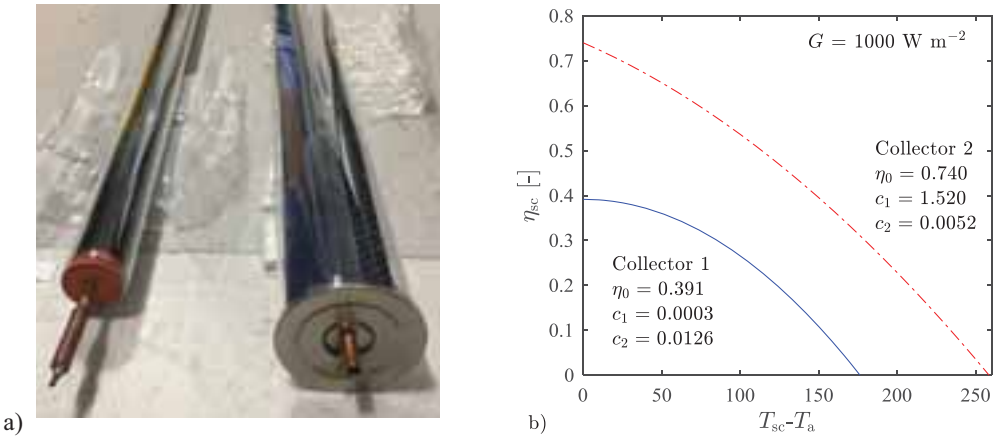

Fig. 4: (a) Photograph showing two heat pipe collector types investigated for use with the solar-DAR system: Collector 1 (left) and Collector 2 (right). (b) Efficiency curve plots for the two collectors (aperture area basis, G = 1000 W m^{-2}).

The efficiency curves for the two heat pipe collectors are compared in Fig. 2b, showing a higher zero-loss efficiency and stagnation temperature for Collector 2. The efficiency curve coefficients for Collector 2 were taken from a Solar Keymark performance test report (SPF, 2009). In the absence of existing performance data for Collector 1, the collector was tested in-house under irradiance conditions of 1000 W m^{-2} and a temperature range of 30-180 ˚C to obtain the efficiency curve coefficients η_0, c_1 and c_2 in Fig. 2b. The coefficients are used in the solar-DAR system model to calculate the collector's useful heat output $\dot{Q}_{\mathrm{sc}}$ as a function of the solar irradiance (direct and diffuse components G_{b} and G_{d}), collector temperature T_{sc} and ambient temperature T_{a}:

$$\dot{Q}_{sc} = \eta_0 A\left(K_{\theta,\mathrm{b}} G_{\mathrm{b}} + K_{\theta,\mathrm{d}} G_{\mathrm{d}}\right) - c_1 A(T_{\mathrm{sc}} - T_{\mathrm{a}}) - c_2 A(T_{\mathrm{sc}} - T_{\mathrm{a}})^2. \qquad \text{(eq. 9)}$$

The main dynamic component considered in the system model is associated with the thermal capacity C of DAR generator, which will be determined experimentally. The collector's effective thermal capacity is assumed to be small by comparison and is therefore not included in the model. The thermal conductance $(UA)_{\mathrm{gen}}$ between heat pipe collector and the DAR generator is also required to solve the following energy balance at 1-min intervals:

$$\dot{Q}_{\mathrm{sc}} = \dot{Q}_{\mathrm{gen}} + C\frac{dT_{\mathrm{gen}}}{dt} = (UA)_{\mathrm{sc-gen}}\left(T_{\mathrm{sc}} - T_{\mathrm{gen}}\right). \qquad \text{(eq. 10)}$$

3.3. Climate data for diurnal simulation

In the present study, the system operation will be simulated for a "peak solar" day in Chennai, India, using climate data published by ASHRAE (2001). The region of Chennai experiences high solar irradiance during the summer season, between the months of March to May. From June onwards, the weather is typically cloudier with periods of heavy rainfall. The day chosen for the simulation is the 3$^{\mathrm{rd}}$ of May.

4. Results and discussion

4.1. Experimental results – steady-state performance

Plots of cooling power and COP over the range of steady-state heat inputs are presented in Fig. 5 at the three system charge pressure settings 14 bar, 17 bar and 21 bar. It was found that for $p_{\mathrm{ch}} \geq 17$ bar, it was not possible to achieve the cooling delivery temperature of 5 ºC at $\dot{Q}_{\mathrm{gen}}$ values < 150 W.

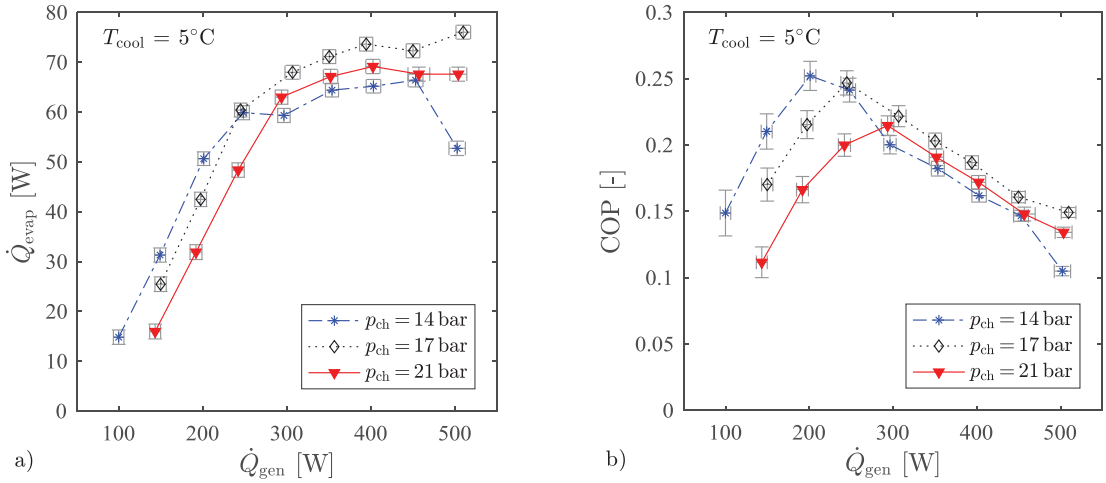

Fig. 5: Experimental results: (a) cooling power and (b) COP, at various charge pressures and for a cooling temperature of 5 °C.

The cooling output is shown to increase with generator heat input, however a change in the trend is observed at values of $\dot{Q}_{gen}$ around 200-300 W, that also corresponds to the peak COP of the system. The same behaviour was also observed in the study by Chen *et al.* (1996) who noted that for a further increase in heating input power beyond this point, liquid refrigerant begins to exit the evaporator.

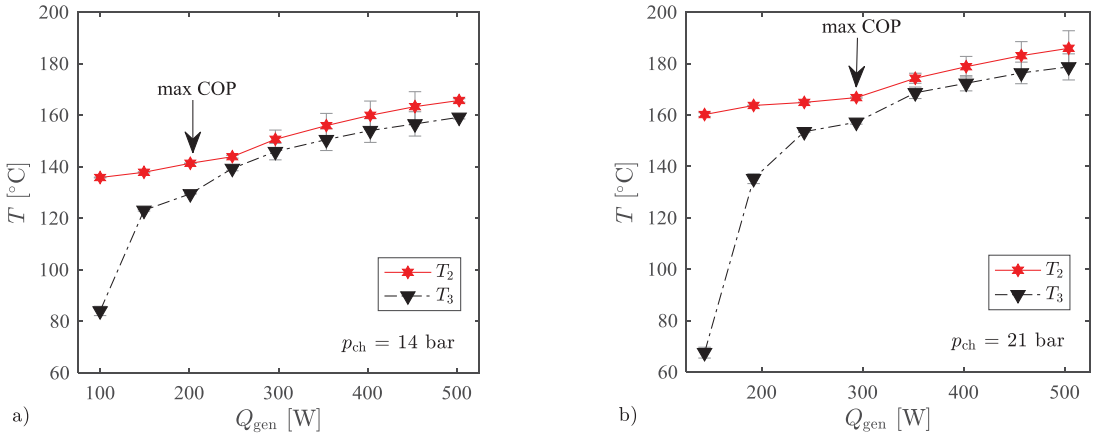

Fig. 6: Temperature at States 2 and 3 (generator outlet and top of the bubble pump, respectively), for system charge pressures of: (a) 14 bar and (b) 21 bar. Error bars denote standard deviation of measured values over the measurement period.

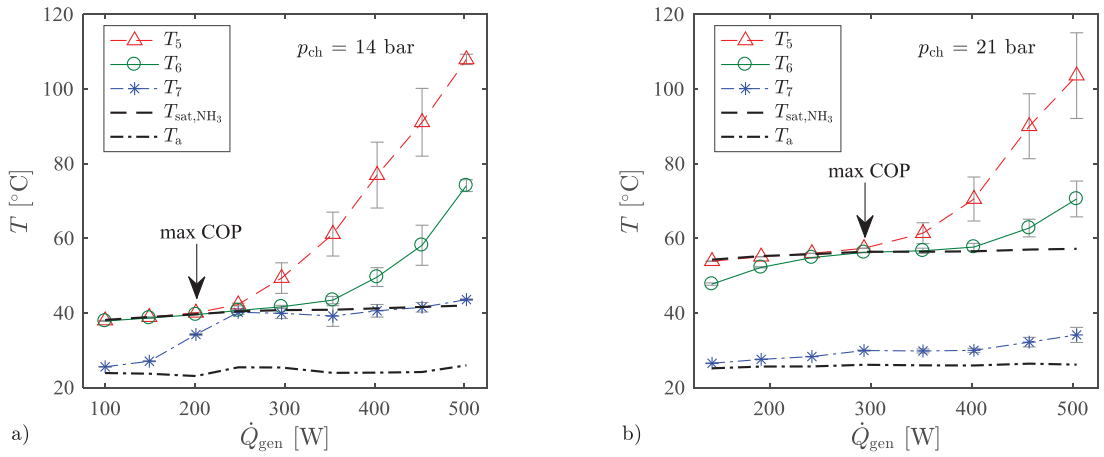

Fig. 7: Temperature at States 5, 6 and 7 (rectifier, condenser inlet and condenser outlet, respectively), for system charge pressures of: (a) 14 bar and (b) 21 bar. Also shown are the ambient air temperature T_a and the saturated liquid temperature of the refrigerant T_{sat,NH_3}. Error bars denote standard deviation of measured values over the measurement period.

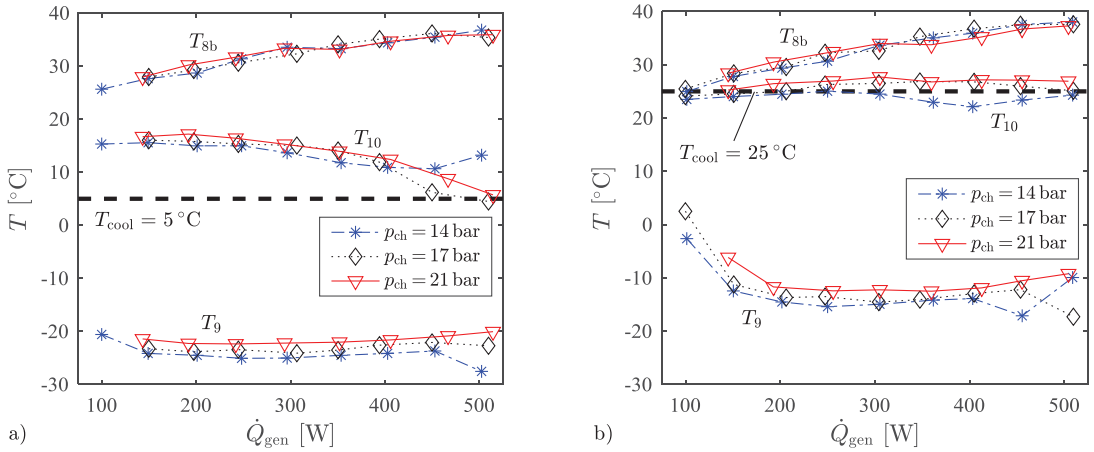

Fig. 8: Temperature at State 8b, 9 and 10 (absorber gas outlet, evaporator inlet and evaporator outlet, respectively), for cooling delivery temperatures (indicated by the dashed line) of: (a) 5 ºC and (b) 25 ºC, and for various values of p_{ch} and $\dot{Q}_{gen}$.

The mean temperatures measured along the bubble pump are plotted in Fig. 6. At low heat input rates, a large difference can be observed between the temperature at the top of the bubble pump T_3 and at the lower part of the bubble pump close to the generator T_2. At higher heat input rates this temperature difference is far smaller, indicating a change in flow regime that results in a lower level of heat dissipation according to Eq. 1b.

Full utilization of the rectifier and condenser is found to be a key factor in maximizing COP. Figure 7 shows the measured rectifier and condenser inlet and outlet temperatures; also indicated are the ambient air temperature and the saturation temperature of pure ammonia at the operating pressure of the DAR system. The highest COP is achieved at the point where the temperature at the condenser inlet (T_6) is very close to (slightly higher than) the saturation temperature of ammonia, such that the maximum flow-rate of ammonia with the minimum of water content was conveyed to the evaporator. At lower heat inputs, temperatures measured along the rectifier indicate that the condensation of ammonia occurs prior to the inlet of the condenser, thus resulting in some drain back of ammonia to the generator and a lower COP. At higher heat input rates, higher temperatures at the condenser inlet indicate that a larger fraction of water is present in the saturated vapour entering the condenser.

At the lowest heat inputs, significant subcooling is achieved at the condenser, where exit temperatures approach that of the ambient air. However, at the lowest system pressure p_{ch} = 14 bar and $\dot{Q}_{gen}$ > 250 W, Fig. 7a indicates that the fluid exiting the condenser is no longer subcooled, exiting the condenser in a two-phase state at the refrigerant saturation temperature. The uncondensed fraction of the refrigerant flow is diverted from the evaporator to the absorber via the gas bypass tube, and the result is a lower cooling output at higher values of $\dot{Q}_{gen}$ than achieved at p_{ch} = 17 bar (see Fig. 5a).

The evaporator inlet and outlet temperatures (T_9 and T_{10}, respectively) were found to vary with cooling delivery temperature more than system pressure or generator heat input. At a cooling delivery temperature of T_{cool} = 5 ºC (Fig. 8a), the evaporator inlet temperature is between -22 and -25 ºC across most of the heat input range, while for a cooling delivery temperature of T_{cool} = 25 ºC (Fig. 8b) it is between -12 and -15 ºC. In the former case, it should be noted from Fig. 8a that the evaporator outlet temperature is higher than the cooling delivery temperature due to the counterflow heat exchange with the warmer flow of hydrogen gas flowing upwards from the absorber, which enters the gas heat exchanger at the higher temperature of T_{8b}.

4.2. Experimental results – dynamic performance during system start-up

Figures 9a and 9b show generator temperature plotted against time during the start-up process, for a range of fixed heat input rates and for system charge pressures of 14 bar and 21 bar respectively. Temperature is shown to increase until the point at which the bubble pump begins to lift the solution from the generator, which is then replaced by a continuous flow of lower-temperature fluid from the reservoir. The start times and peak generator start-up temperatures for the range of test conditions are presented in Fig. 10.

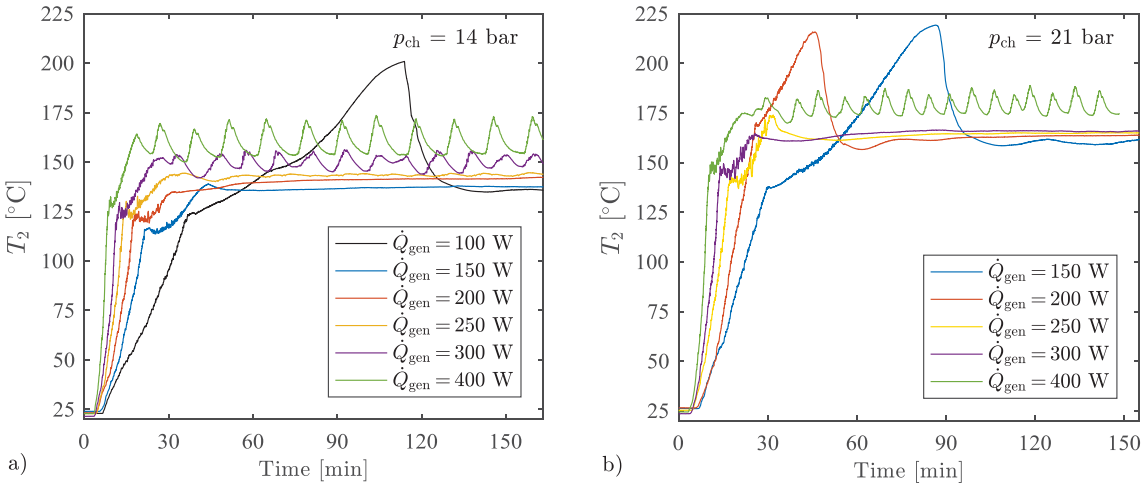

Fig. 9: Generator temperature at various steady heat input rates during start-up for: (a) 14 bar and (b) 21 bar charge pressure.

The lowest values of $\dot{Q}_{gen}$ are characterized by an "overshoot" of the generator temperature followed by a sudden drop in temperature as the system transitions to steady-state operation. Meanwhile, for the highest values of $\dot{Q}_{gen}$, an oscillating behaviour is observed for the generator temperature after the transition to steady-state. At intermediate values of $\dot{Q}_{gen}$ corresponding to peak COP, neither of these aforementioned behaviours are observed. In all cases there is a noticeable change in the rate of increase of the generator temperature during the initial heating of the solution that represents the onset of boiling, after which the temperature continues to increase at a slower rate (as is characteristic for non-isothermal phase-change processes in two-component mixtures) until the start of the bubble pump operation.

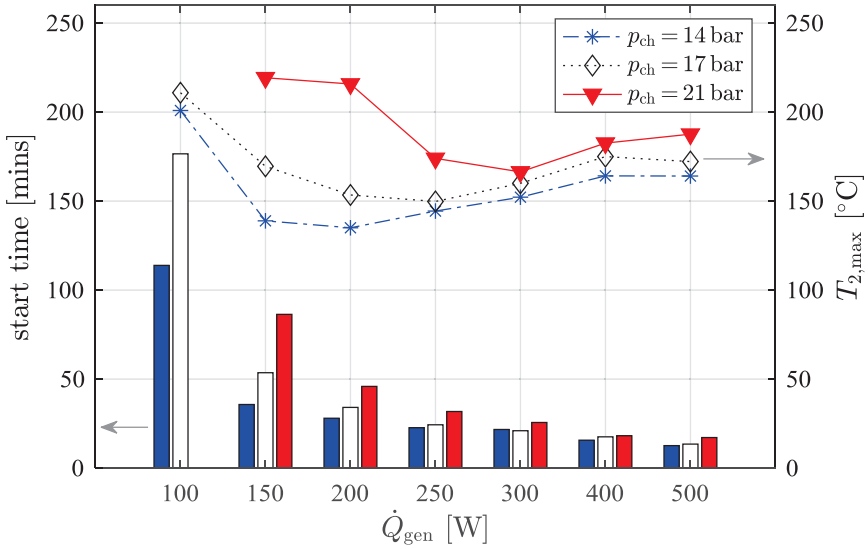

Fig. 10: Experimental results showing start-up time (bar plots) and peak generator start-up temperature (line plots) at various steady heat input rates. Shown for system charge pressures of 14 bar (blue), 17 bar (white) and 21 bar (red).

The peak in temperature observed at low values of $\dot{Q}_{gen}$ is significant. At p_{ch} = 14 bar and $\dot{Q}_{gen}$ = 100 W, the generator temperature reaches a maximum value of 201 ºC, which is 65 ºC above the temperature observed during steady-state operation. A likely reason for this is that slow nucleate boiling of stagnant fluid in the generator under low heat-flux conditions leads to a depletion of ammonia from the solution. This gradually raises the temperature at which the coalescence of bubbles is sufficient to lift liquid solution upwards in the bubble pump, before cooler solution can flow from the reservoir. At higher values of $\dot{Q}_{gen}$, there is a faster transition from nucleate boiling to flow boiling before significant depletion of the ammonia-rich solution occurs, with the result that no observable overshoot of the generator temperature occurs.

4.3. Model calibration

The results of the steady-state experiments were used to calibrate the system model. Table 1 contains a list of relations that were used to determine the state of the system according to certain environmental parameters or operational settings. The DAR system pressure p at each time instant in the model is determined as a function of the initial charge pressure p_{ch} and the generator temperature T_2. An additional equation is also included to describe the relationship between $\dot{Q}_{\mathrm{gen}}$, T_2 and p based on the experimental data. The conductance value $(UA)_{\mathrm{sc-gen}}$ describing the heat transfer between the solar heat pipe collectors and the generator was estimated from observations of the temperature difference between the cartridge heaters and generator during the tests. The parameters C and $(UA)_{\mathrm{gen-amb}}$ were estimated from the time constant of the temperature response of the generator during start-up and after shut-down. The conductance value $(UA)_{\mathrm{cond}}$ was estimated using temperature profiles measured along the two-phase (condensation) and single-phase (subcooling) zones of the condenser.

Figure 11 shows that the calibrated model gives a reasonably good prediction of cooling output, particularly at the lower end of the range of $\dot{Q}_{\mathrm{gen}}$ values, and correctly captures the trend of the COP curve. However, at higher values of $\dot{Q}_{\mathrm{gen}}$ (beyond those corresponding to the peak COP) the model is shown to over-predict $\dot{Q}_{\mathrm{evap}}$ by ~10% at $p_{\mathrm{ch}} = 14$ bar, and under-predict $\dot{Q}_{\mathrm{evap}}$ by ~15% at $p_{\mathrm{ch}} = 21$ bar.

Tab. 1: Supplementary equations and input parameters used in the solar-DAR system model.

Parameter	Value / Equation
p	$p = p_{\mathrm{ch}} + 0.123 \times 10^{-3} \cdot (T_2 - 25)^2$
$\dot{Q}_{\mathrm{gen}}$	$\dot{Q}_{\mathrm{gen}} = 14.2\,T_2 + 34.8\,p - 1293$
$\varepsilon_{\mathrm{rect}}$	$\varepsilon_{\mathrm{rect}} = 0.85$
$(UA)_{\mathrm{cond}}$	$(UA)_{\mathrm{cond}} = 5.5$
$(UA)_{\mathrm{sc-gen}}$	$(UA)_{\mathrm{sc-gen}} = 5$
$(UA)_{\mathrm{gen-amb}}$	$(UA)_{\mathrm{gen-amb}} = 0.3$
T_9	$T_9 = T_{\mathrm{cool}} - 28$
T_{10}	$T_{10} = T_9 + 37$
T_{11}	$T_{11} = T_{\mathrm{amb}} + \left(2.406 + 36.7\dot{Q}_{\mathrm{gen}}/1000\right)$
T_{8b}	$T_{8b} = T_{11} - 0.5(T_{11} - T_{\mathrm{a}})$
$\dot{Q}_{\mathrm{bp,loss}}$	$\dot{Q}_{\mathrm{bp,loss}} = \dot{Q}_{\mathrm{gen}}\left(0.65 + 0.025p - 0.0039\dot{Q}_{\mathrm{gen}}\right)$
$T_{\mathrm{gen,min}}$	$T_{\mathrm{gen,min}} = 85 + 3.6p_{ch}$
$T_{\mathrm{gen,start}}$	$T_{\mathrm{gen,start}} = 90 + 10.3p_{\mathrm{ch}} - 0.536\dot{Q}_{\mathrm{gen}}$

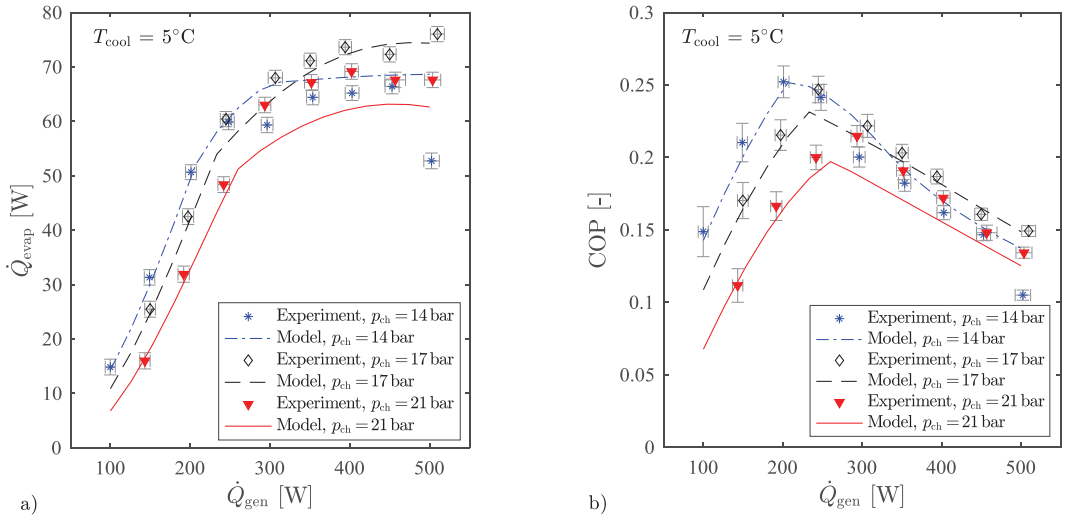

Fig. 11: Line plots showing predictions of (a) cooling power output and (b) COP from the calibrated DAR system model, overlaid with experimental data points for the corresponding charge pressures and heat input rates.

4.4. Solar-DAR system performance simulation

The solar-DAR system model, with the calibration parameters listed in Table 1 as inputs, was used to simulate the performance of the solar-DAR system on a "peak solar" day in Chennai, India. From the climate dataset, the maximum solar irradiation was found to occur on 3rd May. The peak ambient air temperature on this day is 39 ºC. Diurnal simulations were performed at system charge pressures between 12-21 bar and a delivered cooling temperature of 5 ºC. The solar collector array area was varied between 0.5-5 m^2, using Collector Types 1 and 2 presented in Section 3.2.

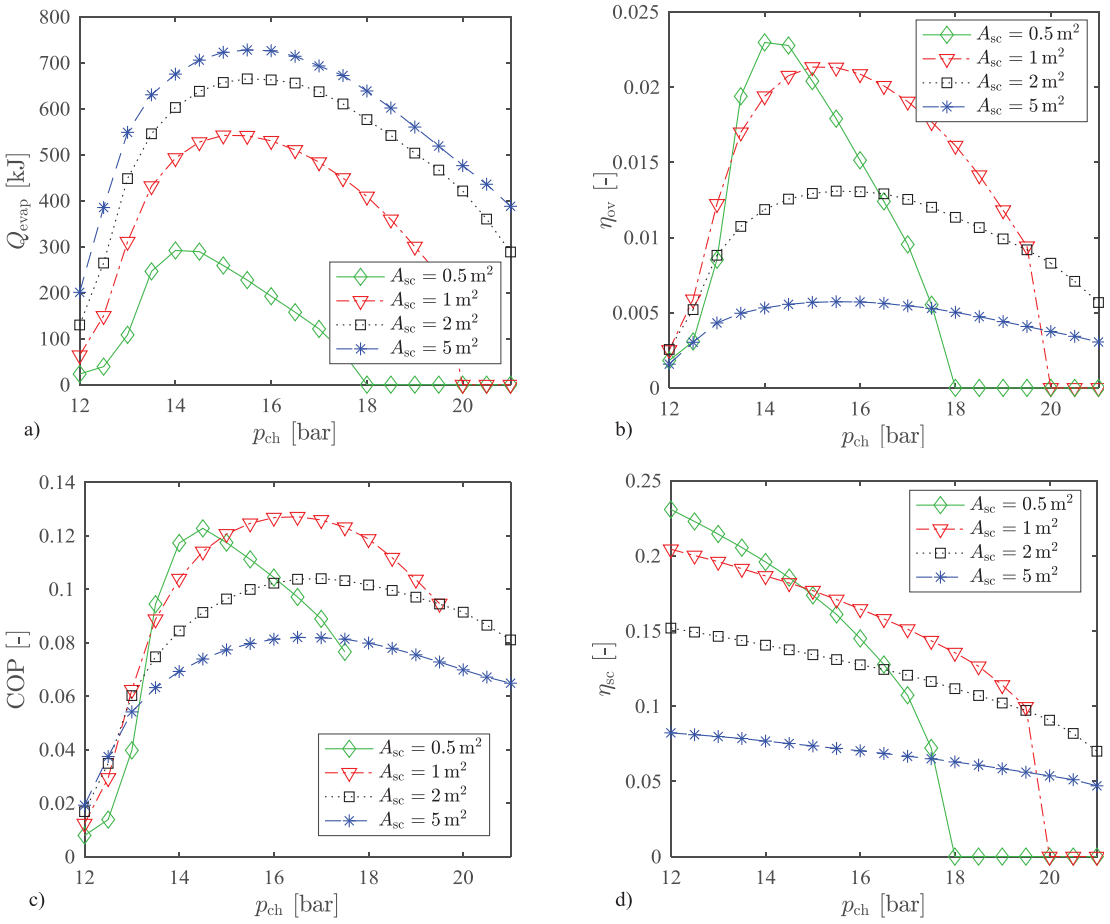

Fig. 12: Diurnal simulation results for the solar-DAR system with Collector Type 2, showing (a) total cooling output, (b) overall (solar to cooling) efficiency, (c) refrigeration cycle COP and (d) solar collector efficiency, plotted against DAR system charge pressure. Simulations are performed with various collector array areas, and a cooling delivery temperature of 5 °C.

The plots in Fig. 12a show the total daily cooling energy delivered with Collector 2 over the range of operating pressures and collector areas. As expected, cooling output increases with solar collector area, however for each doubling of the array size beyond 1 m^2, the improvement in maximum cooling output becomes smaller, indicating a higher cost per unit of cooling energy delivered; while maximum cooling output occurs at progressively higher system pressures as the array size is increased. Figure 12b shows that a maximum overall (solar to cooling) efficiency of 2.3% is achieved with 0.5 m^2 of collector array and a system pressure of 14 bar. For 1 m^2 of collector array area, a slightly lower maximum overall efficiency is achieved, however the system is able to operate over a wider range of system pressures and the DAR operates with a slightly higher COP, delivering an average power of 26 W over a 5.8 hour operating period. Figure 12c shows that with 1 m^2 of collector a DAR daily COP of up to 12.7% is achieved for a system pressure 16.5 bar. It can be seen in Fig. 12d that as system pressure is increased, the solar collector efficiency decreases due to higher collector temperatures and shorter operating periods of the DAR system; while larger collector array areas are needed to provide sufficient heat to the generator. Thus, from these results it can be predicted that an "optimal" summer-day configuration for the DAR system in Chennai is between 14-16.5 bar, with a collector array area of 0.5-1 m^2.

The simulated performance of the solar-DAR system was considerably poorer with Collector 1, delivering less than 25% of the daily cooling energy predicted with Collector 2 for an equivalent collector array area. Furthermore with Collector 1, a minimum array area of 2 m^2 was required in order to deliver sufficient thermal energy to start the system; while with an array area up to 10 m^2 the system could only operate at pressures < 14 bar.

Figures 13a and 13b show profiles of the system temperatures and energy flows over the diurnal operating period for the solar-DAR system charge pressure of 14 bar and 19 bar respectively, and with a 1 m^2 array area of the higher efficiency solar collectors (Collector Type 2) as the heat source. The figures illustrate the trade-off between the lower operating temperatures, higher collector efficiency, and longer operational period achieved at the lower system pressure; compared to the higher cooling power output during the middle of the day achieved at the higher system pressure. It can also be observed in Fig. 13a that at 14 bar the lower saturated liquid temperature of the working fluid in the condenser (shown by the green line) results in only partial condensation of the working fluid under the warm ambient conditions. As a result, 40% of the mass-flow of refrigerant bypasses the evaporator, resulting in a significant loss of cooling potential illustrated by the energy flow $\dot{Q}_{gb} = X_7 \dot{m}_r \Delta h_{fg}$. At the higher system pressure of 19 bar in Fig. 13b, the difference between the saturated liquid temperature of the working fluid in the condenser and the temperature of the ambient air is larger and therefore for most of the operating period, full condensation is achieved.

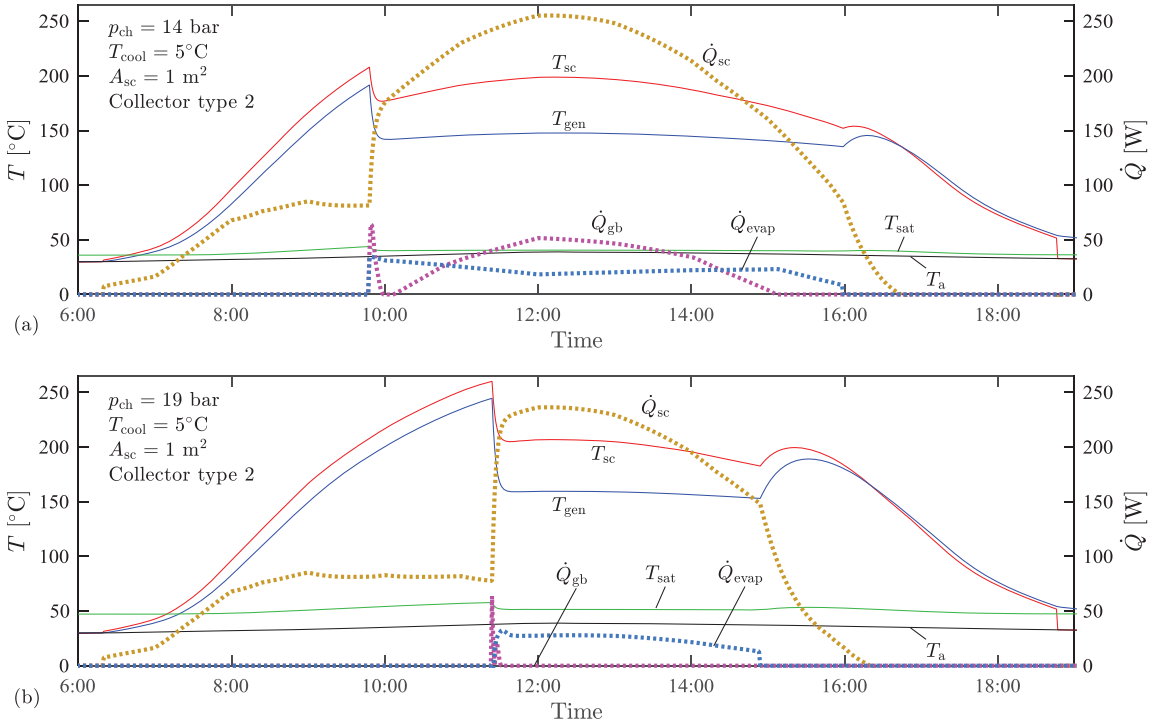

Fig. 13: Diurnal simulation profiles showing system temperatures and energy flow rates for two configuration cases.

5. Conclusions

A solar-cooling system based on a diffusion absorption refrigeration (DAR) cycle was presented, using heat-pipe solar collectors as the heat source. Based on experimental results from a DAR system operating over a range of charge pressures and heat input rates, a thermodynamic model was calibrated and used to simulate the system's performance in the climate of Chennai, India. The experimental analysis has shown that the DAR system can operate over a wide range of heat input rates, but that the maximum COP achieved is highly dependent on the system pressure. As the system pressure was lowered, a higher maximum COP was obtained for a lower corresponding generator heat input rate. For a cooling delivery temperature of 5 ºC and a charge pressure of 14 bar, a maximum COP of 0.25 was obtained with a heat input of 200 W. The observations relating to the condenser have shown that there is a limit to how far the lowering of the system pressure results in an increase in the COP of the system. This has further implications for the application of the system in the high-

ambient temperature environment of Chennai; the diurnal simulation of the solar-DAR system demonstrated that the optimal setting for the system pressure is a trade-off between reducing the generator temperature required to start the system and maximising the ability to reject heat in the condenser. Future work should investigate the effect of changing the ammonia-water solution concentration, while the diurnal simulation of the solar-DAR system should be extended to an annual analysis. The performance of this system in other geographical locations of interest with lower ambient temperatures should also be investigated.

Experimental Study of a Solar Collector/Regenerator for Liquid Desiccant Systems

Fernando M. Gómez-Castro and Ursula Eicker

University of Applied Sciences Stuttgart/Centre of Applied Research Sustainable Energy Technologies zafh.net, Stuttgart (Germany)

Abstract

One of the key components of a solar liquid desiccant system is the regenerator, in which the diluted solution from the absorber is reconcentrated for its reuse in the air dehumidification task. Among the different types of regeneration units stands out the solar collector/regenerator (C/R), in which the liquid sorbent is exposed simultaneously to the solar radiation and the air stream, thus enhancing the regeneration process. In order to assess its thermal performance, an experimental study of a single-glazed forced convective C/R has been carried out using calcium chloride solution. The results of the conducted tests show that the water desorption rate increases strongly with the rise of the solar radiation and the inlet solution temperature as well as with the diminution of the gap height and the tilt angle. For the analysed measuring range, the water desorption rate firstly increases and then reaches a stable value by augmenting the air volumetric flow rate. Finally, the regeneration performance diminishes by increasing the solution volumetric flow rate.

Keywords: Liquid desiccant, solar collector/regenerator, experimental performance.

1. Introduction

The imperative need to mitigate the global environmental problems of greenhouse effect and ozone layer depletion, as well as the electrical energy consumption associated with the widespread use of vapour compression machines in air conditioning applications has recently contributed to renew the interest in direct solar thermally-driven liquid sorption systems, in which the diluted desiccant solution is reconcentrated by means of its simultaneous exposure to the solar radiation and the scavenging air stream into a single device named collector/regenerator (C/R). This equipment offers a great potential not only for simplifying and reducing the costs of liquid sorption systems via the elimination of the regeneration chamber, but also for improving the thermal regeneration efficiency through the further heating of the liquid sorbent.

When integrated to liquid desiccant systems, the solar collector/regenerator plays a key role since for every kilogram of water vapour absorbed by the concentrated solution in the dehumidifier, the same amount should be desorbed from the diluted one in the C/R (Collier, 1979), giving a direct measure of the system performance (Hawlader et al., 1992; Yang and Wang, 1995).

The solar collector/regenerators can be classified as open-type, closed-type and convective-type. Several theoretical works (Yang and Wang, 2001; Kaushik et al., 1992) and experimental studies (Gezahegn et al., 2013; Kabeel, 2005; Hawlader et al., 1997) carried out under different operating conditions have demonstrated that the convective C/R performs generally better than the other types in both humid and temperate climates, since its glazing limits the thermal losses to the ambient and also keeps the desiccant solution free from contamination due to dirt and rains. Furthermore, depending on the use of blowers, the convective collector/regenerators can operate in natural and forced ventilation modes.

Experimental studies on the performance of both counterflow forced and natural convective solar C/Rs operated under the hot humid climate of Kaohsiung, Taiwan, were realised by Yang and Wang (1994) by using aqueous LiCl solution as liquid desiccant Their findings indicated that, the water desorption rate of the forced convective C/R rose more significantly with increasing ambient temperature than for the natural convective one. Additionally, the forced convective C/R performed much better than the natural convective one for low inlet solution mass fractions from 40.90 to 42.50%. When the inlet mass fraction became higher than 42.50%, forced

doi:10.18086/swc.2017.28.08 Available at http://proceedings.ises.org

convection was unnecessary. It was also observed that the evaporation rate decreased with the glazing height for the forced convective C/R, while the natural convective C/R had an optimum glazing height.

Kabeel (2005) tested a cross flow forced convective collector/regenerator and a natural convective solar regenerator with aqueous $CaCl_2$ solution as liquid sorbent. It was observed that the desorption rate and the regeneration efficiency of both C/Rs rose strongly with enhancing the air mass flow rate. However, for higher air mass flow rates, said performance indices diminished again due to the fall of the solution temperature. Furthermore, the evaporation rate and the regeneration efficiency fell with rising the inlet solution mass fraction, operating the forced cross flow regenerator better than the natural one for medium solution mass fractions. Nevertheless, the performance difference between both C/Rs was small at higher mass fractions.

Despite the studies carried out by the aforementioned authors, the relevant experimental data of convective collector/regenerators are still very scarce. This work provides some light on this issue by experimentally investigating the effect of operating parameters such as the solar radiation, the inlet solution temperature and the volumetric flow rates of air and solution as well as geometric parameters such as the gap height and the tilt angle on the performance of a single-glazed forced convective C/R.

2. System description

In order to investigate the influence of both climatic and operating conditions on the performance of a forced convective collector/regenerator, a test bench comprising a collector/regenerator, fans, solution tanks, pumps, flow regulator/indicator, PID controller, and data acquisition devices was designed and constructed in the sorption laboratory at the University of Applied Sciences Stuttgart (see Fig. 1).

The collector/regenerator is made of polycarbonate and has a total area of 0.65 m² (0.5 m width × 1.3 m length), a gap height of 0.04 m or 0.1 m and a sprinkling area of 0.5 m² (0.5 m width × 1.0 m length). Its inclination angle can be variably set. The stainless steel absorber plate is painted with a special black nanocoating lacquer and is covered with a black cotton cloth for ensuring uniform wetting and absorption of the solar radiation. The C/R can be operated in both counterflow and parallel flow modes. The forced air is supplied by an axial fan with continuous flow control in the range of 2.5 to 25 m^3/h. A solution pump delivers the desiccant solution to the liquid distributor header at flow rates between 2.5 and 15 l/h. The temperature of the liquid sorbent is controlled before entering the C/R by the combination of an ARCTIC cold bath/circulation thermostat HAAKE AC 150-A10 and a plastic heat exchanger B3-12A-30-2.0. The volumetric flow rates, temperatures, relative humidities and the densities of the fluids involved in the regeneration process are measured both at the inlet and outlet of the collector/regenerator by means of the sensors summarised in Tab. 1. Data are taken at 5 seconds interval after the initial wetting and stabilising.

3. System performance measures

The performance of the collector/regenerator is evaluated on the basis of the water desorption capacity and the water desorption rate. The water desorption capacity ($\Delta\chi_{des}$) in [kg/kg] is defined as the amount of moisture added to an air stream during the regeneration process:

$$\Delta\chi_{des}=\chi_{a,out}-\chi_{a,in} \quad \text{(eq. 1)}$$

On the other hand, the water desorption rate ($\Delta\dot{m}_{des}$) indicates the change of the amount of water vapour transferred to the air stream $\dot{m}_a$, and therefore evaporated from the hygroscopic solution per unit time:

$$\Delta\dot{m}_{des}=\dot{m}_a\cdot(\chi_{a,out}-\chi_{a,in}) \quad \text{(eq. 2)}$$

Where $\chi_{a,in}$ and $\chi_{a,out}$ are the absolute humidities of the air at the inlet and outlet of a sorption unit, respectively.

The fluids involved in the regeneration process are characterised through the changes of their temperature ($\Delta T_{a/s}$) and mass fraction ($\Delta\xi_s$):

$$\Delta T_{a/s}=T_{a/s,out}-T_{a/s,in} \quad \text{(eq. 3)}$$

$$\Delta\xi_s=\xi_{s,out}-\xi_{s,in} \quad \text{(eq. 4)}$$

The mass and energy balance between air and desiccant solution are analysed through the dimensionless quantities κ_{mass} and κ_{energy}, which are given by (Jaradat et al., 2011):

$$\kappa_{mass}=\frac{\dot{m}_a\cdot\Delta\chi_{des}}{\dot{m}_s\cdot\Delta\zeta_s} \quad \text{(eq. 5)}$$

$$\kappa_{energy}=\frac{\dot{Q}_a+\dot{Q}_s}{\dot{Q}_{solar}} \quad \text{(eq. 6)}$$

Where ζ_s is the water content in the desiccant solution given as function of the solution mass fraction ξ_s by eq. 6.

$$\zeta_s=\frac{1-\xi_s}{\xi_s} \quad \text{(eq. 7)}$$

4. Experimental results and discussion

To analyse the performance potential of the collector/regenerator several measurement series were carried out

under different boundary conditions for the aqueous calcium chloride ($CaCl_2$) solution at natural sunlight. The volumetric flows of the regenerating air and the hygroscopic solution were varied between 2.5 m^3/h and 25.0 m^3/h and 2.5 l/h to 15.0 l/h, respectively.

4.1 Effect of the solar radiation on the C/R performance

Fig. 2 shows that the desorption rate, the desorption capacity, the temperature differences of air stream and $CaCl_2$ solution between inlet and outlet as well as the mass fraction difference of liquid sorbent between inlet and outlet increased strongly as the solar radiation rose at the boundary conditions summarised in Tab. 2, since the absorbed solar radiation is the energy source for water evaporation from the diluted solution. Furthermore, it can be observed from Fig. 2(d) that the values of κ_{mass} for test sequences at solution volumetric flow rates of 5.24 l/h and 9.77 l/h were very close to the unity, while the values of κ_{energy} exhibited an average relative deviation of 43.8%, which reflected the heat losses mechanisms such as the radiative heat transfer between the absorber plate and the collector glazing as well as the convective and radiative thermal losses to the environment.

2	7.56	29.08	8.72	10.07	24.45	37.89

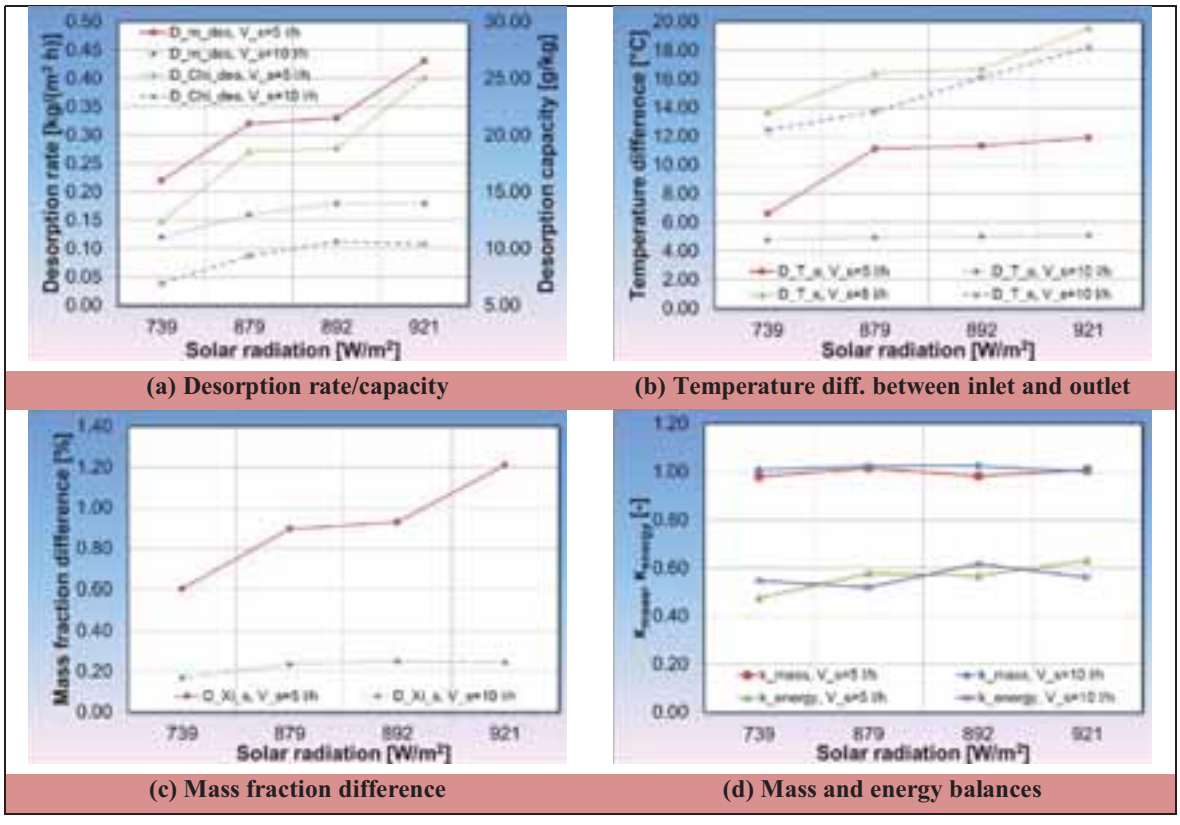

Fig. 2: Experimental results for the collector/regenerator with different solar radiation levels.

4.2 Effect of the inlet solution temperature on the C/R performance

From Fig. 3(a), it is clearly shown that both the desorption rate and the desorption capacity averagely increased by 56% as the inlet desiccant temperature rose from 25.1 °C to 37.3 °C at the boundary conditions summarised in Tab. 3. This was a consequence of the higher solution vapour pressure and the associated greater driving force for the mass transfer between the liquid sorbent and the regenerating air. According to Fig. 3(b), the

temperature difference of the regenerating air averagely augmented from 7.2 °C at an inlet solution temperature of 25.1 °C to 12.3 °C at an inlet solution temperature of 37.3 °C. Moreover, the temperature difference of the liquid sorbent fell from a high value of 12.5 °C to a low one of 5.8 °C at an inlet solution temperature of 37.3 °C due to the heat transfer from the desiccant film to the adjacent air stream. Conversely, the temperature difference of the hygroscopic liquid followed an upward trend at an inlet solution temperature of 25.1 °C because of the progressive solar heating of the liquid film. On the other hand, the mass fraction difference of desiccant solution between inlet and outlet averagely rose by 54% as the inlet solution temperature enhanced from 25.1 °C to 37.3 °C (see Fig. 3(c)). Finally, the values of κ_{mass} for test sequences 3 and 4 were very close to the unity, whereas the values of κ_{energy} for same tests exhibited average relative deviations of 39.1% and 55,6%, respectively (see Fig. 3(d)), which could be result not only of the heat losses from the collector/regenerator but also of sensors' accuracy and measurement errors.

4.3 Effects of the fluid volumetric flow rates on the C/R performance

For the operating conditions analysed in experimental runs (see Tab. 4), the desorption rate obtained with the solar collector/regenerator firstly augmented with increasing the air volumetric flow rate, until it stabilised at a certain value as shown in Fig. 4(a). This net effect resulted from the combination of two facts:

- Increase of the mass transfer coefficient between the desiccant solution film and the regenerating air by enhancing the air volumetric flow rate.

- Further decrease of the solution temperature and consequently, of the solution vapour pressure and the driving force of mass transfer within the C/R by rising the air volumetric flow rate.

At a solution volumetric flow rate of 7.5 l/h, doubling the air volumetric flow rate from 5.0 m^3/h to 10 m^3/h increased the desorption rate by about 11% from 0.26 kg/(m^2 h) to 0.29 kg/(m^2 h). Said enhancement slightly rose by increasing the solution volumetric flow rate.

Conversely, as shown in Fig. 4(b), the desorption capacity decreased with augmenting the air volumetric flow rate due to the reduction in the temperature increase of the air stream in the collector/regenerator, which led to a lower vapour pressure difference between the desiccant solution and the air. At a solution volumetric flow rate of 7.5 l/h, doubling the air volumetric flow rate from 5.0 m^3/h to 10 m^3/h decreased the desorption capacity by about 43% from 21.65 g/kg to 12.26 g/kg.

Tab. 4: Boundary conditions for the experiments with fluctuating fluid volumetric flow rates (gap height = 4 cm, tilt angle = 30°).

Test seq.	Solar radiation [W/m^2]	Air volumetric flow [m^3/h]	Air temperature [°C]	Air absolute humidity [g/kg]	Solution volumetric flow rate [l/h]	Solution temperature [°C]	Solution mass fraction [%]
5	873-918	4.96- 25.08	28.57-30.03	9.52-10.40	2.47	24.93-25.87	37.70-38.18
6	870- 920	4.96-24.97	25.79-28.66	8.76- 9.80	4.98	24.61-25.80	37.49-38.16
7	886-928	2.52-25.03	26.03-32.40	9.43-9.93	7.44	24.53-25.47	37.42-38.25
8	875-922	2.61-24.95	25.45-31.37	8.64-9.44	10.03	24.59-25.22	37.42-38.12
9	872-904	2.41-24.99	24.70-28.88	8.93-9.85	15.01	24.78-25.23	37.30-38.00

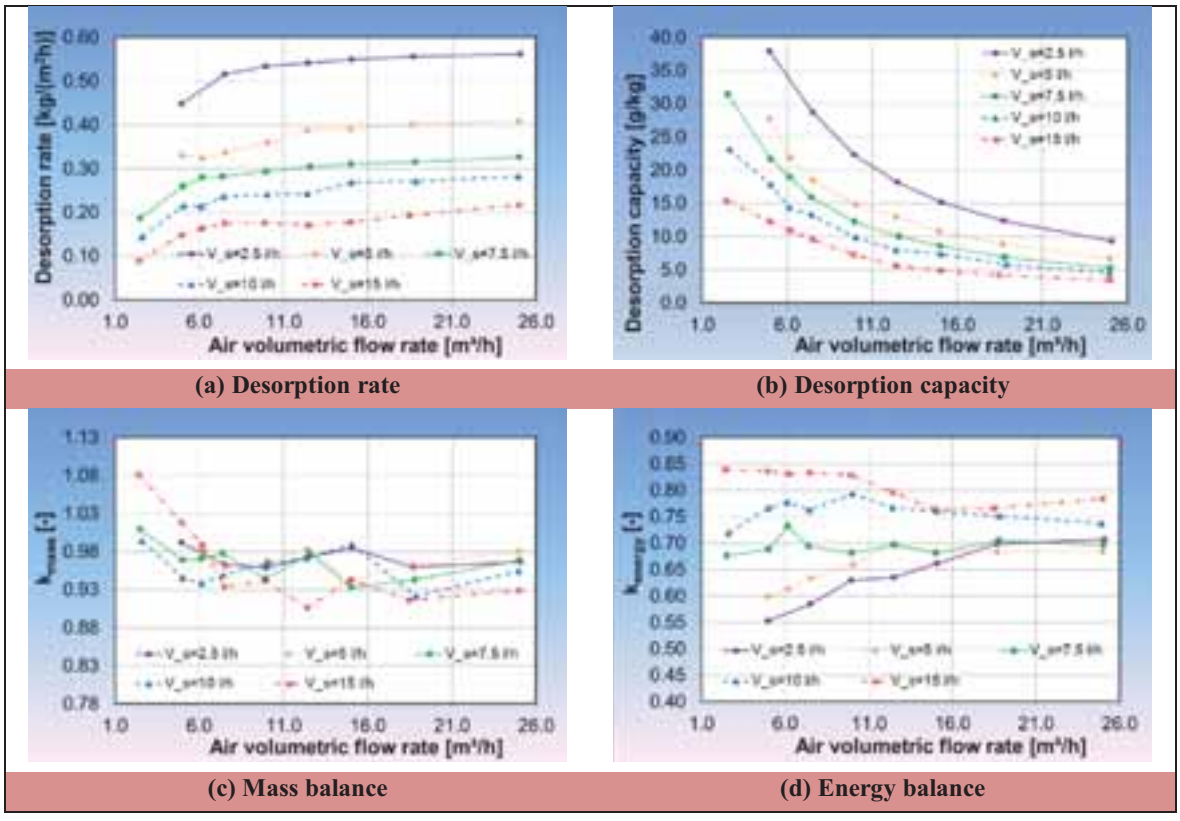

Fig. 4: Experimental results for the collector/regenerator at different fluid volumetric flow rates.

On the other hand, the desorption rate and the desorption capacity decreased with augmenting the solution volumetric flow rate as shown in Fig. 4(a) and Fig. 4(b). The higher the solution volumetric flow rate, the shorter the residence time of the liquid sorbent within the collector/regenerator. Consequently, the hygroscopic solution was heated little, thus reducing the vapour pressure difference between the solution film and the air. At

an air volumetric flow rate of 15.0 m^3/h, doubling the solution volumetric flow rate from 5.0 l/h to 10.0 l/h reduced both the desorption rate and the desorption capacity by about 31% from 0.39 kg/(m^2 h) to 0.27 kg/(m^2 h) and from 10.79 g/kg to 7.39 g/kg, respectively. These reductions slightly increased by enhancing the air volumetric flow rate. Finally, according to Fig. 4(c) and Fig. 4(d), the values of κ_{mass} were very close to the unity, whereas the values of κ_{energy} were deviated from the unity, especially at lower solution volumetric flow rates. These deviations reflected both the heat losses mechanisms from the collector/regenerator and problems related to sensors' accuracy and measurement errors.

4.4 Effects of the gap height on the C/R performance

At a constant air volumetric flow rate, the reduction of the gap height led to an average increase in the flow velocity of the regenerating air within the collector channel. The higher the air volumetric flow rate, the greater the enhancements in the air flow velocity and in the Reynolds number. As a result, the heat and mass transfer coefficients between the desiccant solution and the regenerating air also augmented. According to the operating conditions summarised in Tab. 4 and Tab. 5 for a solution volumetric flow rate of 7.5 l/h, the desorption rate and the desorption capacity averagely increased by about 5% by reducing the gap height from 10 cm to 4 cm (see Fig. 5). Greater increases in the regeneration performance were achieved at low air volumetric flow rates.

Tab. 5: Boundary conditions for the experiments with fluctuating fluid volumetric flow rates (gap height = 10 cm, tilt angle = 30°).

Test seq.	Solar radiation [W/m^2]	Air volumetric flow [m^3/h]	Air temperature [°C]	Air absolute humidity [g/kg]	Solution volumetric flow rate [l/h]	Solution temperature [°C]	Solution mass fraction [%]
10	863-909	5.09-25.20	30.06-35.03	9.09-11.08	2.41	24.58-26.48	37.54-38.13

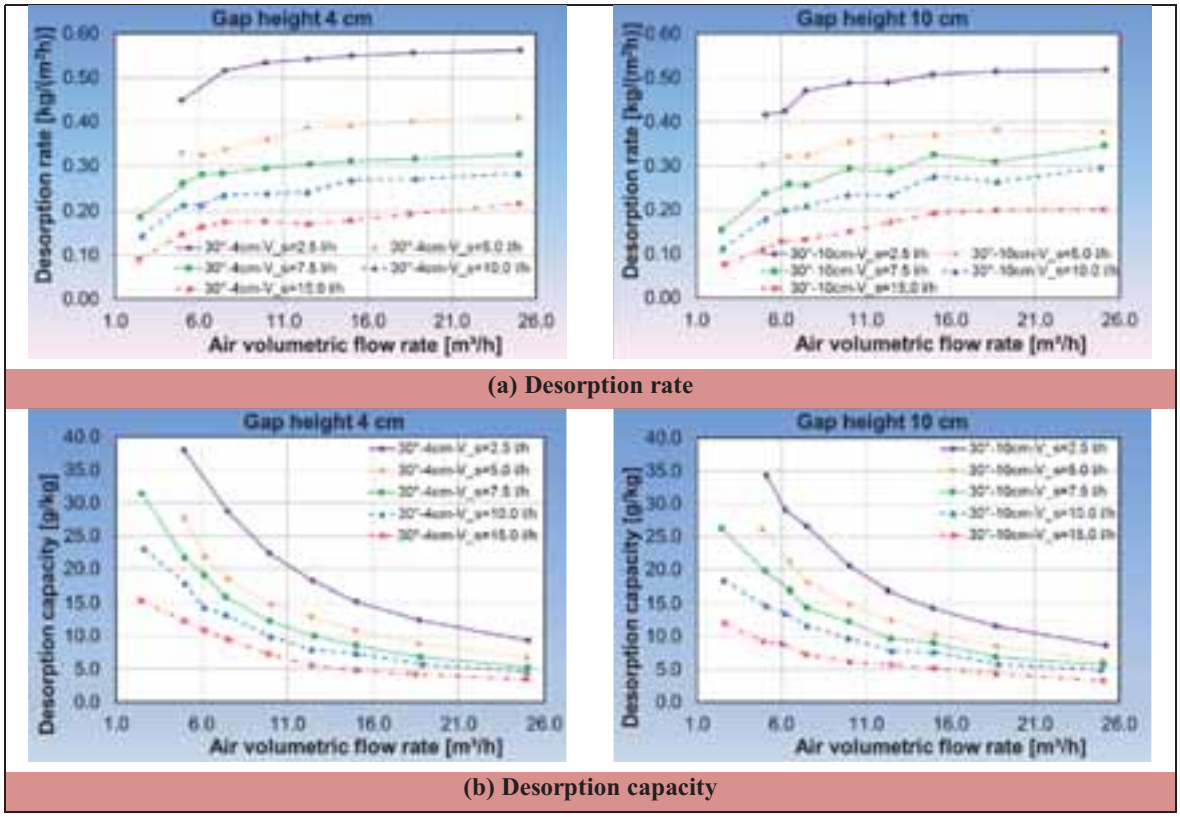

Fig. 5: Experimental results for the collector/regenerator at different fluid volumetric flow rates and gap heights.

4.5 Effects of the tilt angle on the C/R performance

From Fig. 6, the regeneration performance could be increased by reducing the inclination angle of the collector/regenerator from 30° to 15° due to the longer residence time of the desiccant solution on the absorber surface. Consequently, the liquid sorbent was quickly heated. According to the operating conditions summarised in Tab. 5 and Tab. 6 for a solution volumetric flow rate of 7.5 l/h, both the desorption rate and the desorption capacity averagely augmented by about 6% by decreasing the tilt angle from 30° to 15°.

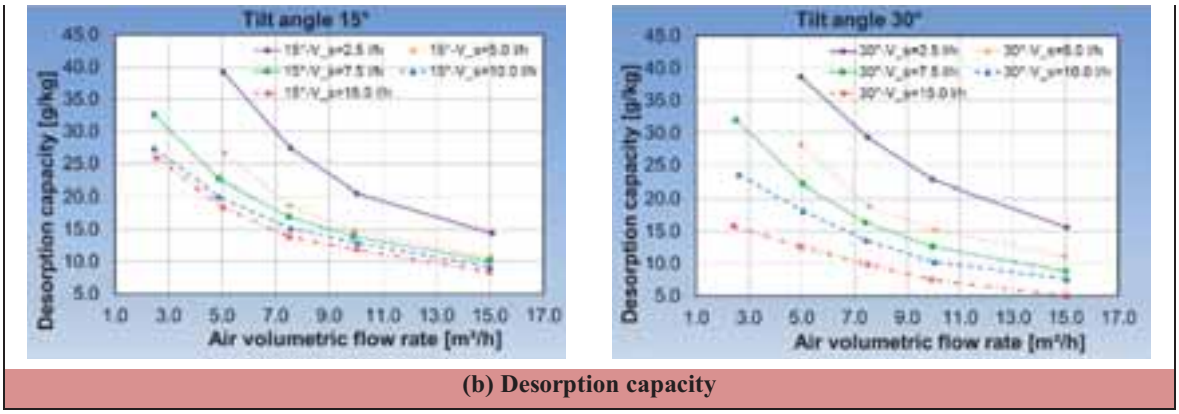

Fig. 6: Experimental results for the collector/regenerator at different fluid volumetric flow rates and tilt angles.

5. Conclusions

A single-glazed forced convective collector/regenerator was experimentally tested at the climatic conditions of Stuttgart. The experimental tests results indicated that the volumetric flow rates of the air and the desiccant solution as well as the gap height and the tilt angle of the collector played an important role in the assessment of the regeneration performance. Further studies will be carried out in order to optimise the construction of the C/R for specific requirements of air conditioning applications.

Theoretical Analysis of Indirect and Direct Solar Regenerators for Liquid Desiccant Systems

Fernando M. Gómez-Castro and Ursula Eicker

University of Applied Sciences Stuttgart/Centre of Applied Research Sustainable Energy Technologies zafh.net, Stuttgart (Germany)

Abstract

Solar liquid desiccant air-conditioning systems have recently attracted attention due to their sustainability and good energy saving potential, since only heat is required in the solution regeneration process. The solar regenerators can be classified as indirect and direct regeneration units. In the first type, the solar heat can be transferred either to the air stream via solar air collectors or a combination of solar water collectors and water-to-air heat exchangers or to the liquid desiccant via a combination of solar water collectors and water-to-solution heat exchangers before entering the regeneration chamber. In the second type, the diluted solution is exposed simultaneously to the solar radiation and the air stream within a solar collector/regenerator. A performance comparison between both types of regeneration units is presented in this paper. The simulation results demonstrate that direct solar regenerators have a high potential for enhancing the water desorption rate from a diluted solution and, consequently, the air dehumidification capacity within the absorber.

Keywords: Liquid desiccant, indirect solar regenerator, solar collector/regenerator, performance comparison.

1. Introduction

Air conditioning in buildings is a large and growing market, almost exclusively covered with electrical compression systems. Therefore, in order to supply this market with sustainable technologies, cost-effective solar thermally-driven liquid sorption systems, which rely on the capacity of hygroscopic solutions in removing the air moisture content by the absorption process (Grossman and Johannsen, 1981) and on the solar heat for regenerating the solution in a temperature range of 40 to 70 °C (Katejanekarn and Kumar, 2008), need to be developed.

Indirect solar regenerated systems comprise the main components absorber, in which the moisture of the inlet process air is removed by bringing it into contact with sprinkled desiccant solution, and regenerator, in which the water content of the solution gradually diluted within the absorber is reduced by enhancing both its temperature and vapour pressure, and by subsequently removing the evaporated water through an air stream. Among the direct contact sorption chambers commonly used as heat and mass exchangers in both the air dehumidification and solution regeneration processes stand out the packed bed towers, which are filled with random or structured packing materials that increase the mass transfer area per unit volume as well as the contact time between the fluids involved in the sorption process, leading to more compact units (Martin and Goswami, 2000). Nevertheless, they require high enough solution mass flow rates for a proper wetting of the packing material as well as high fan energy consumption due to high air pressure drops. The heat required for the regeneration process can be supplied by either air-led (Kabeel et al., 2017) or water-based solar collectors (Jamar et al., 2016) and, more recently, by photovoltaic/thermal (PV/T) modules (Guo et al. 2017), which provide both heat for reconcentrating the liquid desiccant and electricity for powering the parasitic components (fans and pumps). The resulting strong solution is then stored without thermal losses for carrying out the air dehumidification process when solar radiation is not available. The dehumidified process air, heated by exothermic reactions during the moisture absorption in the desiccant solution, is generally precooled by the outdoor air or the return air from the room and moistened adiabatically in the next step to produce the desired cooling effect for air conditioning applications. However, some barriers like the high costs of manufacture and installation of the equipment, high system complexity due to the large number of individual components and the need of highly sophisticated control systems drastically limit the market entrance of indirect solar regenerated

doi:10.18086/swc.2017.28.09 Available at http://proceedings.ises.org

liquid desiccant systems (Gommed and Grossman, 2007).

The needed system simplification and its associated cost reduction can be accomplished by transferring the regeneration process into the solar collector. In this way, and contrary to the indirect solar regenerator, the hygroscopic solution is exposed simultaneously to the solar radiation and the air stream, which contributes to enhance the thermal regeneration efficiency. The direct solar regenerators can be classified as open-type, closed-type and convective-type. Several theoretical works (Yang and Wang, 2001; Kaushik et al., 1992) and experimental studies (Gezahegn et al., 2013; Kabeel, 2005; Hawlader et al., 1997) carried out under different operating conditions have demonstrated that the glazed forced convective collector/regenerator performs generally better than the other types in both humid and temperate climates, since its glazing limits the thermal losses to the ambient and also keeps the desiccant solution free from contamination due to dirt and rains.

However, there is a lack of works in the literature on the performance comparison between the indirect solar regeneration chambers and the solar collector/regenerators. This paper provides some light on this issue by comparing the performance curves obtained for both types of solar regenerators at specified operating conditions from calculation models developed in the equation-oriented simulation environment EES and by outlining under what conditions the direct solar regenerator outperforms the indirect ones.

2. System description

Three indirect solar regeneration units, which essentially comprise an adiabatic packed bed sorption reactor, an array of solar water/air heaters as well as heat exchangers, and a forced convective direct solar regenerator were theoretically analysed in this study. These configurations are depicted in Fig. 1 and described as follows:

- **Variant SWH+WA-HX+Reg (solar water heater + water-air heat exchanger for preheating of the regenerating air):** A 16 m² south-oriented collector field of solar water heaters (Topson TX) with 40% aqueous propylene glycol solution as working fluid and a tilt angle of 30° is connected with a finned coil water-air heat exchanger (WA-HX, Brazetek BT-HTL 12×12), in which the regenerating air stream is warmed-up before entering a counterflow adiabatic regeneration chamber (see Fig. 1(a)), whose packed bed (400 mm width × 400 mm length × 400 mm height) is filled with ceramic Novalox® saddles (volumetric mass transfer area = 255 m²/m³, void fraction = 0.74).
- **Variant SAH+Reg:** A similar field of compact solar air heaters (SAH TwinSolar) is directly coupled to the aforementioned packed bed regenerator as shown in Fig. 1(b).
- **Variant SWH+WS-HX+Reg:** The finned coil water-air heat exchanger of the variant SWH+WA-HX+Reg is replaced by a water-solution parallel plates heat exchanger (WS-HX, Kaori K095) for heating up the liquid sorbent before its entrance to the sorption reactor (see Fig. 1(c)).
- **Variant SWH+WS-HX+WA-HX+Reg:** A finned coil water-air heat exchanger and a water-solution parallel plates heat exchanger, identical to those of the variants SWH+WA-HX+Reg and SWH+WS-HX+Reg respectively, are connected in parallel with the solar water heaters field for simultaneously preheating the regenerating air and the desiccant solution (see Fig. 1(d)).
- **Variant SCR:** The diluted hygroscopic liquid and the regenerating air stream are simultaneously, directly heated through a field of counterflow, single-glazed solar collector/regenerators for reconcentrating the desiccant solution (see Fig. 1(e)).

Based on the energy conservation laws, thermodynamic equilibrium, as well as the heat and mass transfer laws for each system component, all these regenerator variants were modelled in the equation-oriented simulation environment EES to assess the water desorption rate ($\Delta \dot{m}_{des}$) for the specified operating conditions, which indicates the change of the amount of water vapour transferred to the air stream $\dot{m}_a$ and, therefore, evaporated from the hygroscopic solution per unit time:

$$\Delta \dot{m}_{des} = \dot{m}_a \cdot (\chi_{a,out} - \chi_{a,in}) \quad \text{(eq. 1)}$$

Where $\chi_{a,in}$ and $\chi_{a,out}$ are the absolute humidities of the air at the inlet and outlet of a sorption unit, respectively.

3. Mathematical modeling of the system components

3.1 Indirect solar regenerators

The efficiency of the sola collector η_c is given in terms of the average bulk temperature of the heat transfer medium $T_{f,m}$ and the ambient temperature T_{amb} by:

$$\eta_c=\eta_0-U_{L,1}\cdot\left[\left(T_{f,m}-T_{amb}\right)/G_{g,c}\right]-U_{L,2}\cdot G_{g,c}\cdot\left[\left(T_{f,m}-T_{amb}\right)/G_{g,c}\right]^2 \quad \text{(eq. 2)}$$

Where η_0, $U_{L,1}$, and $U_{L,2}$ are the collector optical efficiency, the linear heat loss coefficient and the quadratic heat loss coefficient for the solar collectors. For the collectors employed in this simulation, these coefficients are summarized in Tab. 1.

Tab. 1: Model parameters for the analysed air- and water-based solar collectors.

Parameter	TwinSolar compact	Topson TX
η_0 [-]	0.82	0.797
$U_{L,1}$ [W/(m² K)]	6.50	2.833
$U_{L,2}$ [W/(m² K²)]	0.032	0.0133

Fig. 2 shows a schematic diagram of the finite difference of a conventional counterflow regeneration unit with the heat and mass transfer interactions between the liquid desiccant and the regenerating air stream. By assuming negligible heat loss from or gain to the finite element, the 1D steady-state mass and energy balances can be written as follows:

Desiccant solution:

Mass balance

$$\dot{m}_{s,i}\cdot\xi_{s,i}=\dot{m}_{s,i-1}\cdot\xi_{s,i-1} \quad \text{(eq. 3)}$$

$$\dot{m}_{s,i}=\dot{m}_{s,i-1}-\Delta\dot{m}_{des,m,i} \quad \text{(eq. 4)}$$

Energy balance

$$\dot{m}_{s,i-1}\cdot h_{s,i-1}=\dot{m}_{s,i}\cdot h_{s,i}+h_{conv,s\text{-}a,m,i}\cdot A_{w,i}\cdot\left(T_{s,m,i}-T_{a,m,i}\right)+\Delta\dot{m}_{des,m,i}\cdot\left(h_{fg,i}+\Delta h_{d,i}\right) \quad \text{(eq. 5)}$$

Regenerating air:

Mass balance

$$\dot{m}_a\cdot\chi_{a,i-1}=\dot{m}_a\cdot\chi_{a,i}+\Delta\dot{m}_{des,m,i} \quad \text{(eq. 6)}$$

Energy balance

$$\dot{m}_a\cdot h_{a,i}+h_{conv,s\text{-}a,m,i}\cdot A_{w,i}\cdot\left(T_{s,m,i}-T_{a,m,i}\right)+\Delta\dot{m}_{des,m,i}\cdot\left(h_{fg,i}+\Delta h_{d,i}\right)=\dot{m}_a\cdot h_{a,i-1} \quad \text{(eq. 7)}$$

Where $\dot{m}$, h and T stand for the mass flow rate [kg/s], the specific enthalpy [J/kg] and the temperature [K] of the fluids involved in the regeneration process, while χ_a and ξ_s are the absolute humidity of the air [kg/kg] and the mass fraction of the hygroscopic liquid. The subscripts a and s stand for the air and the desiccant solution, whereas the subscripts i-1 and i denote the inlet/outlet and outlet/inlet characteristics of the solution/air. The symbols $h_{conv,s\text{-}a,m,i}$, $A_{w,i}$, $\Delta\dot{m}_{des,m,i}$, $h_{fg,i}$ and $\Delta h_{d,i}$ correspond to the local values of the convective heat transfer coefficient between the solution film and the air stream [W/(m² K)], the finite element area wetted by the

solution [m²], the water desorption rate [kg/s], the latent heat of water vaporisation [J/kg] and the differential enthalpy of dilution [J/kg], respectively.

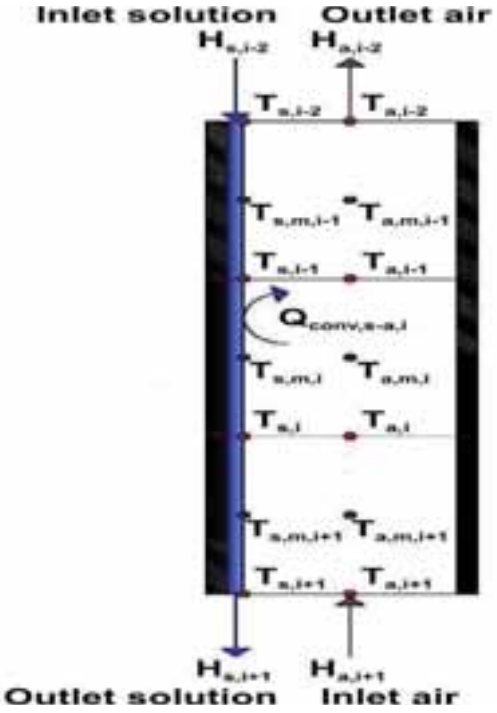

Fig. 2: Heat and mass transfer mechanisms in a finite element of the adiabatic counterflow packed bed regenerator.

On the other hand, the local water desorption rate $\Delta\dot{m}_{des,m,i}$ from the diluted liquid sorbent can be calculated as follows:

$$\Delta\dot{m}_{des,m,i}=\frac{\beta_{m,i}\cdot M_{H_2O}}{R_m\cdot T_{a,m,i}}\cdot A_{w,i}\cdot\left(p_{s,m,i}-p_{a,m,i}\right) \quad \text{(eq. 8)}$$

With M_{H_2O} and R_m as the molar mass of the water vapour (0.01802 kg/mol) and the molar gas constant (8.31451 J/(mol K)), and $p_{s,m,i}$ and $p_{a,m,i}$ as the vapour pressures [Pa] of the solution and the regenerating air at their average temperatures $T_{s,m,i}$ and $T_{a,m,i}$.

The local mass transfer coefficient based on the gas-phase concentration $\beta_{m,i}$ [m/s] is determined in terms of the heat transfer coefficient $h_{conv,s-a,m,i}$ by applying the Chilton-Colburn analogy:

$$\beta_{m,i}=\frac{h_{conv,s-a,m,i}}{\rho_{a,m,i}\cdot c_{p,a,m,i}\cdot Le_a^{2/3}} \quad \text{(eq. 9)}$$

Where $\rho_{a,m,i}$, $c_{p,a,m,i}$ and Le_a stand for the density [kg/m³], the isobaric specific heat capacity [J/(kg K)] of the regenerating air, and the Lewis number of the water vapour-air mixture. The local convective heat transfer coefficient between a fluid and the particles in the packed bed reactor is calculated according to the relationships given in the VDI Heat Atlas (Gnielinski, 2010).

3.2 Direct solar regenerators

The simultaneous heat and mass transfer mechanisms occurring within a single-glazed forced convective collector/regenerator are shown in Fig. 3. By neglecting the gradients of temperature and water content in both the air stream and the liquid film along the collector width, disregarding the heat conduction and mass diffusion

in both the air and the solution along their flow directions, and considering uniform wall temperature and concentration boundary conditions for the heat and mass transfer in the finite element, the following 1D steady-state mass and energy balances can be formulated for the counterflow case:

Collector housing;

Energy balance

$$U_{cond,p\text{-}h,m,i}\cdot\left(T_{p,m,i}-T_{h,m,i}\right)=h_{conv,h\text{-}amb,m,i}\cdot A_{c,i}\cdot\left(T_{h,m,i}-T_{amb}\right) \quad \text{(eq. 10)}$$
$$+h_{rad,h\text{-}sky,m,i}\cdot A_{c,i}\cdot\left(T_{h,m,i}-T_{sky}\right)$$
$$+h_{rad,h\text{-}gr,m,i}\cdot A_{c,i}\cdot\left(T_{h,m,i}-T_{gr}\right)$$

Absorber plate:

Energy balance

$$\left[\left(\tau_g\cdot\tau_s\cdot\alpha_p\right)_{eff}\cdot F_w+\left(\tau_g\cdot\alpha_p\right)_{eff}\cdot(1-F_w)\right]\cdot G_{g,c}\cdot A_{c,i}=U_{cond,p\text{-}h,m,i}\cdot A_{c,i}\cdot\left(T_{p,m,i}-T_{h,m,i}\right) \quad \text{(eq.11)}$$
$$+h_{conv,p\text{-}a,m,i}\cdot(1-F_w)\cdot A_{c,i}\cdot\left(T_{p,m,i}-T_{a,m,i}\right)$$
$$+h_{conv,p\text{-}s,m,i}\cdot F_w\cdot A_{c,i}\cdot\left(T_{p,m,i}-T_{s,m,i}\right)$$
$$+h_{rad,p\text{-}g,m,i}\cdot(1-F_w)\cdot A_{c,i}\cdot\left(T_{p,m,i}-T_{g,m,i}\right)$$

Desiccant solution:

Mass balance (see eq. 3 and eq. 4)

Energy balance

$$\dot{m}_{s,i-1}\cdot h_{s,i-1}+h_{conv,p\text{-}s,m.i}\cdot F_w\cdot A_{c,i}\cdot\left(T_{p,m,i}-T_{s,m,i}\right)=\dot{m}_{s,i}\cdot h_{s,i}+\Delta\dot{m}_{des,m,i}\cdot\left(h_{fg,i}+\Delta h_{d,i}\right) \quad \text{(eq.12)}$$
$$+h_{conv,s\text{-}a,m,i}\cdot F_w\cdot A_{c,i}\cdot\left(T_{s,m,i}-T_{a,m,i}\right)$$
$$+h_{rad,s\text{-}g,m,i}\cdot F_w\cdot A_{c,i}\cdot\left(T_{s,m.i}-T_{g,m,i}\right)$$

Regenerating air:

Mass balance (see eq. 6)

Energy balance

$$\dot{m}_a\cdot h_{a,i}+\Delta\dot{m}_{des,m,i}\cdot\left(h_{fg,i}+\Delta h_{d,i}\right)+h_{conv,s\text{-}a,m,i}\cdot F_w\cdot A_{c,i}\cdot\left(T_{s,m,i}-T_{a,m,i}\right) \quad \text{(eq.13)}$$
$$+h_{conv,p\text{-}a,m,i}\cdot(1-F_w)\cdot A_{c,i}\cdot\left(T_{p,m,i}-T_{a,m,i}\right)+h_{conv,g\text{-}a,m,i}\cdot A_{c,i}\cdot\left(T_{g,m,i}-T_{a,m,i}\right)=\dot{m}_a\cdot h_{a,i-1}$$

Glass cover:

Energy balance

$$\alpha_g\cdot G_{g,c}\cdot A_{c,i}+h_{rad,s\text{-}g,m,i}\cdot F_w\cdot A_{c,i}\cdot\left(T_{s,m,i}-T_{g,m,i}\right)+h_{rad,p\text{-}g,m,i}\cdot\left(1-F_w\right)\cdot A_{c,i}\cdot\left(T_{p,m,i}-T_{g,m,i}\right)= \quad \text{(eq.14)}$$
$$h_{conv,g\text{-}a,m,i}\cdot A_{c,i}\cdot\left(T_{g,m,i}-T_{a,m,i}\right)+U_{conv,g\text{-}amb,m.i}\cdot A_{c,i}\cdot\left(T_{g,m,i}-T_{amb}\right)$$
$$+U_{rad,g\text{-}sky,m,i}\cdot A_{c,i}\cdot\left(T_{g,m,i}-T_{sky}\right)+U_{rad,g\text{-}gr,m,i}\cdot A_{c,i}\cdot\left(T_{g,m,i}-T_{gr}\right)$$

With $\dot{m}$, h and T as the mass flow rate [kg/s], the specific enthalpy [J/kg] and the temperature [K] of the fluids involved in the regeneration process. The subscripts *h*, *p*, *s*, *a*, *g*, *amb*, *sky* and *gr* refer to the collector housing, the absorber plate, the hygroscopic solution, the regenerating air, the glass cover, the ambient, the sky and the ground, while the subscripts *i-1* and *i* indicate the inlet/outlet and outlet/inlet conditions of the solution/air. The symbols F_w, $A_{c,i}$, $\Delta\dot{m}_{des,m,i}$, $h_{fg,i}$ and $\Delta h_{d,i}$ correspondingly stand for the wetting factor, the total finite element

area [m²] as well as the local values of the water desorption rate [kg/s], the latent heat of water vaporisation [J/kg] and the differential enthalpy of dilution [J/kg]. The approaches to estimate the effective transmittance-absorptance products for the glass cover-absorber plate $\left(\tau_g \cdot \alpha_p\right)_{eff}$ and the glass cover-desiccant solution-absorber plate $\left(\tau_g \cdot \tau_s \cdot \alpha_p\right)_{eff}$ optical systems are given by Duffie and Beckman (2013). Finally, h_{conv}- U_{conv}, h_{rad} - U_{rad}, and U_{cond} denote the convective heat transfer coefficients, the radiative heat transfer coefficients, and the heat conductance value, respectively.

The air channel of a forced convective collector/regenerator is asymmetrically heated since its absorber plate is considerably warmer than its glass cover. For analysis purposes, the convective heat transfer coefficients between the absorber plate and the air stream ($h_{conv,p\text{-}a,m,i}$), the desiccant solution and the air stream ($h_{conv,s\text{-}a,m,i}$), and the glazing and the air stream ($h_{conv,g\text{-}a,m,i}$) are considered to be equal. In this way, the convective heat transfer coefficient $h_{conv,s\text{-}a,m,i}$ [W/(m² K)] is evaluated as follows:

$$h_{conv,s\text{-}a,m,i} = Nu_{s\text{-}a} \cdot k_{a,m,i} / D_h \qquad \text{(eq. 15)}$$

For laminar flow ($Re_{a,D_h} \leq 2300$), the Nusselt number $Nu_{s\text{-}a,lam}$ can be determined by means of the correlation of Mercer et al. (1967) for one-sided heated air channels at constant wall temperature:

$$Nu_{s\text{-}a,lam} = 4.86 + \frac{0.0606 \cdot \left(Re_{a,D_h} \cdot Pr_a \cdot D_h / L_c\right)^{1.2}}{1 + 0.0909 \cdot \left(Re_{a,D_h} \cdot Pr_a \cdot D_h / L_c\right)^{0.7} \cdot Pr_a^{0.17}} \qquad \text{(eq. 16)}$$

For turbulent flow ($Re_{a,D_h} \geq 3000$), in which the influences of the boundary conditions and the channel geometry are minor, the modified equation of Petukhov (Gnielinski, 1976) is used for assessing the Nusselt number $Nu_{s\text{-}a,turb}$:

$$Nu_{s\text{-}a,turb} = \left[\frac{(f/8) \cdot Re_{a,D_h} \cdot Pr_a}{1 + 12.7 \cdot \sqrt{f/8} \cdot \left(Pr_a^{2/3} - 1\right)}\right] \cdot \left[1 + \left(\frac{D_h}{L_c}\right)^{2/3}\right] \qquad \text{(eq. 17)}$$

$$f = \left\{0.78 \cdot Ln\left(Re_{a,D_h}\right) - 1.5\right\}^{-2}$$

With L_c and D_h as the channel length [m] and the hydraulic diameter [m].

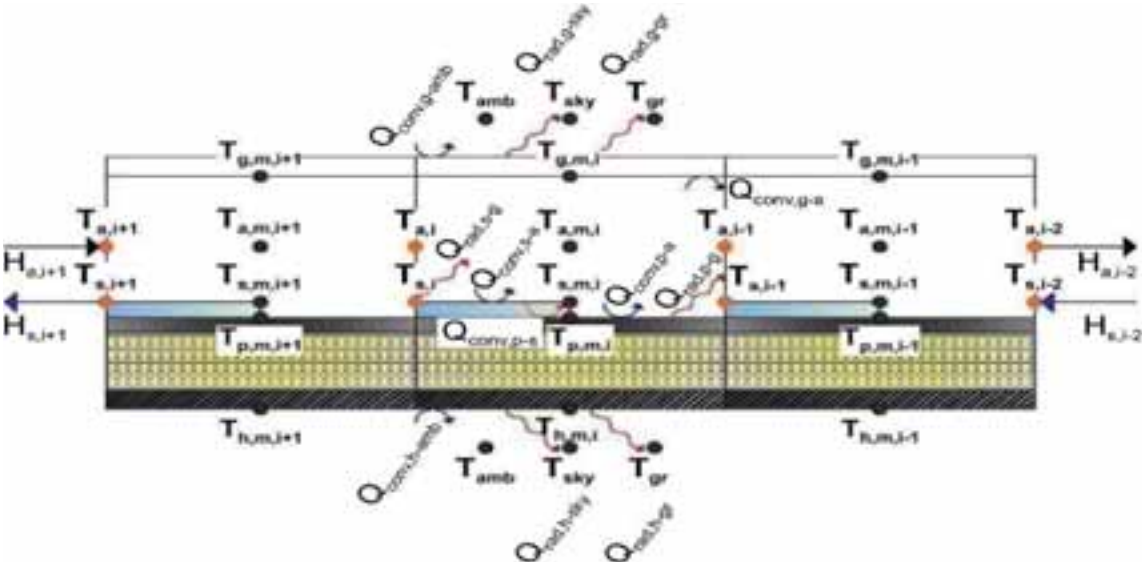

Fig. 3: Heat and mass transfer mechanisms in a finite element of the counterflow collector/regenerator.

4. Simulation results and discussion

This section presents the performance comparisons between the indirect and direct solar thermal regeneration units. Aqueous lithium chloride solution (LiCl-H_2O) was used as liquid desiccant. The parameters for this simulation study are summarised in Tab. 2.

Tab. 2: Parameters for the simulation of the analysed solar regeneration systems.

Component	Operating parameter	Unit	Range (reference value)	Variant

4.1 Effects of inlet air parameters on the regeneration performance

Fig. 4 shows that, for all configurations, the desorption rate increased with the rise of the inlet air temperature due to the enhancement in the driving force for the heat transfer between the regenerating air and the hygroscopic solution, which consequently augmented the temperature and the vapour pressure of the liquid sorbent. The desorption rate obtained from the direct solar regenerator (SCR) was in average 11% and 9% greater than those respectively achieved from the variants with indirect solar preheating of both air and liquid sorbent (SWH+WS-HX+WA-HX+Reg) and of only desiccant solution (SWH+WS-HX+Reg), which were the best indirect solar regeneration units at the analysed operating conditions. By contrast, the regenerators with air preheating via solar air heaters (SAH+Reg) and solar water heaters (SWH+WA-HX+Reg) exhibited the worst performances among the conventional regeneration units with average desorption rates 37 % and 49% lower than that from the direct solar regenerator.

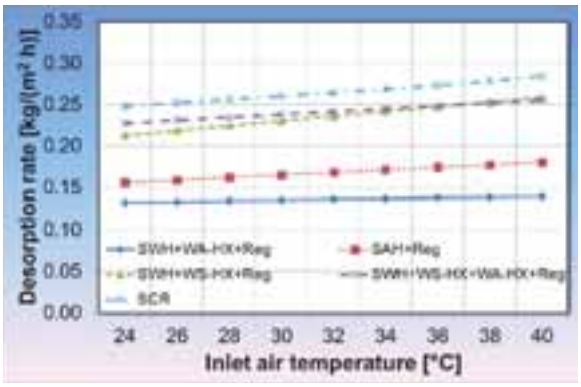

Fig. 4: Effect of the inlet air temperature on the desorption rate of the solar regenerators with indirect and direct (pre)heating of the regenerating air and the desiccant solution.

The desorption rate linearly decreased in all analysed solar regenerators with increasing absolute humidity of the air stream (see Fig. 5) due to the inherent rise in the air vapour pressure, which indeed diminished the vapour pressure difference between the desiccant solution and the air. This decrease was less severe in the direct solar regenerator than in the conventional regeneration units at the analysed operating conditions. The desorption rates achieved with the variants with simultaneous indirect solar preheating of the liquid sorbent and the air (SWH+WS-HX+WA-HX+Reg) and indirect solar preheating of the desiccant solution came next and were on average about 17% and 21% lower than those for direct solar regenerators, respectively. On the other hand, the regeneration systems with air preheating through solar air heaters (SAH+Reg) and solar water heaters (SWH+WA-HX+Reg) had the worst desorption rates, which were approximately 47% and 60% less than the respective value for collector/regenerators.

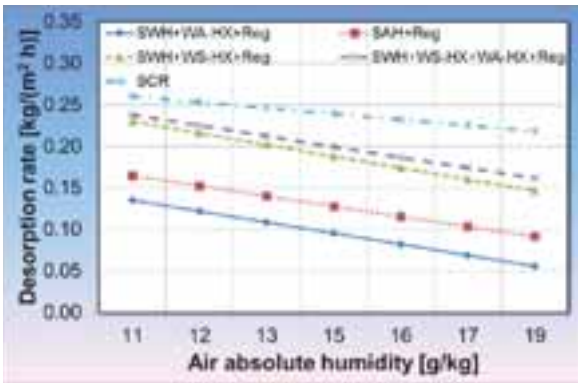

Fig. 5: Effect of the air absolute humidity on the desorption rate of the solar regenerators with indirect and direct (pre)heating of the regenerating air and the desiccant solution.

According to Fig. 6, the desorption rate for all configurations augmented at the analysed operating conditions by increasing the air volumetric flow rate due to the enhancement in the mass transfer coefficient, which counteracted the decrease in the solution temperature and its vapour pressure. From an air volumetric flow rate

of 300 m^3/h ($\dot{m}_a/\dot{m}_{s,in}=1.187$ with $\dot{V}_{s,in}=200\,l/h$), the direct solar regenerator exhibited considerably high values of said performance index compared with those of indirect solar regenerators because of the proximity to the turbulent regime of air flow within the collector/regenerator channel ($Re_{a,ch}=2374$). In average, the desorption rate achieved with the direct solar regenerator was 14% greater than those for the variants with indirect solar preheating of air and liquid desiccant (SWH+WS-HX+WA-HX+Reg and SWH+WS-HX+Reg). Moreover, the variants with indirect solar preheating of air by means of solar air heaters (SAH+Reg) and solar water heaters (SWH+WA-HX+Reg) were clearly outperformed with average desorption rates 44% and 53% lower than that of the direct solar regenerator.

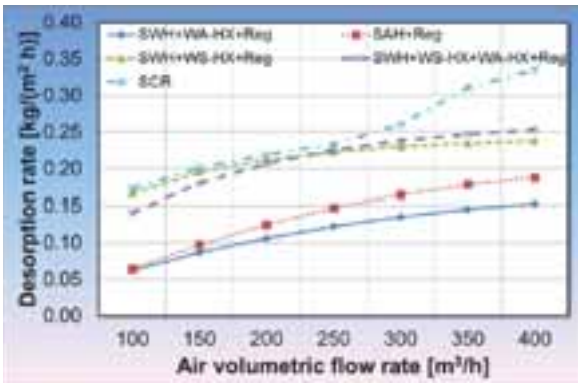

Fig. 6: Effect of the air volumetric flow rate on the desorption rate of the solar regenerators with indirect and direct (pre)heating of the regenerating air and the desiccant solution.

4.2 Effects of inlet solution parameters on the regeneration performance

When the desiccant solution entered the analysed regeneration units at high temperatures, the consequent increasing in the heat and mass transfer driven potentials led to higher desorption rates (see Fig. 7). Comparing with the effect of the inlet air temperature, it can be concluded that preheating the desiccant solution was more efficient than preheating the air stream. Although the average desorption rate attained with the direct solar regenerator was approximately 11%, 17%, 26% and 37% higher than those corresponding to the conventional regeneration units SWH+WS-HX+WA-HX+Reg, SWH+WS-HX+Reg, SAH+Reg and SWH+WA-HX+Reg, the performance differences among them were considerably reduced from an inlet solution temperature of 60°C.

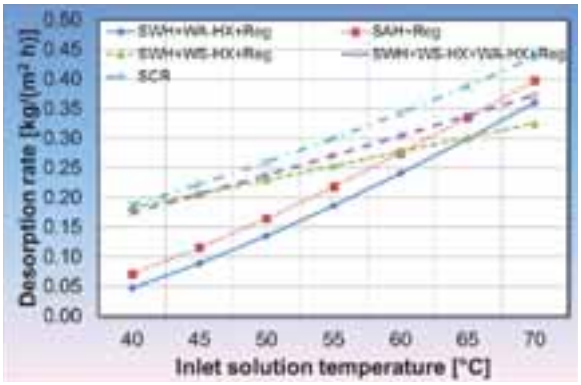

Fig. 7: Effect of the inlet solution temperature on the desorption rate of the solar regenerators with indirect and direct (pre)heating of the regenerating air and the desiccant solution.

Under the given operating conditions, the higher the solution mass fraction, the lower the desorption rate for all the analysed regeneration units due to the lower vapour pressure of the solution, which indeed reduced the mass transfer driven potential as shown in Fig. 8. The desorption rate achieved with the direct solar regenerator was 10% and 13% higher than the corresponding values for the variants with indirect solar preheating of both the air and desiccant solution (SWH+WS-HX+WA-HX+Reg) and of only liquid sorbent (SWH+WS-HX+Reg). Besides, the performance of the configurations with indirect solar preheating of air by using solar air heaters (SAH+Reg) and solar water heaters (SWH+WA-HX+Reg) were widely surpassed with average desorption rates 39% and 51% lower than that of the solar collector/regenerator.

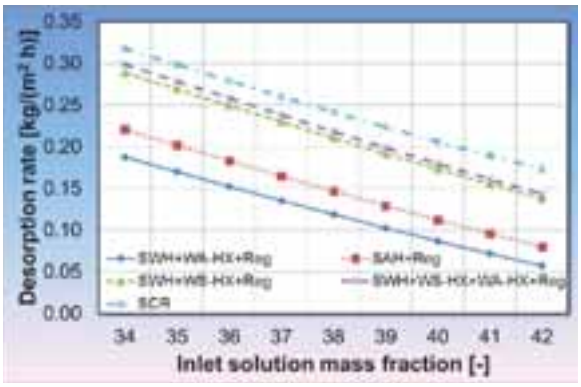

Fig. 8: Effect of the inlet solution mass fraction on the desorption rate of the solar regenerators with indirect and direct (pre)heating of the regenerating air and the desiccant solution.

For the analysed range of operating conditions, the increase of the solution volumetric flow rate affected in different ways the desorption rate for direct and indirect solar regenerators (see Fig. 9). In the case of the collector/regenerator, the desorption rate strongly decreased with the rise of the solution volumetric flow rate due to the reduced residence time of the liquid sorbent within said device, which contributed to diminish both the solar warming of the solution and the resulting mass transfer potential. On the other hand, the desorption rate obtained from the indirect solar regeneration units exhibited the inverse behaviour since the shortening of the residence time of solution within the sorption reactor led to the decrease of the temperature falls for both the air and the liquid sorbent, thus keeping the heat and mass transfer driven potentials relatively high. It was observed that the direct solar regenerator clearly outperformed the investigated indirect solar regeneration units until reaching a critical solution volumetric flow rate of approximately 225 l/h ($\dot{m}_a/\dot{m}_{s,in}=1.282$ with $\dot{V}_a=300\ m^3/h$). At higher flow rates, the performance of the collector/regenerator was clearly surpassed by that of the indirect solar regenerator with preheating of liquid desiccant (SWH+WS-HX+Reg).

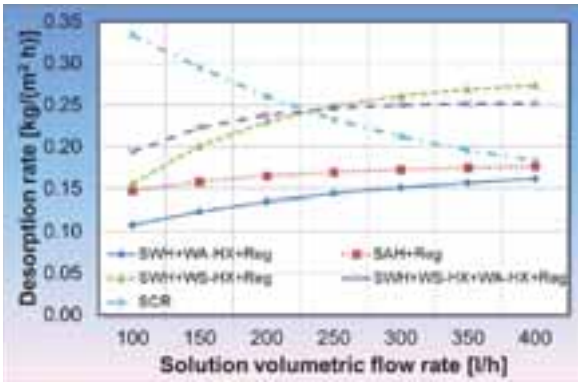

Fig. 9: Effect of the solution volumetric flow rate on the desorption rate of the solar regenerators with indirect and direct (pre)heating of the regenerating air and the desiccant solution.

5. Conclusions

The use of collector/regenerators contributes to reduce the installation costs and complexity of liquid desiccant systems by diminishing their number of components and by simplifying their control strategies. Moreover, the direct solar regenerator clearly outperforms the indirect ones at high absolute humidities, air volumetric flow rates higher than 300 m^3/h ($\dot{m}_a/\dot{m}_{s,in}$ = 1.187 with $\dot{V}_{s,in}=200\ l/h$), high inlet temperatures of air and solution as well as solution volumetric flow rates lower than 225 l/h ($\dot{m}_a/\dot{m}_{s,in}=1.282$ with $\dot{V}_a=300\ m^3/h$) while keeping constant the other operating parameters.

Establishment and Theoretical Analysis of a Solar Driven NH_3-H_2O Resorption Heat Pump Cycle

Teng Jia, Yanjun Dai*

Institute of Refrigeration and Cryogenics, Shanghai Jiao Tong University, Shanghai (China)

Abstract

To make full utilization of low-temperature solar thermal, a novel balanced-type absorption-resorption heat pump (ARHP) cycle with a simple construction is proposed in this paper. The novel cycle is based on concentration difference of strong solution, weak solution and ammonia vapor (in fact a very small amount of water vapor inside). In order to achieve the optimal operating conditions, a mathematical model is developed and the feasibility and performance are investigated when factors like high and low generation pressure and ambient air temperature vary. Performance of the novel cycle is compared with that of the conventional single-stage absorption heat pump (AHP) cycle. The novel cycle is proved to have a smaller operation pressure differential compared to the conventional AHP cycle and is more suitable for the temperature characteristics of commonly used solar collectors. Coefficient of performance (COP) value of 1.42 can be obtained when high pressure (P_H) and low pressure (P_L) are respectively 1.40 MPa and 0.41 MPa under given working conditions. COP increases with the increasing of solar thermal temperature and ambient air temperature.

Key words: Solar thermal, absorption-resorption heat pump, simulation, COP

Nomenclature	
COP	coefficient of performance
PV	photovoltaics
AHP	absorption heat pump
GAX	generator–absorber exchanger (GAX)
FPC	flat plate collectors
ETC	evacuated tube collectors
HPG	high pressure generator
LPG	low pressure generator
HPA	high pressure absorber
LPA	low pressure absorber
SHX	solution heat exchanger
FRV	flow regulating valve
TV	throttling valve
Subscripts	
hpg	high pressure generator
lpa	low pressure generator

1. Introduction

Heat pumps gain popularity by helping improve the quality of life by means of supplying heating in heating seasons and producing domestic hot water throughout the year. Improving their performance, reliability, and environmental impacts has been an ongoing concern (Chua et al. 2010). Conventional compression heat pumps are driven by electric power, and high-power compressors are often required to improve the performance (Fatouh and Elgendy 2011), which leads to many environmental problems. Solar energy is potential in driving heat pumps for different applications due to its cleanliness and accessibility (Fraga et al. 2015; Jradi et al. 2017; Zhou et al. 2016; Dai et al. 2015; Ozcan and Dincer 2013). Solar driven heat pumps can be divided into 3 kinds, i.e. heat pumps driven by thermal arrested by solar collectors, vapor compression heat pumps driven by solar photovoltaics (PV) and those combining solar thermal and vapor compression heat pumps. Among all the technical routes of solar driven heat pumps, the first kind has the highest solar thermal efficiency, which can theoretically convert 80% of the incident solar radiation energy into heating capacity. The combined heat pump systems use solar energy as the low-temperature heat source and are often combined with periodic heat storage devices to improve the cycle's COP by lifting the evaporation temperature (Omojaro and Breitkopf 2013). Electricity is still the basic power source for winter heating. Wu et al. (2014a, 2014b) reviewed recent absorption heating technologies and ammonia-based absorption heat pumps and pointed out that vapor compression and resorption heat pumps were suitable for wider temperature range than absorption ones. Van de Bor D. M. et al. (2014) numerically investigated many compression-resorption heat pumps with ammonia-water as working fluid for 50 specific industrial cases. The simulation results showed that the optimal performance, along with the lowest compression power and reduced investment and operating costs, is obtained under conditions which make the quality of vapor into the resorber be exact 100%. In practice, the vapor quality cannot reach 100% and compressors often work in the wet compression regime with a lower isentropic efficiency. Limited by cycle modes and high driven temperature, these products didn't utilize solar energy. Velázquez N. et al. (2002) presented a methodological analysis and energy evaluation of an air-cooled ammonia–water absorption heat pump with a generator–absorber heat exchanger (GAX) and operated by a hybrid natural gas–solar energy source. The heat pump allowed 19% of solar contribution at full load. A COP value of up to 1.86 was calculated by using ambient air up to 40°C with a relative humidity of 24% as cooling source. The system had a working pressure difference of up to 1.50 MPa and must be equipped with a rectifier. The required temperature of heat source is up to 150 °C, making function time of solar thermal relatively short, which together with the complex structure and high investment cost limited its application.

An absorption-resorption heat pump is formed when the evaporator and condenser in a conventional absorption heat pump are displaced by a low-pressure generator and a high-pressure absorber, respectively, and it completes the inner cycle relying on the concentration difference change of the binary mixtures. Although solar energy utilization is plagued by its intermittence and volatility, absorption-resorption heat pumps are still viable alternatives to supply winter heating in low-temperature environment when utilizing proper working fluid and high-temperature heat sources. Moreover, efficient and stable heating can be achieved by capacity regulating, energy complementary and working fluid storage, making solar driven absorption-resorption heat pump a research hotpot in the field of solar heating worldwide. Du et al. (1991, 1993) analyzed an unbalanced type of absorption -resorption heat pump with ammonia-water as working fluid. The simulation results showed that the system's highest working pressure is determined by the ammonia concentration in the cycle. The cycle appeared stronger adaptability to the environment by regulating ammonia concentration under varying operating conditions. The system was equipped with two solution pumps and the required temperature of generating is too high for efficient application of solar thermal.

This paper presents a novel balanced-type ammonia-water absorption-resorption heat pump which can be driven by solar thermal of lower temperature and of wider temperature range than the abovementioned GAX ones and the unbalanced types, which makes it possible to use flat plate collectors (FPC) and evacuated tube collectors (ETC).

As depicted in Fig. 1, in a conventional AHP cycle, concentration of solution out from condenser is 100%, while in a balanced ARHP cycle, outlet solution concentration of HPA is lower than 100%. Therefore, given the same temperature of solutions out from HPA and condenser, P_H of the novel cycle is lower than that of a conventional AHP cycle (ΔP_H), consequently resulting in a temperature decline of ΔT_h at the generator side, which makes it possible to utilize low-temperature heat source to drive ARHPs for space heating. Besides, given the same inner pressure difference in the two types of heat pumps, a pressure difference (ΔP_L) can also be achieved between evaporator and LPG. "Balanced" here means that there is overlap between the solution concentration range of the left and right sub-cycle Solution streams out from LPG and LPA are mixed together and then pumped to HPA and HPG to complete high-pressure absorption and generation process, respectively.

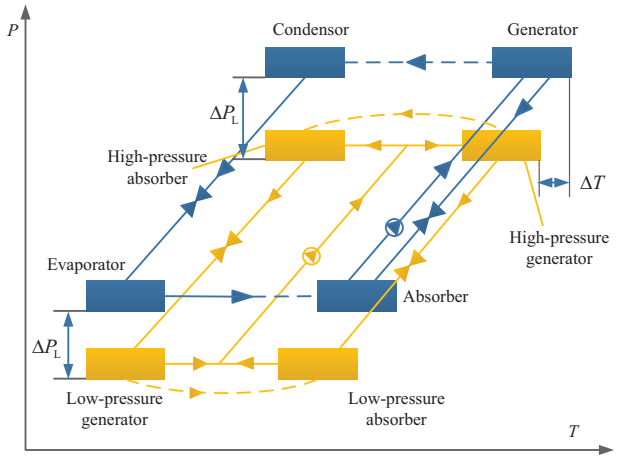

Fig. 1: Comparison of the conventional AHP cycle and the ARHP cycle proposed in this paper

2. Cycle description

The schematic diagram of the proposed balanced ARHP cycle is shown in Fig. 2. The pressure-temperature ($P-T$) diagram of the aqueous ammonia is shown in Fig. 3. The novel cycle comprises the following main components: HPG (high pressure generator), SHX1, 2 (solution heat exchanger 1, 2), TV1, 2 (throttling valve 2), LPA (low pressure absorber), solution mixing tank (SMT), P1 (solution pump1), solution separation tank (SST), HPA (high pressure absorber), LPG (low pressure generator). In order to clarify different heat absorption processes in low pressure generator, LPG is functionally divided into two parts, LPG1 which takes heat from the ambient and LPG2 which recovers heat from warm solution out from HPA. Ammonia/water is utilized as working pair in this work. The working principle is detailed as follows.

1-2-3-4-5-6-7-8-9-1 is a closed solution circuit. The weak solution out from HPG (1) is precooled by the solution out from SHX1 to state point (2) and then throttled in TV2 to low-pressure (P_L) (3). The solution (3) then absorbs the vapor (16) from LPG, releasing the absorption heat and becoming strong solution (4). The strong solution discharged from LPA (4) is then blended in the SMT with the solution (5) from LPG to make solution (6). The solution (6) is preheated in SHX2 by the hot solution from HPG to solution (7). The solution (7) is pressurized through P1 to high-pressure solution (8). Solution (9) (a portion of solution (8)) then enters HPG and heated by solar thermal to generate, making high-temperature and high-pressure vapor (17/18) and weak solution (1). The solution circuit of the right sub-cycle is finished.

15-6-7-8-9-10-11-12-13-14-5 is another solution circuit. The weak solution out from LPA (5) (which is stronger than the solution (1)) is blended in the solution mixing tank with the solution out from LPA (4) into the solution (6). The solution (6) is then preheated in SHX2 by the solution (1) out from HPA to (7). The solution (7) is pressurized through P1 to high-pressure solution (8). Solution (10) (the remaining portion of solution (8)) then enters LPA and absorb the vapor (18/17), giving off the resorption heat and forming strong solution (which is stronger than solution (4)). The strong solution out from HPA (11) is precooled by solution (14) in LPG2 to solution (12). The high-pressure solution (12) is then depressurized by TV1 to low-pressure solution (13). The low-temperature solution (13) then enters LPG and takes heat from the ambient to

generate, discharging low-temperature and low-pressure vapor in turn in LPG1 and LPG2 and making weak solution (5) (which is stronger than solution (1)). The solution circuit of the left sub-cycle is finished.

t should be pointed out that the amount of solution (4) and solution (9) are not the same due to the different amount of vapor (17/18) and (16). In the same way, the amount of solution (14) and solution (10) are different.

17-18 and 15(15a)-16 are the high- and low-pressure ammonia vapor flow, respectively. 23-24 is the ambient air flow acting as the low-temperature heat source. 19-20-21-22 is the series supply/return water flow. 25-26 is the working medium out from/ into solar collectors, which serves as the high-temperature heat source (80~100 °C in this paper).

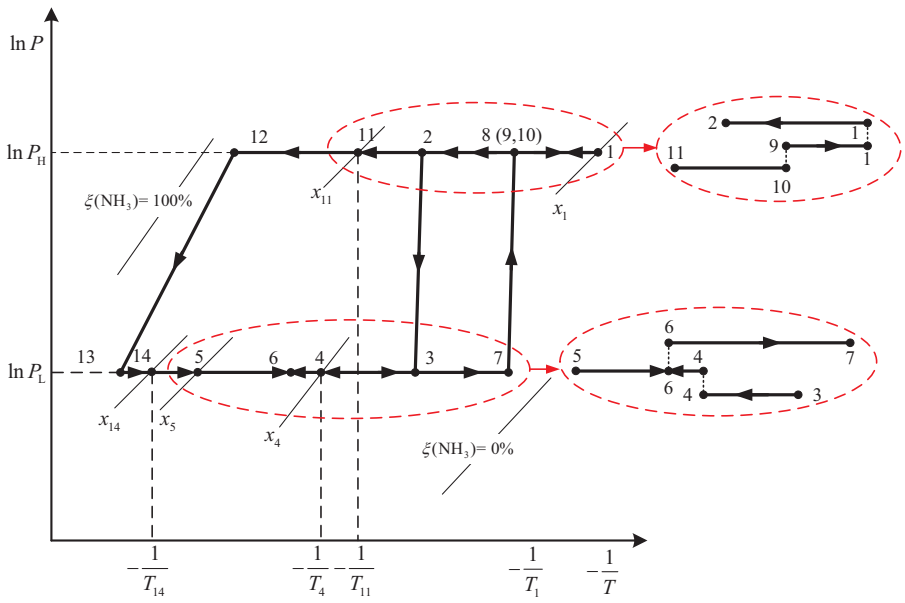

Fig. 3: *P-T* diagram of the novel ARHP cycle

3. Mathematical model

In this paper, low-temperature solar thermal of about 80℃-100℃ works as the high-temperature heat source. A mathematical model is developed to analyze the performance of the proposed cycle. Performance of the proposed cycle is simulated and compared to conventional single-stage cycle. The model can be simplified by the following assumptions:

(1) The system runs in a steady state;

(2) Heat losses to the surroundings and pressure drops along the pipelines are neglected;

(3) The solutions out from the LPG, HPG, LPA and HPA are all saturated;

(4) The vapor out from the LPG and HPG are saturated;

(5) The process in the solution pump is adiabatic.

(6) The expansion processes in throttling valves are isenthalpic.

(7) The mixing process in the solution mixing tank is adiabatic.

The proposed cycle comprises several relatively simple components such as the solution pump, heat exchangers, solution mixing tank, valves, and solution separation tank, HPG, LPG (1 and 2), HPA and LPA. Each component can be taken as a control volume with inlet and outlet fluid, heat transfer and work interactions (Hong 2011). The basic models for all of the components include energy balance equation, solution mass balance equation and ammonia mass balance equation, which are shown respectively as follows in Table 1.

ab. 1: Basic equations of the main components in the heat pump cycle

Components	Balance equations	
HPG	$m_9 h_9 + Q_{hpg} = m_1 h_1 + m_{17} h_{17}$	(eq. 1)
	$m_9 = m_1 + m_{17}$	(eq. 2)
	$m_9 x_9 = m_1 x_1 + m_{17} x_{17}$	(eq. 3)
SHX2	$m_1 h_1 + m_6 h_6 = m_2 h_2 + m_7 h_7$	(eq. 4)
	$m_1 = m_2$	(eq. 5)
	$m_1 x_1 = m_2 x_2$	(eq. 6)
	$m_6 = m_7$	(eq. 7)
TV2	$m_2 h_2 = m_3 h_3$	(eq. 8)
	$m_2 = m_3$	(eq. 9)
	$m_2 x_2 = m_3 x_3$	(eq. 10)
LPA	$m_3 h_3 + m_{16} h_{16} = m_4 h_4 + Q_{lpa}$	(eq. 11)
	$m_4 = m_3 + m_{16}$	(eq. 12)
	$m_4 x_4 = m_3 x_3 + m_{16} x_{16}$	(eq. 13)
SMT	$m_5 h_5 = m_4 h_4 + m_{14} h_{14}$	(eq. 14)
	$m_5 = m_4 + m_{14}$	(eq. 15)
	$m_5 x_5 = m_4 x_4 + m_{14} x_{14}$	(eq. 16)
LPG1	$m_{13} h_{13} + Q_{lpg1} = m_{14} h_{14} + m_{15} h_{15}$	(eq. 17)
	$m_{13} = m_{14} + m_{15}$	(eq. 18)
	$m_{13} x_{13} = m_{14} x_{14} + m_{15} x_{15}$	(eq. 19)
TV1	$m_{12} h_{12} = m_{13} h_{13}$	(eq. 20)
	$m_{12} = m_{13}$	(eq. 21)
	$m_{11} h_{11} + m_5 h_5 = m_{12} h_{12} + m_6 h_6$	(eq. 22)
SHX1	$m_{11} = m_{12}$	(eq. 23)
	$m_{11} x_{11} = m_{12} x_{12}$	(eq. 24)
	$m_6 = m_5$	(eq. 25)
	$m_6 x_6 = m_5 x_5$	(eq. 26)
	$m_{10} h_{10} + m_{17} h_{17} = m_{11} h_{11} + Q_{hpa}$	(eq. 27)

HPA	$m_{11}x_{11} = m_{10}x_{10} + m_{17}x_{17}$	(eq. 28)
	$m_{11} = m_{10} + m_{17}$	(eq. 29)
P1	$m_7h_7 + W_{p1} = m_8h_8$	(eq. 30)
	$m_7 = m_8$	(eq. 31)
	$m_7x_7 = m_8x_8$	(eq. 32)
SST	$m_8h_8 = m_9h_9 + m_{10}h_{10}$	(eq. 33)
	$m_8 = m_9 + m_{10}$	(eq. 34)
	$m_8x_8 = m_9x_9 + m_{10}x_{10}$	(eq. 35)
LPG2	$m_{14}h_{14} + m_{11}h_{11} = m_{12}h_{12} + m_5h_5 + m_{15a}h_{15a}$	(eq. 36)
	$m_{14} = m_5 + m_{15a}$	(eq. 37)
	$m_{14}x_{14} = m_5x_5 + m_{15a}x_{15a}$	(eq. 38)

In this paper, COP is adopted to evaluate performance of the proposed NH_3-H_2O absorption-resorption cycle. It can be defined as heating capacity output divided by the total energy input, given by

$$\mathrm{COP} = \frac{Q_{\mathrm{hpa}} + Q_{\mathrm{lpa}}}{Q_{\mathrm{hpg}}} = 1 + \frac{Q_{\mathrm{lpg1}}}{Q_{\mathrm{hpg}}} \quad \text{(eq. 39)}$$

Where Q_{lpg1} and Q_{hpg} are the total heat input of LPG1 and HPG, respectively.

All the properties of ammonia-water and pure ammonia are calculated by the REFPROP 8.0.

4. Results and discussion

In this paper, all the simulation results are based on the assumption that mass flow rate of low-pressure refrigerant vapor is 0.034 kg/s, i.e. m_{16} = 0.034 kg/s. The initial working conditions are listed in Table 2.

Tab. 2 Initial working condition

Working conditions	Given values (°C)
Temperature of solution out from HPG (1)	90
Temperature of solution out from HPA (11)	40
Temperature of solution out from LPA (4)	35
Temperature of the return water (19)	30
Ambient air temperature	10
Temperature difference between ambient air and solution (14)	3
Cold end temperature difference of SHX2, i.e. $T_2 - T_6$	10
Temperature difference between HTF outlet and solution (1), $T_{25} - T_1$	5
Temperature difference in LPG2, i.e. $T_5 - T_{14}$	5

Performance of the proposed cycle has been simulated under working conditions listed in Table 2. Simulation results are illustrated in Figs. 4-8.

Fig. 4 shows the effect of P_H (high generation pressure) values and P_L (low generation pressure) values on COP of the novel cycle. It can be seen that for a given P_H value, the COP increases rapidly with the increasing of P_L at first and then decreases with the increasing of P_L value. Under given working conditions, each P_H value corresponds to an optimum P_L to make the cycle's COP to its maximum value. The optimum P_L value increase with the increasing of P_H value, and so does the maximum value of COP. For instance, the maximum COP values for P_H values of 0.80 MPa, 0.90 MPa, 1.00 MPa, 1.10 MPa, 1.20 MPa, 1.30 MPa and 1.40 MPa are 1.17, 1.20, 1.23, 1.26, 1.31, 1.36, 1.42, respectively, and the corresponding optimum P_L values are 0.18 MPa, 0.21 MPa, 0.24 MPa, 0.28 MPa, 0.31 MPa, 0.36 MPa and 0.41 MPa, respectively. For a given P_H value, the corresponding P_L value is limited in a certain range and the proposed heat pump cycle will not work beyond that range.

Fig. 5 depicts effect of P_H and P_L values on ΔT_1 of LPG1, ΔT_2 of LPA, ΔT_3 of HPG and ΔT_4 of HPA. It can be seen that ΔT_1, ΔT_2 and ΔT_4 decreases while ΔT_3 increases with the increasing of P_L value within its range. It indicates that when P_L increases, the amount of heat needed to drive the high-pressure generation process

increases.

Fig. 6 describes heat source temperature (T_{hs}) corresponding to different P_H and P_L values. It can be seen that for given P_H value, T_{hs} increases with the increasing of P_L value. It is also obvious that the maximum T_{hs} of the cycle under given working conditions reaches 51.0 °C when P_H and P_L are with the value of 0.80 MPa and 0.22 MPa, respectively, where the cycle's COP is 1.114. It can basically meet the temperature demand of winter hot water supply. It is worth mentioning that, when the cycle is operated at its maximum COP (1.42) when P_H and P_L are 1.40 MPa and 0.41 MPa, respectively, T_{hs} can still reach 43.7 °C, which can meet the temperature demand of building floor heating. Furthermore, for other selected P_H/P_L values such as 1.30/0.36 MPa, 1.20/0.31 MPa, 1.10/0.28 MPa, 1.00/0.24 MPa, 0.90/0.21 MPa and 0.80/0.18 MPa the T_{hs} values are 44.1 °C, 44.3 °C, 45.2 °C, 45.4 °C, 46.1 °C and 46.7 °C, which are all suitable for fan coil heating.

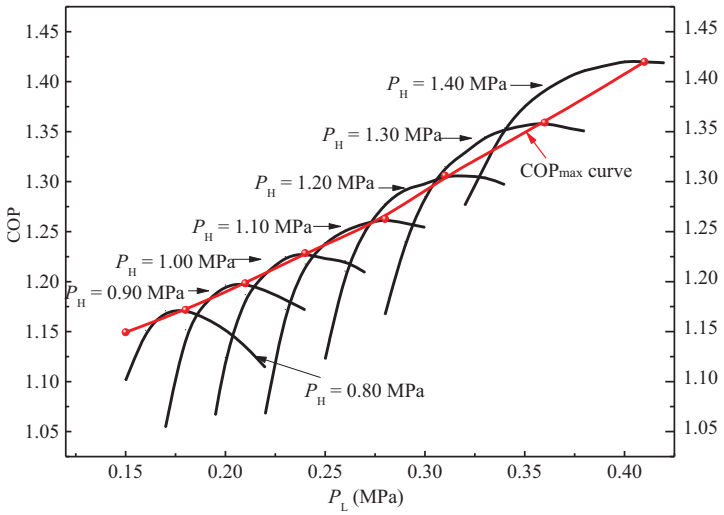

Fig. 4: The effect of P_H and P_L values on COP

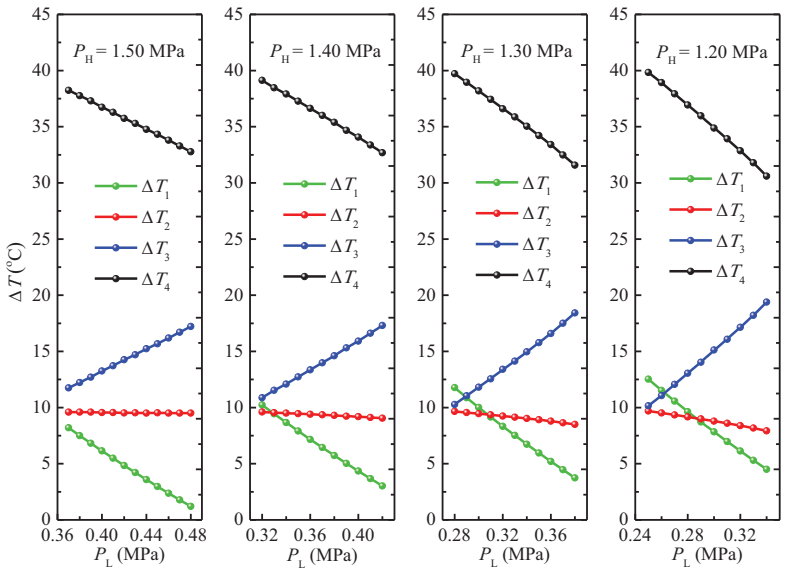

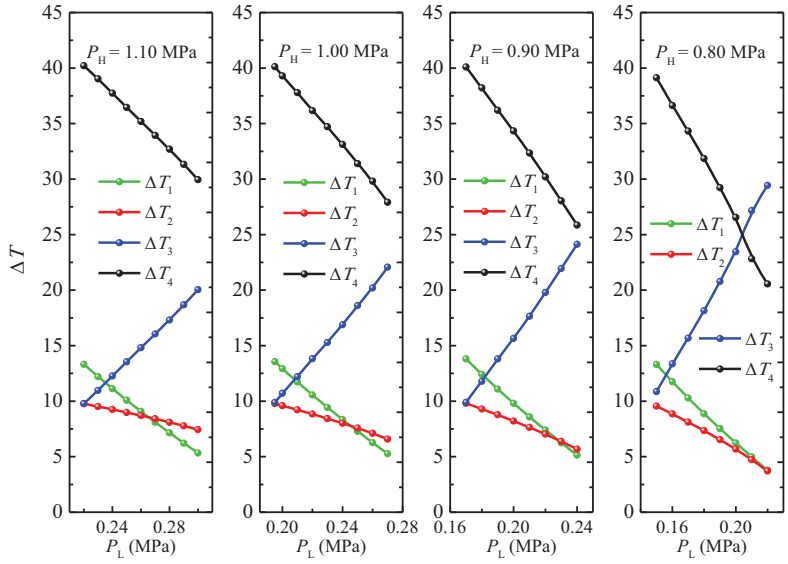

Fig. 5: Effect of P_H and P_L values on ΔT_1 of LPG1, ΔT_2 of LPA, ΔT_3 of HPG and ΔT_4 of HPA

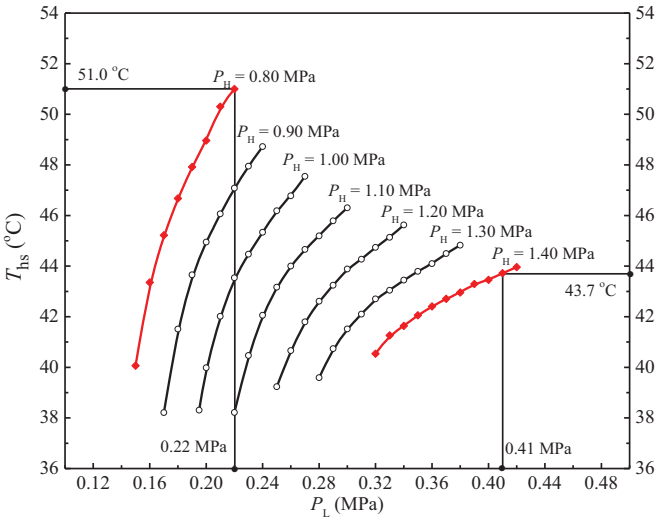

Fig. 6 Heat supply temperature (T_{hs}) corresponding to different P_H and P_L values

Fig. 7 depicts the effect of heat source temperature (T_h) on COP under the P_H/P_L pair values corresponding to the maximum COPs obtained in Fig. 4. It can be found that for the novel balanced ARHP cycle, T_h must be above 85 °C which happens when P_H/P_L pair value is 1.40/0.41 MPa and the corresponding COP value is 1.17. Meanwhile, For given P_H/P_L pair, COP firstly ascends rapidly with the increasing of T_h, and then increases slowly when T_h is higher than 95 °C. The maximum COP under given working conditions can reach 1.425.

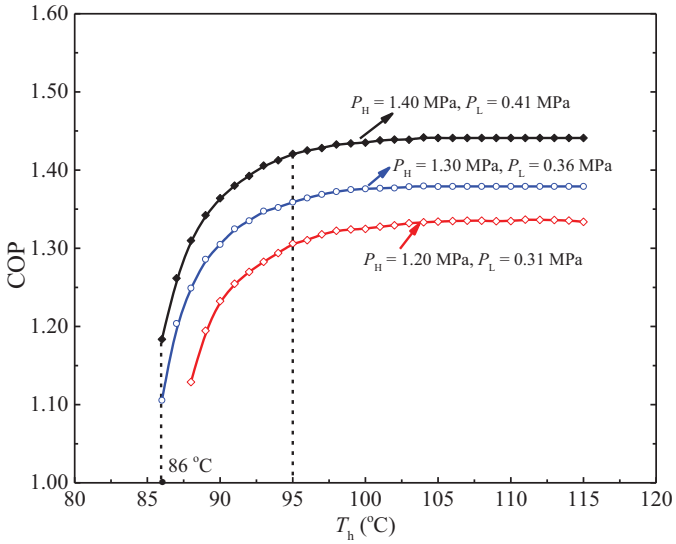

Fig. 7: Effect of heat source temperature (T_h) on COP

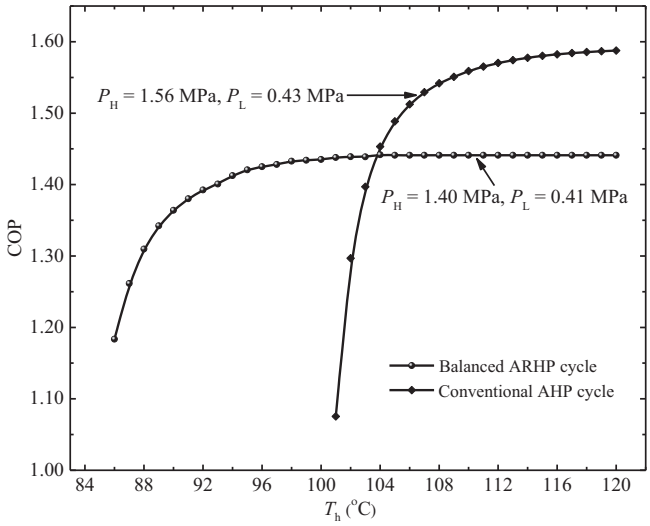

Fig. 8 Comparison of the novel ARHP cycle and the conventional AHP cycle

For comparison, effect of T_h value on COP of the conventional AHP cycle when T_e, T_c, T_a are 0 °C, 40 °C, 48 °C, respectively, and effect of T_h value on COP are also illustrated in Fig. 8. For the conventional AHP cycle, T_h must be higher than 101 °C, and when T_h is higher than 104 °C, COP of the balanced ARHP cycle is lower than that of the conventional AHP cycle. However, COP of the conventional AHP cycle declines quickly when T_{hd} is lower than 108 °C. Furthermore, the AHP cycle will stop working whereas the balanced ARHP cycle could still operate when T_h is lower than 100 °C. Apparently, the balanced ARHP cycle we proposed could function under a larger heat source temperature range than the conventional AHP cycle.

5. Summary and conclusions

To make efficient use of low-temperature solar thermal, this paper proposes a novel absorption-resorption heat pump cycle. The new resorption heat pump cycle without distillation device is more suitable for temperature characteristics of the solar heat source. Parameters like the pressure of the cycle, heat source temperature and heat supply temperature are investigated. COP of the novel cycle in this paper can reach up to 1.42 with low temperature of solar thermal acting as the high-temperature heat source. P_H and P_L value are important on the performance of the heat pump cycle. Pressure of the high-pressure generator and pressure of the low-pressure generator could be optimized to get a maximum COP at any given working conditions. The novel cycle can supply water that can meet space heating temperature demand.

Multiple heat sources with different temperatures can also be efficiently used at the same time by slightly modifying the configuration of the cycle. And when the ambient temperature is too low to drive the cycle, solar thermal collectors can be used to lift the temperature in the low-pressure generator.

Preliminary Assessment of a Solar Absorption System for Air Conditioning Applications

J.C. Jiménez-García, W. Rivera

Instituto de Energías Renovables, Universidad Nacional Autónoma de México, Temixco, Morelos, México.

Abstract

A low-capacity solar absorption system for air conditioning applications has been developed. The system uses the mixture ammonia-lithium nitrate and plate heat exchangers as the main components. Several experimental test runs were carried out at different operating conditions for the generator, condenser and absorber. The system achieved an internal cooling power close to 3.1 kW, with cooling temperatures around 6 °C and an internal coefficient of performance around 0.62.

Key-words: absorption cooling system, solar air conditioning, ammonia-lithium nitrate

1. Introduction

In the last years absorption systems have gained increasing interest by the fact that they can be operated with either solar thermal energy or residual heat from industries. Around 15% of the electricity produced worldwide is used for air-conditioning and cooling (Statistics, I. E. A., 2011), so absorption systems may help to reduce this percentage. Currently, the research on absorption systems has focused in three main aspects:

(i) the study of alternative mixtures,
(ii) the development of more efficient and low cost components, and
(iii) the development of advanced systems

Up to now, several studies have been carried out on the development of absorption cooling prototypes operating with ammonia-water (Jakob et al., 2008) and water/lithium bromide (Achuthan et al., 2011; Agyenim et al., 2010; González-Gil et al., 2011; Lizarte et al., 2012, 2013; Qu et al., 2010; Venegas et al., 2011; Yin et al., 2013;). These two mixtures have been the most used since they possess great advantages. However due to their well-known drawbacks, Best and Rivera (2015) presented a review of thermal cooling systems. According to their study, the ammonia-lithium nitrate mixture possesses some advantages over the conventional ones. Regarding ammonia-lithium nitrate mixtures, some of the most relevant studies are cited below. Rivera et al. (2012) and Moreno-Quintanar et al. (2012) reported the assessment of an intermittent solar absorption refrigeration system operating with NH_3-$LiNO_3$ using a cylindrical parabolic collector as a generator–absorber. The results showed that it was possible to produce up to 8 kg of ice per day. Generation temperatures varied from 75 °C to 110 °C achieving evaporation temperatures as low as -11 °C and solar coefficients of performance of 0.08. Llamas et al. (2007, 2014) reported the results of a 10 kW solar absorption air conditioning system for a cooling capacity between 5 and 10 kW operating with the ammonia-lithium nitrate mixture. The system was air cooled and the heat was supplied by evacuated solar collectors. Coefficients of performance up to 0.53 were achieved with chilled water temperatures as low as 0 °C. Hernández-Magallanes et al. (2014) reported the experimental assessment of an absorption cooling system operating with the ammonia-lithium nitrate mixture. The generator and absorber were helical coil falling film heat exchangers while condenser, evaporator and economizer were plate heat exchangers (PHE). The COP values varied between 0.45 and 0.7 while the cooling capacity was between 0.52 to 2.52 kW, for generator temperatures between 85 °C and 105 °C and condenser temperatures from 18 °C to 36 °C. Zamora et al. (2014, 2015) reported two studies on the assessment of an absorption chiller operating with the ammonia-lithium nitrate mixture using compact heat exchangers as the main components. The authors reported that the water-cooled

doi:10.18086/swc.2017.28.11 Available at http://proceedings.ises.org

prototype yields 12.9 kW of cooling capacity and an electrical COP of 19.3, when operating at 15 ºC for chilled water, 90 ºC for heating water and 35 ºC for cooling water. Dominguez-Inzunza et al. (2016) carried out the evaluation of an ammonia/lithium nitrate absorption cooling system. The generator temperatures varied between 80 °C and 100 °C, while the cooling water temperatures varied from 20 °C to 34 °C. Cooling capacities up to 4.5 kW and evaporator temperatures as low as 4 °C were achieved with coefficients of performance ranging from 0.3 to 0.62.

On the other hand, regarding to the use of PHE as components in absorption cooling systems, some of the most relevant works are the following: Goyal et al. (2017) reported the evaluation of a small-capacity, waste-heat driven ammonia-water absorption chiller. The system developed used waste heat from diesel generator exhaust to desorb the refrigerant solution. The system was designed to deliver 2.71 kW of cooling at extreme ambient temperature of 51.7 °C obtaining a coefficient of performance of 0.55. The system utilizes air-cooled finned-tube in the absorber and condenser and microchannel array in the evaporator. Experiments were carried out at ambient temperatures of 29.7–44.2 °C, delivered cooling duties of 2.54–1.91 kW. Zacarías et al. (2013) reported the results on the experimental assessment of the adiabatic absorption of ammonia vapor in an ammonia-lithium nitrate solution using a fog jet nozzle. The system utilizes compact heat exchangers in all the components with exception of the absorber. The authors reported that the approach to adiabatic equilibrium factor for the conditions essayed was always between 0.82 and 0.93. Khan et al. (2012a, 2012b) carried out an experimental investigation on evaporation heat transfer and pressure drop for ammonia in 30º and 60º chevron PHE. The experiments were performed for saturation temperatures ranging from 25 ºC to 2 ºC and the heat flux varied between 21 kW m^{-2} and 44 kW m^{-2}. The experimental results showed a significant effect of saturation temperature, heat and exit vapor quality on heat transfer coefficient and pressure drop. The authors proposed correlations for the Nusselt number and friction factor. Stasiek (1998) carried out experimental studies of heat transfer and fluid flow across corrugated-undulated heat exchanger surfaces. The authors used a true color image processing of liquid crystal images for temperature and heat transfer distribution measurements in six element-shapes of heat exchangers. The authors reported that the technique could be of considerable use in improving the design of all types of plate heat exchangers. Ibarra-Bahena et al. (2015) reported the experimental results of a single stage heat transformer using PHE in all its main components. The system operated with the water-carrol mixture. The experimental gross temperature lift achieved values from 18.5 to 22.2 ºC and the coefficients of performance varied from 0.30 to 0.35.

From the literature review it can be seen that just a few prototypes have been developed using the ammonia-lithium nitrate mixture and only the research carried out by Zamora et al. (2014, 2015) involves plate heat exchangers as main components. However, their studies only present some global results for the coefficients of performance for very specific conditions and they did not do a parametric study in order to evaluate the system's performance under several operating conditions. Therefore, this paper presents the evaluation of a single-stage absorption cooling system operating with the ammonia-lithium nitrate mixture at different temperatures heating and cooling water.

2. System description

2.1 Experimental setup

The absorption system proposed consists of the following components: generator, absorber, condenser, evaporator, economizer, pump, throttle device, and a couple of tanks. The system was operated with the ammonia-lithium nitrate mixture, and it was built using five plate heat exchangers (PHE) as the main components which were oriented in vertical configuration. The PHE utilized in the system were manufactured by *Alfa Laval*, and it was considered the model *Alfanova 52* for generator, economizer and absorber, the number of plates for each heat exchanger is 40, for condenser and evaporator the model *Alfanova 27* was chosen with 20 plates in each heat exchanger. A *Milton Roy* diaphragm pump with a nominal power of 745 W was used in order to pumping the working fluid from the absorber to the generator. The throttle device used was a stainless steel low-pressure metering valve coupled with vernier handle, which has a maximum flow

coefficient equal to 0.004. Besides, a couple of tanks with a volume capacity near to 2 liters were included in the system: one of them is located at the exit of the generator, whose function is to enable the phases' separation, thus it allows the ammonia vapor flow to the condenser and the liquid solution flow to the absorber. On the contrary, the second tank acts as a mixing chamber, because the solution with a low refrigerant's concentration (weak solution) that comes from the generator and the solution that is being recirculated get mixed there. The system's measures are: 1.06 x 1 x 0.65 meters (front-height-depth). All the components utilized in the system are 100% stainless steel, in order to avoid their degradation caused by ammonia and lithium nitrate. The described components can be seen in the system's schematic diagram shown in figure 1.

Although the aim of the system is to be driven by solar energy, in order to perform the experimental assessment under controlled conditions, up to now, the experimental tests were carried out using three auxiliary systems. The thermal energy required to separate the refrigerant from the working mixture is supplied to the generator by means of an auxiliary heating system. This auxiliary system uses an electric resistance to heating up a mass flow rate of water, the hot water is supplied to the generator at a gauge pressure near to 200 kPa (2 bar), thus, avoiding the boiling of the water at generation temperatures.

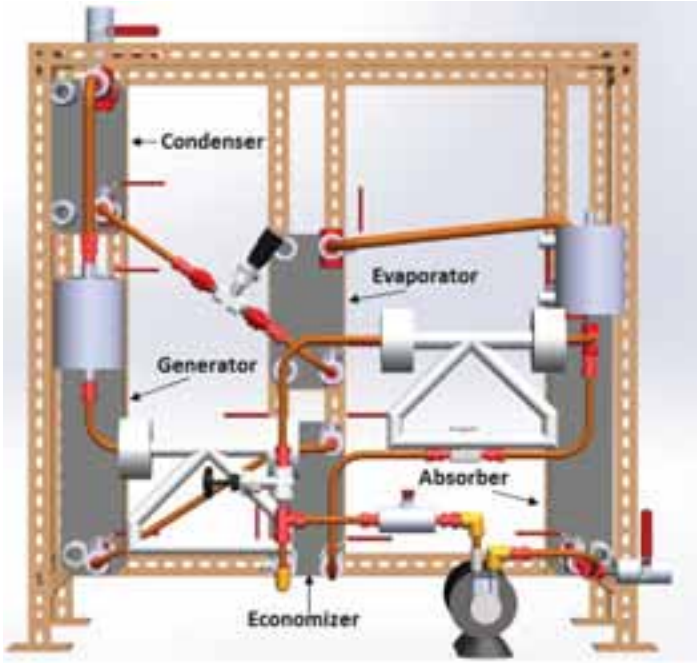

Fig. 1: Schematic diagram of the absorption cooling machine

On the other hand, the thermal power removed from the condenser and absorber is dissipated by means of an auxiliary cooling system, this cooling system consists of a storage tank, a recirculating water pump and a commercial chiller. Once the flow of water has removed heat from the condenser and absorber, its temperature is reduced in the chiller, transferring the heat to the ambient air, when the water leaves the chiller it is stored in the tank, the recirculating pump takes the low-temperature water from the storage tank and pumps it to the condenser and absorber, hence, the water is able to take thermal energy from the condenser and absorber again. The third auxiliary system is intended to supply a mass flow rate of water to the evaporator, in order to be cooled by the absorption system. This system also has a storage tank, a pump and an electric resistance, and it was designed to provide the heat necessary to keep the water's temperature constant.

2.2 Operation of the system

A mass flow rate of hot water is supplied to the generator in order to get the ammonia and the solution separated. The two phase mixture (ammonia vapor and weak solution) leaves the generator and enters to a separation tank, there, the ammonia vapor flows to the condenser where it is liquefied by means of the cooling water supplied by the chiller. The ammonia in liquid phase, leaves the condenser and goes through the

expansion valve, reducing its pressure and temperature. Once the ammonia has passed through the valve, its thermodynamic state is a saturated liquid-vapor mixture and its temperature is the lowest temperature of the entire cycle. Under these conditions, the ammonia mixture enters into the evaporator extracting a thermal load from the water circulating in the adjacent channels of the PHE as a countercurrent flow, producing the system's cooling effect. The ammonia leaves the evaporator as superheated vapor and goes to the absorber where it is mixed with the weak solution coming from the generator. This mixture process releases thermal energy, which is transferred to the cooling water that flows in the absorber. Finally, the solution with high concentration of refrigerant (strong solution) leaving the absorber is pumped to the generator starting the cycle again.
Furthermore, an economizer is included in the system, whose purpose is to exchange heat between the solution flows going to and leaving the generator, in order to enhance the coefficient of performance (COP) by reducing the heat rejection in the absorber as well as the heat supplied to the generator.

2.3 Instrumentation

In order to evaluate the system's performance while the operative conditions are modified, a set of temperature, pressure and mass flow rate sensors were included in the absorption system. The pressure in the system was measured in the generator, condenser, evaporator and absorber. *Ashcroft* piezoelectric transducers were utilized. Regarding the mass flow rates in the absorption system: two types of sensors were considered: in order to obtain the refrigerant produced and the weak solution mass flow rates, a couple of *Micro Motion Elite Coriolis Flow Meters* was used. The strong solution as well as the external mass flow rates of water were registered by several turbine flow meters. The temperature for each current was measured at the inlet and outlet ports in every PHE. Every measuring device used for the system's experimental assessment was calibrated and a set of calibration equations was obtained. Each outlet signal was received, processed and stored by a *HP* data acquisition system using the software *Agilent VEE Pro 9.3*, were the equations obtained were utilized in order to find the expected values. The sensors' position in the system is shown in the schematic diagram presented in figure 2.

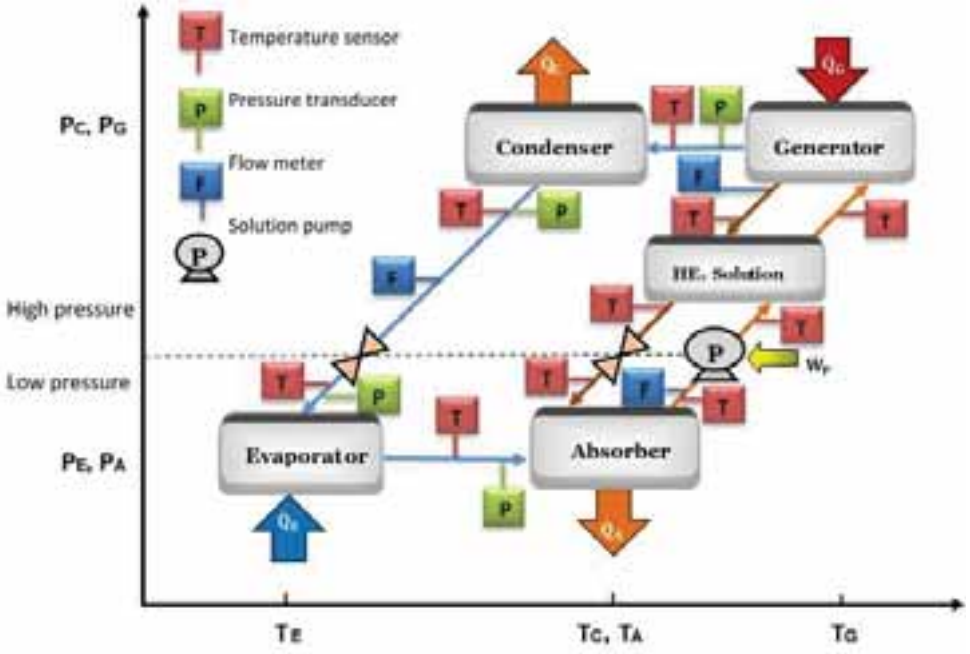

Fig. 2: Schematic diagram showing the sensors location in the absorption cooling machine

Fig. 3: Developed absorption cooling machine

The uncertainties associated to the cited instrumentation are presented in Table 1.

Tab. 1: Instruments uncertainties

Measuring instrument	Uncertainty
Elite Coriolis flowmeter	± 0.10%
Omega rotameter	± 1%
Turbine flowmeter	± 1%
Pressure transducer	± 1%
RTD sensor	± 0.3°C

3. Main equations

The coefficient of performance is a measure of the system's efficiency and it can be determined based on internal or external parameters. Internal parameters are related to the conditions for the weak and strong solutions and the refrigerant produced. External parameters are influenced by the conditions of the mass flow rates of heating and chilled water, at inlet and outlet of the generator and evaporator, respectively, as well as the work supplied by the related pumps.

The internal coefficient of performance (COP_{int}) can be determined by equation 1:

$$COP_{int} = \frac{\dot{Q}_{e,int}}{\dot{Q}_{g,int} + \dot{W}_{b,int}} \qquad \text{(eq. 1)}$$

In equation 1 $\dot{Q}_{e,int}$ represents the system's cooling power, this term is the thermal power transferred to the ammonia in the evaporator and it is calculated as shown in equation 2.

$$\dot{Q}_{e,int} = \dot{m}_{ref}(h_{e,o} - h_{e,i}) \quad \text{(eq. 2)}$$

On the other hand, the term $\dot{Q}_{g,int}$ represents the actual heat power supplied to the strong solution in the generator, it is calculated as an energy balance considering the mass flow rates across the PHE. The energy balance calculation can be advertised in equation 3.

$$\dot{Q}_{g,int} = \dot{m}_{weak}\left(h_{g,o-weak}\right) + \dot{m}_{ref}\left(h_{g,o-NH3}\right) - \dot{m}_{strong}\left(h_{g,i}\right) \quad \text{(eq. 3)}$$

The term $\dot{W}_{b,int}$ in equation 1 expresses the mechanical power supplied to the system in order to pump the strong solution from the absorber to the generator. It is determined calculating the enthalpies difference (before and after the pump) for the strong solution mass flow rate. Equation 3 exposes the manner in which the mechanical power for the internal pump is determined.

$$\dot{W}_{b,int} = \dot{m}_{strong}\left(h_{ec,i-strong} - h_{a,o}\right) \quad \text{(eq. 4)}$$

The properties for the ammonia-lithium nitrate mixture were calculated using the equations reported by Farshi et al. (2014). The ammonia properties were determined from the *REFPROP* software using the international institute of refrigeration (IIR) reference state.

4. Results

In order to assess the absorption cooling system, approximately 40 test runs have been carried out. A parametric analysis was performed with the aim of demonstrating the effects of the change in a parameter on the others. Thus, the condensation temperature was varied while parameters as the strong solution mass flow rate and temperatures of heating water and water to be chilled, were kept constant. The working mixture employed in the experimental assessment had an ammonia's mass concentration equal to 54 % and it was kept constant for the test runs presented.

The preliminary assessment was performed for generation temperatures between 80 and 95 °C, and condensation temperatures from 22 °C to 32 °C. Generation temperature was varied in 5 °C increments. The condensation temperature steps were equivalent to 2 °C.

For each test run steady state conditions were achieved and kept by a minimum period of 30 minutes. The figures 4 to 7 present the temperature profiles obtained in the main components for a chosen test run, where the generation temperature was 80 °C while the condensation temperature was 28 °C. The mass flow rate values utilized for the system's assessment are presented in table 2.

Tab. 2: Mass flow rate values for parameters enternal and internal

Parameter	Mass flow rate (kg/s)
Heating water	0.25
Cooling water	0.2
Chilled water	0.183
Solution to generator	0.016

In figure 4 is advertised that generator temperatures are constant for the test's period of time. The highest temperature corresponds to heating water entering to generator (Tg,wi). On the contrary, the lowest temperature is the solution going into the generator (Tg,i), which almost reaches the highest temperature when it leaves the PHE. That means the selected parameters such as solution mass flow rate and flow arrangement (countercurrent arrangement) are adequated for the conditions presented. The average temperatures for the solution entering and leaving the generator are 64.1 °C and 78.2 °C, respectively.

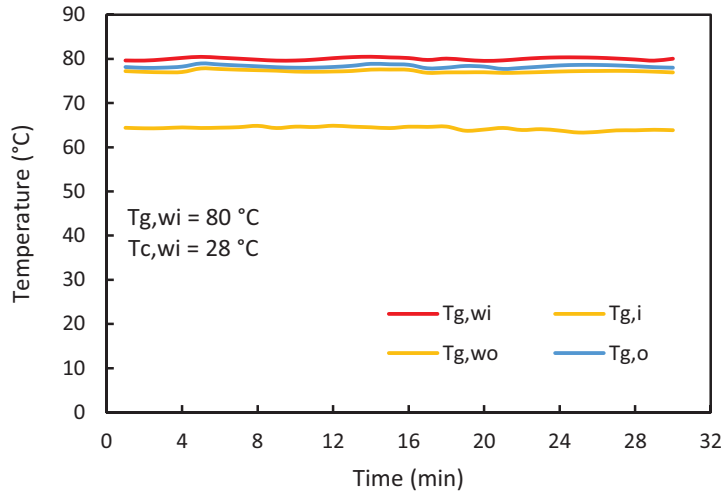

Fig. 4: Temperature profiles in generator during the test run

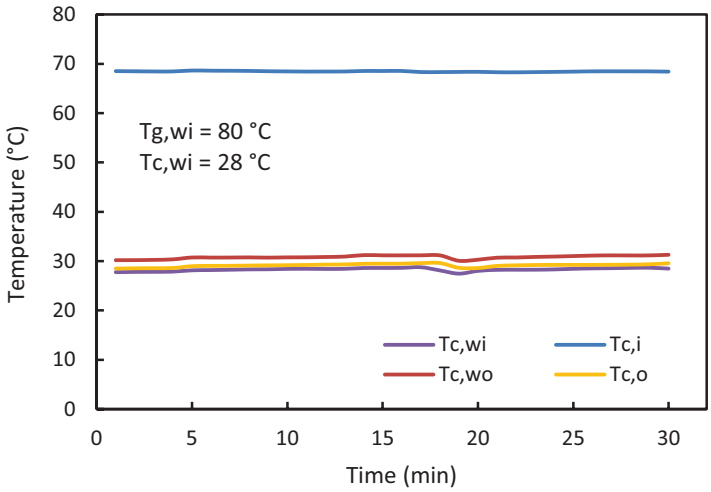

Fig. 5: Temperature profiles in condenser during the test run

In the case of the temperature profiles in condenser, from figure 5 it can be seen the steady state is also kept. The refrigerant enters to the condenser at an average temperature of 68.5 °C ($\mathbf{T_{c,i}}$), and leaves the heat exchanger at an average temperature near to 29.12 °C ($\mathbf{T_{c,o}}$). The pressure measured in this test run is approximated to 1.25 MPa (12.5 bar) which means that for the $\mathbf{T_{c,o}}$ measured it is assured that refrigerant condensation is achieved. In the case of cooling water an average temperatures difference between the inlet and outlet near to 2.6 °C is accomplished.

The profiles for attained temperatures in evaporator are shown in figure 6, where it is possible to observe that for the test conditions, the refrigerant at the inlet's port in evaporator ($\mathbf{T_{e,i}}$) had a temperature near to 10 °C. The water to be chilled ($\mathbf{T_{e,wi}}$) entered the evaporator at an average temperature of 20 °C and experimented a reduction of 2.5 °C in average. It is important to mention the refrigerant temperature leaving the evaporator ($\mathbf{T_{e,o}}$) is very close to $\mathbf{T_{e,wi}}$, this probably means that refrigerant is overheated, which would imply that the mass flow rate of refrigerant produced is low, regarding the evaporator's capacity.

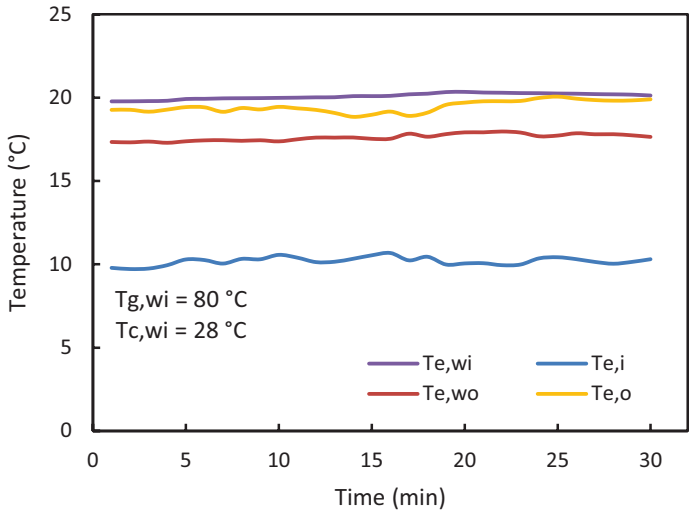

Fig. 6: Temperature profiles in evaporator during the test run

In figure 7 is possible to see the temperature profiles through the absorber. The cooling water entering the PHE has an average temperature of 28 °C ($\mathbf{T}_{a,\mathbf{wi}}$) and leaves it at an average temperature of 30.65 °C ($\mathbf{T}_{a,\mathbf{wo}}$). On the other hand, a two phase mixture of ammonia vapor and weak solution arrives at an average temperature ($\mathbf{T}_{a,\mathbf{i}}$) near to 47 °C. After the absorption process has taken place, the solution with a higher ammonia concentration leaves the absorber at an average temperature approximated to 32.4 °C.

In figures 5 and 7 a temperature perturbation is seen on the water profiles, this disturbance is induced by the auxiliary cooling system which has an intermittent behavior which is determined by the temperature variations in the storage tank. The described disruption causes, at the same time, a disturbance on the exit temperature of the opposite flow, which is reflected on its temperature profile of both PHE: condenser and absorber.

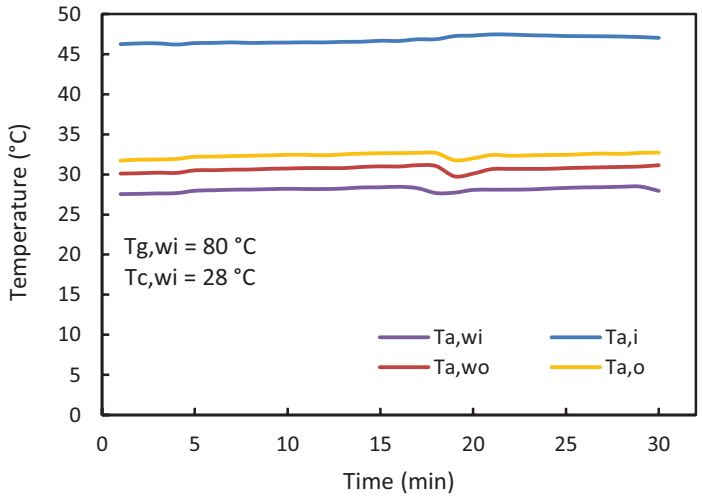

Fig. 7: Temperature profiles in absorber during the test run

The thermal power transferred to ammonia in evaporator (calculated as $\dot{\boldsymbol{Q}}_{\boldsymbol{e,int}}$ from eq. 2) is presented in figure 8. Figure 8 shows the downward trend for this parameter as the condensation temperature grows up. In other words, the system's cooling capacity is reduced at higher condensation temperatures. This fact was expected

because the higher condensation temperatures the higher pressures in the components are gotten, and higher evaporation temperatures for ammonia are obtained, which means the cooling capacity is reduced. The figure 8 also shows a direct relationship between generation temperatures and cooling power, having that the lowest generation temperatures the lowest cooling capacities are attained. When the system was operated at $\mathbf{T_{g,wi}} = \mathbf{95\ °C}$, the pressures attained were very similar to those for $\mathbf{T_{g,wi}} = \mathbf{90\ °C}$, for that reason some key temperatures and thermal powers are very close, as it can be seen in figure 8.

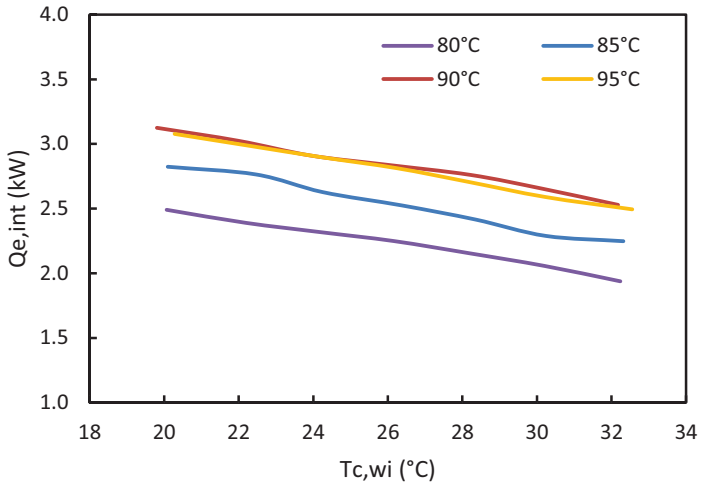

Fig. 8: Internal thermal power transferred in evaporator for several generation temperatures

Figure 9 exhibites the ammonia mass flow rate produced for every generation temperature tested. As condensation temperature increased, the ammonia mass flow rate produced was diminished, presenting a downward linear changement for every trend. On the other side, it could be seen from figure 9 that there is a direct relationship between the generation temperatures and the amount of ammonia circulating throught the condenser and evaporator. Thus, at higher generation temperatures a higher amount of ammonia is produced and a higher cooling effect is obtained as it is demonstrated in figure 8.

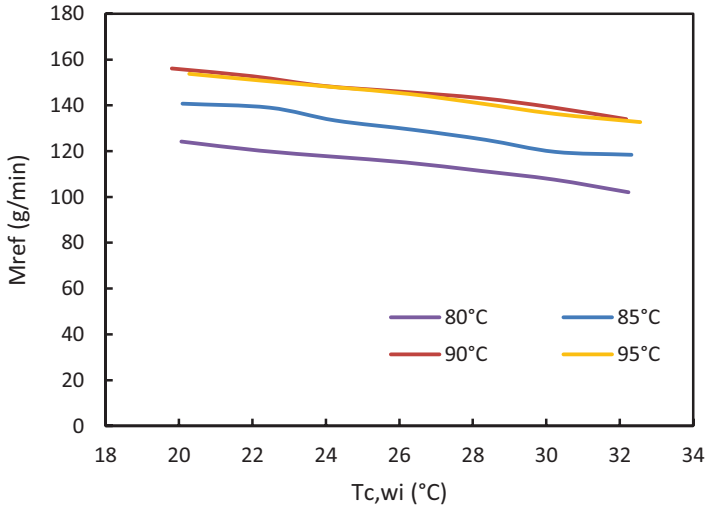

Fig. 9: Refrigerant mass flow rate produced during the assessment

The lowest system's temperature is reached after the ammonia has passed through the throttle valve ($\boldsymbol{T_{e,i}}$), just before the inlet to evaporator. The ammonia temperature was measured at this point and it was plotted in figure 10 against condensation temperature, for each generation temperature considered. As it is presented in figure 10, this temperature augmented as condensation temperature grew up. This was due to the fact that at higher condensation temperatures higher pressures in absorber and evaporator are gotten, which causes the saturation temperature for ammonia to increase.

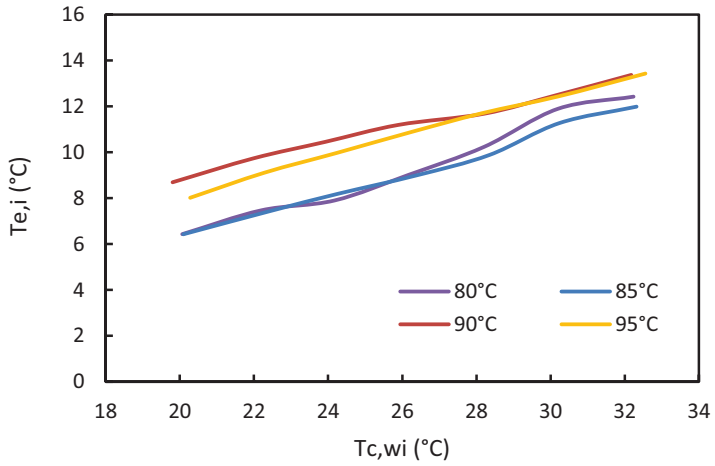

Fig. 10: Ammonia evaporation temperatures registered

The variation of internal COP with respect to condensation temperatures for each generation temperature tested is shown in figure 11. From this figure, it is possible to see that, as a general trend, the internal COP decreases as the condensation temperature increases, besides this, the figure 11 makes evident that for higher generation temperatures, higher coefficients of performance are reached, according to what was expected.

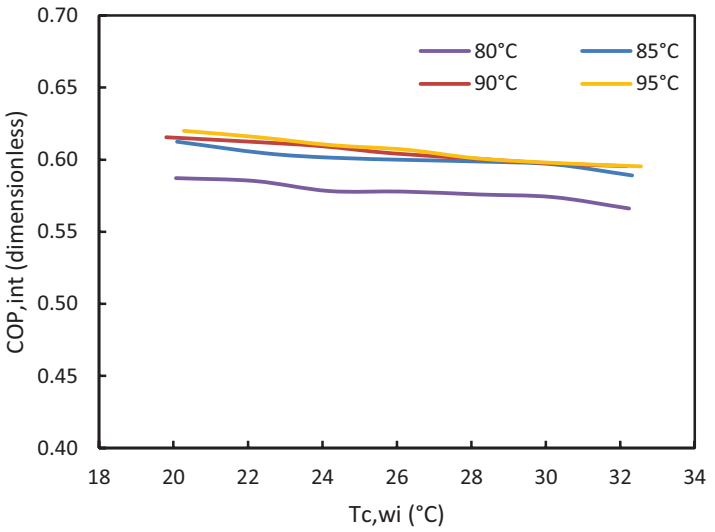

Fig. 11: Internal coefficient of performance for the absorption system

For the lowest $\boldsymbol{T_{g,wi}}$ (80 °C) the highest $\boldsymbol{COP_{int}}$ value was 0.587 when $\boldsymbol{T_{c,wi}}$ was 20 °C, while the minimum COP was 0.566 when 32 °C were kept in condenser. The $\boldsymbol{COP_{int}}$ for $\boldsymbol{T_{g,wi} = 85\ °C}$ varied from 0.612 to 0.589 for the condensation range specified. Regarding 90 and 95 °C generation temperatures, the highest $\boldsymbol{COP_{int}}$ obtained were 0.612 and 0.619 at $\boldsymbol{T_{c,wi} = 20\ °C}$ respectively, while the lowest value was close to 0.595 for both cases.

5. Conclusions

The preliminary assessment of an experimental absorption cooling system operating with the ammonia-lithium nitrate working mixture was presented. The assessment was performed for generation temperatures from 80 to 95 °C, while condensation temperatures were varied from 20 to 32 °C. A mass flow rate of solution going to generator was kept constant at 0.016 kg/s (1 kg/min). Key parameters such as main temperatures, cooling powers, mass flow rates of refrigerant produced and internal coefficients of performance were presented and discussed. It was found the system achieved a cooling power close to 3.1 kW for a generation temperature equal to 90°C. On the other hand, for the lowest generation temperatures, cooling temperatures around 6 °C were attained. A maximum internal coefficient of performance near to 0.62 was obtained when $T_{g,wi} = 95\ °C$ and $T_{c,wi} = 20\ °C$.

Abstract

Commercial refrigerants used for vapour compression cycle show positive adsorption capacity with various activated carbon adsorbents however most of them appeared to have high global warming potential (GWP) values. Nevertheless, refrigerants such as R1234yf, R1234ze (E), R450A, R290, R600a, R744 and R717 have been proposed as low GWP alternatives in vapour compression cycles.

Properties of some vapour compression cycle refrigerants qualify them as the good alternative adsorbate for solar adsorption refrigeration systems. Maximum adsorption capacity of 2kg/kg-adsorbent reported for commercial refrigerant R134a on activated carbon, while the maximum for classical adsorption pairs is 0.259 kg/kg-adsorbent which appears for activated carbon-methanol pair.These refrigerants will add the availability of the adsorbates, reduced scale of problems associated with material compatibility and leakages. These systems have good potential applications in off grid areas in developing countries with abundant availability of solar energy including food preservation, vaccine and medicine storage.

Keywords: Refrigerant, GWP, Adsorption refrigeration, off grid application,

1. Introduction

Refrigeration is the cooling effect of the process of extracting heat from a lower temperature heat source, a substance or cooling medium, and transferring it to a higher temperature heat sink, probably atmospheric air and surface water, to maintain the temperature of the heat source below that of the surroundings for purposes of comfort or preservation (Kreith et al., 1999). Refrigeration technology includes the classical cycle with a compressor and an expansion valve, absorption processes, adsorption processes and desiccant systems. Vapour compression cycle is the common refrigeration technology however, significant implications of refrigerants to the environment such as ozone layer depletion, greenhouse effect, global warming and huge electrical energy consumption have forced scientists to develop environmentally friendly refrigerants and refrigeration technologies (Anupam et al., 2016).

Refrigerants are used in a wide variety of heating, ventilation, air conditioning and refrigeration (HVAC&R) equipment in both industrial and domestic equipment from household refrigerator, cooling chambers and air conditioners (Benhadid-Dib and Benzaoui, 2011; Goetzler et al., 2014). The first generation of refrigerants involved whatever worked and was available, including familiar solvents and other volatile fluids of which majority were flammable, toxic, or both and some were also highly reactive included substances such as hydrocarbons, ammonia and carbon dioxide. The second generation refrigerants shifted to fluorochemicals for safety and durability which included CFCs and HCFCs which became widely used because were efficient, non-flammable and non-toxic. However, in the 1980s CFCs and HCFCs were determined to play a major role in depleting the stratospheric ozone layer, therefore phased out in the 1990s in favor of a third generation of refrigerants HFCs which presented zero ODP but along with CFCs and HCFCs were greenhouse gases that contribute to the radiative forcing of climate with significantly GWP when released to the atmosphere (Calm, 2008; Goetzler et al., 2014; Velders et al., 2009). This shifts ignited renewed interest in natural refrigerants particularly ammonia, carbon dioxide, hydrocarbons and water (Calm, 2008).

The growing international emphasis on global warming mitigation stimulated interest for the fourth generation of

doi:10.18086/swc.2017.28.12 Available at http://proceedings.ises.org

low GWP refrigerants with countries like the United States, Canada and Mexico proposed an amendment to the Montreal Protocol in 2014 to reduce production and consumption of HFCs by 85% during the period 2016-2035 for Non A5 (developed) countries and the European F-gas legislation issued in 2014 which will reduce HFC consumption by 79% over the period 2016-2030 (Goetzler et al., 2014).

On other hand, adsorption refrigeration systems can utilize environment friendly refrigerants and low temperature waste heat and renewable energy sources like solar radiation and biomass derived thermal energy to generate the cooling effect (Anyanwu, 2004; El-Sharkawy et al., 2008).

2. Low GWP refrigerants for vapour compression cycle refrigeration

Various researchers are on board searching for new refrigerants which will be both efficient and environmental friendly. Velders et al. (2009) reported the hydrocarbons, ammonia and CO_2 as the suitable low GWPs refrigerants if compared to HFCs for small refrigerant charges systems where a refrigerant leak would not pose unacceptable flammability or toxicity risk, however for industrial systems with large refrigerant charges expert to managed fire and toxicity risk were required. Koyama et al. (2010) carried out drop-in experiments in order to investigate the possibility to introduce R1234ze (E) and its mixture with R32 as low GWP alternatives for vapour compression heat pump/refrigeration systems. The results obtained proved that the heating effect and COP of R1234ze (E) could be improved by adding R32 as the second component into R1234ze (E) and the mixtures found to be strong candidates for replacing R410A in domestic heat pump system. The mixture of 50% R1234ze (E) and R32 produced the COP of about 7.5% lower than that of R410A at the same heating load of 2.8 kW. Pure R1234ze (E) at 1.6 kW produced the COP value of 20% lower than that of R410A at 2.8 kW. Evaporator and condenser sides pressure drops in both HFO-1234ze(E) and its mixture with R32 were almost at the same level as R410A though the refrigerant flow rates were lower, enlargement of diameter of heat transfer tubes and connecting tubes required as compared with the case of R410A. Drop-in replacements of R1234yf and R1234ze to R134a refrigerants were also tested with no performance enhancing modifications to the refrigerators to evaluate energy consumption, results indicates that R1234yf was a suitable drop-in replacement for R134a in domestic refrigeration applications however the lower capacity of R1234ze in domestic refrigerators would need to be addressed therefore R1234ze might not be suitable for drop-in replacement (Karber et al., 2012). Table 1 show low GWP refrigerants for vapour compression cycle.

Tab. 1: Alternative Vapour Compression Refrigerant (Low GWP refrigerants)

S/N	Refrigerant	Chemical formula	ODP	GWP 100 yrs.
1	R1234yf	CH2=CFCF3	0	<4.4
2	R1234ze (E)	CHF=CHCF3	0	6
3	R450A	(R134a/R1234ze commercial mixture)	NA	NA
4	R290	CH3CH2CH3-propane	0	20
5	R600a	CH(CH3)2CH3-isobutane	0	20
6	R744	CO2-carbon dioxide	0	1
7	R717	NH3-ammonia	0	<1

Navarro-Esbrí et al. (2013) did an experimental analysis of a vapour compression system using R1234yf as a drop-in replacement for R134a in vapor compression system. The tests were performed by varying the condensing and evaporating pressure, superheating degree, the compressor speed and the use of IHX. The energetic comparison was performed on the basis of the cooling capacity, volumetric efficiency, compressor power consumption and the COP. The energy performance parameters of R1234yf in a drop-in replacement were close to those obtained with R134a at high condensing temperatures and making use of an IHX. The cooling capacity of R1234yf was 9% lower in an R134a refrigerant facility in the tested range of which difference decreased when the condensing temperature increases and when an IHX was used. The volumetric efficiency was about 5% lower for R1234yf compared with R134a. Also, the compressor volumetric efficiency using R1234yf showed a greater dependence on the compressor speed. The values of the COP obtained using R1234yf were between 5% and 30%

lower than those obtained with R134a. However, when the condensing temperature raises from 313.15 K to 333.15 K the difference decreases from 25% until 8%, even more when using an IHX.

Mota-Babiloni et al. (2014) did energy performance evaluation of two low GWP refrigerants, R1234yf and R1234ze (E) as drop-in replacements for R134a. Tests were carried out in a monitored vapour compression system combining different values of evaporation and condensation temperature without/with the adoption of an internal heat exchanger. The volumetric efficiency, cooling capacity and COP taking R134a as baseline were analyzed with results showed that without IHX the average volumetric efficiency for R1234yf and R1234ze was 4% and 5% lower compared with R134a. The cooling capacity obtained with R1234yf and R1234ze was reduced, with an average difference of 9% and 30% without IHX. Also, COP values were about 7% lower for R1234yf and 6% lower for R1234ze than those obtained using R134a. The use of an internal heat exchanger reduced the COP differences for both replacements as shown in Table 2.

Tab. 2: R1234yf and R1234ze (E) as drop-in replacements for R134a without IHX (Mota-Babiloni et al., 2014)

Refrigerant	Volumetric efficiency	Cooling Capacity	COP
R134a (baseline)	100%	100%	100%
R1234yf	4% lower (96%)	Reduced 9%	7% lower (93%)
R1234ze(E)	5% lower (95%)	Reduced 30%	6% lower (94%)

Mota-Babiloni et al. (2015a) presented a drop-in analysis of an internal heat exchanger (IHX) used in a monitored vapour compression system. They compared R134a and two of its alternatives, R1234ze and R450A (R134a/R1234ze commercial mixture). Study, concluded that IHX produced benefits for all refrigerants tested and could be considered its use for R450A as drop-in or retrofit R134a replacement and new design installations using R1234ze. However, without IHX in an R134a system, alternative R450A would overcome the R134a COP results but for R1234ze more system modifications would be needed. Experimental performance of non-flammable refrigerant R450A (contrary to R1234ze and R1234yf) as R134a replacement in a vapour compression system under a wide range of operating conditions were studied by Mota-Babiloni et al. (2015b) . The cooling capacity of R450A found to be slightly lower than those obtained with R134a (6% lower as average). The COP of R450A found to be 1% average higher than R134a due to compressor power consumption for R450A being much lower than R134a. The IHX affected positively the R450A energy efficiency in a similar proportion to R134a. The discharge temperature of the alternative was found to be lower, 2K as average than of R134a. R450A could be used directly in R134a systems with slightly lower cooling capacity and similar COP, however redesign and optimisation would lead to better energy performance and hence, lower power consumption.

Janković et al. (2015) reported the analysis of R1234yf and R1234ze (E) as drop-in replacements for R134a in a small power refrigeration system. The first analysis was based on equal evaporation and condensation temperatures before and after the refrigerant replacement. The second analysis was carried out for equal cooling medium conditions in the condenser, so that the transport properties and the heat transfer features in the condenser were considered for the three refrigerants. Results showed that different conclusions may be drawn if the drop-in analysis was carried out for equal condensation temperatures or for equal temperatures of the cooling medium in the condenser, as well as that these results were affected by the condenser design. R1234yf was found as an adequate drop-in refrigerant for R134a, but R1234ze (E) may perform better when used an overridden compressor to match the refrigerating system cooling power. Sethi et al. (2016) evaluated the performance of R1234yf and R1234ze (E) in a representative vending machine system and compared against the baseline refrigerant R134a as promising replacements for new small refrigeration systems. In the theoretical analysis, it was estimated that R1234yf has pressures similar to R134a whereas R1234ze (E) has pressures lower than R134a. Based on actual drop-in system testing, it was found that R1234yf shows capacity and efficiency similar to R134a as estimated based on thermodynamic properties. R1234ze (E) was estimated to have about 25% lower capacity. To match the capacity of R134a larger compressor was needed as result lower efficiency observed due to higher pressure drop in the system. R1234yf may show even better performance by using a slightly larger diameter suction line and employing a suction line liquid line heat exchanger in new systems. R1234ze (E) may show performance similar to R134a by use of a compressor with larger displacement, a slightly larger diameter suction line and by increasing the number of refrigerant circuits in the heat exchangers.

Brown et al. (2010) reported thermodynamic properties of eight fluorinated olefins, namely: R-1225ye(E), R-1225ye(Z), R-1225zc, R-1234ye(E), R-1234yf, R-1234ze(E), R-1234ze(Z), and R-1243zf. The group contribution method were used to predict the critical temperatures, critical pressures, critical densities, acentric factors, and ideal gas specific heats at constant pressure. The Peng-Robinson equation of state was used to predict thermodynamic properties and the results were presented in pressure-enthalpy and temperature-entropy state diagrams. Higashi (2010) presented the thermo physical properties of R1234yf and R1234ze (E). He predicted the difficulties of finding the next generation refrigerant from pure substances hinted that, the combination among HFCs, HFOs, and HCs should be expected in the next generation refrigerant. Lai (2014) described the thermodynamic properties of the R1234ze (E) with the molecular based BACKONE and PC-SAFT equations of state (EOS). The investigation indicated that the relative deviations among corresponding cycles' characteristics were mostly within 1% compared with multi-parameter EOSs. Thus, molecular based EOSs could be used in the investigation of a refrigeration cycle in case of no multi-parameter EOS due to the insufficient numbers of accurate experimental data in full fluid region. For the refrigeration cycle using R1234ze (E), R1234yf, R22, R134a, and R32 as refrigerants, R1234ze (E) and R1234yf were reported to be potential alternative refrigerants for the replacement of R134a.

Mota-Babiloni et al. (2015c) reviewed the current status of commercial refrigeration for food freezing and conservation in retail stores and supermarkets as one of the relevant energy consumption sectors. They reported that new GHG regulations impose strong GWP limitations that were going to phase out currently used HFC refrigerants in commercial refrigeration (R404A and R507A). In low charge applications propane, showed a good performance, while low GWP HFC or HFC/HFO mixtures as drop-in or retrofit replacements (with little system modifications), and CO_2 systems in trans-critical systems or at the low-stage of cascade systems were proposed as the different alternatives. Mota-Babiloni et al. (2016) reviewed thermo physical and compatibility properties, heat transfer, pressure drop characteristics and vapour compression system performance of R1234ze (E) HFO refrigerant. Pure R1234ze (E) was found to be a good option only in new HVACR systems. Nevertheless, if it was combined with other refrigerants, the final GWP value was also considerably reduced and maintaining the efficiency parameters at levels that allow them to replace R134a, R404A or R410A in existing systems with minor modifications.

There are importance of proper selection of refrigerant (Calm, 2012). Most refrigerant were selected as per the application, the environmental and physical properties together with performance parameters. Global warming issues suggested to phase out presently most used refrigerant R134a and use natural refrigerants such as ammonia, carbon dioxide and hydro carbons (isobutene R600a and propene R290) in vapour compression refrigeration system for sustainable environment. R1234yf also reported to be a suitable candidate for refrigeration and air conditioning systems. However eco-friendly technologies like thermo-electric, magnetic and adsorption refrigeration will receiving more attention as energy environmental problems keep increasing (Bhatkar et al., 2013)

3. Performance of commercial refrigerants as adsorbate in adsorption refrigeration system

Several researchers have reported the performances of commercial vapour compression refrigerant in adsorption studies. Akkimaradi et al. (2001) presented adsorption isotherms for R134a on activated charcoal, in the temperature range of 273-353 K and pressures up to 0.65 MPa using volumetric method. Experimental isotherm data were obtained for three specimens of activated charcoal (Chemviron, Fluka and Maxsorb Charcoal) adsorbing R134a. A mathematical description of the isotherms was provided by using the D-A equation and the isosteric enthalpy of adsorption evaluated from the transformed isotherm data. Habib et al. (2010) measured adsorption rates of R134a and R507A onto pitch based activated carbon of type Maxsorb III with temperatures varying from 20-60 ^{0}C. The experimental data were found to match fairly with the Fickian diffusion model while the surface diffusions followed the classical Arrhenius trend for both pairs. It was noted that Maxsorb III can adsorb R134a as high as 1.6 kg/kg within an adsorption time interval of 1200 s at an adsorption temperature of 25 ^{0}C, while R507A can adsorb as high as 1.3 kg/kg within an adsorption time interval of 1100 s at adsorption temperature of 20 ^{0}C.

Askalany et al. (2013a) designed and built an adsorption cooling system using granular activated carbon GAC-R134a pair. The theoretical mathematical model results presented good agreements with experimental results. COP was theoretical 0.35 at 373 K driving temperature and 293 K evaporator temperature. The system operated between the pressures of 3.3 bar and 7 bar where the difference in the adsorption uptake reached up to 0.3 kg/kg and time of the intermittent cycle of about 900 s. The experimental SCE was up to 70 kJ/kg, while the theoretical SCE was 83 kJ/kg at 373 K driving temperature and 295 K evaporator temperature. SCE and COP was increased by raising the driving or evaporator temperatures. Increase of cycle time increased COP and SCE at constant evaporator temperature and decreased COP and SCE at constant driving temperature. Attalla et al. (2014) investigated experimentally the adsorption capacity of R134a on a GAC for adsorption/desorption process. The bed was designed and built with finned tubes heat exchanger to increase the heat transfer area. The experiments were conducted over a temperature range from 20 ºC to 60 ºC and pressure up to 10 bars. The data were correlated with D–A equation corresponding to adsorption/desorption process. The maximum adsorption capacity uptake found to be 1.92 kg/kg at 20 ºC after 1200 s, later Attalla and Sadek (2014) found the isosteric heat of adsorption which varied from 120 to 340 kJ/kg for adsorption capacities ranging from 0.2 to 1.8 kg/kg-adsorbent. AquaSorb 2000-R407C pair was tested over a temperature range of 25-75 ^{0}C, maximum adsorption capacity of 0.43 kg·kg-1 of adsorbent was obtained (El-Sharkawy et al., 2016).

Askalany et al. (2013b) reported adsorption isotherms for refrigerant R32 on activated carbon powder (ACP) and fiber (ACF) forms over the range of 25-75^{0}C and pressures up to 1400 kPa, measured using constant volume apparatus. The data were correlated by Toth and Dubinin-Astakhov with the adsorbed phase volume correction isotherm models. Adsorption parameters were evaluated from the least-squares fit of experimental data, whereas the D-A equation with volume correction fitted the data better. The uptake and pressure dependence of the isosteric heat of adsorption was extracted from the D-A equation using the Clapeyron equation. ACP observed to have better adsorption than ACF. Adsorption isotherms and kinetics of R410A onto ACP (Maxsorb III) and ACF (A-20) studied by Askalany et al. (2014), the maximum adsorption capacity of the ACP was found to be 1.6 times higher than that of ACF at same adsorption temperature. Both investigated adsorption isotherms (Tóth and D-A) models and kinetics (LDF) models have been found to fit the experimental data within ±5% deviations. D-A equation was used to determine the isosteric heat of adsorption pairs. Adsorption isotherms and kinetics were also investigated experimentally and theoretically over a temperature range of 25-75 0C for Maxsorb III-R152a and AquaSorb 2000-R404A pairs (Ghazy et al., 2016a; Ghazy et al., 2016c). Table 3 shows the commercial vapour compression refrigerant reported on adsorption studies.

Tab. 3: Commercial Vapour Compression Refrigerants used in Adsorption Research

S/N	Refrigerant	Chemical formula	Adsorption capacity kg/kg	ODP	GWP 100 yrs. (CO_2 =1)
1	R134a	CH2FCF3	1.6-2.0 with ACP	0	1,370

3	R404A	R-125/143a/134a (44.0/52.0/4.0)	0.52 with AquaSorb 2000	0	3,700
4	R507A	R-125/143a (50.0/50.0)	1.3 with ACP	0	3,800
5	R410A	R-32/125 (50.0/50.0)	NA	0	2,100
6	R152a	CH3CHF2	1.3 with ACP	0	133
7	R407C	R-32/125/134a (23.0/25.0/52.0)	0.43 with AquaSorb 2000	0	1,700

Askalany and Saha (2015) investigated experimentally and theoretically the adsorption kinetics of Difluoromethane (R32) onto activated carbon powder (Maxsorb III) and activated carbon fiber (A-20) at various adsorption temperatures ranging from 25-65 ^{0}C. Two commonly used theoretical models (LDF and FD) fitted experimental data well within ±5% error. Jribi et al. (2013) reported a transient mathematical model of a 4-bed adsorption chiller using Maxsorb III as the adsorbent and low GWP refrigerant R1234ze (E). The performance of

the cyclic-steady state of the system for different heating and cooling water inlet temperatures presented. With 80 kg of Maxsorb III the chiller produced 2 kW of cooling power at driving heat source temperature of 85 ^{0}C along with a cooling temperature of 30 ^{0}C, the performance which compared slightly higher than that of the Maxsorb III-R134a based adsorption cooling cycle. Consequently propose R1234ze (E) as potential replacement of R134a based adsorption cooling system. Ghazy et al. (2016d) reported adsorption isotherms and kinetics of HFC-152a onto activated carbon of type Maxsorb III over a temperature range of (25 to 75) ^{0}C. The D-A and Toth equations were used to correlate the adsorption isotherms with D-A found to be more suitable. Maxsorb III adsorbed up to 1.3 kg of HFC-152a per kg of adsorbent. Adsorption kinetics data were correlated using LDF and FD models and isosteric heat of adsorption was estimated. Activated carbon/CO_2 pair reported to show the maximum COP of 0.16 for evaporation and desorption temperatures of 15ºC and 80ºC (Jribi et al., 2010).

Ghazy et al. (2016b) investigated experimentally and theoretically over a temperature range of 25-75 ^{0}C adsorption isotherms and kinetics of AquaSorb 2000-R404A pair. D-A and Tóth equations were used to fit equilibrium uptake while adsorption kinetics was correlated using LDF and FD models. The experimental maximum adsorption capacity of AquaSorb 2000-R404A pair was about 0.52 kg/kg. The activation energy and the pre-exponential coefficient were estimated to be 10488.49 J/mol and 1.11 respectively. Using the Clausius-Clapeyron equation, Isosteric heat of adsorption found to vary from 145 to 330 kJ/kg depending on the adsorbate loading. Both LDF and FD models found suitable to simulate the adsorption kinetics of AquaSorb 2000-R404A with an acceptable error of ±5%. The D-A equation was used to fit the P-T-C diagram of AquaSorb 2000-R404A.

Classical pairs which includes activated carbon-methanol, activated carbon-ethanol, activated carbon-ammonia, silica gel-water and zeolite-water reported to have the maximum adsorption capacity of 0.259 kg/kg-adsorbent which occurs on activated carbon-methanol pair, while the commercial refrigerant R134a presented maximum adsorption capacity of 2 kg/kg-adsorbent with activated carbon adsorbent (Shmroukh et al., 2015). The application of commercial refrigerants as adsorbates will positively contribute to adsorption refrigeration systems as it will add the availability of the adsorbate, reduce the problems associated with material compatibility like on ammonia with copper and reduced leakage problems associated with the negative pressure systems (Zhong et al., 2006). These adsorption refrigeration systems have good potential for off grid applications in developing countries with abundant availability of solar energy including food preservation, vaccine and medicine storages.

4. Conclusions

The potential for adsorption refrigeration system using the commercial refrigerants is evident. The maximum adsorption capacity for the classical working pairs (activated carbon-methanol, activated carbon-ethanol, activated carbon-ammonia, silica gel-water and zeolite-water) of 0.259 kg/kg which appeared for activated carbon-methanol is small compared to adsorption capacity of 2 kg/kg-adsorbent which appeared for modern adsorption working pair of activated carbon-R134a (Shmroukh et al., 2015).

Commercial refrigerants such as R134a, R32, R404A, R507A, R410A, R152a and R407C have been studied as the potential adsorbates for adsorption cooling systems or for mixture separation in the blended refrigerant (Akkimaradi et al., 2001; Askalany and Saha, 2015; Askalany et al., 2013a; Askalany et al., 2014; Askalany et al., 2013b; Attalla and Sadek, 2014; Ghazy et al., 2016b; Ghazy et al., 2016d; Habib et al., 2010). Though they have shown the positive adsorption capacity with various type of activated carbon adsorbents, they also possess high GWP values (Calm and Hourahan, 2007).

Several refrigerants including R1234yf, R1234ze (E), R450A, R290, R600a, R744 and R717, have been proposed to be possible alternatives or drop in replacement of commercial high GWP refrigerants in vapour compression cycles (Bhatkar et al., 2013; Brown et al., 2010; Higashi, 2010; Koyama et al., 2010; Lai, 2014; Mota-Babiloni et al., 2015a, 2015b; Mota-Babiloni et al., 2015c; Navarro-Esbrí et al., 2013; Sethi et al., 2016). These refrigerant could be the good alternative for adsorption pairs for solar adsorption refrigeration system. And therefore increase the availability and options for the adsorption refrigerants, reduced scale of problem associated with material compatibility as is there ammonia system and copper, positive pressure system therefore avoiding the leakage problem associated with the vacuum systems.

Besides the adsorption properties, it is also important to understand the kinetics of these adsorption pairs before

the conclusions of best adsorption pairs as the kinetics data are essential and useful in designing adsorption refrigeration systems.

Abstract

With the increased emphasis on building energy-saving in China, solar heating and cooling (SHC) has become one of the best promised technologies to achieve ultra-low energy consumption. To achieve improved economy performance, enhancing energy system efficiency, SHC system requires scientific calculation and analysis according the architectural features. In this paper, building and system models have been established for hourly simulation of energy consumption. The deviation of tested and simulated solar fraction and system COP is about 5%. It indicates the system model established in this paper is accurate enough for design and optimization of SHC systems. With verified models, SHC system has been optimized considering the solar contribution and economy index. Results show that, after the system scheme and configuration optimization, SHC system applied in office building in Turpan can be achieved in the solar contribution of more than 30%. Meanwhile, the payback period could be reduced to less than 20 years.

Keywords: solar heating and cooling, solar contribution, system design and optimization, payback period

1. Introduction

With the increased emphasis on building energy-saving in China, the limit of building energy consumption is stricter than ever. Nearly zero energy building, passive building has become a new trend (Xu et al. 2016). As the energy consumption for space heating and cooling accounts for a large part of the building energy consumption, solar heating and cooling (SHC) has become one of the best promised technologies to achieve ultra-low energy consumption.

After years of development, SHC technology has made great progress in the technical maturity and practical application. However, SHC system has not been promoted widely because its high initial cost and low efficiency. Sarabia et al. (2011) proposed a design method for solar cooling systems with single effect absorption cooling machine directly coupled to a solar collector field, then analyzed the feasibility of the system in 12 Spanish Cities. Syed et al. (2005) designed a solar cooling system for residential buildings in Madrid. And the test results showed that the average coefficient of performance is around 0.6. Mateus et al. (2009) investigated solar absorption cooling and heating system in different building types and climates. With TRNSYS software, contributions of SHC system in building energy-saving had been analyzed. Li Z. et al. (2000, 2001) proposed a solar absorption cooling system with a layered heat storage tank, and the system was optimized and applied in Hong Kong.

To achieve improved economy, enhancing energy system efficiency, SHC system requires scientific calculation and analysis according the architectural features. In this paper, building and system models have been established for hourly simulation of energy consumption. With verified models, SHC system has been optimized considering the solar contribution and economy index.

2. Method

2.1. Contribution rates

Similar to solar fraction, contribution rates of solar heating and cooling systems in building energy-saving means the proportion of building heating and cooling demands meet by solar energy. The calculation method is as follows:

$$f_s = \frac{E}{Q} \qquad \text{(eq. 1)}$$

Where, f_s is the contribution rates in building energy-saving; E is building heating and cooling demands meet by solar energy; Q is total heating and cooling demands.

2.2. Optimization method

Contribution rate of SHC systems is affected by many factors. To achieve an optimal contribution rate, building and system models have been established first. Then hourly energy consumption and system performance have been simulated. During the simulation, Effects of climate, building type, and SHC system type have been considered, as shown in Fig. 1. With simulation results, the system contribution rates in building energy-saving could be determine considering following key indicators:

- *Indoor temperature*, *heating and cooling capacity*: the indoor temperature, system heating and cooling capacity have to meet the design requirements;
- *Energy saving*: reduction rate of primary energy consumption as the main index;
- *Economy*: payback period as the main index.

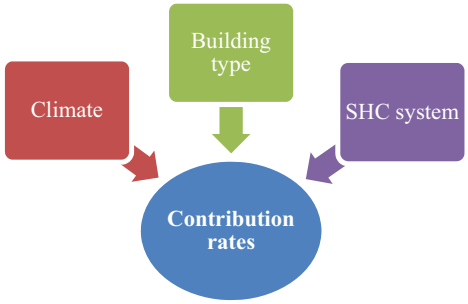

Fig. 1: Affect factors on contribution rate

3. Modeling

3.1. Building model

An office building model and an inpatient building model have been established to analyze the heat and cooling demands in different building types. Construction dimensions of both models are determined according to the design drawings of actual buildings. Building envelope conditions meet requirements of the *Design standard for energy efficiency of public buildings* (GB 50189-2015) in China. Operation time of the office building and inpatient building is different: the office building is used from 08:00 to 18:00 during workdays while the inpatient building is used 24 hours all year round.

As the actual buildings is still under construction, another office building is selected and modeled to verify the building and system models. Brief information of three buildings are shown in Tab. 1.

To analyze the effect of climates on contribution rates, heating and cooling loads of both office building and inpatient building have been calculated according the climates of different locations, results shown in Tab. 2.

Tab. 1: Building Information

Building	Height	Floors	Gross floor area (m^2)
office building	18.6 m	4 floors above ground 1 floor under ground	6144
inpatient building	24.9 m	6 floors above ground	5904
office building for validation	11.8 m	2 floors above ground	1850

Tab. 2: Heating and cooling loads of the office building and inpatient building in different locations

Location	Building	Cooling		Heating	
		Load (kW)	Annual demand (MJ)	Load (kW)	Annual demand (MJ)
Beijing (Northeast China)	office building	512	254,715	580	93,340
	inpatient building	504	348,776	456	146,808
Turpan (Northwest China)	office building	644	274,512	494	110,243
	inpatient building	625	374,172	381	141,172

3.2. System description

Based on investigation and analysis of practical projects, three types of SHC systems are summarized and compared with the conventional system. The SHC systems and conventional system are listed in Tab. 3.

Tab. 3: The SHC systems and conventional system

System			Heating and Cooling Souce
SHC systems	System I：Solar absorption cooling + Water cooled chiller + Gas boiler	Cooling	Solar collectors＋WFC + Water cooled chiller
		Heating	Solar collectors＋Gas boiler
	System II：Solar absorption cooling+ WSHP + Gas boiler	Cooling	Solar collectors＋WFC＋WSHP
		Heating	Solar collectors＋WSHP＋Gas boiler
	System III: Optimized SHC system	Cooling	Solar collectors＋WFC＋WSHP
		Heating	Solar collectors＋WSHP＋Gas boiler
Conventional system	Water cooled chiller + Gas boiler	Cooling	Water cooled chiller
		Heating	Gas boiler

WFC: Hot water fired absorption chiller WSHP: Water source heat pump

System I: Solar absorption cooling + Water cooled chiller + Gas boiler

The main components of this system include the Solar collectors, an Hot water fired absorption chiller (WFC), a Heat storage tank, Cooling towers, a Gas boiler and a Water cooled chiller for summer cooling. The system schematic is showed in Fig. 2.

Cooling mode:

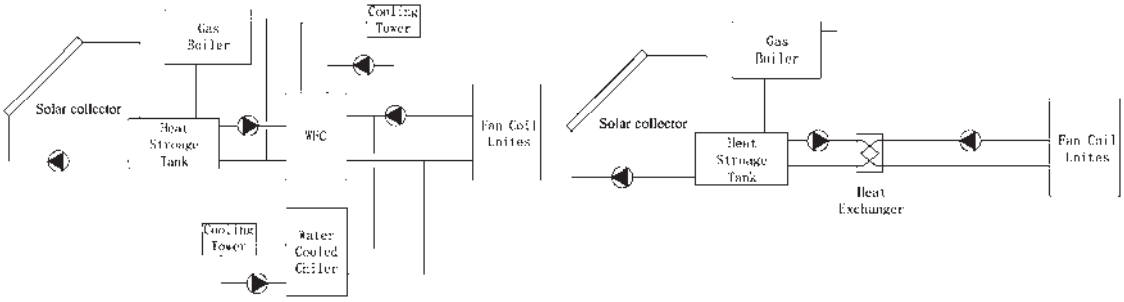
1. When the heat storage tank temperature is higher than the set point, WFC is used in priority to meet the cooling demand. When WFC cooling capacity can not meet the cooling demand, Water cooled chiller starts.

2. If the heat storage tank temperature is below the set point, Water cooled chiller is used to meet the cooling demand.

Heating mode:

1. If the heat storage tank temperature is higher than the heating requirement in winter, heating demand is satisfied directly by solar.

2. If the heat storage tank temperature is lower than the requirement, Gas boiler starts to satisfy the heating demand.

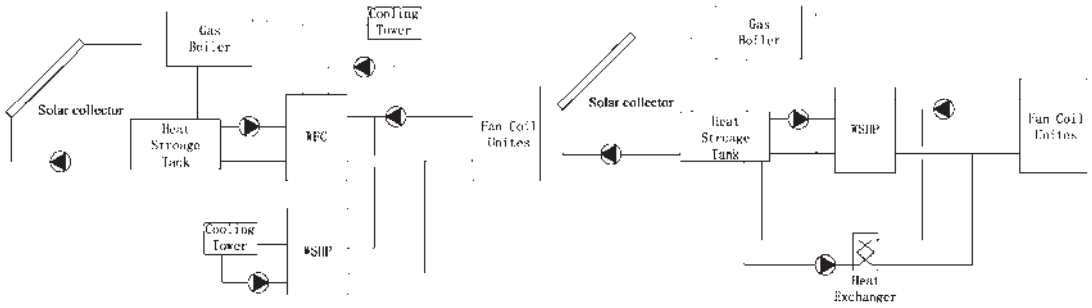


(a) cooling mode (b) heating mode

Fig. 2: Schematic of System I

System II: Solar absorption cooling+ WSHP + Gas boiler

The main components of this system include the Solar collectors, an Hot water fired absorption chiller (WFC), a Heat storage tank, Cooling towers, a Gas boiler and a Water source heat pump (WSHP) for both heating and cooling. The system schematic is showed in Fig. 3.



(a) cooling mode (b) heating mode

Fig. 3: Schematic of System II

Cooling mode:

1. When the heat storage tank temperature is higher than the set point, WFC is used in priority to meet the cooling demand. When WFC cooling capacity can not meet the cooling demand, WSHP starts.

2. If the heat storage tank temperature is below the set point, WSHP is used to meet the cooling demand.

Heating mode:

1. If the heat storage tank temperature is higher than the heating requirement in winter, heating demand is

satisfied directly by solar.

2. If the heat storage tank temperature is lower than the requirement, but higher than WSHP's requirement, WSHP starts to satisfy the heating demand.

3. System could also provide heating by Gas boiled directly.

Main difference between System I and System II is that the WSHP could provide heating by lower temperature water. Solar contribution rate could be increased in winter.

System III: Optimized SHC system

The main components of this system is same as System II. Main difference between System III and System II is that the heating capacity of WSHP can fully satisfy the heating load, but the cooling capacity is not required to meet the cooling load. So, the system could use a WSHP with lower volume to improve the economy indexes.

When cooling in summer, if the heat storage tank temperature is below the set point, WSHP co-works with WFC to meet the cooling demand.

3.3. System model

With TRNSYS software, all systems have been modeled and simulated based on typical meteorological year (TMY) weather data and building data of both Beijing and Turpan. The TRNSYS model of System I is shown in Fig. 4. The TRNSYS model of System II & System III is shown in Fig. 5.

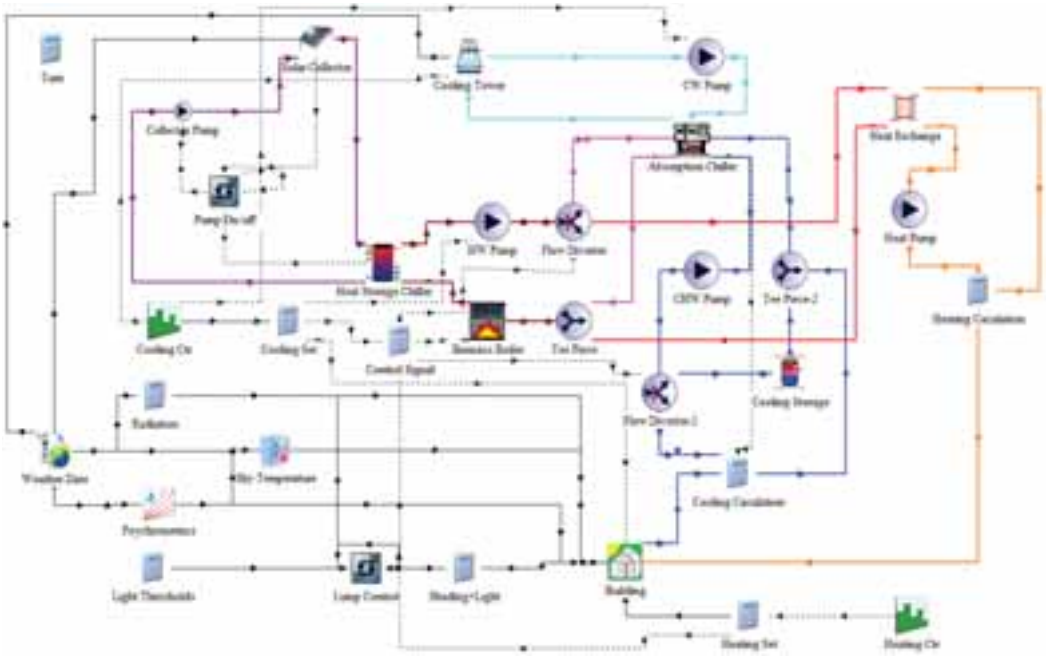


Fig. 4: The TRNSYS model of System I

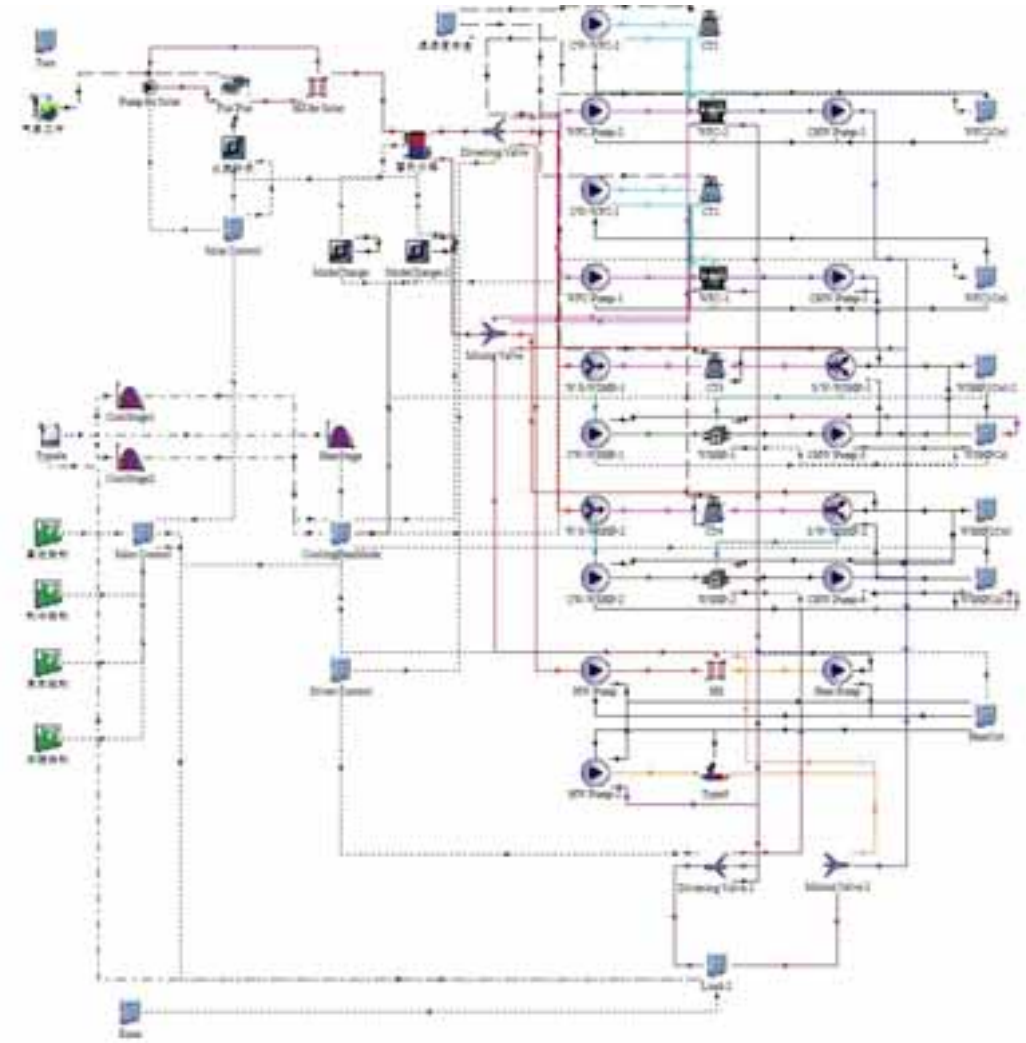

Fig. 5: The TRNSYS model of System II & System III

4. Model Validation

In this study, an office building with SHC system in Beijing is selected and modelled. Simulated and measured results are compared to verify the system model.

This two floors office building is located in Beijing, China. The SHC system applied for space cooling and heating is same as System I. Building and system information is published in previous study (He et al. 2014). The system had been tested during the summer of 2013 by China Academy of Building Research. There were 4 days selected to test the system performance under typical weathers. The solar irradiation levels of the 4 days were respectively very good, good, medium and poor.

To verify the system model, measured data of environmental parameters was integrated into the weather data of TRNSYS model of System I. Then Several operating data, such as tank temperature, flow rate, had been used to set the initial simulate conditions. Tested COP and solar fraction were compared with simulated results, as shown in Fig. 6.

Comparison of tested and simulated results show that the deviation of tested and simulated solar fraction and system COP is about 5%. It shows that the system model is accurate enough to caculate system performance.

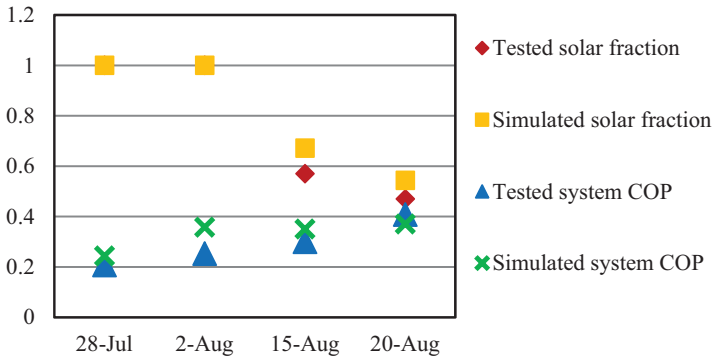

Fig. 6: Comparison of tested and simulated results

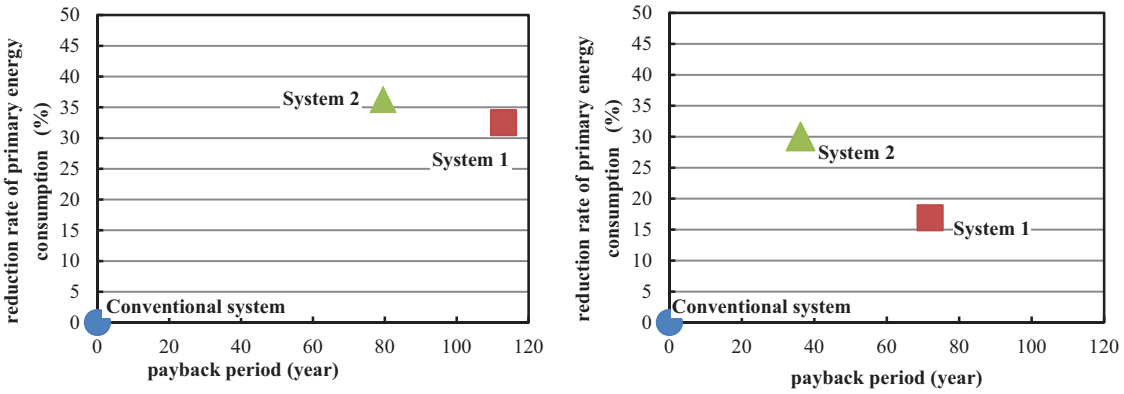
5. Optimization

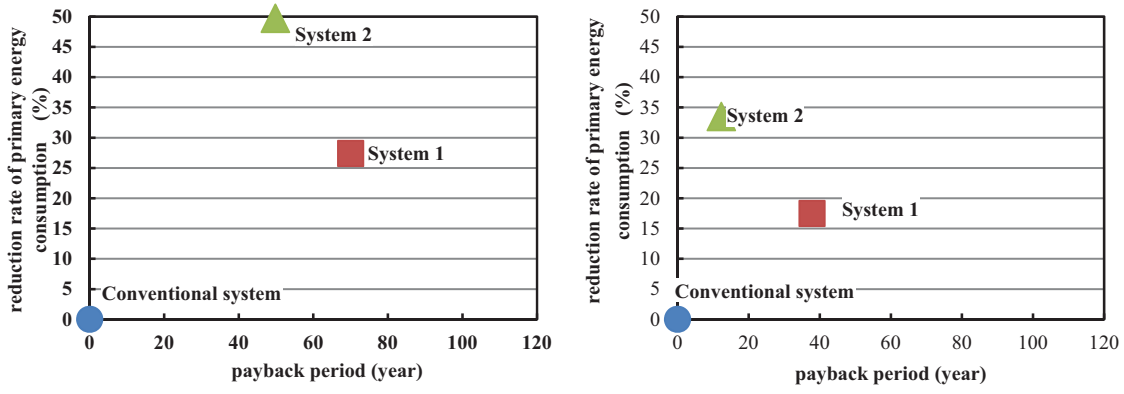
5.1. Simulation results

In this study, Solar contribution rates of System I and System II applied in different building types and climates have been simulated separately. Results is shown in Fig. 7 to Fig. 8.



(a) Turpan (Northwest China) (b) Beijing(Northeast China)

Fig. 7: Simulated results of System I and System II in office building



(a) Turpan (Northwest China) (b) Beijing(Northeast China)

Fig. 8: Simulated results of System I and System II in inpatient building

Results shows that the reduction rate of primary energy consumption of System II is larger than 30% in all buildings. In the inpatient building, the primary energy consumption could be reduced by 50%. It indicates the

SHC system has significant effect in energy-saving. But nearly all payback periods are more than 30 years, except the System II applied in inpatient building in Beijing. These unacceptable payback periods show the optimization of SHC system needs to focus on enhancing the economic performances.

5.2. System optimization

Based on System II, System III is proposed to improve the economic performances of SHC systems. Compared with System II the optimization includes:

- The heating capacity of WSHP can fully satisfy the heating load, but the cooling capacity is not required to meet the cooling load. The system could use a WSHP with lower volume to reduce initial cost.
- When cooling in summer, if the heat storage tank temperature is below the set point, WSHP co-works with WFC to meet the cooling demand.
- Increasing system scale, solar contribution rate of solar district heating and cooling system in regional heating and cooling has been simulated.

Tab. 4 shows the simulated results of System III applied in a district heating and cooling project in Turpan. The simulated results indicates that the economic performance of System III has been improved while the energy-saving effect is still significant (Reduction of primary energy consumption is more than 30%). After system optimization, the contribution rate of System III in energy-saving is about 36.8%.

Tab. 4: Simulated results of System III applied in a district heating and cooling project in Turpan

		System III	Conventional system
Summer	Cooling capacity (kW)	4269.4	4357
	Heat gain by collectors (MJ)	6.75E+06	0
	Cooling load (MJ)	1.21E+07	1.21E+07
	Solar contribution	40%	0%
Winter	Heat gain by collectors (MJ)	3.38E+06	0.00
	Heating load (MJ)	1.02E+07	1.02E+07
	Solar contribution	33%	0%
Electricity (kW/h)		**841431**	**1173764**
Gas consumption (m^3)		**206015**	**308216**
Reduction rate of primary energy consumption		**30.8%**	**-**

6. Conclusion

With the increased emphasis on building energy-saving in China, solar heating and cooling (SHC) has become one of the best promised technologies to achieve ultra-low energy consumption. To achieve improved economy, enhancing energy system efficiency, SHC system requires scientific calculation and analysis according the architectural features.

In this paper, building and system models have been established to simulate the contribution rate of different SHC systems in energy-saving. Effects of climate, building type, and SHC system type have been considered during simulation. Results show that:

- The deviation of tested and simulated solar fraction and system COP is about 5%. The system model

established in this paper is accurate enough for design and optimization of SHC systems.

- Traditional SHC system has significant effect in energy-saving, but the economic performance needs to be enhanced.
- After the system scheme and configuration optimization, SHC system applied in office building in Turpan can be achieved in the solar contribution of more than 30%. Meanwhile, the payback period could be reduced to less than 20 years.

Abstract

The current paper presents a case study of a PV-driven air-conditioning system with battery and latent heat storage applied for an off-grid resort in Bintan (Indonesia). The lead-acid battery bank has a nominal energy storage capacity of 47 kWh and the ice storage can store up to 92 kWh latent heat. The entire energy system of the resort was equipped with a comprehensive real-time data acquisition system to measure different parameters such as solar irradiation, temperatures, flow rates and power consumptions. More than 100 parameters are transferred minutely and monitored remotely across country borders. A TRNSYS model has also been developed to simulate the case study system dynamically. To assure accurate simulation results, the chiller and the Thermal Energy Storage (TES) models were calibrated using measured data from the monitoring system. Initial simulation results show the usage of the energy storages. The battery is utilised as a buffer to run the chillers with least disruptions and the TES is used to shift the cold generated during daytime to cool bedrooms at nighttime. The later one can also serve as a short-term energy storage over a few rainy days. For future works, we propose a comparative study of chilled water, ice and battery storage to design an optimal energy storage system for the resort based on the insights provided by this case study.

Keywords: Solar air-conditioning, PV-driven cooling, energy storage solutions, off-grid

1. Introduction

At present, a significant reduction in PV module costs pares the broader integration of PV systems. Hence, PV-driven cooling systems have gained attention. Compared to solar thermally driven cooling systems, at present PV-driven cooling systems' footprint is lower (Otanicar et al., 2012; Noro et al., 2014; Eicker et al., 2014) and they are economically more favorable (Otanicar et al., 2012; Noro et al., 2014; Eicker et al., 2014). The primary driver for the superior results of PV-driven cooling is the substantial decrease in PV costs and the higher Coefficient of Performance (COP) (Otanicar et al., 2012; Noro et al., 2014). Furthermore, the individual components are well-known, and the solution is flexible, which has the potential to improve situations in off-grid areas where grid-connections are not viable so far (Wang and Ge, 2016). However, there are challenges, since the PV power output does not match cooling demand, as the first depends on the solar irradiation whereas the second is also influenced by the ambient temperature and the occupancy. Thus, energy storage is required to buffer the imbalance between power demand and supply.

In the tropics, load-shifting is required to buffer energy and shift it from daytime to nighttime; occasionally also over a few rainy or cloudy days. Typically, battery storage technologies are considered for this energy storage duration of solar energy in an off-grid system (Merei et al., 2013; Eltawil, 2007). Looking at the Southeast Asian region in particular, a significant part of the energy consumption in buildings accounts for air-conditioning. This is a thermal load that allows for Thermal Energy Storage (TES). There are different TES solutions for cooling applications. Sensible energy storage is the most commonly realised in the form of chilled water (Arteconi et al., 2017). On district cooling scale or in large-scale office buildings also latent heat storage in the form of ice is common practice (Sehar et at., 2012; Chan et al. 20016). Other Phase Change Materials (PCM) have been commercialised and are investigated for application in TES systems (Souayfane et al., 2016; Ewert, 2000; Foster, 2017).

In grid-connected systems, the effective utilization of an energy storage such as a chilled water tank depends on the economic viability, i.e., increase the self-consumption of solar energy instead of selling it to the grid for a lower price

doi:10.18086/swc.2017.28.14 Available at http://proceedings.ises.org

(Arteconi et al., 2017). However, in an off-grid environment, energy storage is a necessity. An off-grid PV-driven cooling system can be configured as shown in Figure 1. Energy generated by a PV system is often stored directly via a battery. However, it is also possible to store the cold produced by the chiller via TES.

A prototype of such a system using latent heat and battery storage is installed at the LooLa resort in the rural and remote south-east of Bintan Island (Pulau Bintan) in the Riau Archipelago of Indonesia. The resort focusses on environmental and sustainable aspects as well as empowering their local staff and it is not connected to the public grid. The Solar Energy Research Institute of Singapore (SERIS) was selected as an R&D partner to monitor the existent prototype to optimise its performance and use it as a starting point for further investigation and research.

The objective of the present case study is to gain insights regarding operational and energy performance. It prepares a comparative study of different energy storage for the PV-driven cooling system at the resort. Therefore, the existing system is described, equipped with a monitoring system and dynamically modelled. Preliminary results are shown and research opportunities are discussed to round the study off.

2. Case study description

The LooLa eco-resort has two villas offering higher-class hotel rooms with air-conditioning at night. To demonstrate sustainable technologies, a prototype of a PV-driven air-conditioning system was implemented in each of the villas. Additionally, a diesel generator is operated during nighttime to augment the power requirement in the resort. There is no public electricity grid access available in this part of Bintan. The main components of the PV powered air-conditioning system are electrical in nature including the PV system, the diesel generator and the chillers. It is only after the chillers that there is the switch to a thermal energy system as shown in Fig. 2.

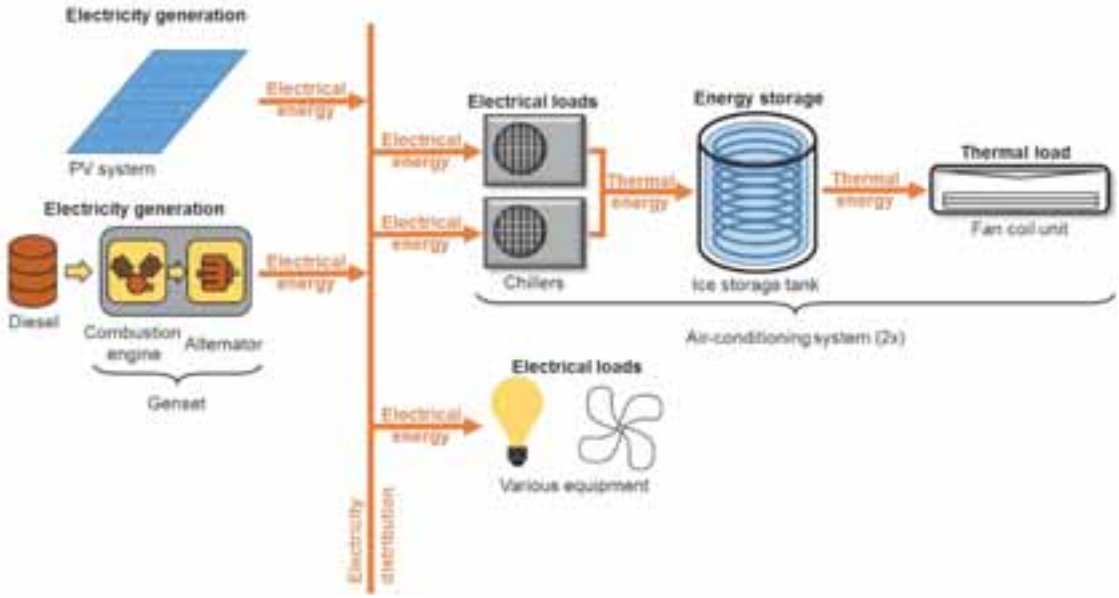

Fig. 2: Schematic of the energy system of the resort. On the left side PV system and diesel generator supply electricity to the distribution network. On the right side, both electrical and thermal loads are shown.

The PV system consists of different components – PV modules, PV inverters, batteries and battery inverters. During

daytime, it powers the air-conditioning systems for storing solar energy in the form of ice and supplies power for the shop, kitchen and office. The space cooling is scheduled to operate only during nighttime by discharging the thermal energy from the ice storage tank. To maintain the set point (room) temperature, FCUs supply cold air utilizing the latent energy from the ice storage tank without the need of operating the energy-intensive chillers. From 5.00PM to 8.00AM, the diesel generator supplies electricity for the entire resort. The switching of power sources is not automated, but manually conducted. An overview of the systems' and components' specifications is provided in Table 1.

Tab. 1: System and components specifications of the energy system at the LooLa resort

System	Component	Quantity	Specifications
PV system	PV module	72	Chinaland Solar Energy CHN240-60P; module power 240 W_p; multicrystalline silicon cells; 6 strings each having 12 modules; system power 17.3 kW_p
	Battery	48	RITAR OPzV2-490; tubular plate VRLA gel battery; capacity 490Ah
	PV inverter	3	SMA Sunny Boy 5000TL; rated AC power 4600 W
	Battery inverter	2	SMA Sunny Island 6.0H; rated AC power 4600 W; battery depth of discharge 50%
Diesel generator	Diesel Generator	1	Power 30 kVA
Two air-conditioning systems	Condensing unit	4 (2 per system)	Tecumseh FHT4525YHR; cooling capacity 2.4 kW and Power consumption 1.5 kW at 32 °C ambient temperature and -15 °C evaporation temperature; refrigerant R134a
	Evaporator (Heat exchanger)	4 (2 per system)	Gimleo GBH05-CMF; tube in shell heat exchanger; cooling capacity 9.5 kW
	Ice storage tank	2 (1 per system)	Customized design (cuboid shape); volume 1045 l; fiberglass; copper pipe; 15 cm Polyurethane foam insulation
	Water tank	2 (1 per system)	Guangdong LuckingStar New Energy LWT300-T&H-02; volume 300 l; stainless steel
	Fan coil unit small	6 (3 per system)	Eurostars 300WM2; cooling capacity 2.9 kW (max); power consumption 52 W
	Fan coil unit big	2 (1 per system)	Eurostars 400WM2; cooling capacity 3.7 kW (max); power consumption 62 W

2.1. Air-conditioning system design and operation

In order to understand the air-conditioning system design and operation, we look at a single air-conditioning system. The top part of Fig. 3 shows a simplified schematic focusing on the heat exchangers and fluid circuits. This schematic includes only one chiller, whereas the real system has two chillers. Therefore, the bottom part of Fig.3 provides a complementary Piping & Instrumentation (P&I) diagram for deeper understanding of the actual design. The top and the bottom part of Fig. 3 are linked in terms of color coding of key components.

At daytime, the chillers (conventional vapor-compression systems consisting of compressor, condenser, evaporator, expansion valve and refrigerant) operate at an evaporation temperature of below 0 °C. The chiller refrigerant exchanges heat to the ethylene glycol based water solution (glycol) in the evaporator. The glycol flows through the left side of the circuit in order to exchange heat with the water in the ice storage tank. The process is carried out through a tube and shell heat exchanger. Since the temperature of the glycol is below 0 °C, ice is generated in the storage tank. The ice storage is charged and the thermal energy is stored as latent heat.

During nighttime, the glycol exchanges heat with the ice in order to cool the water in the water tank to ~17 °C temperature. The chilled water from the water tank is pumped through the fan coil units that blow the cool air out, providing thermal comfort in the sleeping areas. The air-conditioning operation causes melting of the ice, i.e., discharging of the thermal energy storage.

On a sunny day, the condenser units and the auxiliary equipment run on the PV system for 8 hours, from 8AM to 4PM. In case of heavy rains and prolonged presence of clouds, the PV system is disconnected manually at the discretion of the operators, which means that there is no electricity available in the resort at that time. The loads are then manually reconnected to the PV system when the weather changes to more favorable conditions. This procedure is conducted to keep some buffer storage in the batteries. If there is not enough cooling energy stored in the thermal energy storage on a cloudy or rainy day, the chillers are powered by the batteries of the PV system until they are completely discharged. At night, the auxiliary power for devices such as pumps, valves and FCUs are sourced from the diesel generator.

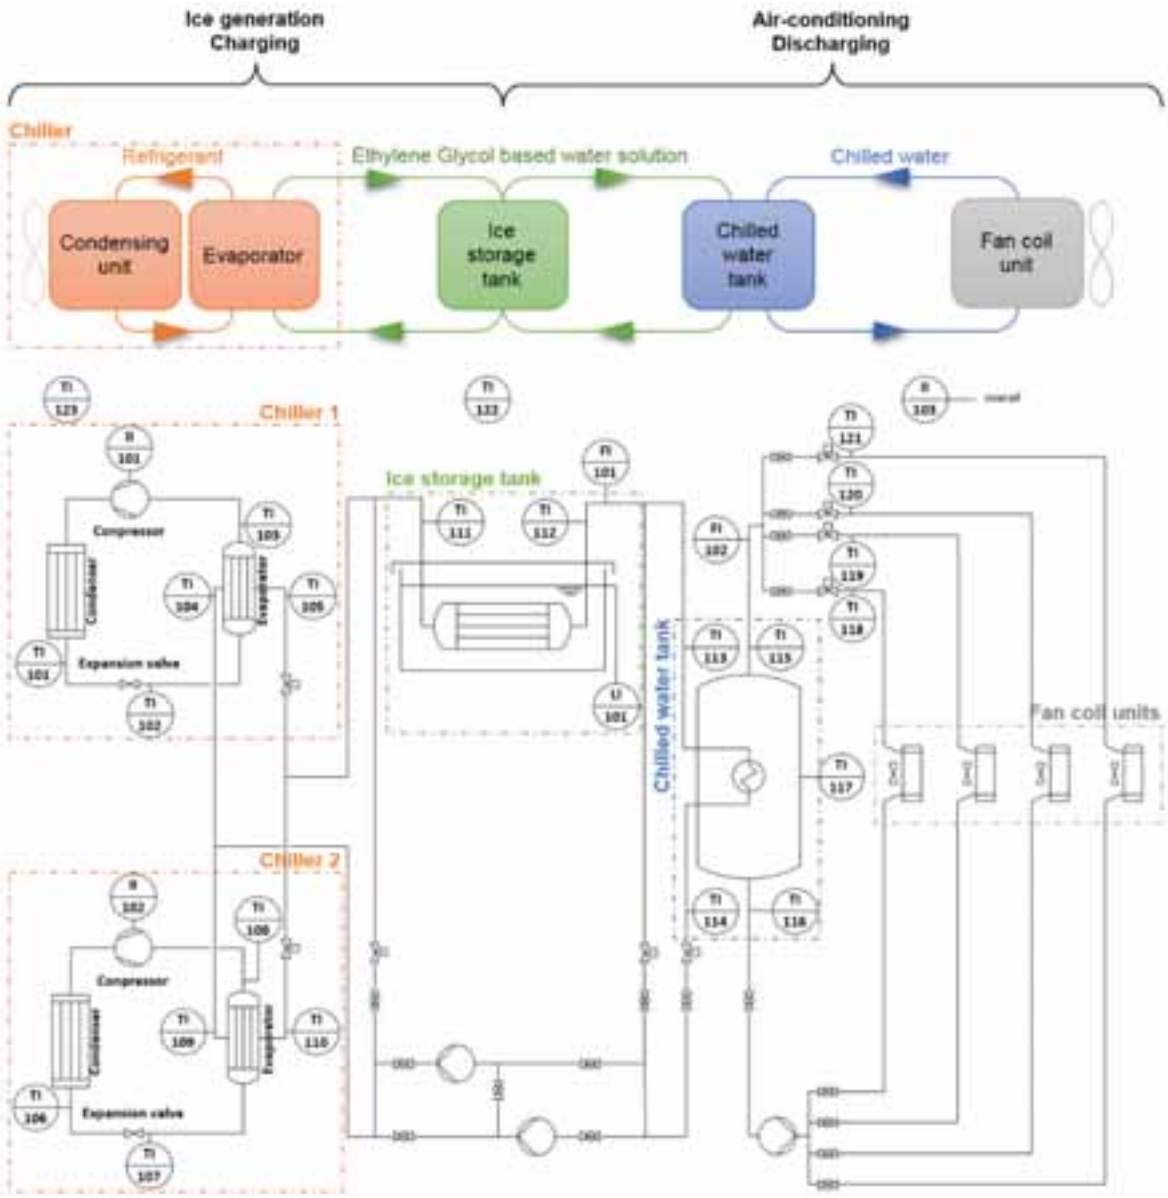

Fig. 3: Simplified schematic diagram describes the operation process of an air-conditioning system with thermal energy storage (top); Piping and Instrumentation diagram of a single air-conditioning system to show the sensor positions: temperature indicator (TI), flow indicator (FI), level indicator (LI), power indicator (II) (bottom)

3. Monitoring system

The prototypes of the PV-driven cooling systems enable the LooLa resort to provide air-conditioning to the clients

staying in the villas in an ecological way. However, the assessment of the performance was not possible due to insufficient data acquisition. Therefore, deployment of a monitoring system was the consequence. The developed monitoring architecture acquires sensor data throughout the entire resort. Three remote stations were deployed, one for each air-conditioning system and one that acquires PV system and diesel generator data. The top part of Fig. 4 shows the monitoring system architecture. On the field level, the relevant heat flows, components' performances/statuses and power consumptions need to be identified. Therefore, the ultrasonic flowmeters, ultrasonic level sensors for the ice storage tanks, temperature sensors and a silicon irradiance sensor are required for the PV and the cooling system. The sensors are hardwired to National Instruments (NI) CompactRIO controllers (cRIO), which are part of the control level. The remote stations consist of a cRIO, an Ethernet switch and a router. The bottom part of Fig. 4 provides a photo of one remote station and its components. They are lightning protected and backed-up through an uninterruptible power supply. The three cRIOs are capable of processing the acquired parameters remotely and fully automated. The LabVIEW software is capable to acquire the data from all the sensors as well as power meters and inverters. The later ones are directly accessed by MODBUS TCP. The cRIOs log the acquired data and transfer it from the remote stations in Bintan to the Central Monitoring Station (CMS) in Singapore by use of cellular network routers. The cellular network was observed to be rather weak at the resort and its vicinity. In order to find the most suitable locations for the routers, location-based tests were conducted a priori. Three spots, all close to one of the cRIOs, were found to have sufficient coverage for the data transmission. The routers are configured for a local SIM card and Virtual Private Network (VPN) to access the internet. At the process control level, the CMS receives one-minute live-data and initiates nightly download routines. The data is sorted into files and databases by the CMS to make it available for analysis.

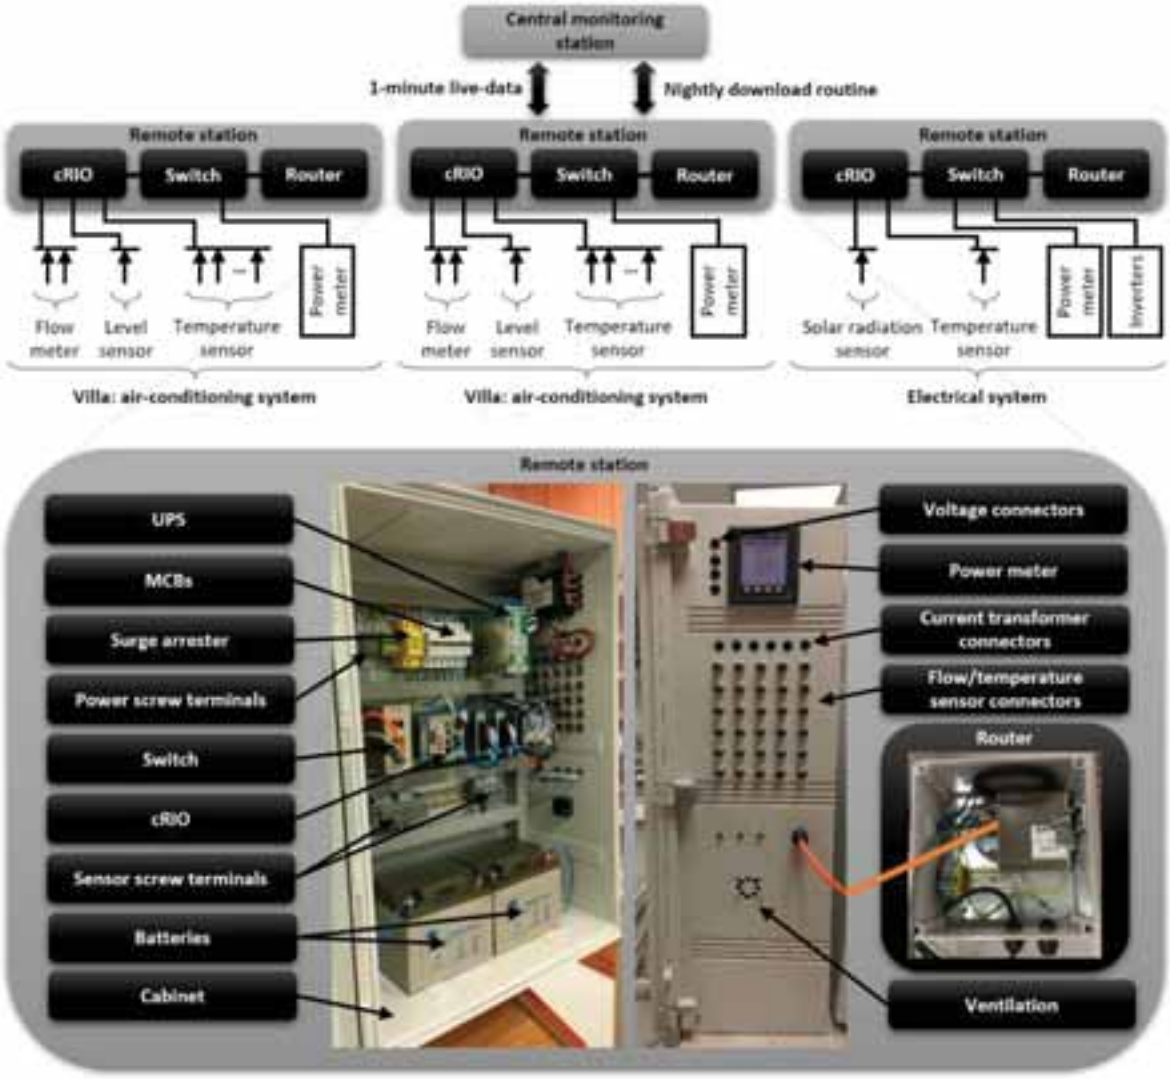

Fig. 4: System architecture of the monitoring system for the energy system at the LooLa resort (top); exemplary remote monitoring station (bottom)

This case study uses data measured by temperature sensors, flow meter and power meter to calibrate parts of a simulation model in Chapter 5. Detailed specifications of the utilised sensors is given in Table 2. To ensure the accuracy of the sensor/meter readings, additional calibration of certain sensors is required. The manufacturer of the temperature sensors provides accuracy class A. However, an additional multi-point calibration with a reference sensor (Isotech Hyperion Site & 935-14-61, overall accuracy: 0.04 °C) was conducted in a cooling bath from -20 °C to 40 °C for each sensor under laboratory conditions. The ultrasonic flow meters are also calibrated for the respective pipe dimensions and fluids, following similar laboratory conditions on-site. The calibration was conducted for the range of 0 to 15 l/min with an in-line reference flow meter (Rosemount 8732E, overall accuracy: ±0.02349 l/min). For both temperature sensors and flow meters, regression analysis was implemented in order to determine the correlation factors. The power meter meets IEC 61557-12 requirements and needs no further calibration.

The sensors were installed according to the P&I diagram in the bottom part of Fig. 3. Condensation and evaporation temperatures of the vapor-compression cycles are measured as well as stream temperatures before and after the ice storage tank, water tank and FCUs. Additionally, the water tank is equipped with a sensor measuring the temperature inside. The flow rates of the glycol and water are measured to be able to calculate the transferred thermal energy. The power meter measures the power consumption of the two chillers and the overall air-conditioning system.

Tab. 2: Specifications of the utilized sensors of the monitoring system

Parameter	Sensor	Range	Accuracy
Temperature	RTD, PT100, 4-wire, Thermotron	-30 to 100 °C	Class A
Flow rate	Ultrasonic flow meter Transmitter: Flexim F704 Transducer: Flexim FSQ	Plow velocity 0.01 to 25 m/s	Repeatability 0.15 % of reading ±0.01 m/s With standard calibration ±1.6% of reading ±0.01 m/s
Power	Current and voltage Schneider Electric PM5320	Depends on current transformers	Class 0.5S

4. Simulation model

A simulation model for the PV-driven cooling system at LooLa was set up using TRRNSYS 17.1, a dynamic simulation software. The model is divided into three main parts, cooling system 1, cooling system 2 and PV system, as displayed in Fig. 5. Additionally, weather data is utilised by all three parts. In the bottom part of Fig. 5, the outputs are processed, plotted and compiled in a text file for further analysis.

Cooling system 1 represents the actual system described in Chapter 2.1. Two chillers charge the ice storage tank (provided by Lerch and Heinz (2012)) during scheduled hours at daytime. Similar to the real system, the air-conditioning is scheduled during certain hours at night. Additionally, an occupancy calendar using the booking data of the resort in 2016 was implemented. The given data provides information about whether a villa is booked, but not how many rooms in which villa are booked, hence the occupancy is a binary input. In the discharging circuit, the chilled water tank was replaced by a controlled tempering valve keeping the glycol solution temperature at 12 °C and the four FCUs are simulated using a single FCU model. The input parameters for the FCU were determined using the psychrometric chart in Fig. 6. The return air is mixed with 15% outdoor air. One air change per hour is achieved by an air flow rate of 790 kg/h for four bed areas, each 12.5 m² and 2 m celling height. This results into a cooling load of 2.76 kW according to the mixed air and supply air conditions from the psychometric chart.

Cooling system 2 is only represented by the electrical load of the two chillers, because the system is similar to cooling system 1. The PV system powers the four chillers of the cooling systems. The power consumption of the auxiliary equipment, such as pumps, valves, control and FCUs, as well as the other loads at the resort that are connected to the PV system are neglected. The parameters for PV modules, batteries and control strategy are chosen according to the on-site system.

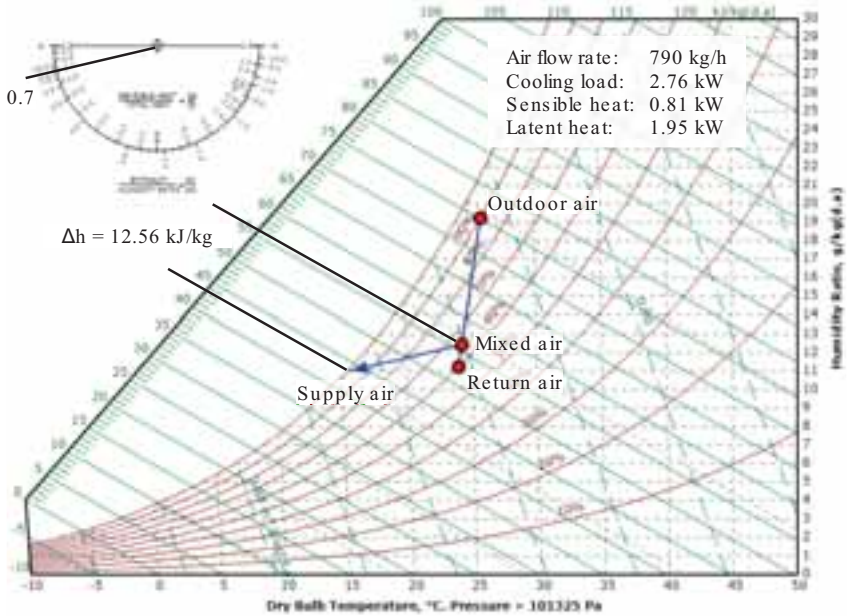

Fig. 6: Cooling load estimation via psychrometric chart; created with http://www.flycarpet.net/en/PsyOnline

5. Calibration results

The critical components, chiller and TES, were tested utilising data acquired by the monitoring system. Therefore, a simplified version of the simulation model was used, see Fig. 7. The chiller model is from the TESS library, Type655 and cuboid storage tank model Type843 was developed by Lerch and Heinz (2012). The TES model can operate as chilled water and ice tank.

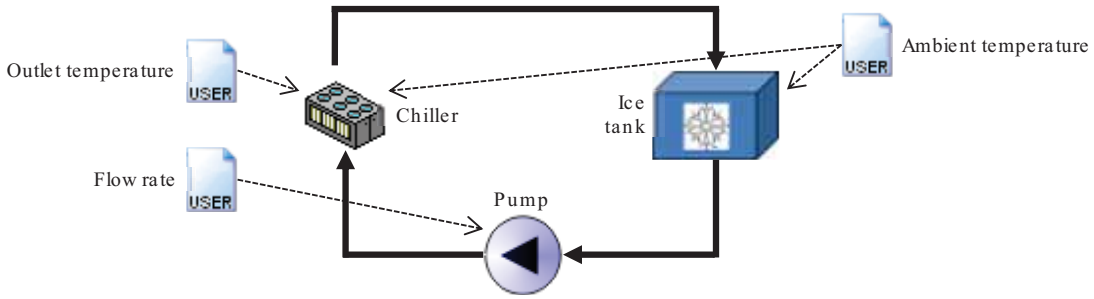

Fig. 7: Simplified TRNSYS simulation model for calibration of chiller and storage tank with measured data inputs

First, the operation as chilled water tank during charging is tested. Therefore, eight hours of measured data with the sample rate 1/min for chiller outlet temperature, ambient temperature and flow rate are used as inputs for the model. The model outputs to be compared with actual measured data are chiller power and tank outlet temperature. The result is plotted in graph 1a and 2a in Fig. 8. The non-fitting chiller power graph is caused by the performance data files of Type 655 that assume the chiller to be capable of operating in part load, which is not the case in the actual system. After adjustment of the performance data files, the Root Mean Square Error (RMSE) is merely 30 W as shown in graph 1b (Fig. 8). The tank outlet temperature decreases faster in the simulation than in the real setup, when the tank inlet temperature is prescript by measured data. This means that the actual heat transfer is lower than the simulated heat transfer. As the heat depends on flow rate, temperature difference and specific heat, where the temperature difference and the flow rate are measured, the specific heat serves as a parameter to match the model performance with the actual performance; the value is adjusted from 3.54 kJ/kgK to 1.7 kJ/kgK. The result is plotted in graph 2b of Fig. 8 and the RMSE has decreased to 0.18 °C.

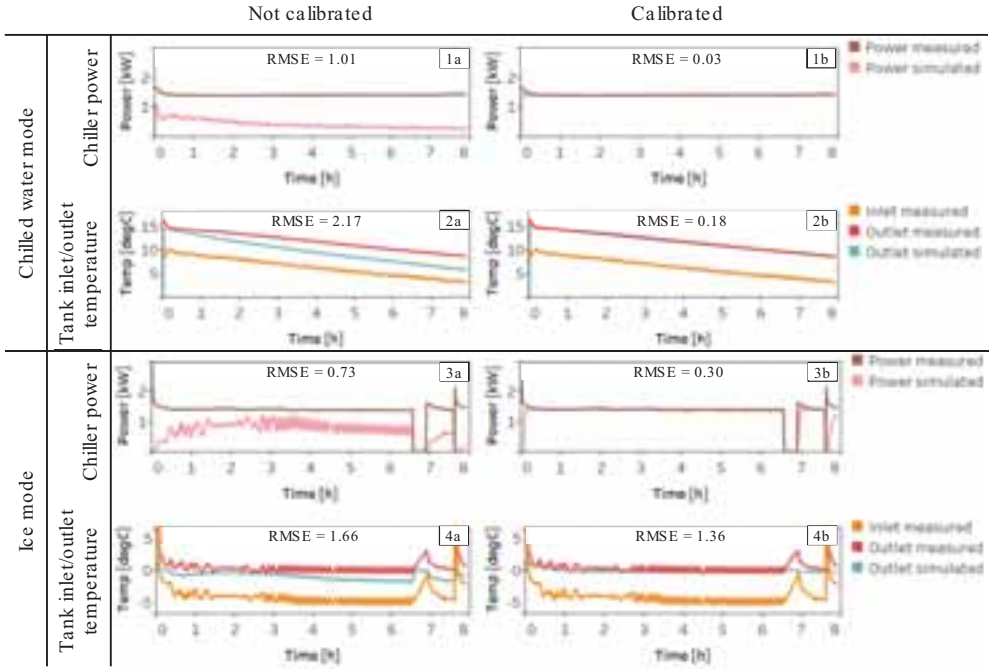

Fig. 8: Calibration of the chiller and storage tank models in chilled water mode (top) and ice mode (bottom) with measured data

The calibrated model represents the actual system accurately as shown by the RMSE values. However, the TES from Lerch and Heinz (2012) can also simulate the phase change from water to ice and, hence, operate as latent heat storage. Therefore, the input data from a day where the TES operates as ice tank during charging is chosen to test the simulation model for this condition. The simulation was run without calibration (graphs 3a and 4a in Fig. 8) and with the calibration measures described above (3b and 4b in Fig. 8). The chiller power RMSE is ten times higher compared to the chilled water operation, however a precise fit can be observed between 0.5 h and 6.5 h. in graph 3b (Fig. 8). The increased error is caused by two operation interruptions after 6.5 h and the starting current that is not modeled. The increase of the RMSE for the outlet temperature can be explained by the chiller operation interruptions as well. An additional factor is the oscillating temperature sensor reading that might have been caused by parasitic frequencies along the sensor wires. Overall, the TRNSYS simulation models the real system sufficiently accurate to produce

initial annual simulation results.

6. Initial simulation results

The TRNSYS simulation was performed for an entire year (8760 h) with a time step of 0.5 h. The initial results discussed in this chapter focus on the utilisation of the energy battery storage (Fig. 9) and the TES (Fig. 10).

The battery is charged to store surplus solar energy and discharged to supply energy for the chillers in case of insufficient solar energy availability. The usable storage capacity is 23.5 kWh considering 50% DoD. The four chillers consume 5.67 kW, which means the battery will ensure continuation of chiller operation for 4.15 h when it is fully charged. On a rainy or overcast day, chiller operation disruptions can occur due to the battery being fully discharged. This situation can be seen in the bottom chart of Fig. 9 when the graph approaches 0 kWh stored energy. Furthermore, the chart shows a high cycling frequency, which means that the battery serves as buffer storage. The bar chart in the top of Fig. 9 supports the finding, as the daily charged and discharged energy even exceeds the usable storage capacity of the battery (23.5 kWh) on many days. On those days, more than one cycle is performed.

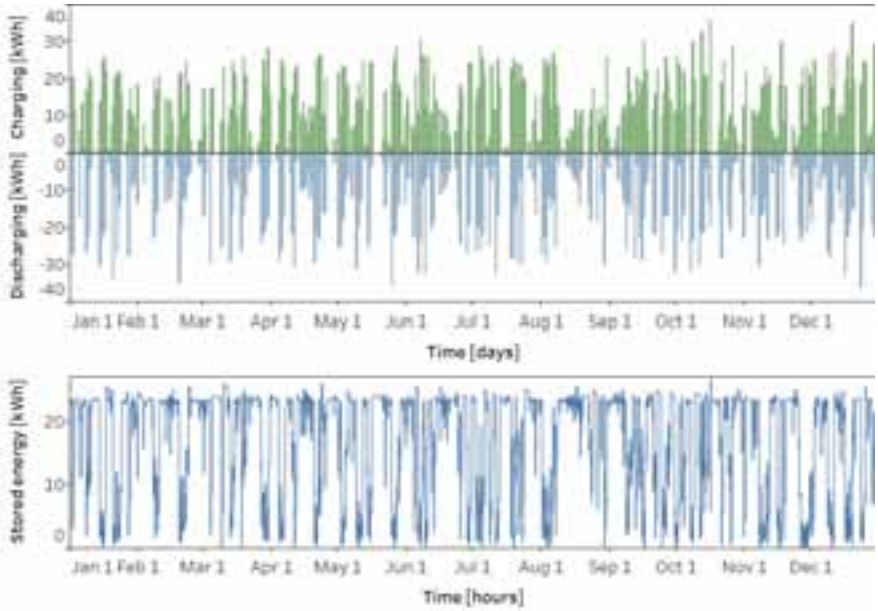

Fig. 9: Battery storage utilization; daily charged and discharged energy (top); stored energy again hours (bottom)

While the utilization of the battery storage occurs during chiller operation hours at daytime, the TES is only charged during that time. The discharging happens at nighttime. Unlike the battery, charging and discharging of the TES cannot occur simultaneously. Thus, the bottom graph of Fig. 10 (stored energy in the TES against time) shows a different pattern than the bottom graph of Fig. 9 (stored energy in the battery against time). The TES is charged nearly every day, but the discharging depends on the occupancy calendar; no occupancy means no discharging (see top chart in Fig. 10). The amount of charged energy (top chart in Fig. 10) decreases with increasing amount of energy stored, because the ice generated in the tank has lower heat conductivity than water, hence, insulating properties. Furthermore, the daily amount of charged energy also depends on the chiller operation hours during that day. In Fig. 10, 0 kWh stored energy is defined as 0% ice in the tank. Below that, it operates as chilled water tank. During high occupancy in December, the tank operates frequently as chilled water tank and might not meet the space cooling requirements.

The TES is cycled less frequently compared to the battery storage. It can store up to 93 kWh of latent heat, approximately four times the storage capacity of the battery. Thus, the TES serves as short-term energy storage that can shift the energy generated during daytime to serve the cooling needs during nighttime. Moreover, it can supply sufficient cooling over a few rainy or cloudy days.

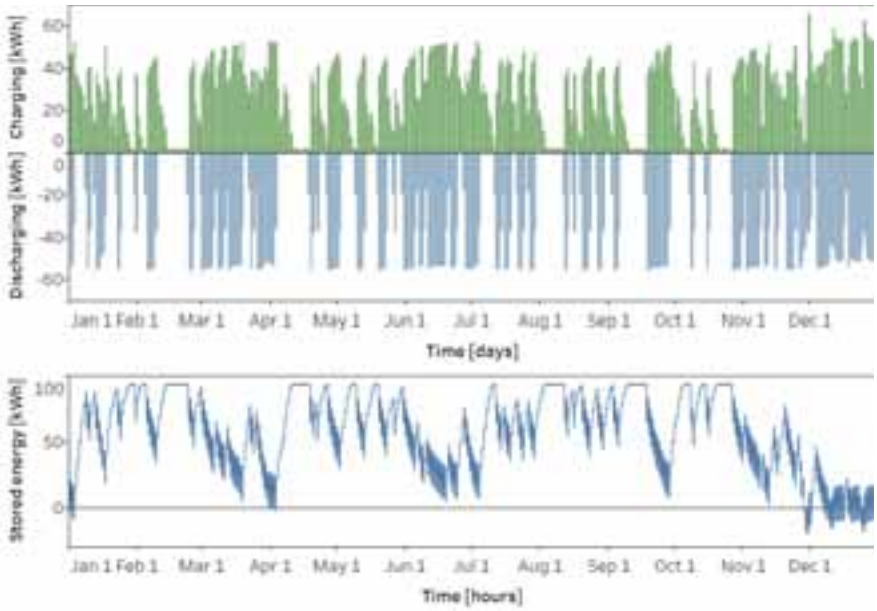

Fig. 10: TES utilization; daily charged and discharged energy (top); stored energy again hours (bottom)

7. Conclusion and outlook

The case study system is monitored in real-time and the data is used to calibrated components of a simulation model. Initial results emphasise the role of the battery and TES in the operation of this PV-driven cooling system. However, the simulation reflects not exactly the on-site situation, because of the following simplifications:

- The load of the PV system consists only of the chiller power consumption. In reality other parts of the resort (e.g. kitchen, shop and office) are also powered by the PV system during daytime, hence frequency of the power outages is likely to be higher.
- The power consumption of the auxiliary equipment of the cooling system, e.g. pumps, valves and control, were neglected. They are powered by the PV system during daytime and by the diesel generator during nighttime.
- The TRNSYS chiller model Type 655 requires a set temperature input, but the real chillers do not have a set temperature; only the evaporation temperature can be adjusted through the expansion valve.
- The cooling load was estimated via space volume and psychrometric chart and not derived from measured data. Furthermore, a binary value was used for the occupancy due to limited booking data.
- On the thermal load side, the water tank and 4 FCUs were replaced by a single FCU and a tempering valve.
- The charging process of the TES was only calibrated by a data set of 8 h and the discharging process was not calibrated.
- Pipe losses were not considered in this simulation.

Further work on enhance the simulation model will be done. Subsequently, three main topics will be addressed to complete the case study:

- A parametric study to size a battery storage, a chilled water tank and an ice storage tank for the prototype system.
- An economic analysis of the PV-driven cooling system at the LooLa resort.
- A comprehensive comparative study of the PV-driven cooling system with the three different energy storage solutions compared to a baseline system powered by a diesel generator in terms of energy and economic performance.

Eventually, the modelling and analysis shall be generalised towards a workflow that can be applied to various cooling applications.

8. Acknowledgements

The study is part of a research project funded by the LooLa Adventure Resort. The authors gratefully acknowledge the cooperation with the local LooLa staff in Bintan and the CEO, Dr. Marc van Loo. Moreover, we want to thank Shantanu Vachhani, a SERIS intern, for investigating various TES models and selecting the ice tank model for this paper. We are glad to be able to fall back on his work, when selecting the ice tank model for this paper. Last but not least, we are more than grateful for the selflessness of Dr. Andreas Heinz who provided the utilised ice tank model (Type 843) for this study.

Abstract

Solar heating and cooling is proposed to be an environmental sound alternative to conventional systems. Both, solar electrical and thermal driven systems can be a suitable solution and are currently under a controversial discussion. Therefore, the comparison of technical and economic performance of Solar Heating and Cooling (SHC) systems becomes a major issue. The assessment in a common comparable format is complicated by the numerous, alternative energy sources and design possibilities. A generalized technical and economic assessment methodology was developed and tested in the course of IEA SHC Task 53.

Ten case studies and best practice plants were analyzed and compared. All systems can achieve non-renewable primary energy savings greater than 40%, and some can show up a cost ratio lower than 1. Trend wise the PV and ST system are compared for southern and northern locations. Although the differences are rather small solar thermal seems to have advantages against PV driven systems. But in certain cases the situation is reversed and PV is advantageous.

A comprehensive sensitivity analysis on boundary conditions is showing the technical and economic performance in the same range for solar thermal and PV. Finally the analysis points out that both technologies - solar thermal and PV driven systems - can become an economic solution.

Keywords: Solar heating and cooling, assessment, benchmarking, solar thermal, photovoltaic

1. Introduction

The growing comfort demand and the increasing number of highly glassed buildings will provoke a further increase of the energy demand for cooling in future. Therefore the usage of an environmentally friendly cooling technology is inevitable. Solar cooling is an interesting alternative to conventional cooling systems when considering a significant reduction of non-renewable energy consumption. An increase on realized solar cooling systems could be observed in the past.

Solar cooling systems have a high diversity of different system designs including different cooling technologies as well as different combinations with renewable or non- renewable backups and storage tanks. In addition the systems are often designed to cover space heating or domestic hot water demand as well.

The IEA SHC Task 53 “New generation solar cooling and heating systems” is dealing with the cost effectiveness and performance of the latest solar cooling and heating systems to make them competitive on the market. (Mugnier, 2016).

One focus is on the analysis and benchmark of solar heating and cooling systems (SHC) against a reference system but also against other renewable technologies. Therefore an overview of realized as well as simulated systems in field tests or laboratory tests has been collected. The most important design issues are described and summarized. Some representative systems are selected for the detailed technical and economic analysis with a tool developed in the Task.

The T53E[4]-Tool is an enhanced Version of earlier developments in IEA SHC Task 48 and enables the

doi:10.18086/swc.2017.28.15 Available at http://proceedings.ises.org

comparison of different system designs. It considers several renewable and non-renewable energy sources as primary heat source or backups, as well as different types of heating and cooling technologies in combination with hot or cold storages. A more detailed analysis is separating the results by their applications (e.g. space heating, domestic hot water or cooling). This ensures that the analysis distinguishes further optimization potentials but the analysis also highlights good performing subsystems. An overview of considered energy flows and division of the subsystems is shown in Fig. 1.

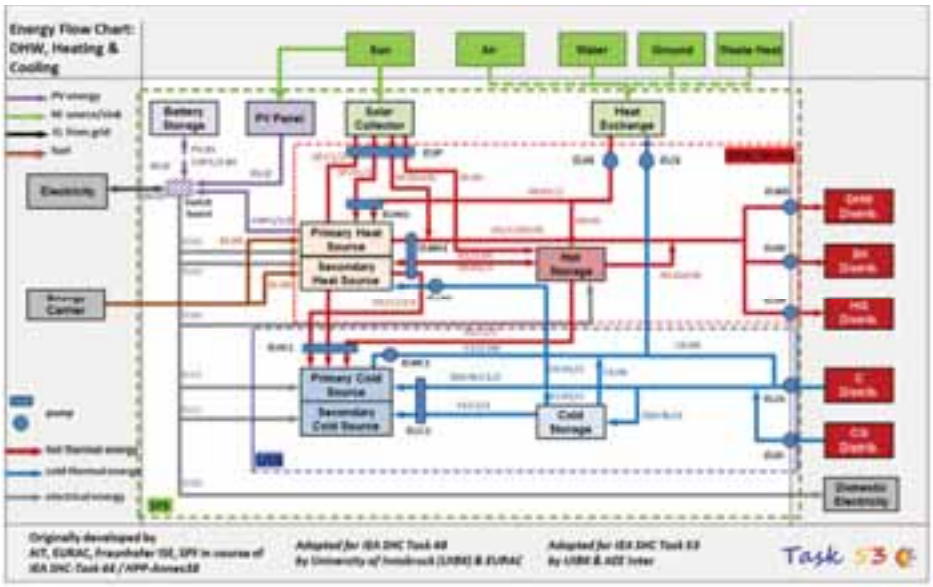

Fig. 1. Energy-flow-chart of all system components that can be taken into account for the assessment by consideration of the different subsystems in T53E[4]-Tool (Neyer et al. 2016)

The main focus of the analysis is on the comparison of solar-thermal and PV driven SHC systems. In the last years more and more conventional compression chiller/heat pumps are combined with a PV system, which is less complex and difficult to control than a solar-driven system. The assessment of the plants should lead to the conclusion which system is more cost effective and can lead to higher reduction of non-renewable energy sources. A number of simulated and demonstrated systems were selected and analyzed with the T53E[4]-Tool. In total 18 SHC systems are considered; their apportionment between technologies and data source is shown in Fig. 2.

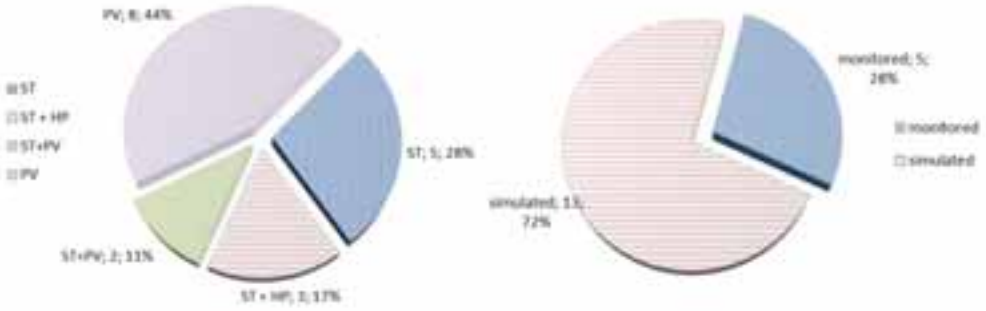

Fig.2: Overview of chosen SHC systems for the assessment summarized by the used technology (left) and the source of annual data for the assessment (right).

Eight of the selected systems are solar thermal driven systems, whereas 5 have thermal backups and 3 an electrical (HP). Eight systems are PV-driven and the remaining 2 include both, PV and solar thermal collectors. Most of the data analyzed is a result of simulation which offers the advantage to compare the same load-profile with different technologies. Five plants are in operation and the monitored data were analyzed.

2. Methodology

2.1 Assessment – T53E^4-Tool

The T53E^4-Tool enables a technical and an economical comparison of renewable and non- renewable systems for heating and cooling. The analysis is based on monthly energy balances of heat and electricity. For an entire assessment the values have to include annual measured or simulated energy quantities. The defined KPI's are compared to a reference system defined in Neyer et al (2016). The reference system uses a natural gas boiler for heating and an air cooled vapor compression chiller (VCC) for cooling. The efficiency of the reference system is depending on the size (technology), energy delivered (full load) and other parameters. The reference system is used to compare the technical and economic performance of the entire SHC system and to calculate the primary energy savings and cost competitiveness.

Technical Assessment

The key performance indicators (KPI) that are calculated are the non-renewable Primary Energy Ratio (PER_{NRE}), the non-renewable primary energy savings ($f_{sav,NRE}$) and the electrical equivalent Seasonal Performance Factor (SPF_{equ}). They are considered as appropriate indicators for the comparison of the high diversity of SHC systems analyzed with the T53E^4-Tool. The KPI's are calculated by the tool for the overall system, as well as the subsystems.

- Non-Renewable Primary Energy Ratio

The non-renewable primary energy ratio (PER_{NRE}) is calculated over a longer period of time (annual or monthly). It is defined as the ratio of useful energy, supplied to satisfy the needs of the application (DHW, SH, Cooling), to non-renewable primary energy input from any energy source (electric or thermal) used within the defined system boundaries.

$$PER_{NRE} = \frac{\sum Q_{out}}{\sum\left(\frac{Q_{el,in}}{\varepsilon_{el}} + \frac{Q_{in}}{\varepsilon_{in}}\right)} \quad \text{(eq. 1)}$$

The higher the PER_{NRE} (in a magnitude of 1 to 2.5) the less non-renewable energy is used by the SHC system to cover the heat and cold demand.

The reference System $PER_{NRE,\ ref}$ is also calculated for the equal heat and cooling demand. The reference system

calculation follows Napolitano (2011) and has a natural gas boiler for covering the heat demand and an air-cooled VCC system for cooling. It includes a small hot water storage for domestic hot water (DHW) purposes and a cold storage volume for a smooth operation of the air cooled VCC. The T53E^4-Tool also provides the possibility to define a specific reference case for individual assessment, but here the defined standard reference system is used.

$$PER_{NRE.ref} = \frac{\sum Q_{out}}{\sum\left(\frac{Q_{out.heat}+Q_{loss.ref}}{\varepsilon_{in}*\eta_{HB.ref}}+\frac{Q_{out.cold}}{SPF_{C.ref}*\varepsilon_{el}}+\frac{Q_{el.ref}}{\varepsilon_{el}}\right)} \quad \text{(eq. 2)}$$

- Non-renewable primary energy savings ($f_{sav.NRE}$)

The $f_{sav.NRE}$ compares the $PER_{NRE.sys}$ of the entire SHC system to the $PER_{NRE.ref}$.

$$f_{sav.NRE} = \frac{PER_{NRE.sys} - PER_{NRE.ref}}{PER_{NRE.sys}} = 1 - \frac{PER_{NRE.ref}}{PER_{NRE.sys}} \quad \text{(eq.3)}$$

The result for $f_{sav.NRE}$ is always below 1 and shows the non-renewable primary energy savings of the SHC system compared to the reference system. A high value indicates also a high solar fraction and low energy input from fossil derived fuels. A negative value points out that the SHC system has a higher non-renewable primary energy consumption than the reference system and no savings could be achieved with the SHC system.

- Electrical equivalent Seasonal Performance Factor (SPFequ)

However, values for PER_{NRE} are not directly comparable with any widely available industry figures of merit such as the EER or SEER of a vapor compression chiller. Therefore the electrical equivalent Seasonal Performance Factor was introduced and enables a comparison with the SEER of VCC systems or the SPF of electric driven heat pump systems. All energy flows are converted into electrical equivalent units by dividing the PER_{NRE} with the primary energy factor of electricity (ε_{el})

$$SPF_{equ} = \frac{PER_{NRE}}{\varepsilon_{el}} = \frac{\sum Q_{out}}{\sum\left(Q_{el,in}+\frac{Q_{in}}{\varepsilon_{in}}*\varepsilon_{el}\right)} \quad \text{(eq.4)}$$

Economic assessment

The bases for the economic assessment are the total annual costs of the system. This is the sum of the annual costs for investment, replacement, residual value, maintenance, energy and water costs and is calculated by the T53E^4-Tool by inserting information of the type and size of system components. If the real costs are known the tool enables the possibility to enter the specific values. The annualized costs for the entire system are calculated by using the annuity method. The calculation for investment costs are considering economy of scale prices, which means that the capacity of the components is taken into account when calculating the specific costs. The maintenance, energy and water costs are based on the consumption and are defined under the consideration of VDI 2067. All the costs (investment, replacement, residual value, maintenance, energy and water costs) are expressed in annualized costs C_{an} and summed up to the total annualized costs $C_{an.tot}$ of the SHC system. The Levelized Costs of Energy is the ratio of annualized costs and the overall annual useful energy provided to the application.

$$LCOE = \frac{C_{an.tot}}{Q_{CD.sys}+Q_{DC.sys}+Q_{HD.sys}+Q_{WD.sys}+Q_{DH.sys}+Q_{el.DE}} \quad \text{(eq.6)}$$

Since the uncertainties in cost calculation are varying, the comparison of absolute costs of different SHC systems is resigned and the economic assessment concentrates on the cost ratio by comparing the total levelized energy costs of the SHC system $C_{an.tot-SHC}$ to the total levelized energy costs of the reference system $C_{an.tot-REF}$.

$$CR = \frac{LCOE_{SHC}}{LCOE_{REF}} = \frac{C_{an.tot-SHC}}{C_{an.tot-REF}} \quad \text{(eq.7)}$$

2.2 Examples

The 10 examples (with extra 8 variations) included in this work are described briefly and summarized in table 2.

- Example 1, SERM (Mugnier, 2015)

The SHC system of the SERM project is realized for a building with different purposes: offices, dwelling and shops in the urban zone "Jacques Coeur" in Montpellier, France. The system provides cooling mainly for the office and shops and domestic hot water for the dwellings. The centralized system consists of 240 m² flat plate collectors, 1.5 m³ buffer storage, a single stage adsorption chiller with a capacity of 35 kW and a hybrid cooling tower (adiabatic aero-cooling device) with a capacity of 85 kW. As backup for DHW purpose a natural gas boiler with a capacity of 70 kW is installed.

- Example 2, iNSPiRe (Fedrizzi et al., 2015)

The iNSPiRe project has created a simulation data-base of performance and costs of different HVAC systems at an extensive variation of boundary conditions in the field of refurbishment. Some crucial examples are selected for the analysis. A single-family house, as well as a multi-family house, with different solar thermal collector field areas or amount of PV modules or a combination of solar thermal collectors and PV at the locations Madrid and Stuttgart are analyzed. In all cases space heating (SH), cooling and domestic hot water production is provided with a centralized air to water heat pump which is connected to a 430 l tank for DHW and SH.

- Example 3, ZAE (Sipilä et al, 2017)

Within the finish-german joint research project "Solar Heating and Cooling for Central and Northern Europe" a small scale solar thermal cooling (10 kW) and heating (24 kW) plant was installed at the Savo-Solar headquarter in Mikkeli, Finland in 2016. It is designed to supply the office building of Savo-Solar. The system consists of the main components solar-thermal collectors, vacuum insulated storage tank, dry air cooler and reversible absorption chiller/heat-pump. The main heat source for driving the chiller is a solar thermal collector field with 36 m² aperture area. A wood chip fired district heating access serves as backup heat. In summertime, cooling is done by an advanced single-effect absorption process. At insufficient solar radiation, the driving heat is provided by the heat storage or the district heating network. In wintertime the system works as thermal driven heat pump, using the biofuel fired district heat to upgrade ambient heat to a useful temperature level.

- Example 4, UMH DHW (Aguilar et al., 2016)

In this example an air to water heat pump is used for the preparation of domestic hot water with a nominal heating capacity of 1.5 kW. The electricity consumption of the heat pump is covered by two PV modules with 470 Wp or electricity from the grid. The system also includes a buffer tank of 190 l and is located at the university in Elche, Spain. The DHW demand is 6.26 kWh/d distributed in 6 extractions.

- Example 5, UMH HVAC (Aguilar et al, 2017)

A PV-driven HVAC system is realized in an office with a heated/cooled area of 35 m² in Alicante, Spain. The inverter air-conditioner is used to cover the cooling and space heating demand of the office. The cooling capacity is 3.52 kW, whereas the heating capacity is 3.81 kW. It is connected to three PV panels with 705 Wp as well as to the grid to provide the necessary electricity consumed by the HVAC system. The indoor temperature was set to 23ºC in cooling mode and the relative humidity was not controlled.

- Example 6, Högskolan Dalarna (Psimopoulos et al. 2016)

The simulated house is a typical Swedish single floor, single family house with a heated area of 143 m² placed in Norrköping. A variable speed, exhaust air heat pump (HP) with a capacity of 5 kW delivers heat both for SH and DHW. A hot water storage tank of 180 litres is used for DHW. If the heat from the HP is not sufficient an electrical auxiliary heater with a power of 6.5 kW is turned on. The system also includes a 5.7 kWp PV System

and lithium-ion battery storage with a capacity of 7.2 kWh.

- Example 7, AEE INTEC (Fink, 2011)

The SHC system is applied for heating, domestic hot water and cooling of a small juice producer. The heat is produced by 100 m² of double-glazed flat plate collectors and as a backup-heater a wood chip boiler with a capacity of 100 kW is used. The heat is stored in a 20 m³ buffer storage and connected to a single-stage absorption chiller with a capacity of 19 kW and a dry cooling tower with a capacity of 50 kW. The chilled water is used for the juice refrigeration only. If no cooling is needed the heat is used for the juice production process, for DHW preparation or to cover the space heating demand of the residential house next to the juice production.

- Example 8, TheBat (Thür et al., 2016)

In the project "TheBat" a single family house located in Innsbruck is simulated with different control concepts with the goal to maximize the PV-self consumption by using a heat pump and the available heat capacities in the building as "thermal battery". The chosen example is covering the space heating and domestic hot water demand with a brine heat pump with a thermal capacity of 10 kW. The HP can charge a water storage (TES) or directly heat the building via thermal activated building structure (TABS). The heat pump is controlled by matching the compressor speed to the available power of the PV and store the produced heat preferably in the TABS or the TES. First, the electricity from the PV is used for running the HP, the remaining electricity is fed into the grid (no household electricity consumption is considered in the simulation studies).

- Example 9, SolarHybrid (Neyer et al 2016a)

In the project SolarHybrid a solar thermal and PV driven HVAC system for a hotel located in Innsbruck and Sevilla is simulated. The cooling of the hotel is provided by a vapour compression chiller (VCC) in combination with an ammonia/water-absorption chiller (ACM). A solar thermal (ST) driven system is compared with a PV supported system. The ST feeds a hot water storage tank, which is used to ensure the heat supply and operation of the ACM. A natural gas backup boiler is used for DHW and SH only. The ACM is used to cover the base load (19 kW) and the conventional VCC (70 kW) covers the remaining demand using grid electricity. Both refrigerators operate with dry back-cooling. The PV supports the heat pump, which operates reversible and feeds the hot water storage tank for domestic hot water and a cold water storage. A PV area, which is designed exclusively for the operation of the reversible HP complements the system.

- Example 10, Yazaki (Inagaki et al. 2017)

The passive house office is located in JINAN in P.R.China, a humid continental climate. The thermal energy for the solar collector fields of 110 m² is stored in a 5 m³ hot water tank. In summer case the heat is used to run the absorption chiller (WFC10) with 35 kW nominal capacity and the heat is rejected via a wet cooling tower. The chilled water is stored in a 1.5 m³ tank and complemented by a reversible air-water electrical heat pump. The energy is delivered into the rooms over a radiant ceiling and the ventilation unit. The ventilation unit includes a heat recovery system, a pre heating/cooling coil, a 20 kW air-air heat pump as backup and the re-heating coil.

A summary of the most important information of the plants is shown in Tab. 2. The solar fraction should give a hint weather the plants are designed for full load (100%) or base load (<30%) only. The solar fraction for thermal (SF_{th}) or PV-driven systems (SF_{el}) is calculated according to Eq. 8 and Eq. 9 respectively.

$$SF_{th} = \frac{Q_{solar,in}}{(Q_{solar,in} + Q_{backup})} \quad \text{(eq. 8)}$$

$$SF_{el} = \frac{Q_{PV,in}}{(Q_{PV,in} + Q_{grid})} \quad \text{(eq. 9)}$$

3. Results

A wide variety of SHC systems is included in the assessment. Systems with different heating and cooling technologies, with different capacities, with simulated and monitored data base as well as a mixture of cooling, space heating and domestic hot water application were selected. An overview of the selected systems on basis of the total capacity and the type of heat source technology is shown in Fig. 3:

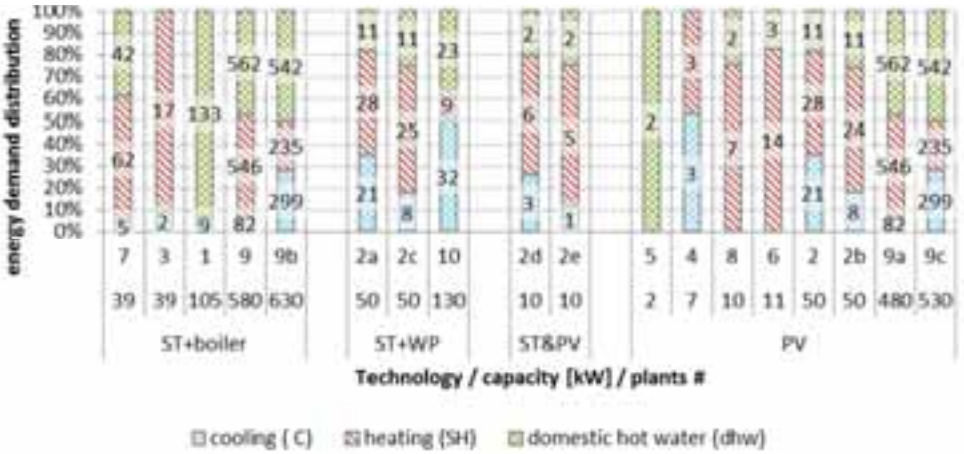

Fig.3: distribution of annual energy demand between cooling (C), heating (SH) and domestic hot water (dhw); numbers in the bars are in MWh; arranged according to the Technology used and total installed heating and cooling capacity (kW)

Seventeen systems include DHW demand, fifteen systems include cooling and sixteen systems include SH. In total eleven systems cover all three demands: SH, DHW and cooling. There is also a wide spread in the size of the systems. The total installed heating and cooling capacity of the systems is between 2 kW and 630 kW, but more than half of the systems are in the range between 10 kW and 130 kW. The graph also illustrates the total yearly energy demand in MWh. Whereas the smallest system covers a heat demand of 2 MWh/y the highest total energy demand which is covered by a system is 1190 MWh.

The base of the economics is presented in Figure 4 by showing the specific investment cost of the entire system and the related reference system. The ratio of investment ($Invest_{SHC}/Invest_{REF}$) is calculated and shown in connection with the achieved non-renewable primary energy savings ($f_{sav.NRE}$).

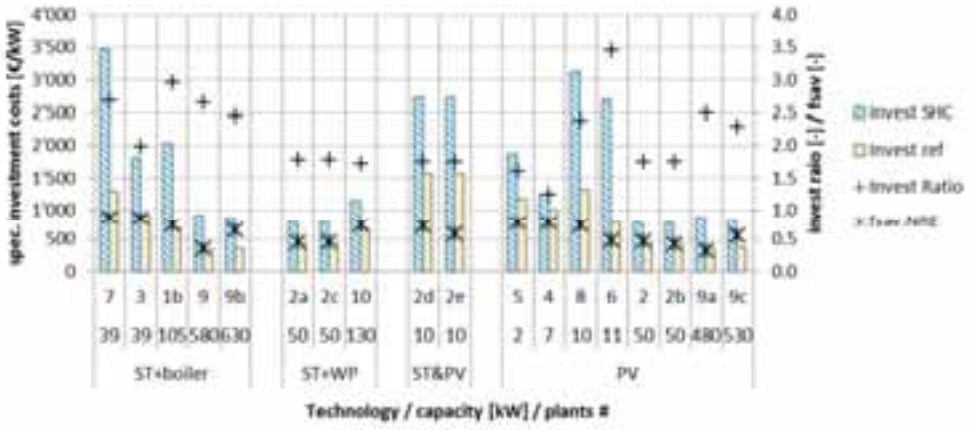

Fig.4: specific Investment costs for each SHC plant and corresponding reference system according to T53E4 Standard (left axis); Investment ratio (SHC/REF) and non-renewable primary energy savings (right axis); arranged according to the Technology used and total installed capacity (kW);

All costs are compiled with the Task 53 Standard values. Trend wise the smaller systems and those with higher savings show higher absolute investment costs and higher investment ratio. But both values are further influenced by the design (size of components, storages…) and the choice of components (HP vs. boiler, etc.). Comparing ST and PV systems produces an equal picture. Roughly half of the plants present investment costs higher 1'500 €/kW, the other half costs below 1'000 €/kW.

The investment is usually the main cost factor, but the total cost also include cost for replacement, electricity, energy carrier, water, maintenance and for grid connected PV systems the feed-in remuneration. The total annualized cost distribution of all systems is shown in Figure 5. The more energy a system is providing the higher the ratio of energy costs; the smaller the system the huger is the ratio of investments. The ratio of investment costs varies from roughly 30% up to almost 60%; if replacement costs are considered the ratio related to investment adds another 5-10%. Maintenance cost ratios are slightly higher for the solar thermal driven system compared to PV supported system. A high PV self-consumption can be observed in almost all system thus the feed-in remuneration does play a minor role.

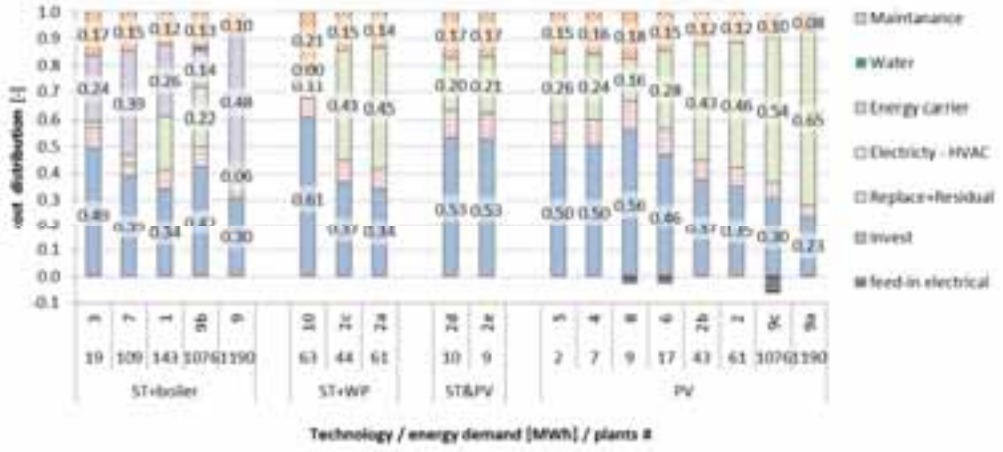

Fig.5: annualized cost distribution for each SHC plant; the fraction for investment, electricity, energy carrier and maintenance are stated in the bars; arranged according to the Technology used and total energy demand (MWh)

Figure 6 presents the summary of non-renewable savings in relation to the entire costs, expressed as CostRatio (CR). Each plant is represented as individual dot. The CR is displayed in reversed order thus the more cost effective and the higher the savings the more the results appear in the upper right side. Further 4 trend lines are drawn summarizing the results technology and location wise.

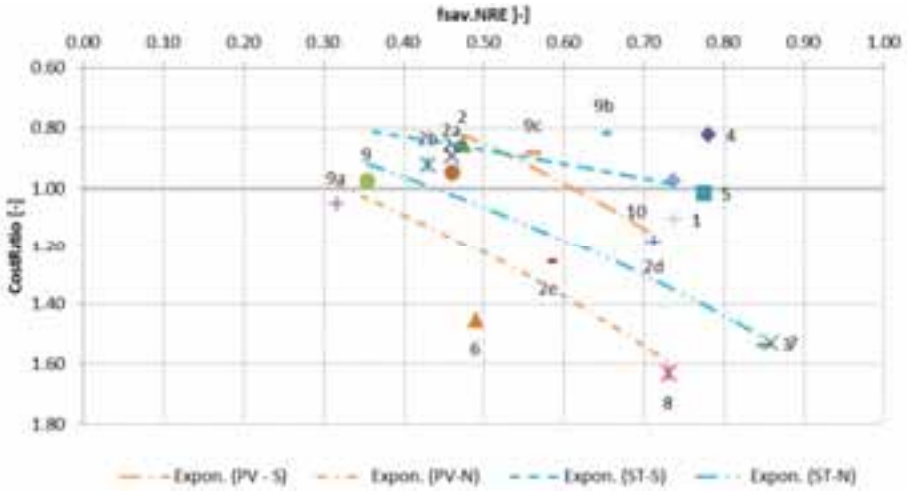

Fig.6: CostRatio (CR) in reverse order vs. non-renewable primary energy savings ($f_{sav.NRE}$); cluster in four groups (i) PV supported system in southern climate (PV-S), (ii) PV system in northern climates (PV-N), (iii) solar thermal supported system in south (ST-S), (iv) solar thermal system in north (ST-N)

The clustering for the trend lines of the results is arranged in the following order (i) PV-S: #2, #2d, 9c; (ii) PV-N: # 2b, #2e, #6, #8, #9a; (iii) ST-S: #1, #2a, #9b, #10; (iv) ST-N: #2c, #3, #7, #9. Only plant #4 and #5 cannot be clustered as they are a not comparable in size and technology used. The quantity of examples is not high enough to dare on the trend lines; nevertheless they can be used for general statements and to show the results of the sensitivity analysis.

Considering the cost ratio, it can be seen that the majority of systems can compete with a conventional system or are even more cost efficient. The most effective plants are PV driven #4, #5 and ST driven #9b, #10 and #1. They represent a good relationship of cost and savings. All these plants have a year around solar usage and either a low investment ratio (small plants) or a low share of investment costs of total annualized costs. ST systems in north and south represent more even gradient than the PV driven systems. The southern locations represent more efficient (higher savings) and more economic (higher solar yield) systems. In southern location the trend lines cross each other, in the northern location the trend line of ST reclines higher. This indicates that solar thermal at the same saving is cheaper than PV or at the same CostRatio the solar thermal can reach higher saving. This might be true as a general finding but individual example (especially #2) show reversed conclusions. Thus the trend line and their interpretation should be used with care!

The question arises whether the chosen boundary conditions are affecting the results or if the design and location is more important. Thus a sensitivity analysis was performed and the effect is shown by means of the shift of the trend lines. The parameters that are varied are the total investment costs (40%~130%), the electricity price (50%~350%), the natural gas price (50%~200%), the conversion factor for electricity (80%~140%) and the electrical efficiency of the systems (90%~200%). As not all results can be presented in this paper two (investment costs in Fig. 7 and electrical efficiency in Fig.8) are selected and discussed here, all other will be published in the course of IEA SHC Task 53.

The result of the sensitivity analysis on investment costs is shown in figure 7 in two diagrams separated according to the location. The results for ±15% of the initial costs are presented in figure 7 in red (+15%) and in blue (-15%). It is obvious that if the costs are dominated by investments the CostRatio will response more intense than if the investment costs ratio is smaller. The analysis will only affect the CostRatio, the non-renewable primary energy savings keep unaffected.

In the northern locations (Fig 7. left) the +15% in solar thermal and -15% in PV systems are overlapping strongly and the results get equal. The same behavior occurs in the southern locations. If the investment costs are changed in the same direction (e.g. -15%) in norther location the difference gets smaller (PV is more investment driven), in the southern locations the difference gets larger (ST is more investment dominant). The effect of minus 15% can take shape in a magnitude of -5 to 20 %points in the CostRatio

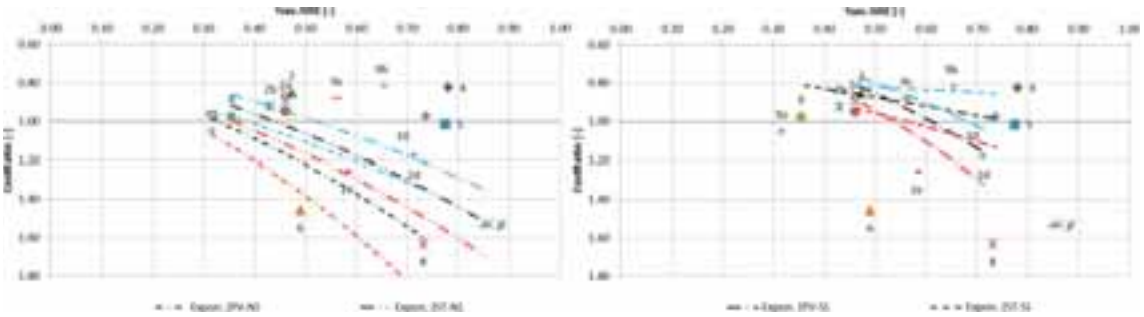

Fig.7: sensitivity analysis on investment costs; +15% investment in red; -15% investment in blue; for northern located system (left) and south located system (right)

The sensitivity analysis on the electrical efficiency of the systems is shown in figure 8. The electrical efficiency is changed by changing the total grid electricity drawn by the entire system. The effect is shown for +25% (red) and for +40% (blue). It is obvious that if the system is electricity driven and the larger the electricity costs ratio is, the more sensitive a system will be. The sensitivity analysis will affect the cost ratio (lower electricity cost) as well as the non-renewable primary energy savings.

For both locations the gap between PV driven and solar driven system gets smaller. Even with (probably unrealistic) 40% efficiency increase the solar thermal systems keep upfront the PV systems. In general the lower efficient systems (lower $f_{sav.NRE}$) benefit more than the already high efficient systems. Thus curves shift to the right and the gradients get steeper. If the efficiency could be increased by 25% the savings increase by a factor of 10 to 15%points, the CostRatio keeps almost unaffected (up -5%points).

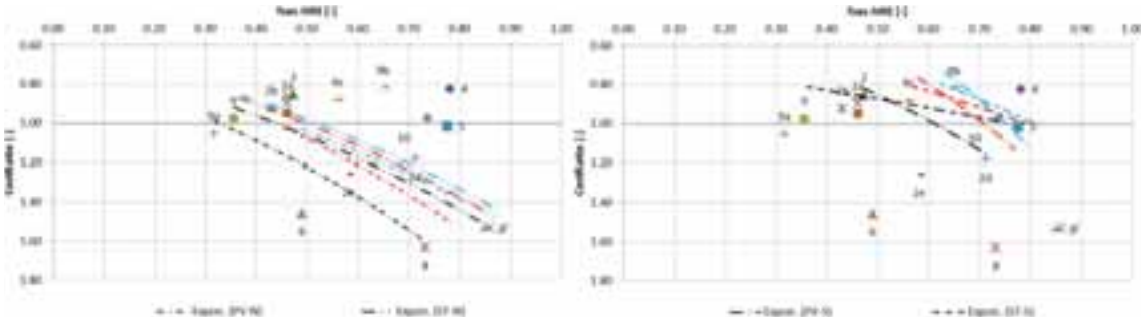

Fig.8: sensitivity analysis on electrical efficiency changes (+25 % red lines; +40% blue lines) for northern located system (left) and south located system (right)

The other sensitivity analyses are showing a similar picture. Decreasing costs lead to lower CostRatio's increasing the efficiency increases the non-renewable primary energy savings and reduces the CostRatio. The natural gas costs effects all system as the reference system is a natural gas boiler. Within a reasonable change of boundary conditions (±20~30%) the magnitude of change in key figures can be expected in the range presented within the two analyses.

Overall it falls into place that with a clever design and a decrease of investment costs the solar technologies are already less expensive than a conventional system for heating and cooling applications or can reach cost equity with minor effort.

4. Summary & outlook

A comprehensive tool was developed in the course of IEA SHC Task 53 and is available for the analysis and assessment of new generation of solar heating and cooling systems. The key figures that are calculated allow a benchmarking and simplify the comparison of different system configurations. The T53E^4-Tool can be used to benchmark against a standardized reference systems or against other renewable heating and cooling technologies. Still, the comparability is challenging if applications and configurations are mixed. Nevertheless, a trend wise comparison of magnitudes can definitely be achieved. The T53E^4-Tool is expected to be published in 2018.

The methodology presented is based on monthly energy balances and focusing on non-renewable primary energy. Thus the results are depending on the non-renewable primary energy conversion factors which depend on the season (summer / winter), daytime (peaks), on political decision (balancing methods) and the repercussion of the entire system on factors itself. Future developments of costs but also primary energy conversion factors are difficult to forecast. Thus a sensitivity analysis on the influencing boundary conditions should be performed anyway.

A majority of the systems can be classified as small or medium scale systems. The economics are investment dominated and the electrical or thermal efficiency is of minor order. Nevertheless a high efficiency is essential for acceptable non-renewable primary energy savings, being aware that the efficiency or technology of the reference system will change in future.

The southern locations represent more effective (higher non-renewable primary energy savings) and more economic systems mainly due to higher solar yields. Southern examples can already reach CostRatio's below one. Accordingly the systems are cost competitive compared to the standard reference system calculated within the T53E^4-Tool.

Summarizing the comparison of ST and PV driven system expresses a clear conclusion that ST is more effective at lower costs. Nevertheless the difference is probably within the uncertainties and when changing the boundary conditions accordingly the results are overlapping. In the end the advantage of the one or other technology is depending on local conditions, the design of the plant and its control strategies. Both Technologies can be optimized intensively to become cost competitive and an attractive alternative compared to conventional heating and cooling systems.

Abstract

This study presents the coupling of a solar-electric driven air conditioning system (VRF, 3-pipe) with thermal storages based on Phase Change Material (PCM). The main objectives are the reduction of PV-related peak feed-in, to give a possibility for applying Demand Side Management and increasing self-consumption of such grid-connected PV-HVAC systems. To accomplish these goals the PCM-storage will be implemented directly in the refrigeration cycle of the system. Using PCM whose melting temperatures are adapted to the cooling process, cold/heat could be used directly without additional brine loops, accompanied by a negative effect on the EER. Furthermore the storage can be used to improve the system efficiency in case of discharge, which lowers the electrical demand when it is appropriate to reduce grid stress. Key issues are the development of the heat exchanger for the storage, the storage integration in the refrigeration cycle and the control strategies how to use the PCM-storage.

Keywords: Air Conditioning, Variable Refrigerant Flow (VRF), PCM, Heat Exchanger, Two-Phase-Flow, PV self-consumption, Demand Side Management

1. Introduction

Air Conditioning and heating based on electrically driven heat pumps is worldwide increasing in residential as well as in business buildings. Due to easy installation and easy access of the energy source/heat sink, air/air based systems are getting more and more relevant. The capability to store energy is limited in these systems. Systems with electric battery are expensive and sensible thermal storages do not fit well to the refrigeration cycle due to exergetic losses. The ability to store energy is mandatory to achieve better integration of PV-production for such combined systems. Especially in future when the numbers of installations will increase and capability to store energy is not given, a significant, negative impact on the electrical grid is expected, because the peak of cooling demand does not correspond to the peak of PV-production during the day.

The project approach is to integrate a thermal PCM-based storage into the refrigeration cycle of an air/air based 3-pipe VRF system. The efficiency of a heat pump corresponds directly to the temperature lift the compressor has to overcome. The approximately constant temperature of PCM at phase change can cause significant advantages in the system efficiency compared to sensible storage materials (Loistl et al., 2016). Therefore it is mandatory to choose materials whose melting temperature is appropriate for the desired effect of the heat storage, acting as heat sink, heat source or subcooler for the refrigeration cycle or as direct heat/cold storage.

2. Modelling Phase

Several melting temperature ranges can be taken into account for implementing the PCM into the system. To get an idea which ranges will be most promising for the integration of PV-production and for the design of the entire system, load and PV-yield simulations have been made in TrnSys. The model consists of transient load simulations of a specific office building in which a pilot installation, based on a 3-pipe VRF system will be built up. Furthermore it contains transient PV-yield simulations, varying the installed peak-power. To simulate the theoretically possible thermal supply of the PV-driven heat pump the model is also fed with ambient temperature- and part load- dependent data of the EER/COP.

To gain reliable load data of the specific building, the known building characteristics and its geometry had been set up in the TRNBuild Editor. The building which is considered is located in Garching, in the south of Germany. It can be classified as a light construction building. The heating and cooling system supplies offices, laboratories and a small server room. The major part of the equipped building is shown in Figure 1.

Figure 1 Main part of the institute building which will be equipped with Indoor Units (IU).

The main thermal features and data of the building are shown in table 1.

Tab. 1: General data and main thermal features of the modeled institute building in Garching.

Main thermal features of the building	
	U Value
Wooden structured external wall	0.24 W/m²K
External Roof	0.18 W/m²K
On-ground concrete floor slab	0.25 W/m²K
Insulated glazing	1.1 W/m²K
General data of building	
Location	Garching, N 48°15´, E 11° 40´
Floor surface Offices	160 m²
Floor surface Laboratories	150 m²
Air change rate	40 m³/h·person
Cooling/Heating set point temperatures	24 °C – 21 °C

For the PV-yield simulation the Standard TrnSys Type 194b for Photovoltaic-Arrays including inverter losses is used. For the investigation the reachable PV-yield was maximized using PV-panels facing south with an inclination of 30°. Under typical operating conditions, there is only limited congruence of PV-generator yield and electric building load. Thus, the storage is applied in order to accomplish a better match, avoiding losses of the possible PV-yield.

The pilot installation will be equipped with a Fujitsu V-II R VRF-System. To implement this system to the model the part-load and ambient temperature dependent data was fed in. This data is published by Fujitsu down to a part-load-ratio of 50%. (Fujitsu, 2014)

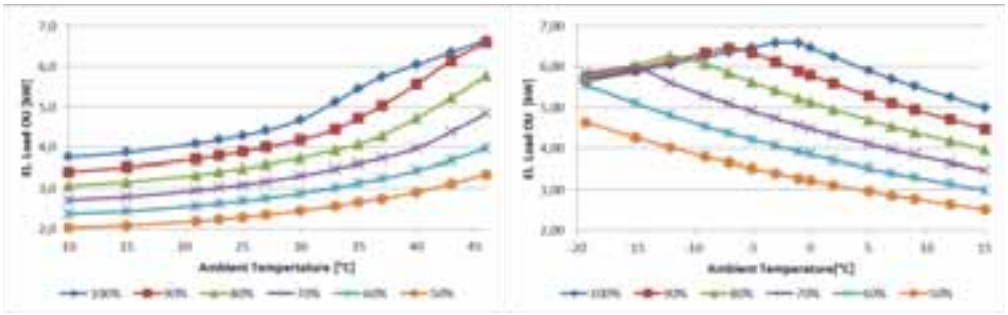

Figure 2 Electrical Load depending on ambient temperature and part-load ratio for cooling (left) and heating mode (right). Database for Fujitsu V-II R Type 72GALH with a rated cooling capacity of 22.4 kW and a rated heating capacity of 25 kW. The nominal electrical load is specified with 5.5 kW.

Figure 2 shows the electrical load of the Outdoor Unit 72GALH of the Fujitsu-System. Every curve represents a different part-load of the system in a range from 50% to 100%. Down to a part load ratio of 50% the EER as well as the COP depends mainly on the ambient temperature and only slightly on the part load of the system. A curve fitting method was used to get continuous data for the electrical load within the known ranges. Using the entire model it is possible to determine sizing and design parameters. Also an assessment of storage temperature levels can be made with the target of maximum reduction of grid stress caused by PV feed in.

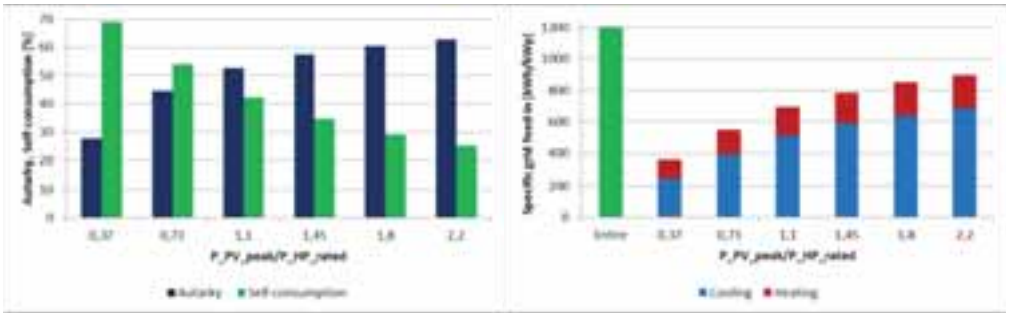

Figure 3 Autarky and self-consumption of system for different PV-installation (left). Specific remaining grid feed-in (right).

Figure 3 on the left hand side shows the possible autarky and self-consumption rate of the PV-HVAC system according to the electric power ratio of installed PV power related to the electric power rating of the heat pump. The right hand side shows the remaining grid feed-in during cooling and heating according to the above mentioned power ratio. Weniger et al. (2015) already shows that oversizing of the PV-generator in PV-storage systems leads to a saturation of autarky, while self-consumption is decreasing. Consequently, PV-peak feed in to the grid is increased. This effect can only be reduced by non-economic, oversized storages. The residual feed in to the electrical grid on the right figure is divided into the main cooling (blue) and main heating (red) period. It can be seen clearly, that the major part of remaining grid feed-in appears in cooling mode.

The model is capable for analyzing the system design aiming at optimal matching of PV, heating and cooling load and PCM-storage capacity. Figure 4 on the left hand side shows the amount of thermal energy which can be charged (blue) and discharged (red) daily in July for different electrical power ratios of PV and VRF (HP) system.

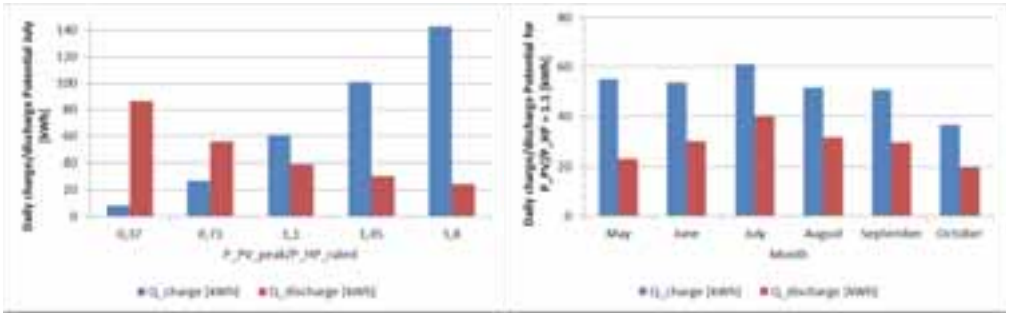

Figure 4 Daily charge/discharge potential of the storage. In July for variable PV-power (left). Daily charge/discharge potential for the entire cooling period with a relation of PV-power/rated power (HP) = 1.1 (right).

While for small scale PV the storage cannot be charged during the day, large scaled PV installations cannot use the stored energy the same day. The diagram on the right hand side shows the results for a slightly oversized PV-plant with a fix power ratio of 1.1. Regarding the average thermal energy which can be charged and discharged in one day during the whole cooling period, a storage capacity between 20 kWh and 30 kWh is found to be suitable for the considered system. It is important to say that this shows the maximum capacity which can be used. Furthermore there can be limits for the useable capacity due to the refrigerant cycle and the implementation/characteristic of the storage. Therefore another model for the cooling circuit and for the PCM-storage had been set up in EES (Engineering Equation Solver). These models are described in the upcoming Chapter.

3. Storage Implementation and Development

3.1. Possible Storage Implementations

As already mentioned there are different options for integration of a PCM-storage into the heat pump cycle. With regard to the desired function different melting temperature ranges can be taken into account. Figure 5 gives a general overview of the different possible storage functions and their operation. The left side shows the functions with the temperature range of each application, while on the right side a description of the cyclic operation of the system is given with charging and discharging phases.

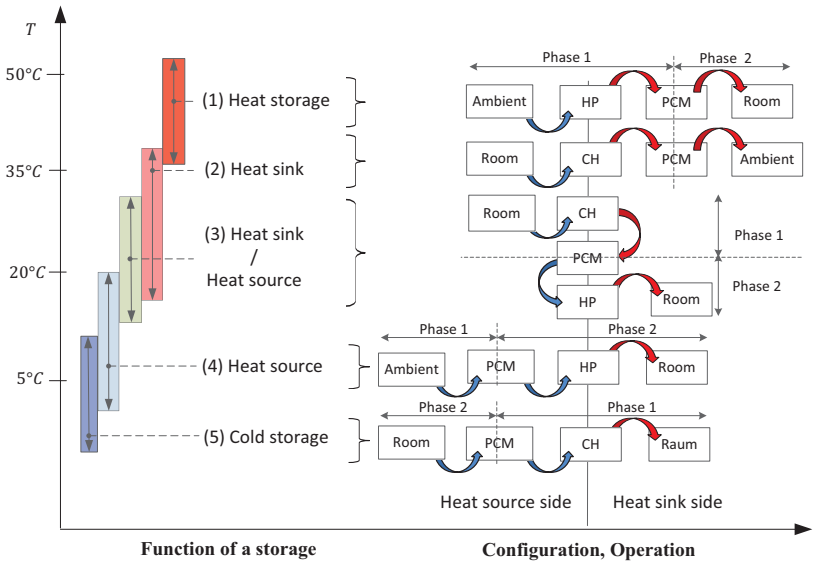

Figure 5 Different implementations of the Storage. Function of the storage with corresponding application temperature (left). Phases of operation on the right for chiller (CH) and heat pump (HP) applications (right). (Loistl et al., 2017)

For example configuration (1) represents a heat storage. In phase one the storage is charged with energy by heat pump (HP) operation, using the ambient as heat source. Subsequently in phase 2 the energy can be used for a heating purpose. Due to results of the TrnSys modelling phase, the possibilities to implement the storage as central cold storage (5), or as subcooler, which can also be categorized as heat sink were considered in more detail. For that purpose an EES model for the cooling circuit had been set up.

The model comprises enthalpy balances for the different steps of the refrigerant cycle characterized by the state points listed in table 2. For the refrigerant the dataset of R410A is used, which is the common refrigerant in state of the art VRF-systems.

Tab. 2: State points of the modelled refrigerant circuit.

Number	Definition
[1]	Beginning of Vaporising
[2]	End of Vaporising
[3]	Superheat of refrigerant
[4]	Hotgas after Compressor
[5]	Hotgas, beginning of Condensation
[6]	Liquid refrigerant, end of condensation
[7]	Liquid, subcooled refrigerant

The considered VRF-system operates with nearly fixed levels of evaporating and condensing temperatures. The following log(p)/h diagrams respect that with the shown isotherms for $T_{Condens}$ and T_{Evap}.

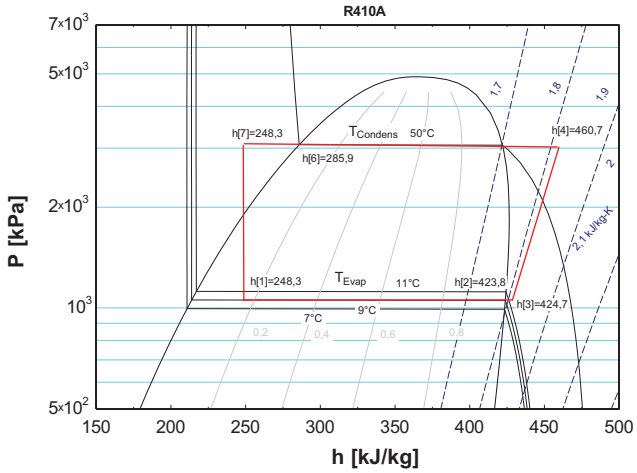

Figure 6 log(p)/h diagram. Example for the calculation of the refrigerant cycle.

Figure 6 shows the cycle state points in a log(p)/h diagram as given in Table 2 for the common system without any modifications of the refrigerant cycle. In this example the system works at its nominal cooling capacity of 22.4 kW with an evaporating temperature of 9 °C and a condensation temperature of 50 °C. The superheating is set to 4 K and the isentropic efficiency of the compressor is assumed to 0.7.

For a better understanding of the system, the storage configuration as subcooler is shown more detailed.

PCM-Storage working as subcooler

One possible implementation of the storage is to use it as additional subcooler in the refrigerant cycle. The idea using a thermal storage for subcooling the refrigerant is not completely new. The Electric Power Research Institute in California already worked on a combination of a VRF-system using an ice-storage for subcooling (Amarnath, 2009). The ice-storage there was charged in nighttime and discharged during the day to prevent peak loads. The main difference to this approach in the present investigation is the possibility to charge the storage in parallel to the regular cooling operation. Therefore it will be possible to charge the storage when PV-peaks occur.

First a simplified P&ID scheme of each storage implementation in case of charge (left hand side) and in case of discharge (right hand side) is shown. The scheme is reduced to a 2-pipe system working in cooling mode. The P&ID is followed up by the corresponding log(p)/h diagram both in case of charge (left) and discharge (right).

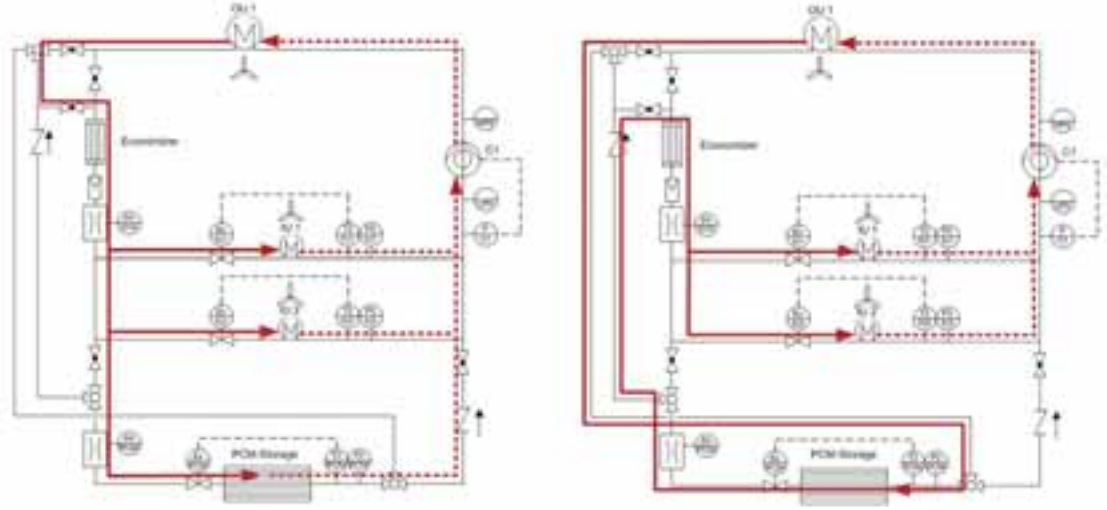

Figure 7 P&ID VRF system with a storage working as subcooler. 1 Outdoor Unit (OU), 2 Indoor Units (IU), Economizer and the PCM-Storage. Charging PCM-Storage on the left. Discharging PCM Storage on the right hand side.

Figure 7 shows on the left hand side the charging of the storage at the common evaporating level of the system, using PV surplus energy. Therefore, the phase change temperature has to be above this level. While charging, the storage is connected to the system like an additional Indoor Unit. Using the common evaporating level, there are no EER losses expected while charging. The storage works as additional load. Due to a higher part load ratio, positive effects on the EER while charging are expected. The right hand side of the P&ID shows the discharge case. When thermal load exceeds solar supply, the liquid refrigerant is led through the storage and is subcooled near the melting temperature of the chosen material. The already subcooled refrigerant is now led through the conventional economizer to ensure safely a sufficient subcooling before the refrigerant is led to the Indoor Units.

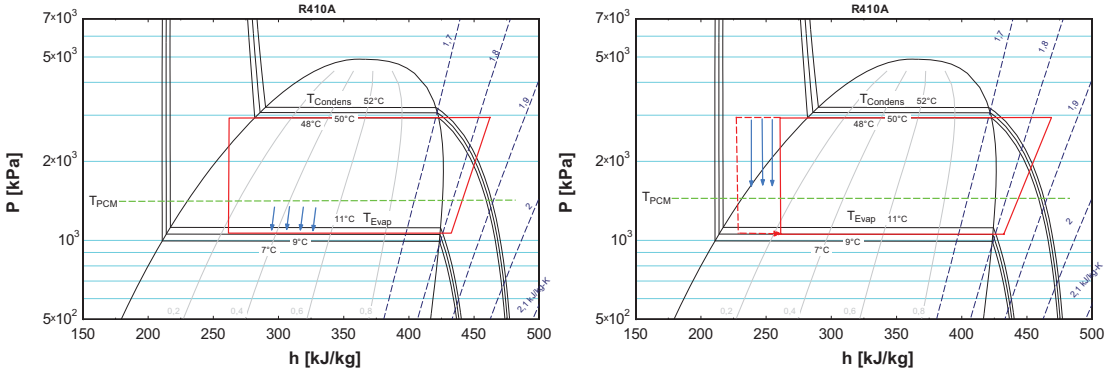

Figure 8 PCM storage used as additional subcooler in case of discharge (right). Charging on the common evaporating level of the system (left).

Figure 8 illustrates the refrigerant cycle of the process while charging (left) and discharging (right). The green line represents the melting temperature of the PCM, which has to be above the common evaporating temperature. With the storage used as subcooler there are two benefits to achieve:

- A higher usable enthalpy difference for cooling compared to conventional subcooling.
- Reaching sufficient subcooling by the storage can relieve the conventional economizer. Those systems usually subcool the refrigerant by evaporating a part of the condensed refrigerant to low pressure level. This part of the refrigerant is lost for the energy conversion but has to be transported by the compressor.

Both benefits lead to an increase of the EER during the discharge phase of the storage compared to conventional systems. This gives the possibility for a lower electrical demand when it is appropriate.

Figure 9 shows the EER improvement of the system at discharging the storage over varying melting temperature for the PCM-storage. It is assumed that the system works on its nominal conditions at an evaporating level of 9 °C. Lower melting temperatures improve the subcooling and also the EER up to 24% during the discharging cycle. On the other hand, a sufficient temperature difference between melting temperature and evaporating temperature needs to be ensured in case of charging. Taking both into account, the ideal melting temperature range for this implementation is between 16 °C and 21 °C. It has to be stated that the increased evaporator efficiency and the related improvement of the EER is a result of an additional input of driving energy during loading of the storage. Integrally, only minor changes of the average EER of the system should occur, related to the change of the load profile along the day.

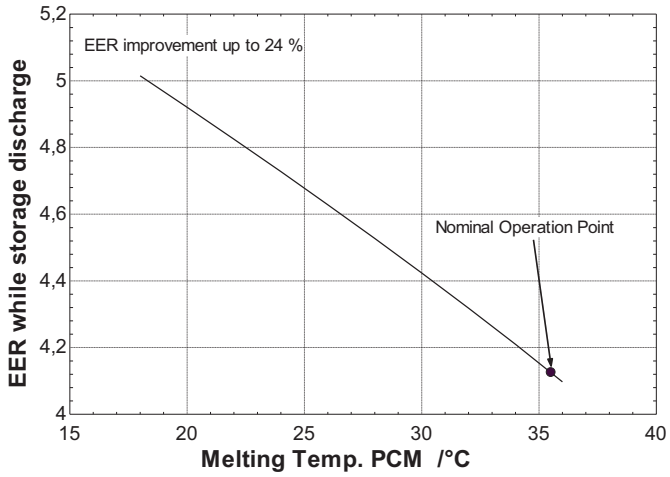

Figure 9 EER improvement in case of discharge for different melting temperatures of the PCM. Comparison to the nominal operation point of the system (storage working as subcooler).

3.2. Sizing/Development of Subcool Storage

Selection of storage material

Since it has been determined that the storage for the pilot installation should be working as a subcooler, a PCM material with a melting range around 16 °C and 21 °C had to be found. Besides a fitting melting point other important factors were a high latent heat and an economically viable price. To improve heat transfer rates it was decided to work with a metal heat exchanger. Hence a non-corrosive storage material was needed which excluded most salt-hydrates.

Regarding the temperature range, paraffin waxes are a good alternative. Their advantages include non-corrosivity, freezing without much supercooling, the ability to melt congruently, no segregation and they are non-hazardous. Parafol 16-97 from Sasol with an onset temperature around 16.5 °C, a latent heat of at least 220 J/g was found to be suitable(Sasol Performance Chemicals, 2017). The relatively low melting temperature range around 18 °C ensures a high temperature difference to the condensation point and therefore leads to a higher EER gain.

Since Parafol 16-97 like most paraffin waxes has a low thermal conductivity, graphite powder will be added to the storage medium to improve the thermal conductivity and allow higher power rates. The used graphite is SIGRATHERM® GFG 600. Tests with the mixture showed that with a mass ratio of 1:5 the thermal conductivity is sufficient and the mixture is still pumpable and therefore easy to fill into the storage container.

Construction of the storage unit

The test building is the institute of the ZAE Bayern located in Garching, Bavaria. Figure 10 shows the modeling result for the available cooling output of the PV driven VRF system and the cooling demand for a typical cooling day in August (left) and a day in transition time at the beginning of May (right, day with solar radiation). The data was generated by available weather data and the TrnSys model explained in chapter 2. Electricity is generated by photovoltaic panels. This electrical power is used to run the cooling cycle of the VRF system. The calculated possible total thermal power output is shown in red. The cooling demand of the building is shown in blue. The difference between available cooling power and cooling demand is shown in green (excess thermal energy) and black (cooling demand exceeding the thermal power output). Due to the lightweight construction of the investigated building, the cooling demand and the solar peak correlate very well as shown in Figure 10. Hence the potential for a load shift is comparably small. The analysis of the data from April to October, which are the months with a sizeable cooling demand in Germany, suggested a storage capacity of about 20 kWh to be sufficient. Would a building with a heavier construction with building materials such as concrete or stone be used, it would take a longer time to heat up the interior. The cooling demand would shift to a later time and therefore the peaks of demand and production would not correlate so well. This would lead to a bigger storage demand.

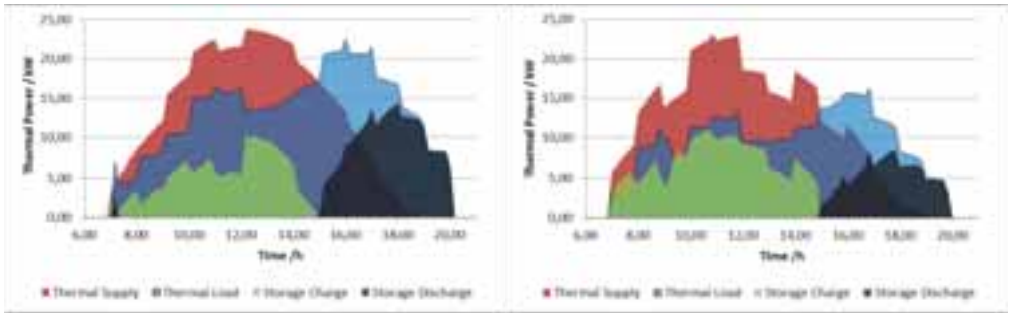

Figure 10 Exemplary thermal course of a typical cooling day for August (left). Thermal course of a day in transition time with solar radiation in May (right). The storage charge (green) and discharge (black) areas are representing potentials.

However, the possible maximum charging and discharging power is not arbitrary, but is limited by the construction of the storage and the heat exchanger. Furthermore it is influenced by the charging history. Hence, an iterative process was necessary to determine an appropriate storage size and heat exchanger construction.

First the volume of the storage container was calculated with the estimated 20 kWh storage capacity. A suitable heat exchanger was modelled using the Engineering Equation Solver (EES) software. Afterwards, the charging and the discharging process were simulated.

Charge

The cooling fluid R410A is injected into the heat exchanger of the storage unit and evaporates, cooling the PCM material. As a result, the selected PCM Parafol 16-97 crystallizes along the heat exchanger. The model took into account the evaporation of cooling fluid on the inside of the heat exchanger as well as the heat transfer through and the phase change in the PCM material. It includes different pressure loss phenomena (static, acceleration, frictional, pipe bends) and the flow boiling effects after Shah (VDI-Gesellschaft Verfahrenstechnik und Chemieingenieurwesen, 2002, Nellis and Klein , 2009). Depending on the distance between phase front within the Parafol 16-97 and the heat exchanger the transferable power varies.

Therefore, the maximum transferable power depends on the way the storage was charged and discharged before. To simplify the model it was assumed that each day was independent of the one before. That means the storage was discharged every morning. The system is not highly reactive, meaning switches between charging and discharging in a short time scale are not favorable. Therefore one can assume that there is only one charging and one discharging cycle per day. Under these assumptions, the possible power transfer is a function of the state of charge (SoC) of the storage, because the distance between the heat exchanger surface and the phase front in the PCM is growing with a larger SoC. The higher the SoC, the larger is the fraction of PCM in the solid state.

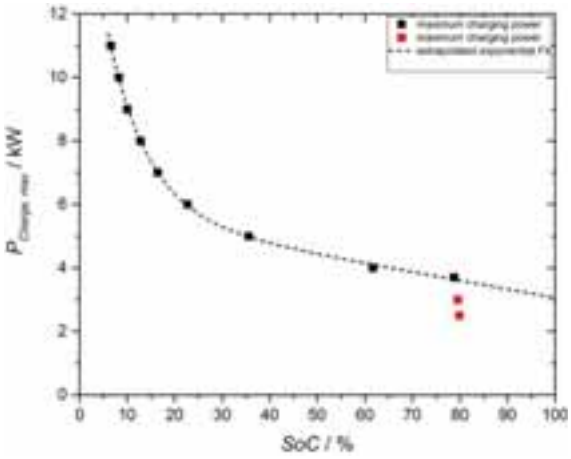

Figure 11 Maximum charging power depending on the SoC

Figure 11 shows the maximum transferable charging power depending on the SoC. Until about 80% of SoC it can be fitted by an exponential function. At higher SoC values (red squares) the maximum charging power decreases rapidly. This is because in the simulation the phase fronts reach symmetric borders at that point. Consequently, the calculated heat exchange surface decreases rapidly, which reduces the transferable power. However, in this simplified model heat transfer parallel to the heat exchanger was not considered. Therefore it is expected, that the decline in the maximum transferable power is not that sharp in a real storage device. This was already confirmed in preliminary tests. For further calculations, the exponential fit was extrapolated to a SoC of 100%.

To calculate the maximum charging energy, the minima of the available thermal power and the maximum possible charging power resulting from the actual SoC were determined.

Discharge

During discharging liquid R410A is injected at high pressure and temperature into the heat exchanger of the storage unit. Within the storage, the cooling fluid is cooled from about 48 °C to nearly the phase change temperature of the PCM (18 °C), melting Parafol 16-97. The maximal possible discharge power can be calculated via equation 1.

$$P_{Discharge} = \dot{m}_{R410A} \cdot \int_{T_c}^{T_h} c_{p,l}(T) \cdot dT \qquad \text{(eq. 1)}$$

Hereby $P_{Discharge}$ is the maximum discharge power. $\dot{m}_{R410A}$ is the mass flow rate of the cooling liquid, $c_{p,l}(T)$ the temperature dependent heat capacity, and T_h and T_c are the temperatures at the in- and outlet of the PCM storage unit. The mass flow rate is given by the actual cooling demand. The cooling power is provided by the evaporation of R410A. Hence, the mass flow rate is given by:

$$\dot{m}_{R410A} \approx \frac{P_{Cooling}}{\Delta h_{R410A}} \qquad \text{(eq. 2)}$$

For a fixed inlet temperature T_h of 48 °C the discharge power is found to be limited to about 28% of the cooling power. The excess energy is necessarily provided by the cooling cycle (liquefaction).

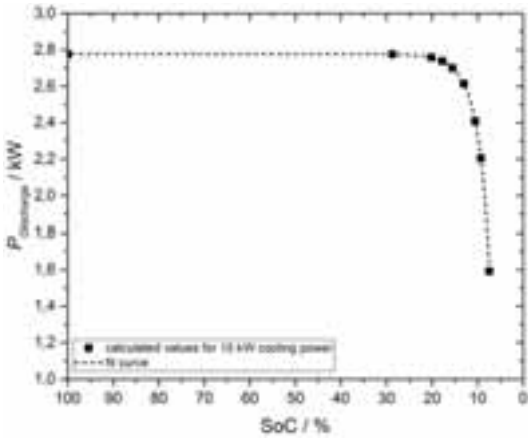

Figure 12 Discharge power depending on the SoC for a cooling power of 10 kW

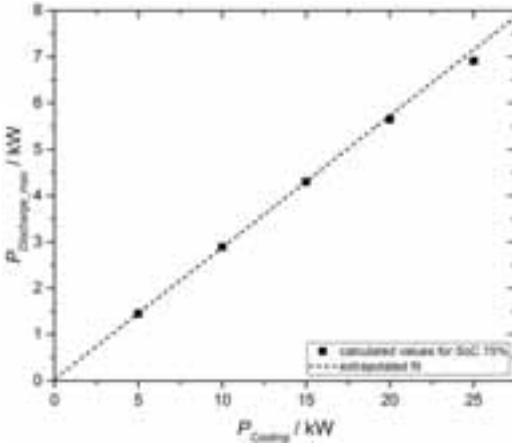

Figure 13 Maximum discharge power depending on the cooling power for a SoC of 75 %

The discharge power is in most cases rather limited by this fact then by the discharge characteristics of the storage unit. Figure 12 shows the SoC dependent discharge power for a cooling power of 10 kW. Down to around 20% SoC the discharge power is virtually constant (100% means the PCM is solid, while 0% means it is liquid). After that there is a fast decay. It results from the heat transfer which in this region limits the discharge power. However, this is a worst case estimation. For example heat conduction parallel to the heat exchanger was not taken into account in these calculations. Hence, it can be expected that the decay is not as steep in reality. In most operating conditions the discharge power will be limited by the cooling power.

In Figure 13 the maximum discharge power is shown as a function of the cooling power for a SoC of 75%. The data yields a nearly linear relation. Only at very high power rates the slope flattens. It confirms that the discharge power is generally limited by about 28% of the cooling power.

Hence, the calculation of the maximum theoretical available discharge energy per day was simplified and calculated by multiplying the cooling demand with a factor of 0.28 when cooling demand exceeds the generated cooling output of the VRF system.

Results of the iteration

The found limits of charging and discharging power have been implemented in the system model. For each day of the cooling period a possible maximum thermal energy which can be shifted was calculated again. These restrictions on the transferable power led to a lower reasonable storage size. The iterative process was continued and a latent heat storage capacity of 16 kWh was determined.

The final heat exchanger unit contains six heat exchangers with each 23 m length which will enable the storage to a peak power of more than 10 kW while charging.

The storage dimensions will be 1400 x 600 x 600 mm. 390 l of the PCM-Graphite compound will be used. This corresponds with a latent heat capacity of 16 kWh. A schematic drawing of the storage and the heat exchanger unit is shown in Figure 14.

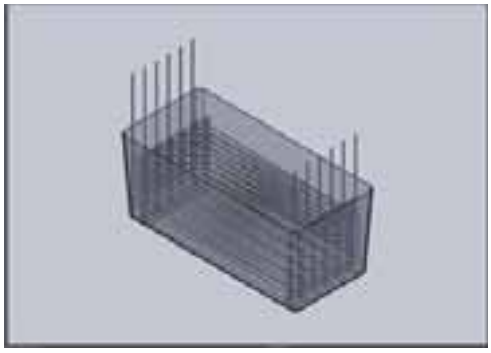

Figure 14 Schematic drawing of the storage container and the heat exchanger

3.3. Implementation of Storage Characteristic to Refrigerant Cycle Model

After the design phase for the storage and the iteration to work out a suitable storage capacity, the characteristic curves for the storage were implemented to the refrigerant cycle model. Figure 15 shows the course of a typical cooling day in August. The data is related to the thermal course shown in Figure 10 on the left representing the theoretical charge and discharge potential independent from the kind of storage implementation.

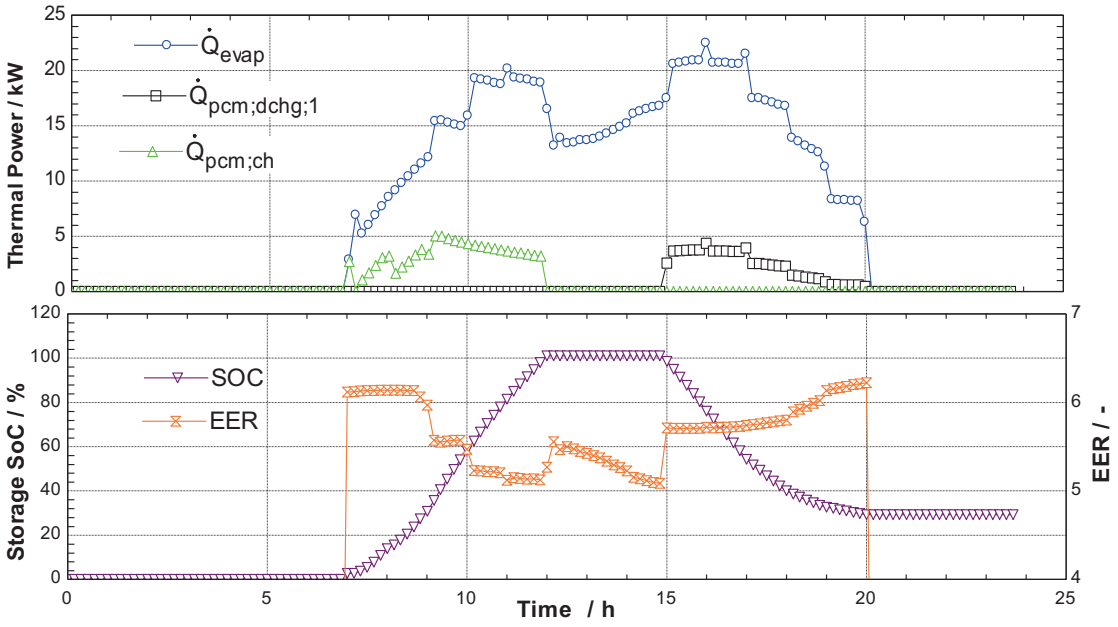

Figure 15 EES model of the refrigerant cycle fed with thermal load data and storage characteristics. Thermal course for a typical cooling day in August (Data out of Figure 10 on the left showing the potential). Thermal load, storage charging and discharging power in the upper part. SOC and EER in the lower part.

The upper part of Figure 15 shows the cooling load (blue, circled) of the system including storage charging. The green line (triangular) represents the storage charging power taking into account the characteristics described by Figure 11. The black line (squares) shows the possible discharge of the storage with respect to the limitation through the current thermal load. The bottom part of Figure 15 shows the variation of the systems EER (orange curve) and the storage SOC (violet, triangular) during the day. As already mentioned due to a higher part load ratio while charging, a slight EER-gain through charging can be expected. The real benefit is shown when discharge begins at 15:00 pm and the EER increases from 5 to nearly 6.

This EER gain while discharging the PCM-storage will significantly reduce electrical load when it is appropriate. In this example, the storage will be completely charged before the PV peak occurs. Thus, the course of the SoC trend line directly indicates that measures have to be taken for controlling the operation of the storage. A predictive control strategy is required in order to charge the storage completely while covering the PV-peak.

4. Summary and Outlook

The study describes the modelling and sizing phase for a PV driven VRF system coupled with a thermal PCM-storage. The integration of the storage as subcooler is described in detail. Considering the thermal load, PV-supply and the systems boundary conditions an adequate PCM was chosen and a storage with sufficient thermal characteristic was designed.

Next steps are the installation and start-up of the VRF pilot installation in Garching. In parallel the designed PCM-storage will be built up for laboratory tests. In a second step a tested and optimized pilot-storage will be implemented to the VRF installation. For the integration of the PV peak without losses of solar fraction, predictive control strategies will be worked out and tested during operation of the system.

Abstract

Solar chimneys have been used for natural ventilation and cooling in the Middle East already hundreds of years ago. In modern buildings, the concept could contribute to energy savings and reduction of greenhouse gas emissions. An optimized system would enable a sustainable and permanent operation of this natural ventilation concept. This study analyzes the effect of wind and the possibilities to increase the ventilation effectiveness of solar chimneys by optimizing the design of the chimney outlet. Computational fluid dynamic (CFD) simulations have been used to investigate the general influence of the wind effects on a building which is naturally ventilated with solar chimneys. The results show that the air change rate increases or decreases depending on the predominating wind direction. To be able to accomplish a system which supports the natural ventilation irrespective of the wind direction, different wind cowls were tested at a test rig located at the University of Applied Sciences Munich. As a result of this study, the flow velocity can be shown as a square root function of the wind speed. An average flow velocity between 0.6 – 1.1 m/s can be reached by using turbine ventilation systems.

Keywords: Solar chimney, wind cowl, energy savings, natural ventilation, CFD simulation, ANSYS FLUENT

1. Introduction

Approximately 15 % of the total electrical energy demand of today's office and factory buildings is used by mechanical ventilation (EnOB 2016). The use of natural ventilation and natural cooling systems could be a possible solution to reduce the energy consumption in the building sector. This paper explores the concept and the potential of an enhanced solar chimney which uses just the sun and the wind as its driving forces. Therefore, no conventional sources of energy are used.

During sunshine, solar radiation enters the chimney through a transparent cover and heats up an absorber surface. The difference between the chimney temperature and the ambient air temperature generates a buoyancy effect. As a result, the air is drawn out of the building. To generate this buoyancy effect also during the night-time, for night cooling or periods with cloudy sky, the effectiveness of such a system needs to be increased. Permanent and sufficient ventilation could be provided by using wind effects with an optimized design of the chimney outlet and wind cowls in addition to the buoyancy effect.

Khan, Su and Riffat (Khan et al. 2008) give a good overview about historical wind towers and modern techniques for wind driven ventilation systems. Kisteledgi and Haber (Kistelegdi, Háber 2012) discuss the direction of wind towers and the design of their outlets for the natural ventilation of a plus-energy manufactory in the South of Hungary. Ismail and Rahman (Ismail, Rahman 2012) show possibilities for future configurations of wind turbines, fans and solar panels and combinations of static and dynamic systems.

To study the effect of wind and its benefit for a natural ventilation concept with a solar chimney, the investigation of this study contains two major parts. The first part describes the general impact of wind on a reference building which is naturally ventilated with solar chimneys. This analysis was done using CFD simulations to see the influence of wind direction and the positioning of the solar chimneys. Afterwards an experimental investigation was conducted to investigate different wind cowl systems which could be integrated in a solar chimney concept using measurement data from a test rig.

2. Impact of wind on natural ventilation of a reference building

2.1. Methodology and simulation set-up

The impact of wind on a building regarding the ventilation effectiveness is analyzed using a standard building model as a reference for the location of Munich, Germany. The reference model is a three story office building and it was taken from the VDI Norm 6009 (VDI 2001). The same model has been used in previews studies to investigate the viability of using solar chimneys for natural ventilation in Germany (Schwan et al. 2017a). A solar chimney was attached to the south façade of each floor, respectively. The inlet window sizes and building geometry for the three floors was identical to the reference model.
The building model was simulated with the software ANSYS workbench 16.2, which consists of different applications. The geometry of the building model was set up using the DesignModeler. In addition to the building, a surrounding area was simulated as well. Both, reference building and its surrounding area can be seen in Fig. 1.

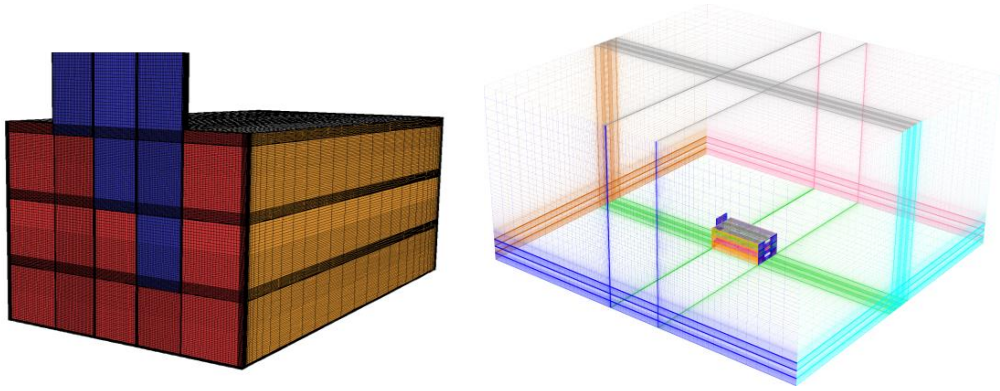

Fig. 1: Model of the reference building (left) and surrounding (right) developed in ANSYS FLUENT

The reference building is 30.6 m long and 16.6 m wide. The solar chimneys are 4 m, 8 m and 12 m high; depending to which floor they are attached to. Every solar chimney is 3 m wide and has an inside air gap of 0.3 m. In previous investigations an air gap of 0.3 m was found to be the ideal size for a maximum air flow without the appearance of backflows (Schwan et al. 2017b). The building, including the solar chimneys, has a height of H = 16 m. In every direction the building is 5H away from the boundaries of the surrounding, respectively. The simulation of the surrounding is necessary to be able to simulate the wind effect properly. It is limited to 5H to retain a manageable simulation time. The distance is chosen to be the same in all directions, because different wind directions are investigated. The parameters for the building and the solar chimneys (SC) can be seen in Table 1 and Table 2.

Table 1: Building parameters

Parameter	Symbol	Value	Unit
Height of building	H_B	16.00	m
Length of building	L_B	30.60	m
Width of building	W_B	16.60	m
Window size (north)	A_W	9.50	m²
Area of each floor	A_F	507.96	m²
Total floor area	$A_{F,ges}$	1523.88	m²

Table 2: Solar chimney parameters

Parameter	Symbol	Value	Unit
Cross section area	A_{SC}	0.841	m²
Height of SC ground floor	H_{SC1}	12	m
Height of SC first floor	H_{SC2}	8	m
Height of SC second floor	H_{SC3}	4	m

The major influence factor for the both, simulation time and the accuracy of the simulated results, is the applied mesh. For this investigation the software package ANSYS ICEM CFD was used for the mesh generation. High numbers of cells are used in the solar chimney and the building floors to provide reliable results in these areas. Lower numbers of cells are used in the surrounding area to reduce the calculation time. A hexahedral mesh was used due to lower numbers of cell element and a higher quality of the mesh compared to a tetrahedral mesh. The used mesh consists of more than 2,000,000 hexahedron cell elements. ANSYS FLUENT was used for the calculation of the fluid dynamics. The post processing and evaluation of the results have been done with ANSYS CFD Post. The investigations were performed with steady simulations for specific reference days to be able to reduce the simulation time. The turbulence of the air flow is calculated with the k-ε model, considering gravity and buoyancy effects. An enhanced wall treatment was used to compensate inaccuracies of the turbulence model for areas next to the walls. The air density was calculated using the Boussinesq model.

2.1. Investigated aspects

The ventilation effectiveness was studied according to the position of the solar chimney, the wind direction and the wind speed for different seasons. Steady simulations were conducted for three reference days (two in summer and one in winter) to be able to validate the impact of the wind on the natural ventilation system. The weather data for the city of Munich was taken from the German Test Reference Year (TRY) of 2010 for the chosen reference days (Deutscher Wetterdienst 2014). The used data can be seen in Table 3.

Table 3: Weather of used reference days

Month, day, time	July, 23rd, 12 pm	August, 12th, 5 pm	December, 5th, 12 pm	Unit
Wind direction	260 (SW)	190 (S)	100 (SE)	°
Wind velocity (H = 10 m)	3	1	5	m/s
Wind velocity (H = 16 m)	3.70	1.23	6.16	m/s
Air temperature (H = 2 m)	24,8 297,95	32,8 305,95	-2,4 270,75	°C K
Air pressure	96,09	95,45	95,54	kPa
Direct solar irradiation	550	59	24	W/m²
Diffuse solar irradiation	291	201	128	W/m²

2.2. Comparison between reference days

The weather data of the three reference days are completely different, as it can be seen in Table 3. The largest influences on the buoyancy effect of the solar chimney are the height of the chimney and the temperature difference between the inner part of the solar chimney and the ambient air temperature.

On the December reference day, the temperature difference is high, because of the low ambient air temperature. As a result the air changes per hour (ACH) are high as well. All simulated results of the ACH for the three reference days can be seen in Fig. 2. The ACH will be even higher with an increased height of the solar chimney. Therefore, the ACH of the ground floor is higher than the ACH of the first and second floor. The wind has a positive effect on the results of the ACH for the December reference day. The ambient air temperature on the reference day in August is significantly higher than the temperature in the building. In addition, the solar irradiation is not strong enough to rise the temperature in the solar chimney. As a result, backflows occur in the solar chimney. Just the wind can balance that effect, although sufficient ventilation cannot be provided. On the July reference day, the ACH is higher and the effect of the height of the solar chimneys can be seen as well. The wind from south west has no significant positive effect of the ACH on that day. These results show the effect of the ambient air temperature as well as the effect of the wind.

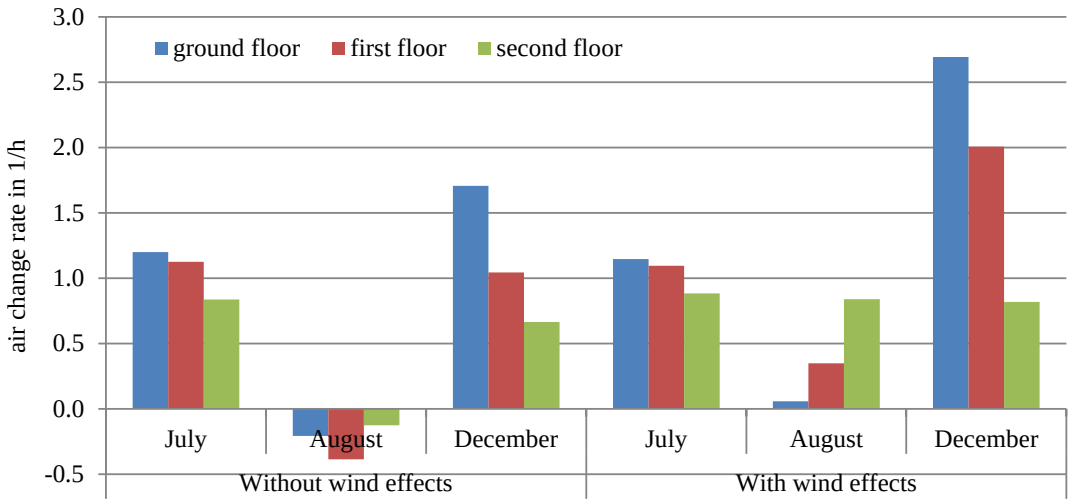

Fig. 2: Air changes per hour without and with wind effects for three reference days

2.3 Investigation of wind direction

Different wind directions have been investigated for the same reference day in July, to ensure a better comparability of the results to neglect the other effects. The considered wind directions can be seen in Fig. 3.

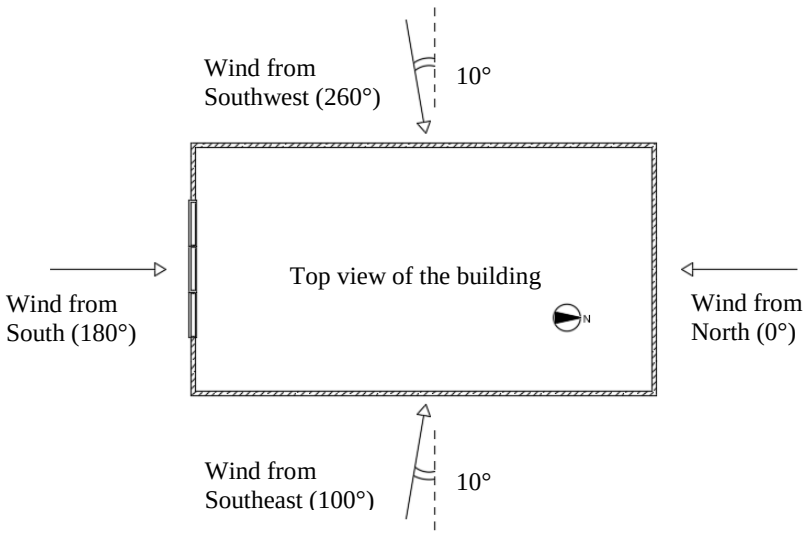

Fig. 3: Considered wind directions

The simulations have been conducted for the four wind directions. The results show that the effect of wind depends considerably on the wind direction. The results of the ACH can be seen in Fig. 4.

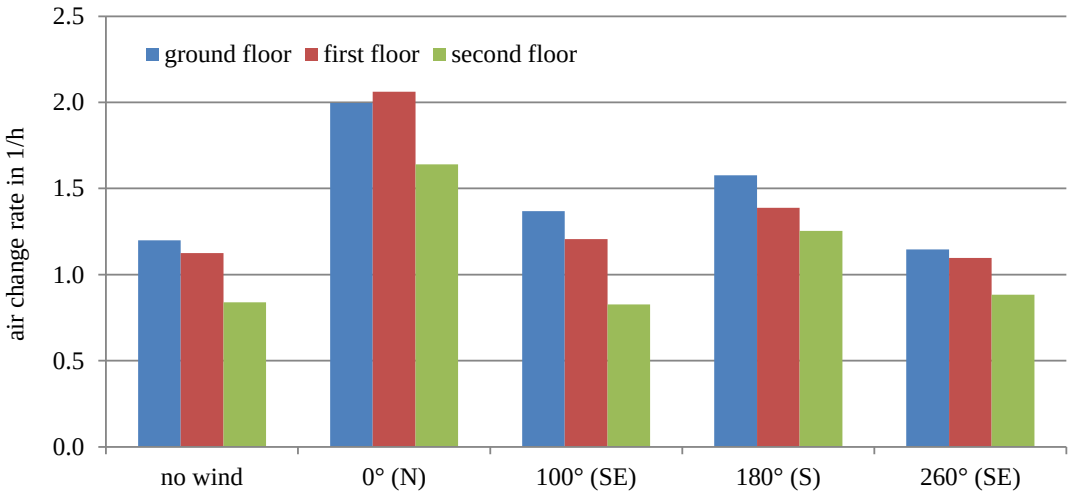

Fig. 4: Air changes per hour for different wind directions for a reference day in July

If the wind direction was North (0°) or South (180°), then a distinct wind profile occurs. The wind increased the provided volume flow in the solar chimney and therefore the ventilation effectiveness (compared to simulations without wind) for all three floors. A velocity profile for the air around the reference building and inside the chimney can be seen in Fig. 5. The air change rate is approximately 30 % higher compared to simulations without wind.

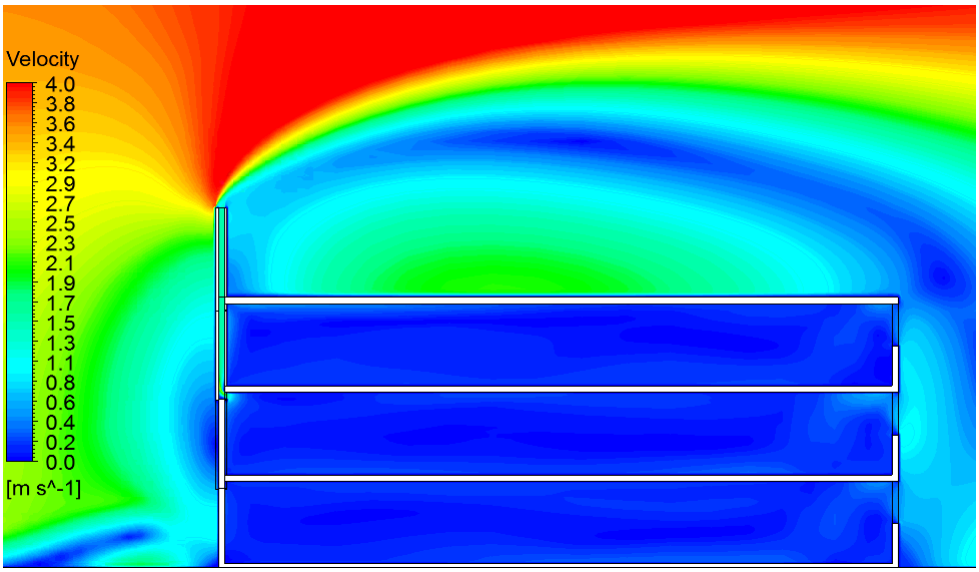

Fig. 5: Velocity profile for air around the reference building (wind direction: South)

If the wind direction is inclined and non-parallel to the small side of the solar chimney, for example for wind from South-West (260°) or South-East (100°), there is a significant change in the resulting air volume flows. At least in one of the three solar chimneys, a reduced volume flow occurred for these wind directions compared to simulations without wind. The air change rate was reduced by up to 10 % in these cases. These results highlight the importance to optimize the design of the solar chimney outlet in order to avoid negative influence of wind effects and rather use wind effects to enhance the ventilation effectiveness.

3. Optimization of the solar chimney outlet through integration of wind driven systems

3.1. Methodology and test-rig

Using wind-driven ventilation systems at the top of a solar chimney should offer permanent and sufficient ventilation and avoid negative influences on the performance of the thermally driven solar chimney. Therefore, different types of cowls and roof ventilation systems were analyzed for their contribution to natural ventilation. Only systems without additional gears (e.g. photovoltaic-wind driven systems) were considered. The systems work independent of the wind direction, which should avoid the problems discussed in the previous chapter. The experimental investigation was mainly focused on findings about the ventilation rate in general and as a function of the wind speed. Also, the influence by the thermal buoyancy effect and the solar radiation was part of the study.

With a height of 4.5 m, the chimney overlapped the adjacent building and enabled an incident flow from all directions. The length of the chimney was 1 m and the width 0.5 m. The diameter of the air inlet and outlet was 0.3 m. The test rig was located at the University of Applied Science in Munich and faced in southwestern direction. The test rig can be seen in Fig. 6.

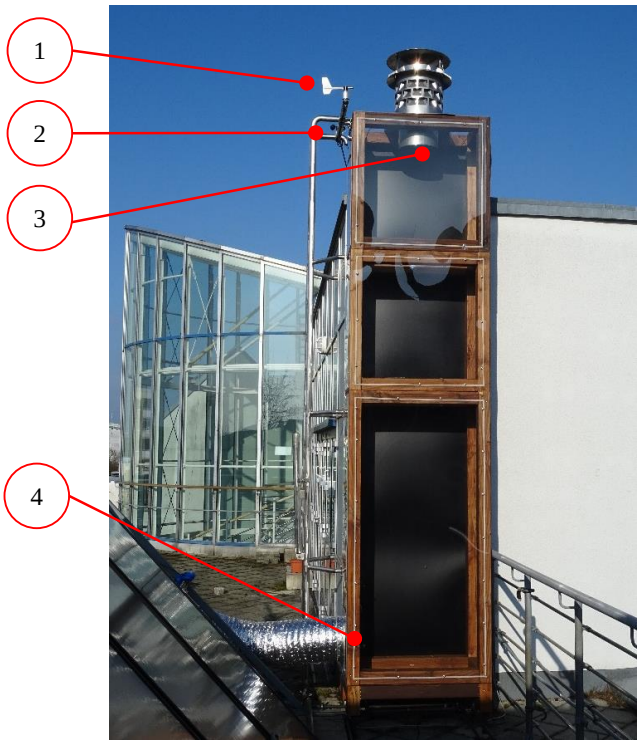

Fig. 6: Test rig at University of Applied Science Munich

A wind direction transmitter (1) and a vane anemometer (2) recorded the wind regimes. Inside the chimney, the flow velocity, pressure and temperature of the air were measured. Therefore, two thermoanemometers were installed at the air outlet (3) and inlet (4). Table 4 shows the installed measurement instrumentation and corresponding measuring range.

Table 4: Installed measurment instrumentation at the test rig

Measured variable	Measuring instrument	Measuring range
Wind speed	Vane anemometer	0 – 50 m/s
Wind direction	Wind direction transmitter	0 – 360 °
Air velocity, pressure and temperature	Thermoanemometer	0.08 – 2 m/s

On a test rig, three different types of dynamic turbine ventilation systems by Rotovent Systems (RS) and an inject nozzle by Euro Windkat were tested (see Fig. 7). The turbine ventilation systems differ from the shapes of their blades.

RS cyclone | RS | RS premium | Injection nozzle

Fig. 7: Three different types of turbine ventilation systems (left) and an inject nozzle (right)

3.2. Correlation between wind speed, buoyancy effect and chimney airflow velocity

During the experimental investigation, global solar radiation, wind speed, the flow velocity inside the chimney, the temperatures inside the chimney and the ambient air temperature have been measured. For each wind cowl systems the data was recorded for at least two weeks to ensure to have different weather situations with varying intensities of wind and solar radiation.

Fig. 8 shows the global solar radiation, the wind speed and the resulting flow velocity in the solar chimney for an exemplary hour of the wind cowl system with straight blades (RS cyclone).

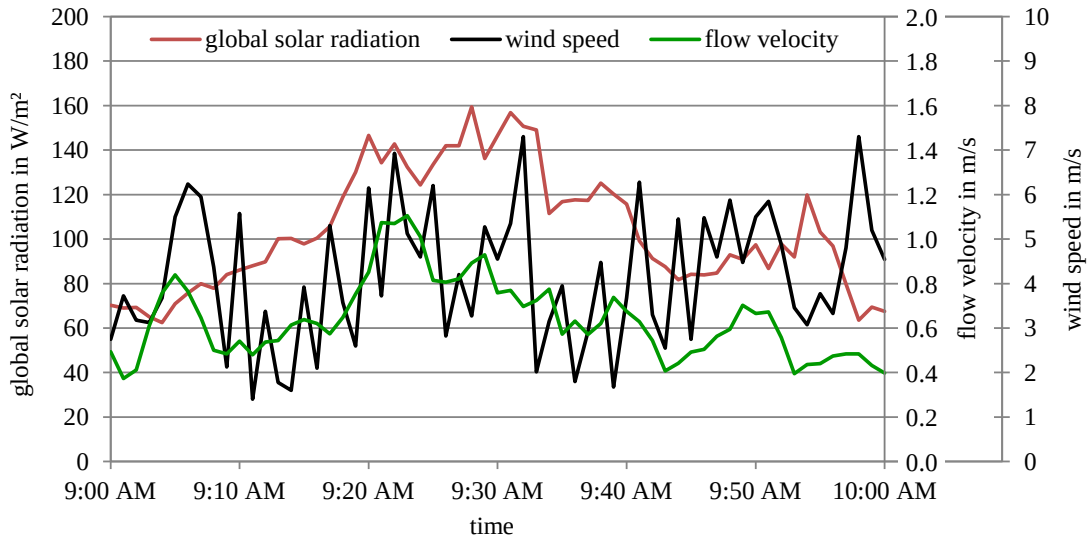

Fig. 8: Solar radiation, wind speed and flow velocity inside the solar chimney (18th March 2017, 9:00 – 10:00 am)

The buoyancy effect and the wind effect are the two major impact factors for the resulting flow velocity inside the solar chimney. The buoyancy effect is mainly influenced by the temperature difference between the ambient air temperature and the temperature inside the chimney and therefore indirectly influenced by the solar radiation as well. To quantify the share of both of these factors – wind and buoyancy – further investigations have been conducted, in which the thermal influence was neglected.

Fig. 9 shows the flow velocity inside the solar chimney as a function of the wind speed for the dynamic turbine ventilation system with straight blades. An average flow velocity more than 1 m/s can be reached. The development of the flow rate equates a root function. In comparison to the thermal buoyancy due to an increased absorber temperature, dynamic wind cowls show the same speed level. Therefore, the integration of wind-driven cowl systems in the concept of a solar chimney shows great promise.

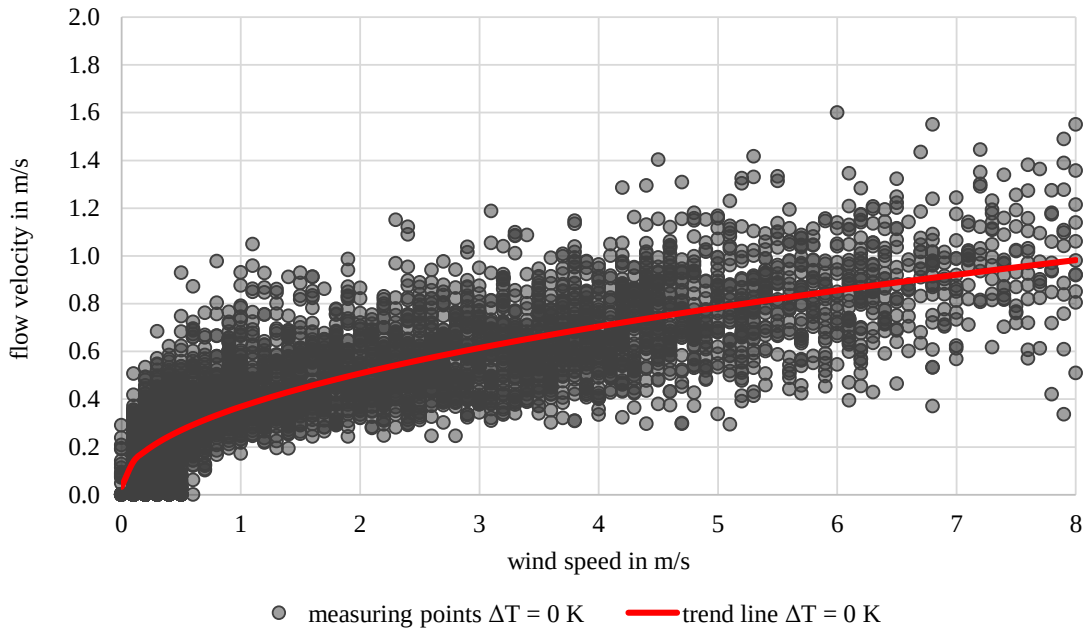

Fig. 9: Flow rate without thermal buoyancy for a turbine vent with straight blades (RS cyclone)

To consider the influence of the two driving forces wind and sun, the flow velocity can also be shown including the thermal buoyancy. Therefore, the air temperature difference between inlet and outlet was divided into six temperature ranges. Fig. 10 shows the flow velocity as a function of the wind speed and thermal buoyancy for a turbine ventilation system with straight blades. In comparison to Fig. 9 the flow velocity increased up to 1.8 m/s.

The measurements also illustrate, that the two driving forces interferer each other. For low wind speed, the impact of the thermal buoyancy is high. Otherwise the temperature differences between inlet and outlet decreased for increasing wind speed. This trend was noticed for all four ventilation systems.

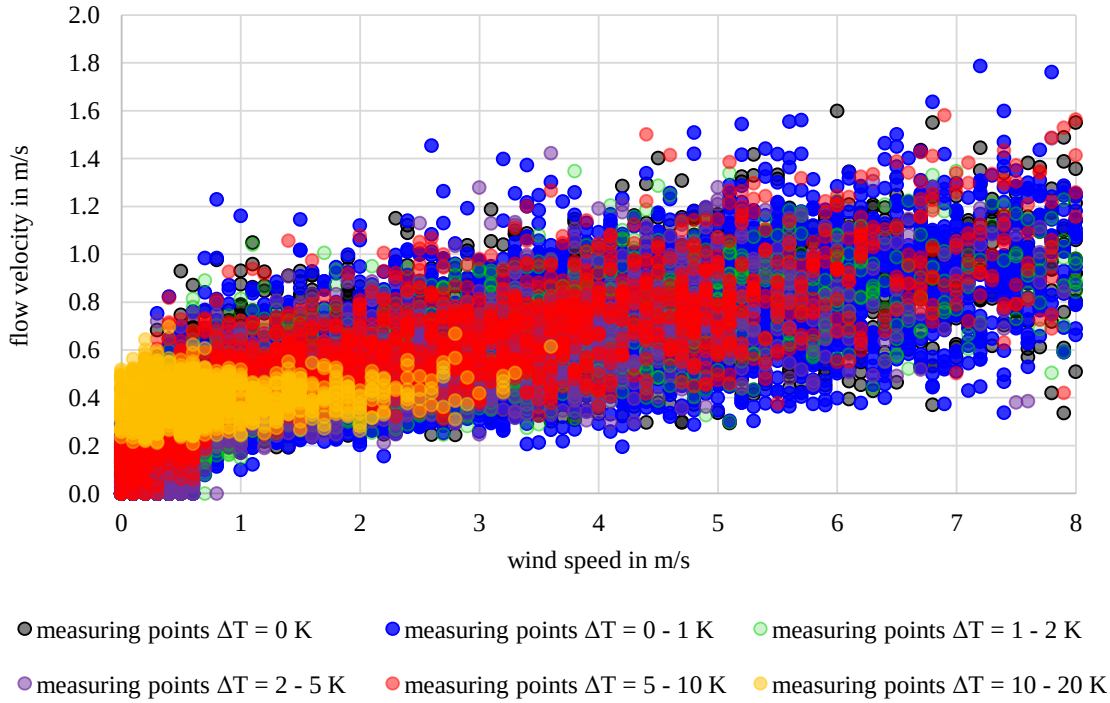

Fig. 10: Flow rate with thermal buoyancy for a turbine vent with straight blades (RS cyclone)

3.3. Comparison between different wind cowl systems

The flow velocity inside the chimney increases with higher wind speeds according to a square root function.

$$f(x) = a\sqrt{x} + b \qquad \text{(eq. 1)}$$

For time steps with a temperature difference between the inner part of the solar chimney and the ambient air, a buoyancy effect occurs. This results in positive flow velocity even in situations without wind with wind speed = 0 m/s. In eq. 1 this offset to the origin of coordinates is represented by the constant b. For time steps without buoyancy effect, the graph starts in the origin of coordinates. The gradient of the graph a is different for all four investigated systems. The different gradients and the trend lines of the measurement points of all four systems can be seen in Table 5 and Fig. 11.

Table 5: Gradient of graph and average flow velocity for a wind speed of 10 m/s for all wind cowl systems

Wind cowl system	Gradient of graph a	Average flow velocity for a wind speed of 10 m/s
RS	0.21	0.66 m/s
RS cyclone	0.34	1.08 m/s
RS premium	0.31	0.98 m/s
Injection nozzle	0.33	1.04 m/s

Based on the measurement results, it can be seen that the best values can be achieved with the RS cyclone system. The measured points of the injection nozzle have the highest deviation compared to the dynamic RS systems.

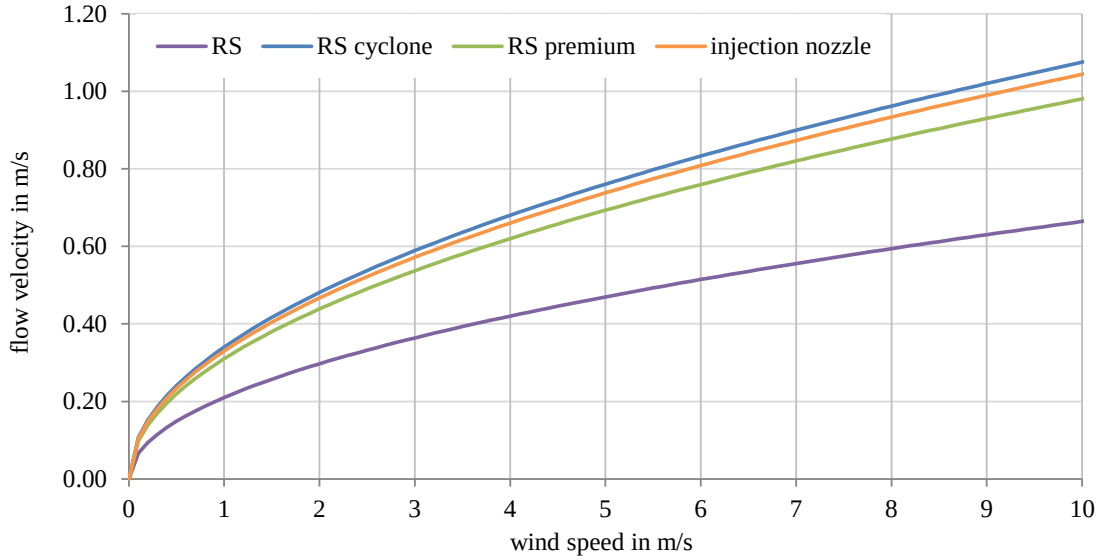

Fig. 11: Trend lines of the flow velocity without buoyancy effect for all four systems

4. Conclusion and Outlook

In this study the influence of wind effects on natural ventilation systems with solar chimneys has been investigated applying CFD simulations and measurements. The results showed the importance of considering wind effects for solar chimney projects and the huge impact of wind on the resulting air change rates. Especially the wind direction is important and can either lower or enhance the effectiveness of the solar chimney. A suitable solution to achieve a system which utilizes the wind effects irrespective of the wind direction, are wind cowl systems. Turbine vents showed the best performance and generated average flow velocities above 1 m/s. A higher effectiveness of solar chimneys can be reached through the integration of wind cowl systems. This offers a longer time of operation of the natural ventilation system, saves more energy and reduces greenhouse gas emissions.

In the future, the presented findings will be used in further research work to develop a planning tool for solar chimney projects. This planning tool should provide information about the expected ventilation rates and increase of the effectiveness of solar chimneys by using wind effects for the specific place of installation. Further research needs to be done to integrate the findings to a simplified calculation method to predict the effectiveness and efficiency of different solar chimney concepts.

MULTI-FUNCTIONAL FAÇADE WITH PV FOR SOLAR AUTONOMOUS COOLING APPLICATIONS

T. Selke[1], T. Schlager[1], M. Rennhofer[1], A. Heinz[2], D. Brandl[2], T. Mach[2]

[1] AIT Austrian Institute of Technology GmbH, Vienna (Austria)

[2] Graz University of Technology, Institute of Thermal Engineering (Austria)

Abstract

The objective of the Austrian research project COOLSKIN is the development, assessment and functionality approval of a façade-integrated energy system for cooling. Façade integrated photovoltaic modules directly convert the solar irradiation onto the vertical surface into electricity, which operates the compressor unit of a heat pump cycle for controlling the indoor temperature of the adjacent room. The COOLSKIN system concept addresses a) decentralization of the energy supply and b) energy autarky by the usage of solar electricity, i.e. no external energy sources are required. Methods to fulfil the project requirements are i) elaborated system simulations, ii) experimental tests with a functional model of the system and iii) field tests under real operating conditions. With this paper, the authors present the a) specification of the COOLSKIN system design and b) first results and findings of both conducted system simulation and laboratory test measurements of electric components.

Keywords: Multi-functional façade, solar autonomous cooling, façade integrated Photovoltaics

1. Introduction

In 2015 the Austrian research project COOLSKIN was launched, in which a multidisciplinary team aims to develop, assess and test different façade concepts with the technical integration of both photovoltaics (PV) and air-conditioning or cooling system into the façade construction. There is a good coincidence between the daily and/or seasonal profiles of the cooling demand in buildings and the solar irradiation hitting the surface area of the façade. Furthermore, there has been a significant cost reduction of photovoltaic modules in the last decade (Fraunhofer ISE). The COOLSKIN energy design concept focusses on technical solutions for achieving high level of energy autarky in the operational phase, i.e. there is no connection to the public grid. The COOLSKIN concept addresses as well a high level of pre-fabrication of the technical façade solution.

The COOLSKIN team formulated additional framework conditions for the development:

- Office buildings offers a greater potential for decentralized cooling system solutions compared to residential buildings. Therefore, primarily office buildings are investigated. The technical configurations of the façade do respect the boundary conditions and specifications of an office façade.
- Europe is the primary target market – Increasing demand for cooling and air-conditioning in the building sector and the climate change will lead to additional markets. All European cities are considered for being a potential application field.
- COOLSKIN concept addresses primarily technical solution for covering the cooling demand in buildings. Nevertheless, there is an emphasis on technical solutions for all-year operation, and other energy demands like heating and electricity for other appliances are going to be investigated as well.

For achieving the COOLSKIN target the research project is sub-divided into three development steps: i) evaluation of promising system configurations, ii) construction and dimensioning of a functional model and iii) implementation and energy monitoring with the help of a field test façade. This paper reports on first results and findings of the two first development steps i) and ii).

2. System design by simulation

Definition of boundary condition

As a first working step, boundary conditions were defined with regard to climatic, geometrical and utilization-related aspects. The definitions serve as the basis for the calculation of cooling and heating loads to be covered, the system considerations and simulations. An office was defined as a reference room, which was analyzed under different conditions with regard to climate and orientation. Three climatic data sets were selected as climatic boundary conditions, in order to represent a cold, medium and warm European climate. A comparison of all European capitals has shown that the cities of Helsinki (cold), Ljubljana (moderate) and Madrid (warm) are well suited to show the range of climatic conditions to be expected in Europe. For these cities a 10-year average climate was therefore created with the software Meteonorm (Meteotest, 2009).

Definition of the reference room

An office with an occupancy of three persons was defined and implemented as a thermal building model in the simulation environment (TRNSYS, 2011). The room has a net floor space of 25 m² and was simulated as four separate thermal zones facing into the main compass directions. An additional space or a thermal zone was positioned in the center as shown in Figure 1 (left). The used wall constructions and U-values are summarized in Figure 1 (right). It is assumed that the rooms are positioned in an intermediate store, thus there is no heat exchange through the floor and ceiling. The same applies to the partition walls, as it is assumed that a similarly conditioned room is adjacent. A façade configuration has been defined concerning the layout and the dimensions of the glazing surfaces, as depicted in Figure 2.

Determination of energy demand and generation profiles

In the simulation the thermal conditioning (heating and cooling) of the reference office room is ideally regulated. This means that the room is supplied with precisely the thermal power, which is necessary in order to maintain a room temperature above 21 °C (heating) and below 26 °C (cooling). An additional thermal zone was positioned in the center of the four virtual rooms, which is in heat exchange with the four rooms and assumed to be "free swinging", i.e. which is not thermally conditioned (Figure 1). External shading was assumed for the transparent surfaces, which is activated with a shading factor of 0.75, when the room temperature rises above 24 °C and deactivated, when it drops below 22 °C. A fresh air supply of 108 m³/h is assumed during the presence time

(working time varying between 8:00 and 18:00), with a controlled ventilation and exhaust air heat recovery (recovery rate 60 %). In the cooling case the heat recovery is deactivated, when the outside temperature is lower than the room temperature.

PV	11.22	59.9
Frame	1.31	7.0
Glazing	6.19	33.1
Sum	18.72	100

Figure 2: Façade configuration

Photovoltaics

For the simulation of the photovoltaics, the model Type 94a included in the TRNSYS library, which is based on a 4-parameter approach (TRNSYS, 2012), is used. The parameterization was carried out according to the manufacturer data of a polycrystalline PV module available on the market. It is assumed that the PV is integrated vertically into the façade with the maximum possible area for the particular façade configuration, as specified in Figure 2.

Heat demand and PV-yield

Simulations with a time step of one hour were carried out for the described configurations concerning the orientation of the room and different climates. As an example, the results on a monthly base are shown in Figure 3 for the location Ljubljana. According to these results the cooling demand coincides well with the PV yield and it can be assumed that sufficient PV electricity is available to cover the cooling demand for all four orientations, assuming a *Coefficient of Performance* (COP) of a hypothetical cooling unit of 2 to 3. With the assumed dimensioning of the PV it should also be possible to cover the heating demand of the room.

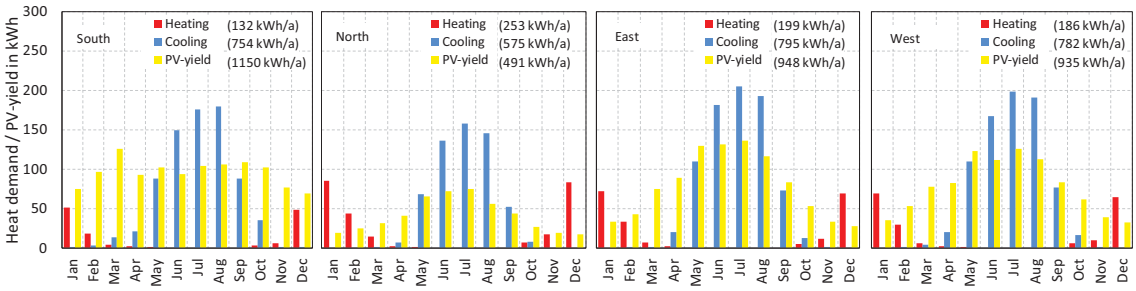

Figure 3: Simulation results: Monthly sums of heating demand, cooling demand and PV-yield for Ljubljana, yearly sums in brackets

However, for a real system it is essential, how well the demand and the PV electricity generation coincide on a smaller time scale and how much energy has to be stored, in order to be able to compensate times with an excess supply or an undersupply of electricity. For an exemplary week in July, hourly values of the cooling demand and the PV-yield are shown in Figure 4. Depending on the orientation, the peaks for both values occur at different times and with different size.

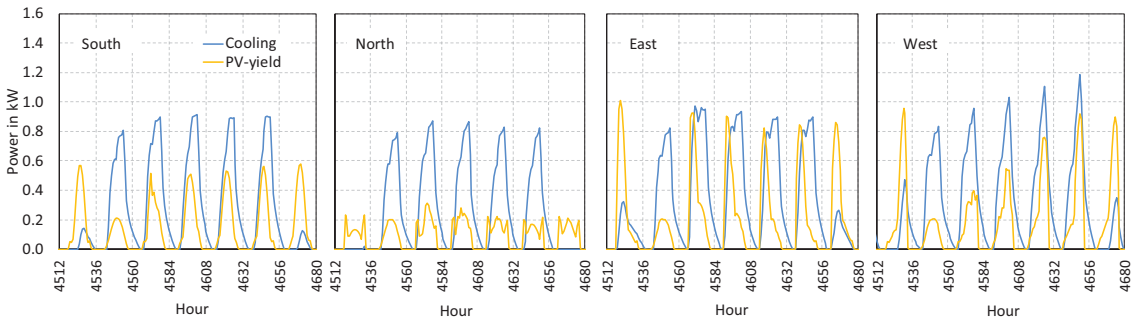

Figure 4: Simulation results: Hourly values of the cooling demand and the PV-yield for an exemplary week in July in Ljubljana

Analysis of the time shift between supply and demand and the need for energy storage

Based on the simulation results described above, an analysis of the temporal shift between supply and demand as well as a rough estimation of the necessary capacity of an energy storage was carried out. A very simple model of a compression chiller is used for the supply of the cooling demand, the cooling capacity and the electrical power consumption being assumed as a function of the room temperature and the outside temperature. In order to compare the occurrence of the power consumption and supply of cooling capacity of the chiller with the cooling load of the building and the PV-power the approach described in the following is used.

It is assumed that the chiller is capacity-controlled and that it is only running, when a cooling load occurs. Due to the temporal offset of the PV yield and the power consumption of the compressor, electrical energy has to be stored. This is shown qualitatively in Figure 5. As cooling capacity is provided at times of an occurring cooling load, the previously generated PV electricity has to be stored in an electrical storage in order to use it at later times. This is indicated by the gray surfaces in the diagram. The green surface represents the share of energy, which can be covered simultaneously and without storage.

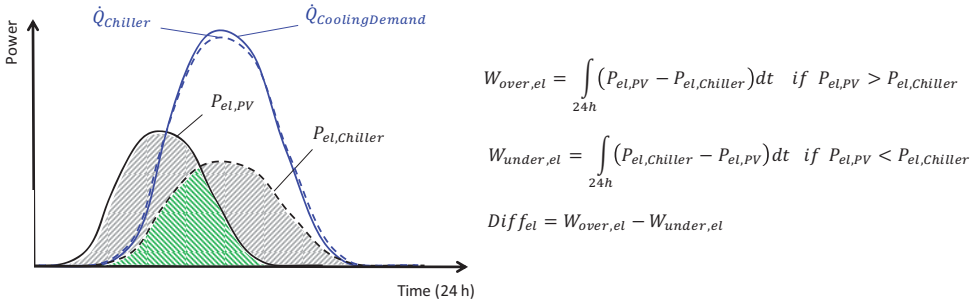

Figure 5: Qualitative daily sequences for the comparison of the electricity consumption of the chiller (Pel,Chiller) and the electricity generation of the PV (Pel,PV)

For each day of the year the electrical over- and under-supply as well as the difference between the over- and under-supply is calculated (equations in Figure 5). Figure 6 shows the results for the Ljubljana climate and the south-orientation in the form of ordered duration curves for two different sizes of the PV (5.6 m² on the left and 8.4 m² on the right). In this example, a chiller with a cooling capacity of 0.85 kW is used. For each case the right diagram shows, on how many cooling days a certain amount of over- and under-supply is exceeded.

According to these results, an under-supply of maximum 2 kWh has to be covered out of an electrical storage. Of course for this a corresponding over-supply is needed beforehand, in order to charge the storage. From the diagram on the left it can be seen that this is not the case on every day for both dimensioning's (negative $Diff_{el}$), of course with better results for the larger PV area. But it has to be mentioned, that these results are of course quite theoretical, as every single day is treated individually, i.e. it is assumed that the storage is empty at the beginning of each day. However, for the desired purpose (rough dimensioning of the storage capacity), the method is considered to be appropriate and a storage of 2 kWh should be appropriate for the considered application. For the other orientations, the results are slightly different, but the required storage capacity of 2 kWh stays the same.

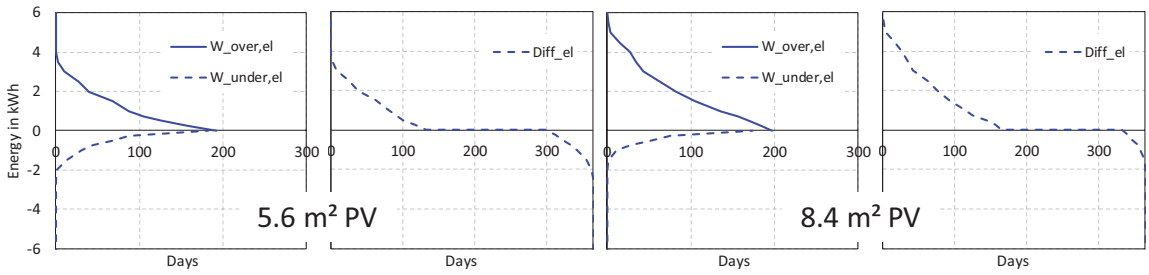

Figure 6: Duration curve of electrical over- and under-supply and daily difference between over- and undersupply for Ljubljana, south orientation for two different PV sizes (cooling capacity chiller 0.85 kW)

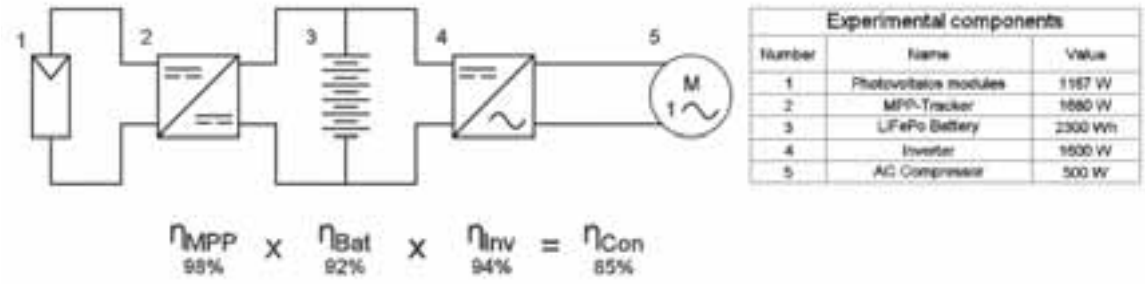
3. Experimental components and system tests

This chapter reports on the laboratory tests of the operational behavior of each single electric component and the compatibility test of the overall system. Main components of the setup are shown in Figure 7. Photovoltaic modules (1) generate electricity used as energy source for the cooling process. The maximum power point (MPP) tracker (2) ensures that the photovoltaic system operates in its most efficient operating point and it controls the battery charging process. A Lithium iron phosphate ($LiFePO^4$) battery (3) functions as an energy storage, when the current PV electricity generation for the compressor motor of the cooling system is not sufficient. The battery voltage of 25.6 V is transformed to 230 V, 50 Hz AC-Voltage by the inverter (4) in order to run the AC-Compressor motor. Due to the energetic conversation losses of MPP-Tracker (η_{MPP}), Battery (η_{Bat}) and Inverter (η_{Inv}), not more than 85 % of energy harvested by the photovoltaic modules can be used to operate the compressor motor of the cooling machine. In part load operation or extreme environmental conditions, the efficiency might be even worse. These energy losses are transformed into 100% heat, which requires an internal active cooling of these electric components. MPP-Tracker and Inverter stop working in case of temperatures higher than 60 °C.



Experimental components

Number	Name	Value
1	Photovoltaic modules	1167 W
2	MPP-Tracker	1680 W
3	LiFePo Battery	2300 Wh
4	Inverter	1500 W
5	AC Compressor	500 W

Figure 7: Block diagram of the electric circuitry with conversation efficiency.

After the successful completion of the laboratory tests, all components were assembled to enable a simple installation at the mounting site. Figure 8 shows the two test boxes at the campus of Graz University of Technology with the installed PV modules. The box on the right with the installed “black line” photovoltaic modules is used as test box where the cooling system will be installed for a long run test under real climate conditions. The box on the left side where the “digital print” photovoltaic modules are installed is the reference box.

Figure 8: Test boxes with installed aluminum frame and the photovoltaic modules, the right box is the test facility with the installed cooling system while the left box is used as reference box (Source: TU Graz)

4.1 Test photovoltaic modules

Two different glass-glass photovoltaic module types, both with mono crystalline cells, were tested: i) “black line”, with blackened bus bars and ii) “digital print”, with screen printed front glass. Four modules of each type were produced. The size of the “digital print” modules are the same as the “black line” modules. Pictures of the used modules are shown in Figure 9. Mounted at the test boxes either the “black line”- or the “digital print”- modules will be used to run the cooling machine. The COOLSKIN project aims to demonstrate that the designed façade integrated energy system operates even when architecturally appealing photovoltaic modules with relatively low efficiency are applied.

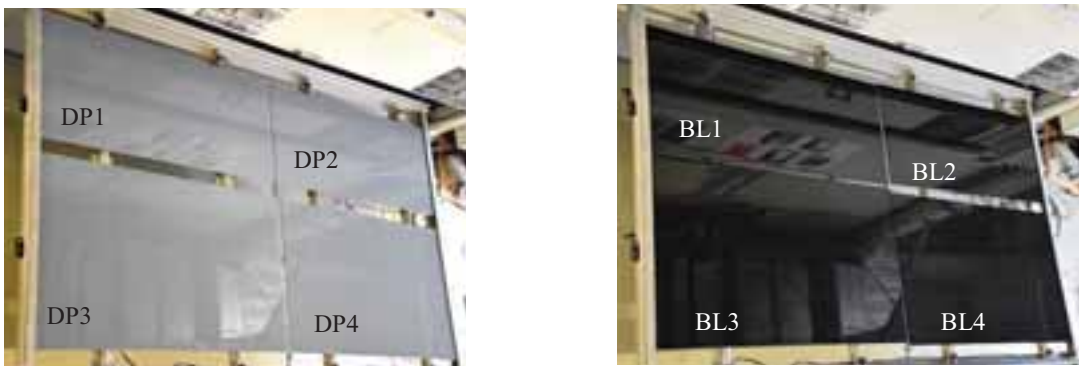


Figure 9: Photovoltaic module type “digital print” DP (left) and type “black line” BL (right) (Source: AIT)

Measurement results show that the module type “digital print” has approximately 2.6 percentage points lower efficiency than the “black line” modules. The cumulated power of the four “digital print” modules is 952 W, which is roughly 18 % lower than the cumulated power of the four “black line” modules with 1167 W. Additionally all glass-glass photovoltaic modules were checked in advance before its test box installation regarding cell cracks. Figure 10 displays an electroluminescence picture of one of the eight tested glass-glass photovoltaic modules.

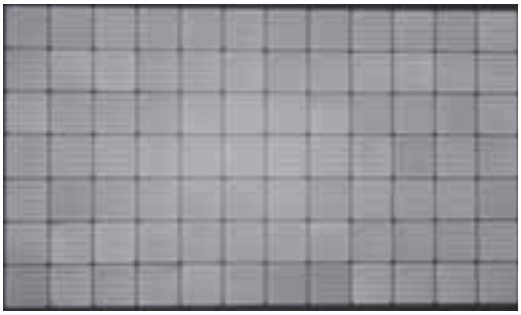

Figure 10: Electroluminescence picture of glass-glass photovoltaic modules without any cell cracks.

4.2 Test batteries

Two Lithium iron phosphate ($LiFePO^4$) batteries are used as buffer storage between the photovoltaic system and the cooling machine. $LiFePO^4$ batteries are a type of lithium-ion battery, with the advantage of a higher energy density, higher power density, longer lifetime and, because of its thermal and chemical stability, improved battery safety. Cell voltage of a $LiFePO^4$ stays close to 3.2 V during discharge until the cell is exhausted. Due to that, the cell can deliver nearly full power until it is discharged. In one battery, four cells are connected in series for a nominal battery voltage of 12.8 V. At cell voltages beyond 3.6 V or under 2.5 V, severe damage will occur in most instances. Therefor a so-called battery management is needed, which balances the cell voltages, stops charging in case of over voltage and stops discharging in case of under voltage.

The two $LiFePO^4$ batteries are connected in series to a nominal Voltage of 25.6 V and a capacity of 2304 Wh when discharged with less than 90 A.

As the used charging system has no temperature compensation, the temperature behavior of a battery cell was tested in a climate chamber. A fully charged $LiFePO^4$ cell was cooled down to -25 °C and heated up to 55 °C while the cell voltage was measured.

Measurement results are shown in Figure 11. The cell voltage is nearly stable from -25 °C to 45 °C. In this temperature range, no temperature compensation is needed for the charging process. At temperatures beyond 45 °C, cell voltage decreases and a battery management with temperature compensation would be recommended. The COOLSKIN system design contains an active cooling system in the façade mock-up to keep temperatures below 45 °C.

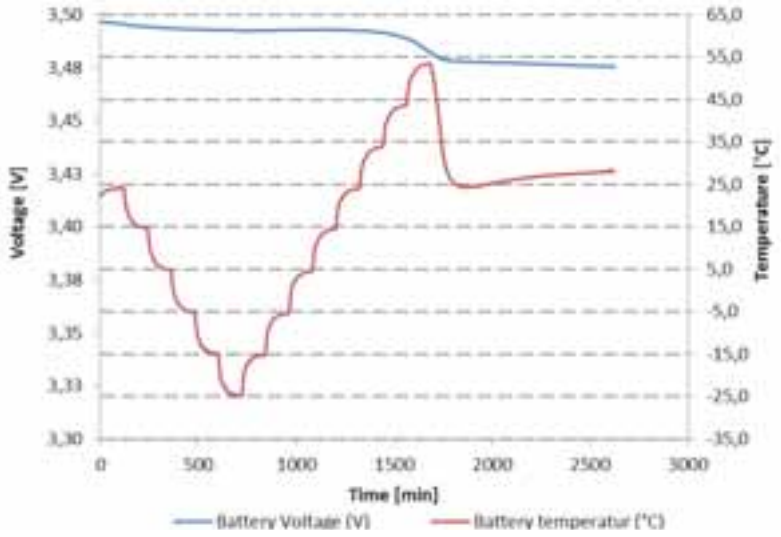

Figure 11: Voltage curve of a LiFePO4 cell in a temperature range from -25 °C to 55 °C.

4.3 System test

Charge process is started in case that the battery voltage is lower than the charge cut-off voltage of 28.4 V and the available photovoltaic power is higher than the load plus conversion losses. The MPP-Tracker (i.e. charge controller) controls the charging progress according to the charge level, which is indicated by the voltage level of the battery. The controller is configured for a three-phase charging process:

1. Bulk: The controller delivers as much charge current as possible to rapidly recharge the batteries.
2. Absorption: When the battery voltage reaches the absorption voltage setting, the controller switches to constant voltage mode. When only shallow discharges occur, the absorption time is kept short in order to prevent overcharging of the battery. After a deep discharge the absorption time is automatically increased to make sure that the battery is completely recharged. Additionally, the absorption period is also ended when the charge current decreases to less than 2A.
3. Float: During this stage, float voltage is applied to the battery to maintain it in a fully charged state. When

the battery voltage drops below float voltage during at least 1 minute a new charge cycle will be triggered.

An example for the three-phase charging process is shown in Figure 12.

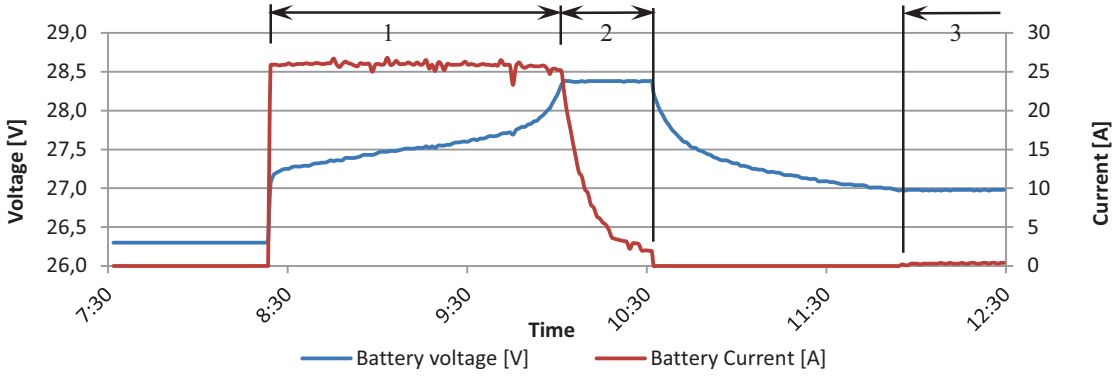

Figure 12: Example of three-phase charging process.

Discharging process starts when the load is higher than the photovoltaic yield. In this application, the main load would be the compressor of the cooling machine with 500 W. Nevertheless also, the monitoring system, the inverter and the MPP-Tracker have standby energy consumptions. In total this standby losses are in a range of 10 W to 20 W. However, a discharge protection is needed to disconnect any load before deep discharging the battery. In this application, the inverter stops before the battery voltage decreases below 23 V. In addition to that a battery protect relay cut off the battery from all loads, including standby consumers, if its voltage decrease below 22 V.

Figure 13 shows a measured battery discharge processes. The average battery voltage of 25.8 V and the average battery current of about -25 A result in an average battery power output of 640 W. The compressor motor consumes 500 W electric power, 140 W can be assigned to conversion losses and standby energy consumptions. This results in an overall efficiency of 78 %. According to the datasheet the total capacity of the battery pack is 2,304 Wh. Concerning a power output of 640 W, this would result in an operation time of 3.6 hours, which correlates to our measurement results.

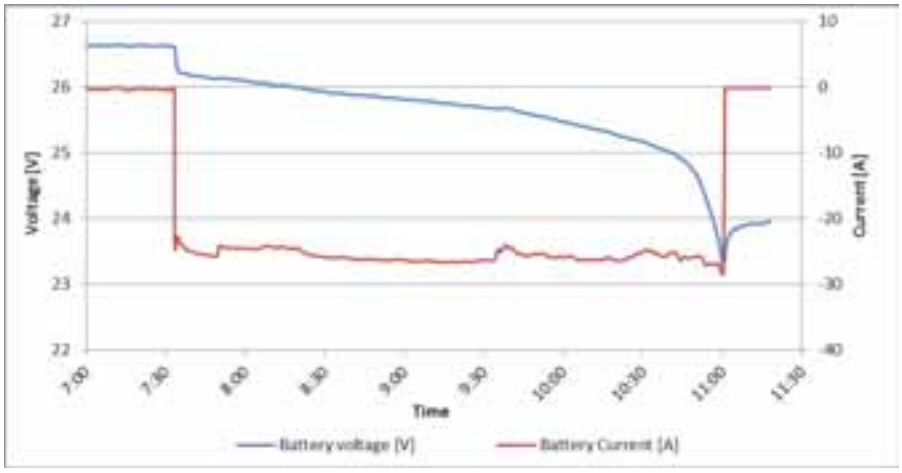

Figure 13: Battery discharge process with a 500 W compressor as load.

Once the inverter stopped because of deep battery voltage, it will not restart until the battery it is recharged to 25 V. In case that battery voltage is low and the energy consumption of the load is higher than the photovoltaic yield, the inverter will start and stop periodically. An example of this undesirable behaviour is shown in Figure 14. The energy need of the load is higher than the photovoltaic yield, which leads to a discharge of the battery and hand in hand with that to a negative battery current. Due to the discharge process, the battery voltage decreases until the inverter stops. As the major part of the load is disconnected when the inverter stops and photovoltaic yield is still available, the battery is charged. The inverter restarts if the battery voltage is higher than 25 V.

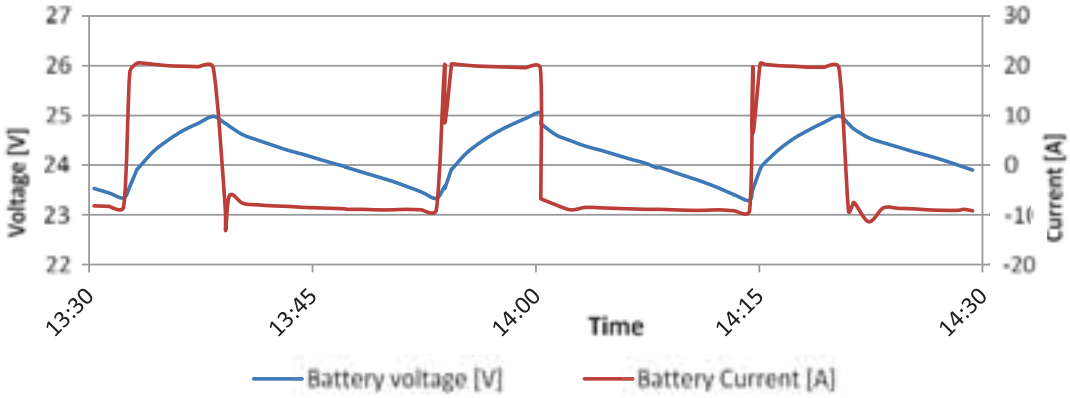

Figure 14: Start-stop behaviour of the inverter at low battery charging state and higher energy consumption than production.

A disadvantage of the used compressor type is shown in Figure 15. The relatively high starting power that may be four to eight times the nominal power could rapidly decrease the battery voltage which would strengthen the above mentioned start-stop behaviour. To avoid this effect a speed controlled compressor will be used in the field tests.

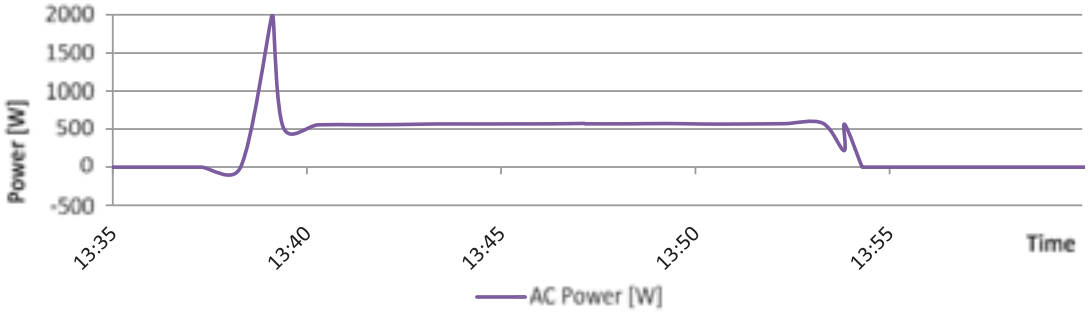

Figure 15: Start-stop behavior of the compressor.

4. Findings

Following key findings were made on the results from the simulations and laboratory tests

(a) Simulation

Based on results of the energy demand simulation some facts could be revealed which are important for the operation of a decentralized cooling system like the one of COOLKSIN. First, it was shown that under the configuration of the free-swinging coupling of the rooms the monthly cooling demand (see Figure 3) of north and south oriented rooms is only slightly different while the energy production from the PV-system is differing significantly. The corresponding analysis of the east orientation towards the west orientation shows that for them the monthly demand and production are more equal. From this, it can be concluded that a completely decentralized supply is mainly possible for south, east and west, where south might produce more than needed. If a north façade should be used for cooling excess energy from the other facades has to be provided via battery storage.

Analyzing the highly resolved data from Figure 4 one finds that for daily cycles the main result stays the same as for Figure 3. The south and north façade consume about the same amount of cooling demand, but the production at north is poor. For the east and west façade one finds that during the week under analysis the cooling demand of east and west façade differs significantly first for its daily evolution and then also for its evolution during the week. This behavior is strongly dependent on the daily and weekly distribution of sun hours. Even for a series of clear sky days the east and west would differ, as during the day the environmental temperature also raises.

An analysis with a simple worksheet approach showed that an electrical storage with a capacity of about 2 kWh should be sufficient to compensate the offset in time between the PV-yield and electricity consumption of the chiller.

(b) Experimental test in laboratory

From the experiments as shown in Figures 11-15 the main advantages and disadvantages of the system set-up can be extracted. First, the direct coupling of the battery and the load in series does not allow to bypass the battery. This might be useful in a real setting, when the battery is empty and should be loaded, there is enough solar energy to run the load, but it will take some time to recover the battery voltage above the security threshold (here this was between: switch off: 23 V, switch back on: 25 V. If load priority is a set target; the bypass is essential, in a setting similar to Figure 14.

Further is was important to test all critical settings of the systems: the lower voltage of the battery and switch of, meaning that there is not enough solar electricity but the load was powered (see again Figure 13, as it is). Very important for the real running of the system out-doors was also the operation point where the load is powered, the battery is full, but the solar production is slightly decreasing, leading to a discharging of the battery. This behavior can show if the PV-system size it at all big enough (including the losses due to the inclination for the modules in the façade).

In a worst case scenario there will be day with cooling demand but not sun irradiation to run the system. From this scenario the needed storage size could be extracted for running the cooling system only via the battery: then the storage system capacity SC is given by the time interval t where the demand is provided, the electric load demand ELD and the DoD of the battery system by: SC = t*ELD / DoD (Compare, 2016). For running for n days this can be expanded by n*t.

The last important test is the test showing the “flickering” of the whole system in Figure 14. It shows that for a certain irradiation budget the system layout from battery capacity and PV-array size is too weak. From such a behavior it would follow that the PV-size or the battery size and the PV-size should be increased. In a setting where the system components can be programmed one should try to avoid this behavior, e.g. by increasing the level, where the battery is reconnected to the load (e.g. from 25 V to 26 V or even above).

(c) Experimental test set up in the façade

Technical description

The setup was built in a way that the most flexible alterations can be done between battery, PV-system and cooling equipment. The system contains of 4 subsystems of PV-arrays. The black-line is high efficient while the colored edition is reduced in its efficiency. It was taken care in the irradiation simulation of the laboratory experiments to include this behavior also. Then the lower panels and the upper panels differ in electric output power also, see table 1. The corresponding sub-arrays of upper digi-print, lower digi-print, upper black-line, lower black-line then give then a maximum electric power of 220 W, 551 W, 481 W and 685W, respectively. This power output has then to be considered also with approx. 0.65 for the daily energy yield compared to an optimal oriented PV-facility due to the façade integration. By standard setting all digital-print or all black-line modules are connected in series to MPP tracker and the battery system. The setting can be switched. Also, only the small systems or only the lower systems can be connected separately in order to simulated bad system layouts with too small PV-capacity.

Field tests planned

For the field tests several runs are planned. The most important experiments are those of continuous running with parallel data evaluation in order to identify times of system behavior reflecting cases from Figure 11 to Figure 15. These are:

- Continuous loading while load is connected
- Continuous de-charging while load is connected
- Voltage all day between 23 V and 28 V
- Flickering

After doing that, single cases can be investigated to higher extent, like altering the system configuration by the PV-panels connected to the battery. Also, the comparison of the influence of the power loss from digi-print will be done systematically

5. Outlook

Next activities in the COOLSKIN project are dedicated to a) the assembling of the outdoor test facility including cooling system and b) the examination of the long-term observation of the energy performance by a scientific monitoring till august 2018. Figure 16 shows a three-dimensional CAD model of the aluminum frame with the integrated cooling system. According to this CAD model, this system will be attached to the test box for long-term tests. The cooling system consists of five main assembly units. The first unit is the electric cycle that receives electricity from the photovoltaic modules, charges the batteries and serves as electrical source for the other units inside the cooling system. The next unit is the heat pump cycle, where energy for cooling as well as for heating is generated. The heat pump cycle is connected with an air channel by an integrated heat exchanger, which serves as condenser in cooling mode and as evaporator in heating mode. The heat pump cycle can either charge into a water cycle via a plate heat exchanger or into the room air. The water cycle is connected to the cooling and heating system of the test box (activated ceiling and/or floor). On the other hand the room air of the test box can be directly conditioned through a conventional air conditioning system (fan coil), which is also integrated in the aluminum frame.

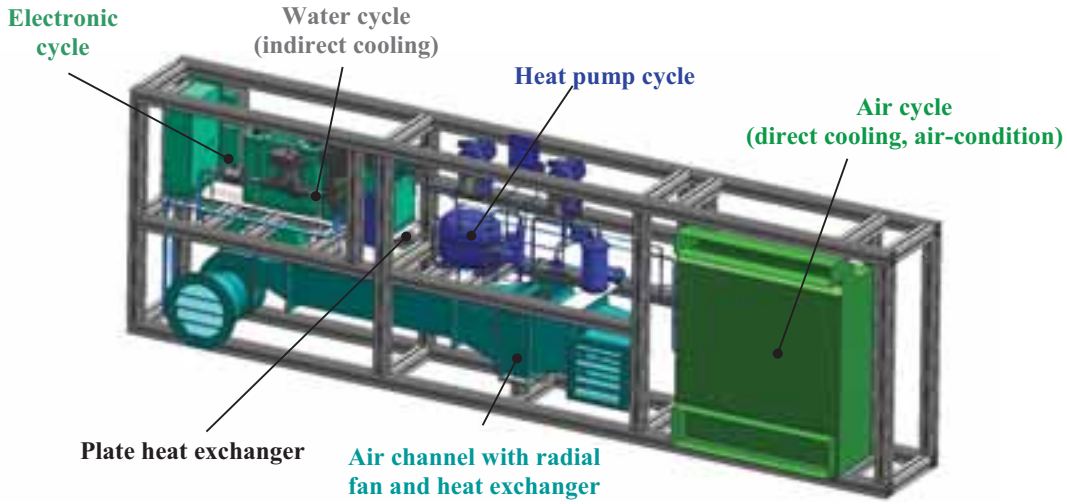

Figure 16: 3D CAD model of the aluminum frame with the integrated cooling system (Source TU Graz)

The whole system is going to be assembled and put into operation in the laboratory of the Institute of Thermal Engineering. After the system is working, it will be attached to the test box (see in Figure 8) for long-term tests under real climate conditions (covering all seasons). In this test, it will be figured out if the system is able to cover the cooling and heating demand for a comfortable indoor climate. Furthermore, the thermal behavior of the interior room can be compared with the indoor climate of the reference box (see in Figure 8). The reference box has only a floor heating system and allows no cooling. For the long run tests, the boxes´ interior rooms will be simulated as an office. Among others in the test boxes are considering interior heat loads and hygienic air exchange from 8 am to 4 pm at working days.

Highest Efficiency Ice Storage for Solar Cooling Systems – Experiences with a Vacuum Ice Slurry Cold Thermal Energy Storage

Christoph Steffan[1], Carsten Heinrich[1], Mathias Safarik[1] and Marcus Honke[1]

[1] Institute for Air Handling and Refrigeration, Dresden (Germany)

Abstract

With an increasing share of renewable energies efficient storage technologies are in high demand. Due to the high specific enthalpy of fusion pumpable water-based ice slurry represents a thermal storage medium which is ecological as well as economical advantageous. A further need for research can be seen in the increase of efficiency for ice slurry generation processes. The high efficient process of ice slurry generation by direct evaporation under rough vacuum conditions including its potential for solar cooling systems is presented in this paper. After installing a first pilot of an integrated ice slurry generation and storage system based on the R718 turbo vapour compression technology a new facility concept for higher capacities has been developed and commissioned. Findings from recent research projects flowed into the conceptional work and have been implemented. The facility has a nominal ice generation capacity of 180kW, a storage capacity of 1MWh and a discharging capacity of max. 300kW.

Keywords: Thermal Energy Storage, Vacuum Ice Slurry, Solar Cooling, water as refrigerant (R718), Natural Refrigerants, Secondary Refrigerants, Load Management, District Cooling

Introduction

In fields of refrigeration and air conditioning technologies the current research focus lies on the transition towards natural refrigerants combined with an increase of efficiency for the whole compression cycle, e.g. development of new compressors with higher efficiencies especially for part load conditions (Heinrich, 2012). In the near future an increasing expansion of the renewable energy sector will gradually challenge us worldwide to use generated power when it is made available. A main question will be how to store energy that is not immediately needed at time of generation. The reduction of peak loads and the compensation of fluctuating availabilities of renewable energy sources requires a comprehensive planning approach. With the integration of a thermal storage system energy demand and availability can be adapted. For refrigeration and air conditioning systems several approaches to store cold thermal energy are applicable. Fig. 1 gives an overview of available storage technologies according to the type of storage media (Urbaneck, 2012).

Fig. 1: Technologies for water-based cold thermal storage systems

From an economical as well as ecological perspective systems with water as storage medium represent a safe, environmentally friendly and efficient approach to store thermal energy (Kauffeld et. al, 2005). The synergy effect of a pumpable secondary refrigerant with the characteristics of a phase change material are the key argument for the usage of water-based ice slurries (see Fig. 2). Besides the high enthalpy of fusion (transport capacity) higher heat transfer coefficients can be achieved. Hence, the dimensions of cooling distribution networks and related pump capacities can be reduced significantly (Kauffeld et. al, 2010).

doi:10.18086/swc.2017.28.19 Available at http://proceedings.ises.org

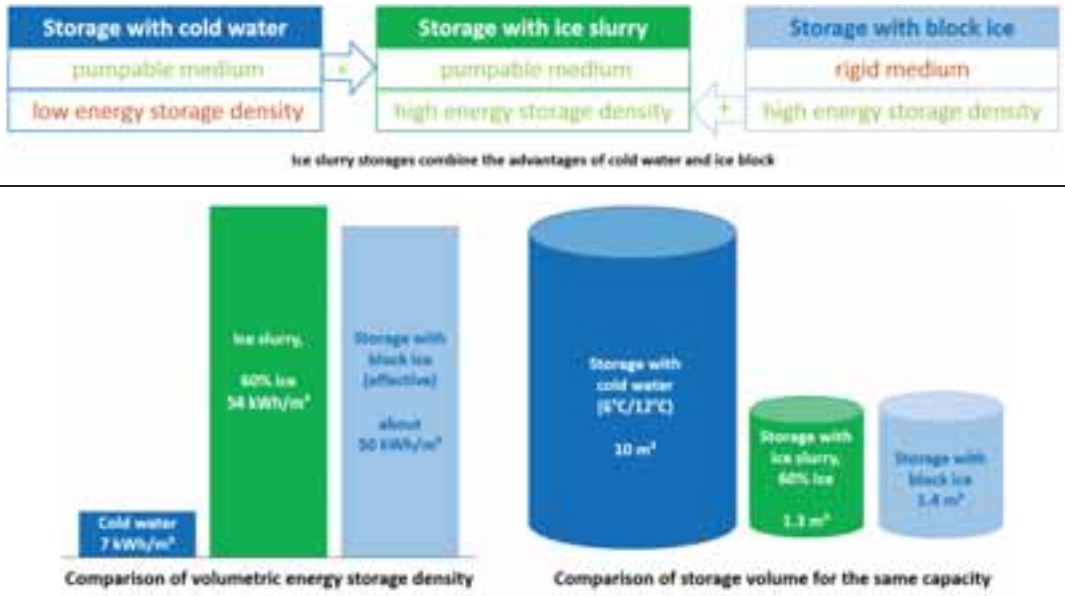

Fig. 2: Synergy effects of ice slurry as thermal storage medium

To date ice slurry based cooling systems are mainly applied in cooling processes for food products, e.g. breweries, fishing and refrigerating counters. In Japan first air conditioning applications were installed by using ice slurry only as storage medium (Snoek, 1993).

For the production of ice slurry various processes have been developed and are available on the market (Kauffeld et. al, 2010). From an energetic perspective vacuum ice slurry technology is a promising approach in terms of efficiency of cold generation for all traditional applications of industrial refrigeration processes and air conditioning of buildings (Albring, 2009). The system can be integrated for cold thermal energy storage in larger PV driven cooling systems to increase efficiency, availability and comfort or to minimize back-up needs. The current research work focuses on the optimization of the vacuum ice generation process as well as investigating new fields for ice slurry applications, e.g.:

Fig. 3: General fields of application for ice slurry as secondary refrigerant and storage medium

Vacuum Ice Slurry Technology

2.1. Process description

The process of ice generation by direct evaporation in a rough vacuum runs at low pressure conditions below the triple point of water (p_{Tr}=611 Pa, ϑ_{Tr}=0.01 °C). Within a vessel which is initially pre-evacuated down to saturation conditions water is cooled sensibly by heat loss through evaporation (Figure 1). Below triple point conditions water cannot cooled down anymore. Thus, the energy for evaporation must be provided by a further phase change – the generation of ice particles within the sump of the evaporator. The quotient between enthalpy of fusion ($h_{lg}\approx 2500\,kJ\cdot kg^{-1}$) and the freezing enthalpy ($h_{ls}\approx 333.4\,kJ\cdot kg^{-1}$) provides the mass relation between evaporated vapor and the amount of produced ice particles. Hence, evaporating one kilogram of water would lead to a generated ice mass of 7.5 kg. Under vacuum conditions the corresponding volume flow is high due to the low density of water vapor ($\rho_g\approx 0.005\,kg\cdot m^{-3}$). The driving thermodynamic potential in the evaporator is given by the pressure difference between saturation pressure (p_{lg}) and the pressure (p_g) in the gas phase above. High energy efficiency can be achieved because of a minimal thermal resistance through direct evaporation. Direct contact between storage medium and refrigerant requires low subcooling temperatures in comparison to other ice slurry generation processes. By increasing the evaporating surface A_O and the heat transfer coefficient α the evaporating performance can be further increased. In order to achieve stable ice generating conditions in the sump of the evaporator the pressure difference must be kept stable, e.g. by using a vacuum pump. Higher water vapor volume flows can be conveyed by applying a centrifugal compressor technology.

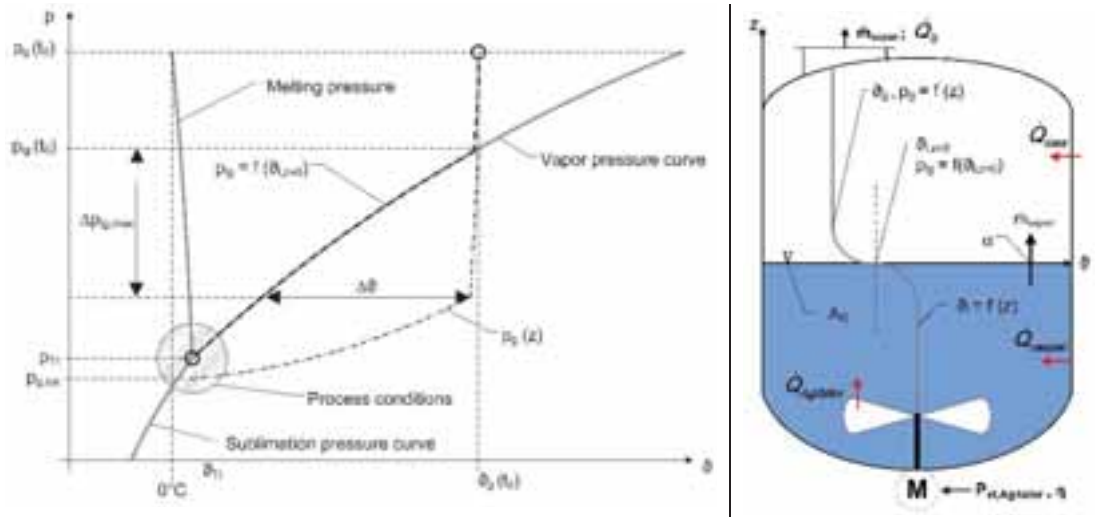

Figure 1: Ice slurry generation by direct evaporation in a rough vacuum

2.2. Efficiency comparison

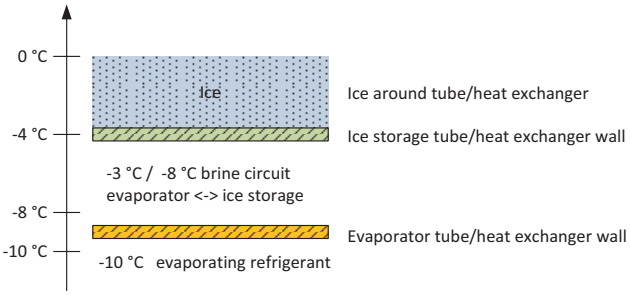

Fig. 4: Exemplary temperatures during charging of a block ice storage using a cold brine circuit

One major disadvantage of conventional ice generators (e.g. in block ice storages) is the low effective evaporation temperature of the cooling cycle which is often operated in the range of -10 °C to -13°C. The low evaporation temperature is caused by the temperature differences necessary for heat transfer between the evaporator of the chiller and the heat exchanger inside the ice storage/ice generator, see Fig. 4. Hence, the low evaporation temperature results in a lower efficiency of the ice generation process. Generating ice slurry by direct evaporation

of water the heat exchanger between the refrigerant and the phase change material water/ice can be eliminated. Here, the water itself is used as refrigerant. The effective evaporation temperature is as high as -0°C which leads to highest efficiencies for ice generation using the direct evaporation process.

Tab. 1: Calculation scenarios and results

Process	t_e [°C]	t_c [°C]	EER	Specific energy demand [kW_e/kW_{th}]
1) On-time chilled water generation 6/12 °C (chiller with R717, η_{is} = 0.7)	4	34	5.71	0.175
2) Ice slurry generation by direct evapocation (refrigerant R718, η_{is} = 0.65)	-0.5	6	26.2	0.038
3) Combined (cascaded) ice slurry generation using the conventional chiller for condensing the compressed water vapour of the vacuum ice process -> combination of 1) and 2)	-0.5	34	4.69	0.213
4) Combined (cascaded) ice slurry generation at nighttime conditions with reduced condensation temperature	-0.5	24	6.67	0.150
5) Conventional ice slurry generation (scraped surface) or block ice storage (chiller with refrigerant R717, compressor η_{is} = 0.7)	-10	34	3.49	0.287
6) Conventional ice slurry generation (scraped surface) or block ice storage at nighttime conditions with reduced condensation temperature	-10	24	4.71	0.212

Tab. 1 shows a comparison of thermodynamic efficiencies of two different approaches for ice slurry generation. Here only the required electrical capacity for the compressor is taken into account. Necessary capacities for mixing or scraping devices and auxiliary systems, e.g. initially or sequentially operating vacuum pumps should not be part of a general comparison and have to be evaluated case by case. Using the method of direct evaporation additional energy demand for ice production compared to chilled water generation can be reduced significantly. If ice generation (charging of storage) can be done during nighttime the efficiency can be further increased by taking advantage of lower ambient temperatures, see #4 and #6 in Tab. 1. The comparison between case 1 in (on-time chilled water generation) and case 4 (vacuum ice slurry generation during nighttime) shows that additional energy demand for ice generation can be overcompensated by saving that results from the decrease of the condensation temperature.

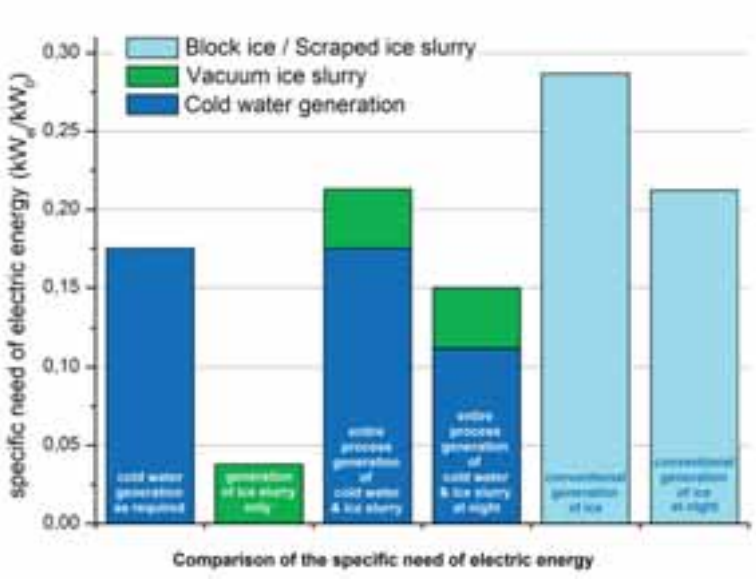

Fig. 5: Efficiency comparison

2.3. Facility Scheme

At Göttingen University a second pilot facility of a vacuum ice slurry thermal storage system has been installed. The system is integrated in the chilled water network of a chemistry building in order to reduce peak loads. An overall scheme of the facility is shown in Fig. 6. The chilled water network is run at 6°C/12°C. The conveyed and compressed water vapor is condensed by a direct condenser which is supplied by an intermediate cold water circuit. The produced condensation heat is transfered to the subordinate chilled water network. This is done by HX2.

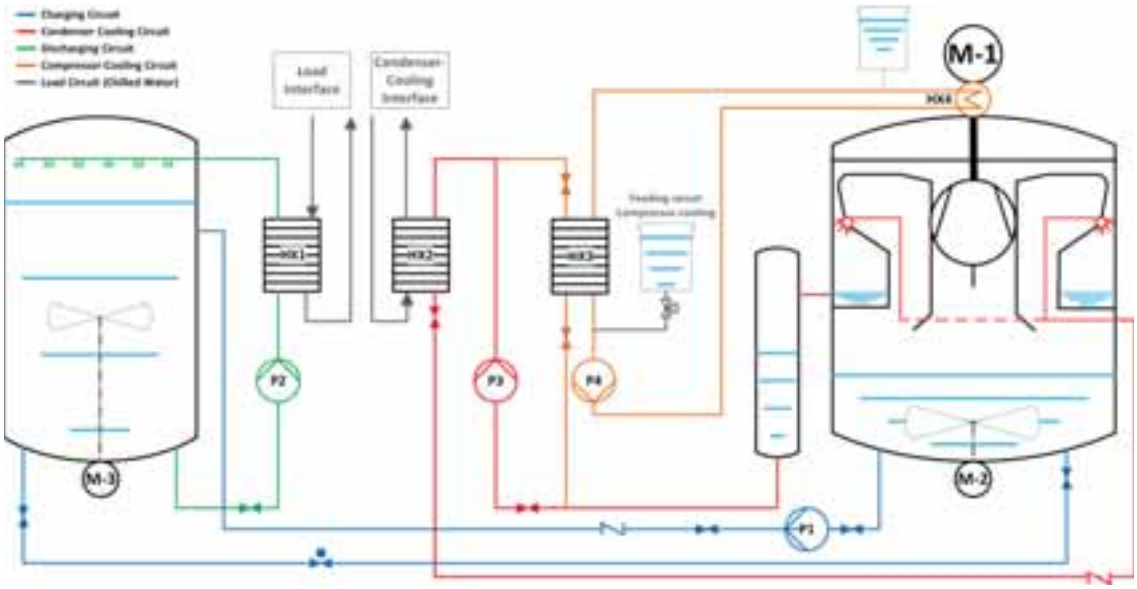

Fig. 6: General scheme of the pilot facility at University of Göttingen

A small fraction of the volume flow (condensed vapor, destillate) is used as return flow to the sump of the evaporator. For cooling parts of the compressor (contour plates, rotary shafts and seals) chilled water from the condenser cooling circuit is used. An agitator in the sump of the evaporator was installed in order to increase evaporation surface and thermal heat transfer coefficients for maximizing the evaporation performance. For discharging the storage a 300kW plate heat exchanger (HX 1) tranfers heat from the chilled water network to the ice slurry. The storage vessel has a diameter of 3 m and takes 28m³ of water. The fully charged storage reaches a capacity of 1.000 kWh which correlates with a mass fraction of 50 % ice produced. As well as for other ice slurry generating processes a freezing point depressant additive has to be used in order to reach smaller crystal sizes and minimizing the risk of frozen evaporation surfaces. At ILK's vacuum ice slurry generators sodium-chloride-solution (1%) is applied which lowers the initial saturation temperature by 0.61 K. The demonstration facility is fully-integrated within the subordinate control system. With an installed data logging and the access via remote control error messages and failure reports can be analyzed. An additional LabVIEW-programme is used for monitoring and data analysis.

2.4. Solar Cooling with Vacuum Ice Slurry

Using solar energy fluctuating availabilities lead to high requirements in order to level supply voltages in power grids. Besides electrical storage technologies peak availabilities can be used to converse and store effective energy for a delayed use, e.g. for cooling purposes. Even conversion losses can be shifted. Consequently energy consumption for the provision of cold thermal energy during trough periods can be minimized significantly. Nevertheless cooling load and energy availability curves has to be analyzed. In Fig. 7 two generic charts for load shifting describe the main approaches for the use of cold thermal energy storages. The upper chart shows an efficiency orientated approach with focus on ideal condensing conditions at times with low ambient temperatures. For instance in continental climate areas (e.g. deserts) high day / night temperature differences resulting in high efficiency values. For the application of solar cooling an availability orientated approach has to be applied. Mainly, this approach can be reasoned by a higher reliability of supply (autonomous energy provision) or overcapacities of solar energy. As a result, financial aspects play more and more an important role. When it comes to troughs in energy availability market prices for energy provision tend to increase. In times of higher availabilities or even overcapacities low market prices or negative market prices can be achieved.

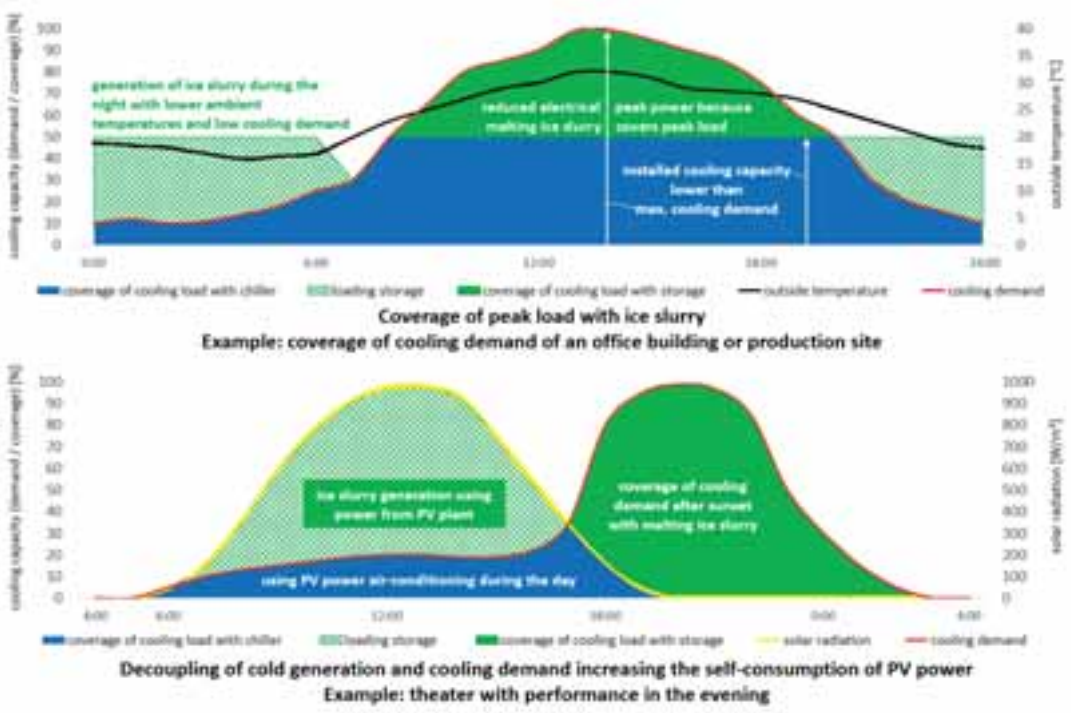

Fig. 7: Schematic charts for load shifting of cold thermal energy

Outlook

The paper presents a comprehensive approach for using water as refrigerant. Taking into account further requirements to integrate renewable energy sources into innovative refrigeration concepts cold thermal energy storages based on ice slurry are a preferable solution. Thermodynamically the process of direct evaporation under triple point conditions reflects a high efficient approach to generate a pumpable ice slurry solution which can be isochronously used as secondary refrigerant and storage medium. At ILK Dresden a further pilot facility was developed and has been tested under laboratory conditions. Due to a delay at customers chilled water system practical experiences cannot be discussed so far. Final commissioning is terminated for the first quarter 2018 and operational data will be presented.

EXPERIMENTAL STUDY ON SOLAR DRIVEN DEHUMIDIFICATION SYSTEM WITH SILICA GEL COATED HEAT EXCHANGER IN WINTER

Yao Zhao, Yanjun Dai, Jingyu Zhang

Institute of Refrigeration and Cryogenic Engineering, Shanghai Jiao Tong University, Shanghai (China)

Abstract

In this paper, a desiccant coated heat exchanger (DCHE) system driven by solar energy is built and tested under winter condition. The purpose of this experimental research is to explore the heating and humidification performance of DCHE system. Effects of hot water temperature, hot water mass flow rate and regeneration air flow flux are discussed as vital factors impacting system performance. Results show that increasing of heat water temperature as well as of hot water mass flow rate both have positive effects on humidification capacity and thermal coefficient of performance (COP) of the DCHE system. Moreover, the latter has a more remarkable influence. When a tradeoff is made between the performance of DCHE system and the thermal comfort of supply air, 40oC and 0.4 kg/s are selected as optimum hot water condition. Under this operation condition, average humidity ratio of supply air is 5.15 g/kg, almost twice of ambient air. Maximum thermal COP can reach 1.78 with a comfortable average temperature of supply air (28.3 ^{o}C). To provide a better supply air state under low humidify ratio of ambient air, small regeneration air flow flux is implemented, which effectively increases the humidity ratio of supply air with the decrease of COP.

Keywords: Silica gel coated heat exchanger, solar energy, experimental study, COP.

1. Introduction

Desiccant coated heat exchanger air conditioning system is a recently developed solid desiccant technology which obtains more and more attention in the HVAC field. Compared with vapor compression (VC) system which is widely used at present, solid desiccant system has several obvious advantages. For example, it can control both sensible and latent loads under summer and winter condition, while VC system has limited capacity in moisture control through heat pump cycle, especially cannot meet the demand of humidification in winter [1,2]. Without the use of refrigerants containing more or less CFCs which generally applied to the VC system, solid desiccant technology has an environmentally friendly property. Moreover, after the Copenhagen Conference, how to reduce building energy consumption and greenhouse gas emission has aroused unprecedented attention[3,4]. The solid desiccant air conditioning system which usually selects silica gel as desiccant provides a promising alternative solution. Since silica gel with a relative low desorption temperature can take advantage of renewable

doi:10.18086/swc.2017.28.20 Available at http://proceedings.ises.org

energy and low-grade thermal energy[5], such as solar energy and waste heat, which can be used as the regeneration heating source instead of electricity. Solid desiccant technologies possess extensive application perspective in new energy utilization and industrial commercialization.

In recent years, a novel concept of desiccant coated heat exchanger (DCHE) air condition system has been proposed and developed in solid dehumidifying. DCHE is based on the traditional fin-tube heat exchanger with the reprocessing on the out surface coated by the desiccant materials. Comparing with rotary desiccant wheel that a common equipment in solid desiccant system, DCHE is chilled by inner cooling water flowing in the copper pipes of heat exchanger, and the adsorption heat can be timely taken away in the dehumidification process. This improvement can realize the approximately isothermal dehumidification and overcome the side effect of adsorption heat accumulation due to the structure limit of rotary desiccant wheel. Therefore, DCHE system effectively enhances the moisture removal obviously which leads to a better control of the latent load. Meanwhile, there is no rotatable part in DCHE system with longer service life and less noisy in operation. Aynur et al. [6] introduced DCHE into VRV (variable refrigerant volume) air conditioning system instead of the traditional heat exchanger, and better dehumidification capacity could be achieved with less energy consumption were confirmed in the field performance test under both cooling season and heating season. Using more environmentally friendly water as working medium, Ge et al. [7] experimentally verified that DCHE could effectively handle both the sensible heat and the latent heat of process air in the dehumidification process. Further works by Zhao et al. [8] successfully introduced solar energy to drive DCHE system and used two paratactic DCHE units to provide continuous dehumidification capacity. Later, Zhao et al. [9] added internal heat recovery to build a new type of DCHE cycle and both the thermal and electrical coefficient of performance significantly increased (1.2 and 13.8, respectively), while providing better indoor thermal comfort in summer condition.

The dehumidification abilities of DCHE which is applied in summer condition have caught the main attention of scholars on no matter in experimentally or theoretically investigations. However, few researches on regeneration process of DCHE system have been done to meet the demand in winter. The main objectives of this paper are to utilize a solar powered desiccant coated heat exchanger humidification air conditioning system and to validate the heating and humidification performance under winter condition. What's more, how the different regeneration conditions (including hot water temperature, hot water mass flow rate and regeneration air flow flux) affect the humidification process are experimented and analyzed.

2. Description of experimental system

Fig.1 shows photographic view of the experimental setup and main components. The DCHE air conditioning system consists of three main components: desiccant humidification unit, solar collecting unit and cooling unit. And its function covers humidification in winter and dehumidification in summer simultaneously.

As the core device of the system, DCHE is based on the traditional fin-tube heat exchanger, the size

of which is 400 mm (length)×150 mm (width)× 400 mm (height). After being soaked by desiccant and dried for 3-5 times, the surfaces of all pipes and fins of the heat exchanger are coated. Solid silica gel with 0.15 mm particle diameters and liquid silica gel are used as the desiccant materials in the experiment. And the final glue quantity of DCHE is 2.53 kg with 0.316 kg on per square meter. The detailed structural parameters of the heat exchanger and specifications of silica gel are shown in Table 1.

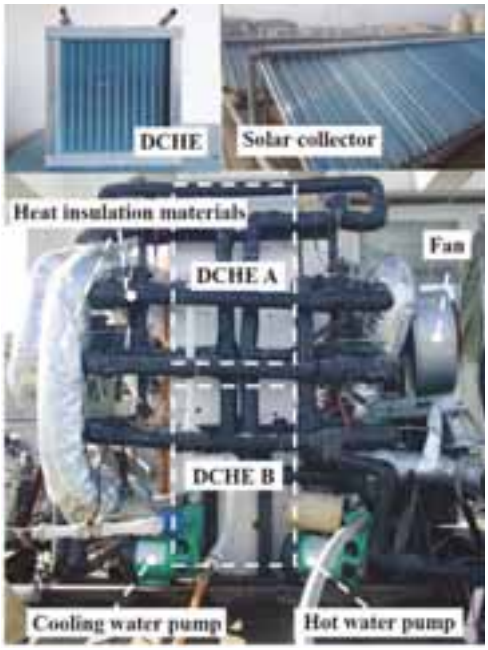

Fig.1 Photographic view of experimental setup and main components

Table 1 The structural parameters of the heat exchanger and specification of silica gel

Name	Parameter
Structural size (mm)	400 (length)×150 (width)×400 (height)
Thickness of the fin (mm)	0.15
Spacing of the fin (mm)	3
Outer diameter of the tube (mm)	9.87
Inner diameter of the tube (mm)	8.67
Silica gel column chromatography	Macro pore, ZCX- II . JN30,30%
Particle diameters of silica gel (mm)	0.15
Glue quantity (kg)	2.53

Solar energy is used as regeneration source in the experiment. The vacuum tube solar collector can supply 8.5 kW heating power with 22 m2 area. The capacity of the matched tank is 500 L. Through adjusting heating time and mass flow rate of circulating water in solar collecting unit, the temperature of hot water can meet the experiment requirements in different sunlight intensity. The cooling water after the dehumidification process flows back to cooling tower. In the cooling tower, the temperature of water decreases by air cooling.

The cooling water and hot water are dominated by two pumps in the water loops. In the experiments, the mass flow rate of cooling water is constant at 0.32k g/s. By adjusting the valve opening of the water loop, the water mass flow rate of hot water can be regulated. The maximum water mass flow rates of the cooling water and hot water provided by two pumps are 0.32 kg/s and 0.4 kg/s, respectively.

Moreover, it is extremely important to complete the airtightness and heat insulation of both air and water pipes to ensure good performance of the system. The leakage of water and air have been checked and precluded before the experiment. To minimize the heat loss, all the pipes are wrapped with heat insulation materials, including fiber-glass on air pipelines and heat insulation felt on water loop.

The basic operation principles of DCHE system consist of dehumidification process and regeneration process. In dehumidification process, ambient air (AA) is dehumidified and cooled in the air side of DCHE, by the desiccant and cooling water, respectively, then the cold dry air discharged to the environment as the exhaust air (EA). Meanwhile, the desiccant absorb moisture from the ambient air with adsorption heat taken away by cooling water and moisture content rise which is well prepared for the regeneration process. Then heat and mass transfer process between air and desiccant has basically completed in the end of dehumidification process. And cooling tower provides cooling water for dehumidification process in the system. In the following regeneration humidification process, when regeneration hot water flows into the copper pipes of DCHE, the humid desiccant coated on the heat exchanger is heated , and it enters the desorption process. As a result, the heat and moisture are taken away by ambient air (AA) which is supplied to the conditioned space with an increase of temperature and humidity ratio as supply air (SA). The sensible and latent loads of the supply air are promoted at the same time in the regeneration process. Then the desiccant become relatively dry which recovers the dehumidification capacity. And hot water in the system for the regeneration process is from solar collecting unit.

Based on above principles, the experimental setup is established, and two alternate operation modes are proposed to realize the continuous operation of the system as shown in Fig.2 (a),(b). Two DCHEs, including DCHE A and DCHE B which are installed in two paratactic air ducts, compose the desiccant humidification unit. In the MODE 1, the two water values (WV1,WV2) in hot water loop open 2’ and 1’ direction, respectively, which provide the regeneration water to DCHE A. The other two water values (WV3,WV4) in cooling water loop open 1’ direction and pump the cooling water into the DCHE B. As a result, DCHE A operates in regeneration process, and DCHE B operates in dehumidification process. Meanwhile, the four 3-way air values open 1’ direction that the cold dry AA through DCHE A is handled

into hot humid SA supplied into conditioned space. In the MODE 2, the two water values (WV1,WV2) in hot water loop open 1' and 2' direction, respectively, which provide the regeneration water to DCHE B. The other two water values (WV3,WV4) in cooling water loop open 2' direction and pump the cooling water into the DCHE A. DCHE B operates in regeneration process, and DCHE A operates in dehumidification process. Meanwhile, the four 3-way air values open 2' direction. The air flowing through the surfaces of DCHE B is heated and humidified which is supplied to the conditioned space. By switching multiple 3-way water valves and air valves completing the conversion of the two modes, DCHE A and DCHE B alternately complete dehumidification and regeneration humidification process which realize the continuous hot and moist air supply.

3. Performance indices

Performance of DCHE humidification air conditioning system in winter is evaluated by the

following indices:

(1) Supply air state(T_t, d_t, T_{ave}, d_{ave})

The temperature and humidity ratio of supply air are the primary criterion to judge whether the system can achieve the required heating and humidification capacity in winter condition.

Among them, transient temperature T_t and transient humidity ratio d_t indicate the change regularity of supply air state in each cycle. And during the humidification process t_e, the average temperature T_ave and humidity ratio d_ave are another two important indices to assess the performance of the whole system. And they are expressed as following Eq. (1) and Eq. (2), respectively:

$$T_{ave} = \overline{\sum_{0 \to t_e} T_t} \tag{1}$$

$$d_{ave} = \overline{\sum_{0 \to t_e} d_t} \tag{2}$$

(2) Average moisture addition (Δd_{ave})

Δd_{ave} is the most intuitive parameter adopted to evaluate the capacity of humidification of the system, which is expressed by average moisture adding of supply air in per cycle as the following Eq. (3):

$$\Delta d_{ave} = \overline{\sum_{0 \to t_e} \Delta d_t} = \overline{\sum_{0 \to t_e} (d_t - d_{in})} \tag{3}$$

where Δd_t is transient moisture addition, d_{in} and d_t are humidity ratio of inlet air and outlet air in regeneration process, respectively in g/kg.

(3) Thermal coefficient of performance(COP)

The energy utilization of the system is measured by COP, which is the ratio of Q_t and Q_w. Q_t is the average enthalpy exchanged of process air in effective dehumidification process, and Q_w is the average enthalpy exchanged of water in effective regeneration process, respectively in kW.

$$COP = \frac{Q_t}{Q_w} = \frac{M_a(h_{a,out} - h_{a,in})}{c_w M_w(T_{w,in} - T_{w,out})} \tag{4}$$

where M_a and M_w are mass flow rate of air and hot water, respectively in kg/s. h is the enthalpy in kJ/kg. $T_{w,in}$ and $T_{w,out}$ are inlet and outlet temperature of hot water, respectively in K. c_w is the specific heat of water in kJ/(kg·K).

4. Results and discussions

The solar powered DCHE humidification air conditioning system is tested to evaluate the feasibility of heating and humidification in the typical winter condition from 15 December 2015 to 31 January 2016 in Shanghai. And the system performances are compared and discussed based on three crucial regeneration factors, including hot water temperature $T_{w,in}$, hot water mass flow rate m_w and regeneration air flow flux V_a. Because the thermo-hygrometric condition of the environment air changed every day, even unstable from day to night. Based on a great deal of experiments, the data is selected and compared with the principle of a single variable. Besides, 600 s is recommended as the experiment cycle

in order to guarantee the experiment performance.

4.1 Effect of hot water temperature

The temperature of hot water has an important influence on the regeneration process of DCHE and makes a further effect on the humidity and temperature of supply air. To explore how the hot water temperature affect the performance of the system, the test water temperatures are specified at 30, 35, 40 and 45 ºC. In addition, the humidity ratio of ambient air is around 2.91 g/kg-3.10 g/kg, the hot water mass flow rate and regeneration air flow flux are 0.4 kg/s and 400 m^3/h, respectively. These three parameters remain constant under this test condition.

The transient humidity ratio of supply air under different hot water temperature is shown in Fig.4. There is an obvious increase of moisture content under every condition compared with ambient condition, which demonstrates that the solar powered DCHE humidification air conditioning system can effectively improve the air humidity ratio in winter condition.

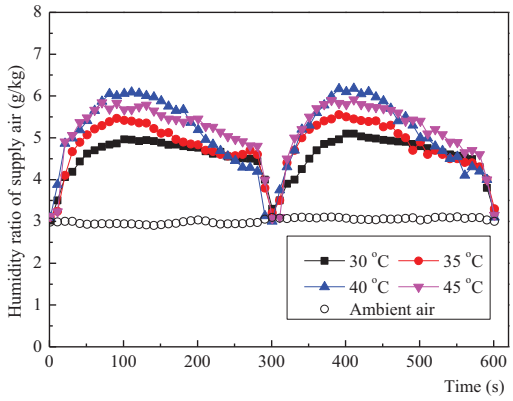

Fig.3 The transient humidity ratio of supply air with different hot water temperatures

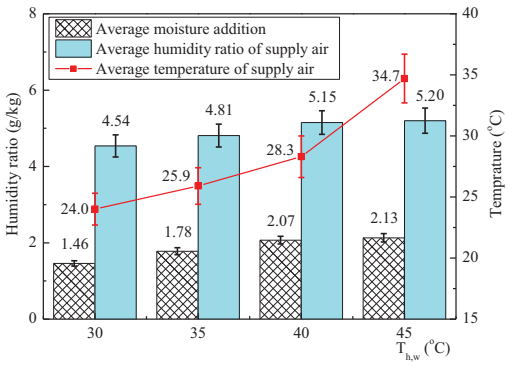

Fig.4 The average moisture addition, humidity ratio and temperature of supply air with different hot water temperatures

With the rising of $T_{w,in}$, the transient and average humidity ratio of supply air both increase as shown in Fig.3 and Fig.4. And the average value increases from 4.54 g/kg to 5.20 g/kg, up 15 %. The average moisture addition rises from 1.46 to 2.13, up 46%. Due to higher hot water temperature for desiccant material more heating power and humidification capacity can be obtained, then the regeneration process is completed thoroughly, which directly leads to the increase of moisture addition and humidity ratio of supply air. On the other hand, the surface of solid desiccant becomes drier at the end of the regeneration process with the rising of $T_{w,in}$, which increases the moisture removal and indirectly accelerates the next regeneration process. As it shows in Fig.4, the temperature of supply air rises from 24.0 ºC to 34.7 ºC due to the increment of the temperature difference between hot water and air/desiccant. And the slope of the curve is elevated. Through analyzing the above variation trends, the increase of $T_{w,in}$ has more effect on the rise of sensible load than latent load in the test condition which reflects on the tendencies of temperature and humidity ratio of supply air, respectively. At the same time, COP increases from 1.05 to 1.85, up 76 %, which increases obviously from 30 ºC to 35 ºC, then gradually

become flat when from 35 ºC to 45 ºC.

Transient supply air states in one cycle are plotted in the psychrometric figure(Fig.5) to measure whether the system can provide satisfied supply air under test condition. The black solid dot represents ambient air state, area circled by blue dashed lines show the designed standard of indoor air in winter China (temperature: 18 ºC-24 ºC, relative humidity ratio: 30 %RH-60 %RH)[24] []and the hollow points are the supply air state under different hot water temperatures. It is found that the supply air states gradually enter the designed standard area with the temperature increase from 30 ºC to 40 ºC. However, the supply air states is far from the area when $T_{w,in}$, is 45 ºC, mainly because the temperature of supply air is too high(the average temperature of supply air is 34.7 ºC). To balance the performance of the system and the thermal comfort of supply air, in spite of the performances of system (including d_{ave}, Δd_{ave}, COP) best in 45 ºC, 40 ºC is selected as the appropriate hot water temperature whose average humidity ratio is 5.15 g/kg, average temperature is 28.3 ºC , average moisture addition is 2.07 and COP is 1.78.

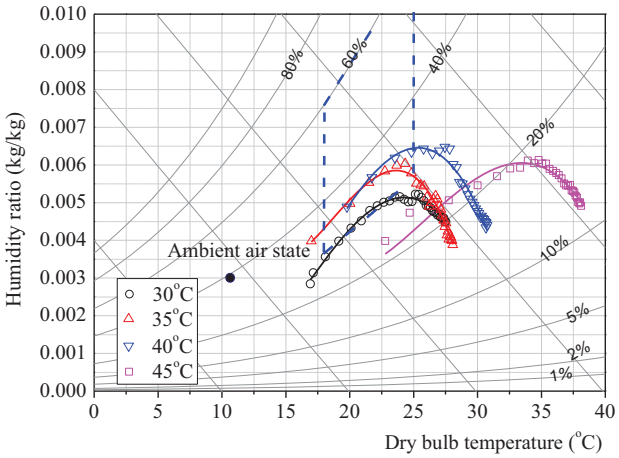

Fig.5 Transient supply air states in psychrometric figure with different hot water temperatures

4.2 Effect of hot water mass flow rate

In the solar powered DCHE system, the hot water flowing in the DCHE provides the desorption heat in regeneration process. The mass flow rate of hot water directly affects the heat exchanger efficiency between air and water, and crucially impacts the humidification and heating performance of the system. In order to explore the effect of m_w, the system is tested under constant condition that the humidity ratio of ambient air is around 2.42 g/kg-2.59 g/kg, the hot water temperature is 40 ºC and regeneration air flow flux is 400 m^3/h. Through adjusting the valve opening of the hot water loops, the different mass flow rates of hot water are controlled to 0.1, 0.2, 0.3, 0.4 kg/s, respectively. And the transient and average experimental results are summarized in Fig.6-9. In Fig.6, when the mass flow rate of hot water is greater than or equal to 0.2 kg/s, transient humidity ratio of supply air first rapidly increases to a maximum value and then gradually falls down. In the beginning period, there is a bigger relative humidity ratio difference between ambient air and pores within desiccant material, which acts as the main driving force for mass transfer and brings in the increase of moisture addition. However, water

in desiccant material is limited, which is the main reason why the humidity ratio of supply air decreases in the following process. But when mass flow rate of hot water is 0.1 kg/s, the variation trend is different. Transient humidity ratio of supply air increases in the beginning and then becomes flat without a drop process. This phenomenon occurs because the mass flow rate (0.1 kg/s) is too small to provide enough desorption heat in regeneration process and the regeneration process proceeds slowly which has not yet emerged the obvious influence due to the water decrease in desiccant material.

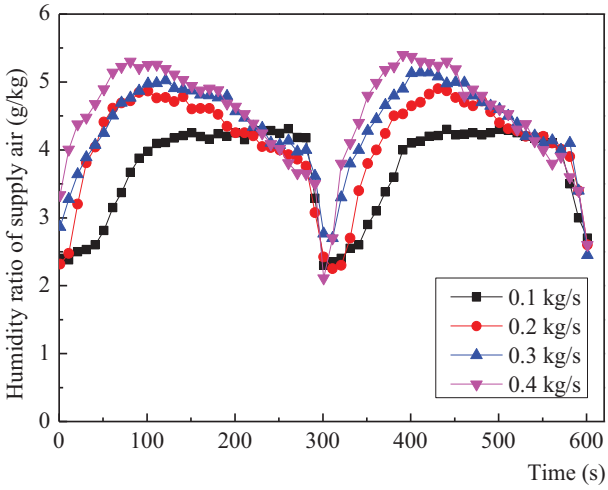

Fig.6 The transient humidity ratio of supply air with different hot water mass flow rate

With the increase of mass flow rate of hot water from 0.1 kg/s to 0.4 kg/s, all the performance indices are enhanced. Average humidity ratio of supply air, moisture addition and COP have approximately linear rises, up 24 %, 71 % and 102 %, respectively. And the increase trend of average temperature differs from others, which is from sharp to flat. This phenomenon indicates that the effect of hot water flow mass on the supply air temperature weaken when it is above 0.2 kg/s. Comparing with hot water temperature(up 15 %, 46 %, 76 %, respectively), mass flow rate of hot water has a greater influence on system performance indices when other parameters remain the same.

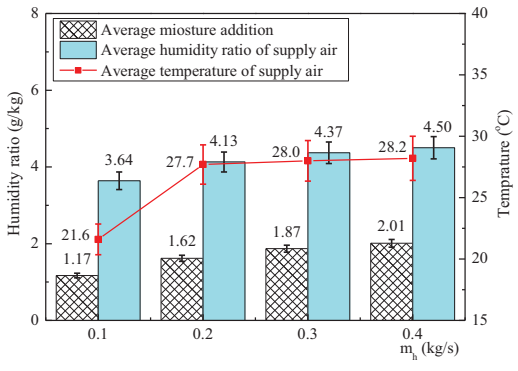

Fig.6 The average moisture addition, humidity ratio and temperature of supply air with different hot water mass flow rate

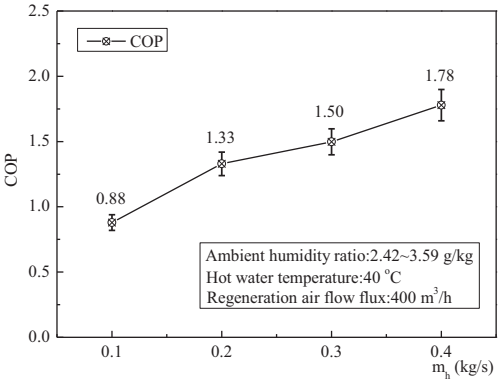

Fig.7 The average COP of the system with different hot water mass flow rate

Except for the performance of system, the thermal comfort of supply air also needs to be taken into account. Fig.8 shows the transient supply air states in psychrometric figure with different mass flow rate of hot water. When mass flow rate of hot water increases, the curves moves towards the upper right of the figure due to the promotion of heating and humidification performance. Compared with the experimental results of 0.1, 0.2, 0.3 kg/s, more points of supply air curve in 0.4 kg/s are included in the designed standard of indoor air, which can provide more comfortable temperature and humidity ratio to the conditioned space.

To sum it up, the maximum hot water mass flow rate (0.4 kg/s) is recommended in this system in order to improve regeneration process and provide better supply air condition.

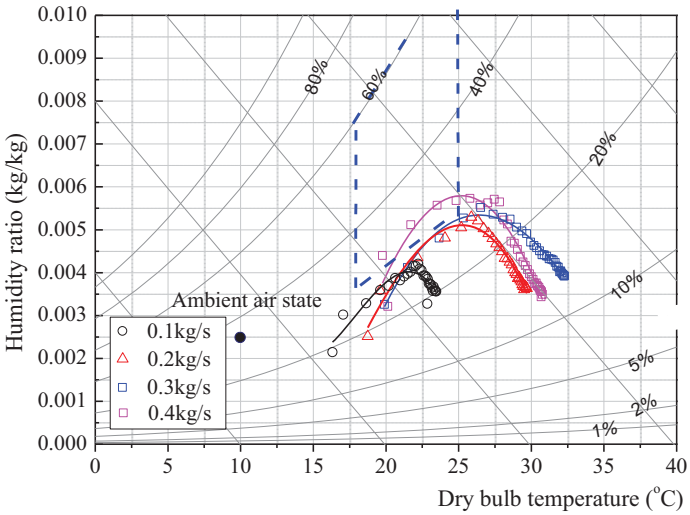

Fig.8 Transient supply air states in psychrometric figure with different hot water mass flow rate

5. Conclusion

In this paper, the solar powered DCHE air conditioning system is established and tested to research the humidification performance of DCHE in winter condition. Three important factors impacting regeneration process are discussed. The main conclusions are as follows:

(1)Experimental results of supply air humidity ratio validate that DCHE system possessed a good humidification and heating performance in winter condition.

(2)Under a single variable, humidification capacity and COP of DCHE system have a prominent increase with the rising of heat water temperature, as well as hot water mass flow rate. And through analysis of results, mass flow rate has a greater influence on all performance indices of the system than water temperature.

(3)To balance the performance of the system and the thermal comfort of supply air, 40 ºC and 0.4 kg/s are optimum temperature and mass flow rate of hot water, respectively. And the best operation state of the system in this hot water condition is concluded that average humidity ratio of supply air is 5.15 g/kg, average temperature of supply air is 28.3 ºC and COP is 1.78.

Abstract

The use of Concentrating Solar Power (CSP) systems for combined cooling and power (CCP) is increasing daily across the global. However, due to some land and other limitations various types of solar fields, CSP technology and specially solar trough Collector (STC) configuration which may have effect on overall performance of Solar thermal power plant (STPP) are used. Thus, performance analysis of these configurations is vital in order to identify their performance uncertainties and weakness. This paper studies and analysis the performance of three types of STC configuration used in most experimental and non conmmercial plants, using Matlab software and analytical approach. The results shows that for the same modules number, 5Loops configuration has higher performance with energy efficiency of 32.75%, exergy efficiency of 32.07% and lowest coefficient of performance for cooling of 0.5751, followed by 10-SCAs configuration, and 15-SCAs configuration has the lowest performance with energy efficiency of 26.45%, exergy efficiency of 25.91%, and highest coefficient of performance of cooling (COPc) of 0.7706. This study is important for identifying the performance uncertainties of various STC configurations using indirect stem generation (ISG) and selecting the most optimal configuration for small size plant in order to maximize the utilization of solar energy in CSP systems.

1. Introduction

Concentrating Solar Power (CSP) systems require direct normal irradiation to effectively function. In order to concentrate the sunlight, the lenses or mirror are used. At the same time, the tracking systems are used to optimize solar thermal power output. The solar trough Collector (STC) can be considered as the most efficiency CSP technology, according with plant number in the world and total energy thermal and electricity production [1]. In California's Mojave Desert Since the 1980s, more than 350 MW of capacity has been developed by the Solar Electric Generating Station (SEGS) using STC technology [2]. A viable alternative that helps to alleviate the challenges associated with renewable energy is a combined cycle (CC) or Rankine cycle power blocks. Solar combined cycle (SCC), uses concentrating solar thermal (CST) energy as the renewable source. V. Zare and M. Hasanzadeh studied closed Brayton cycle combined with Organic Rakine cycle for solar power tower plants in order to optimize electricity generation, in their study they found the efficiencies of the system to be 23.2% [3]. Spelling et al. studied thermodynamic and economic performance of a combined-cycle, based on open air Brayton and steam Rankine cycle was analyzed , in this study it was concluded that the efficiencies of the system was between 18–24% [4]. Organic Rankine cycle (ORC) is a special kind of Rankine cycle that uses an organic fluid as a working fluid instead of water, which is currently used for combined cycle study. ORC could be used with diffferent kinds of low temperatures coming from various heat sources such as geothermal energy, solar energy, biomass energy and waste heat. Suna et Li [5] provided the organic Rankine cycle heat recovery power plant using R134a as working fluid to evaluate and optimize the plant performance. Sun L. et al. [6] proposed an combined power and cooling system power able to use mid/low temperature from heat source, this system consisted of a combination of Rankine cycle (RC) and absorption refrigeration cycle (ARC). During this study Sun L. et al. used the more import portion of waste heat for power generation uusing ORC as was done by V. Zare and M. Hasanzadeh, whereas another portion of this waste heat was used for cooling generation. Today, in order to increase opportunities offered by

doi:10.18086/swc.2017.29.01 Available at http://proceedings.ises.org

renewable energy sources, significant market for the ORC is ready to make more attracted combination of cooling heat and power (CCHP) using waste heat from soloar thermal power plant (STPP) specially. Organic Rankine cycle technology is a challenge to develop an appropriate CCHP scale to meet both energetic, economic and environmental needs increase [7–8]. This paper focus on SCC power plant configuration and performance analysis, in order to show both energetic and exergetic efficiency values of different configurations. In either case this study integrated ARC analysis using waste water from Power combined cycle (PCC) with objective to decrease heat loses.

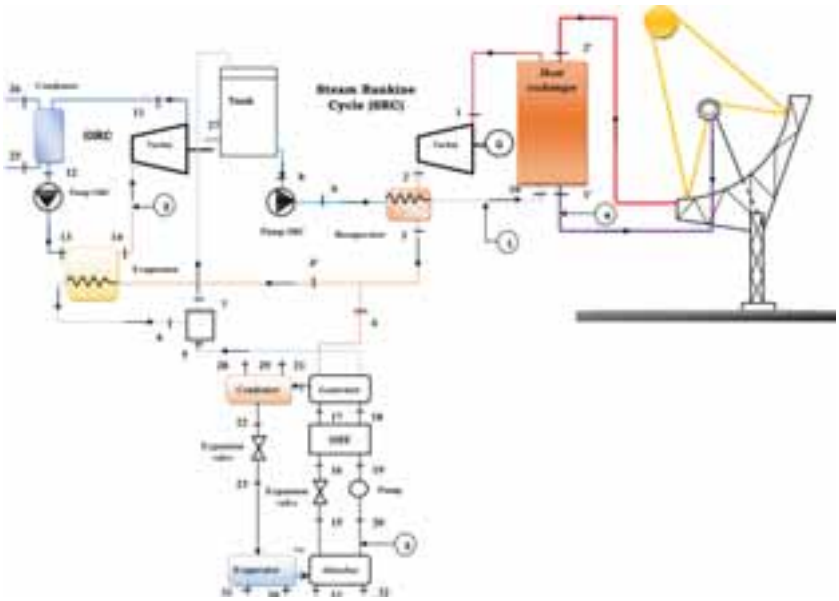

Figure 1: System description

2. System descriptions and assumptions

The following assumptions have been considered in the study

- The system is operating in steady state conditions.
- The kinetic and potential energies and exergies are negleable, due to absence of chemical reactions in the considered system and also in heat transfer fluid.

2.1 System descripton

Fig.1 shows layout of CCP system containing parabolic trough collectors (PTC), heat exchanger , thermal heat transfer fluid and combined power systems able to provide waste heat necessary for cooling system, by using ARC. PTC is a known and commercialized technology. In this study, Luz-S2 and PTR schott technologies are used as receiver type and absorber type respectively. This technology is generally used to provide heat around 500°C using heat tranfer fluids (HTFs) depending o configurtion type, Direct steam generating (DSG) or ISG system. In this case study we are using ISG system on by using Therminol VP-1 as thermal HTF. There after, thermal energy is transfered to water in Intermediate Heat Exchanger (IHE). Before going through IHE, cool water have to be heated by recuperator, to increase its temperature.Steam generated has the temperature close to HTF's temperature according to mass flow rate of water. As indicated in Fig.1 exiting steam from turbine is used for preheating water from tank by using recuperator. Exiting steam from recuperator is used to provide heat for auxilaries cycles both Organic Rankine and Absorption refrigeration. For ORC exiting hot water go through evaporator directly to increase organic heat tranfser fluids temperature (satured vapor state) and for absorption system the hot water is used to seperate Lithium Bromide and Water inside of generator.

2.2 Solar field

Solar energy is one of main key alternative energy sources in Turkey. Therefore, it improtant to consider its utilization in future energy generation mix in the country and especially in Izmir.
Izmir has a mediterranean climate which is characterized by long hot and dry summer with mild to cool and rainy winters[9]. The total average of precipitation for Izmir is around 686 mm per year. However, 77% of the rain falls during December through to March. The maximum temperature during winter months are usually between 10 to 16°C. During summer the ambient air temperature can rise high to as much as 40°C from June to

September. Average relative humidity is between 42 and 70%. Mean monthly sunshine hours are between 124.0 hours in december and 375.1hours in July [9]. Solar energy potential of Izmir is considerable and advantageous due to its geographical position in northern hemisphere as shown in Table 1 [10-11].
During this study direct normal irradiation value used for calculation is 523.7 W/m^2, which correspond to Average value of solar radiation during 1 year in Izmir.The solar field can be defined as a system containing a number of loops, with each Loop consisting of two solar collector assembly which is made of connected modules. The specifications of module and Solar Collectors Assemblies is shown in Table 2.

3. Method and Formula

3.1 Configuration Description

Usually there are two arrangement types in Solar thermal collector plant using parabolic trough collectors, I and H. In this study, three differents configurations of STC fied have been analyzed using a same modules number and characteristics. The main aim of this work is to show which configurations can provide better energetic and exergetic efficiencies using CCP system. The configuration type-A contains 15 SCA's and each one has 8 modules without any loop. Configuration type-B contains10 SCA's each with 12 modules without any loop. Configuration type-C contains 5 loops with each one having 24 modules.

Figure 2: solar field configurations A, B and C

3.2 Solare collector efficiency

The thermal efficiency of solar collector is the ratio of collector thermal power output to the solar power input [13-15] and can be expressed by eq.1:

$$\eta_c = \frac{\dot{Q}_{abs}}{\dot{Q}_{solar}} \qquad \text{(eq. 1)}$$

Where $\dot{Q}_{solar}$ is the solar power input (kW) and $\dot{Q}_{abs}$ is useful energy output of collector(kW). The solar power input can be calculated from the average direct normal irration G_b and total collector aperture area A_{ap} . Thus, the total available solar on the PTC's cover glass has been estimated using the given eq. 2[15]:

$$\dot{Q}_{Solar} = A_{ap}.G_b \qquad \text{(eq. 2)}$$

The amount of total solar radiation that is striking the collector and used as input heat, which is necessary to heat transfer fluid inside of absorber has been calculated using eq. 3[15].

$$\dot{Q}_{use,in} = A_{ap}.F_R.S \qquad \text{(eq. 3)}$$

Where $\dot{Q}_{use,in}$ is the absorber input solar energy, F_R. is heat removal factor, and S is the heat absorbed by receiver. These parameters can be expressed respectively as[15]:

$$A_{ap} = \left(W - D_{r,o}\right).L \qquad \text{(eq. 4)}$$

$$F_R = \frac{\dot{m}.C_P}{A_r.U_L}\left[1 - exp\left(-\frac{A_r.U_o}{\dot{m}.C_P}\right)\right] \qquad \text{(eq. 5)}$$

$$S = G_b.\eta_o \qquad \text{(eq. 6)}$$

Where η_o is optical efficiency, $U_o$is overall heat transfer coefficient, and $\dot{m}$ is mass flow rate of HTF. The values of a receiver and cover surface area, optical parameters and other can be found in Table 2.
The useful energy output of collector has been estimated using eq. 7 written as[15]:

$$\dot{Q}_{abs} = A_{ap}.F_r.\left(S - \frac{A_r}{A_{ap}}U_L.(T_{ri} - T_o)\right) \qquad \text{(eq. 7)}$$

Where receiver area aperture is A_r (Table), U_L is heat losses coefficience, T_{ri} is input temperature of HTF inside receiver, T_o ambient air temperature. Table 3 summarizes the defination of the optimal parameters of the parabolic trough collector.

3.3 Optical and Thermal analysis of parabolic collector

Therminol VP-1 oil has been used as HTF in this study due to its good temperature control and heat transfer properties (Table 5) [16]. Generally mass flow rate of the heat transfer fluid per row is between 0.35 and 0.8 kg/s according with solar collector assembly length [17]. In order to determine thermodynamic properties of heat transfer fluid entering the IHE and also working fluid properties entering in the steam turbine of Rankine cycle. All the equations below have to be used to calculate the temperature of receiver's cover and the value of solar heat absorbed by the receiver of parabolic trough collector.

A. Optical analysis

The concentration ratio (C) of parabolic trough collector is calculated by the given eq.8 [18]:

$$C = \frac{A_{ap}}{A_{c,o}} \qquad \text{(eq. 8)}$$

The geometric factor is a ratio of lost area to aperture area which is estimated using the following eq. 9[18]:

$$A_f = \frac{A_L}{A_{ap}} \qquad \text{(eq. 9)}$$

Whereas the lost area has been estimated using the expression eq. 10 [18]:

$A_L = \frac{2}{3}W_a.H_p + fW_a\left[1 + \frac{{W_a}^2}{48f^2}\right]$ Where H_P is height of parabola and f is parabola focal distance

Optical efficiency is defined as ratio of the energy incident on the collector's aperture [18]. It depends on optical properties of materials involved, geometric of collector and other parameters as errors related to the construction collector. The optical efficeiency has been estimated using the expression as given in eq11[18].

$$\eta_o = \rho_c.\tau_g.\alpha_r.\gamma\left[\left(1 - A_f.\tan(\theta)\right)cos(\theta)\right] \qquad \text{(eq. 11)}$$

Parabolic Trough collector (PTC) structure uses a two axis tracking, the main advantage of using the tracking system is that solar collector assembly can collect all available direct solar energy during the day, because incidence angle of solar radiation is always equal to zero.

B. Thermal analysis

Generally, in order to decrease the heat losses, a cover glass tube is employed around receiver . The space between the receicer and the cover glass is evacuated in order to minimize the conventional losses. The heat losses coefficient has been calculated usıng eq. 12 given by [18].

$$U_L = \left(\frac{A_r}{(h_{c,c-a}+h_{r,c-a})*A_{c,o}} + \frac{1}{h_{r,r-c}}\right) \qquad \text{(eq. 12)}$$

The heat transfer coeefficients between receiver and cover glass and between cover glass and ambient temparature of have been estimated using eq.13a and 13b written as[18].

$$h_{r,\ r-c} = \sigma\left(T_g + T_a\right)\left(T_g^2 + T_a^2\right).\left(\frac{1}{\varepsilon_r} + \frac{A_r}{A_g}\left(\frac{1}{\varepsilon_g} - 1\right)\right)^{-1} \qquad \text{(eq. 13a)}$$

$$h_{r,\ c-a} = \varepsilon_g\sigma\left(T_g + T_a\right)\left(T_g^2 + T_a^2\right) \qquad \text{(eq. 13b)}$$

The overall heat transfert coefficient, including external walls of the cover glass has been calculated using the following expression eq.14 [18].

$$U_o = \left(\frac{1}{U_L} + \frac{D_{r,o}}{h_{c,r-c}.D_{r,i}} + \frac{D_{r,o}.ln\left({}^{D_{r,o}}/_{D_{r,i}}\right)}{2k_r}\right) \qquad \text{(eq. 14)}$$

Between receiver and cover glass , cover glass and ambient terms of heat trnasfer coefficient are written as eq. 15a and 15b [18]:

$$h_{c,\ c-a} = \frac{(Nu_{air}.k_{air})}{D_g} \qquad \text{(eq. 15a)}$$

$$h_{c,\ r-c} = \frac{(Nu_r.k_r)}{D_g} \qquad \text{(eq. 15b)}$$

Where Nu is Nusselt number, k is the thermal conductivity and D is the diameter of cross section . The Reynold and Prandt number has been estimated using eq.16 and 17 [18]:

$$Re = \frac{V_f.D_{cross}}{\vartheta_f} \quad \text{(eq. 16)}$$

$$Pr = \frac{\rho.Cp.\vartheta}{k} \quad \text{(eq. 17)}$$

By ignoring the radiation absorbed by the cover glass, T_c has been estimated from this energy balance eq.18 :

$$A_c.\left(h_{c,c-a} + h_{r,c-a}\right).(T_c - T_a) = A_r.h_{r,r-c}(T_r - T_c) \quad \text{(eq. 18)}$$

Temperature of receiver cover has been calculated as follows eq. 19 [18].

$$T_c = \frac{h_{r,rc}.T_{r,a} + \frac{A_c}{A_r}(h_{c,ca} + h_{r,ca})T_o}{h_{r,rc} + \frac{A_c}{A_r}(h_{c,ca} + h_{r,ca})} \quad \text{(eq. 19)}$$

C. Thermal efficeincies

The collector efficiency factor for this study has been calculated using eq.20 given by[15-18].

$$F' = \frac{U_o}{U_L} \quad \text{(eq. 20)}$$

The collector efficiency has been found by dividing energy useful by solar energy input. Therefore, the collector efficiency is estimated using the following eq. 21[18].

$$\eta = F_R\left[\eta_o - U_L\left(\frac{(T_{ri} - T_o)}{G_b C}\right)\right] \quad \text{(eq. 21)}$$

The thermodynamic properties of the heat transfer fluid used in the study is given in the Table 5 (Appendix1). Using the heat transfer fluid the usefull energy output of collector has been determined using eq. 22 [15-18].

$$\dot{Q}_{abs} = \dot{m}_{Th}\left(Cp_{Th,o}.T_{Th,o} - Cp_{Th,i}.T_{Th,i}\right) \quad \text{(eq. 22)}$$

Where $\dot{m}_{Th}$, Cp_{Th} and T_{Th} are the mass flow rate , the specific heat and temperature of Therminol VP-1 going trough PTC's receiver respectively. The subscripts o and i refer to outlet and inlet position of Therminol VP-1 inside of that receiver.

3.4 Thermodynamic analysis

Overall system is divided into three subsystems namely, Solar Collector system, Power cycle (Steam and Organic Rankine Cycle), and Absorption system. For each subsystem, thermodynamic models are developed and the components of each subsystem are studied using MATLAB program to simulate the subsystem models. For a control volume accompanying a steady state process the energy and exergy balance equations [19]. Where $\dot{\psi}_{out}$ and $\dot{\psi}_{int}$ are the total exergy rates entering and exiting to the control volume respectively, while $\dot{\psi}_D$ is the exergy destruction rate within the component as defined in Appendix 1.

A. Solar sub -system

Solar subsystem contain essentially PTC and intermediate heat exchanger using Therminol VP-1 oil as working fluid. On the other hand, it's one of the most important part of this system. Its major purpose is provide heat collected from concentrated sun rays to power cycle by intermediate heat exchanger. The energetic efficiency of solar subsystem is the ratio of heat provided by working fluid inside of intermediate heat exchanger to heat obtained through absorber . It has been calculated using eq.28 written as[3,20]:

$$\eta_{th,S} = \frac{\dot{Q}_{IHE}}{\dot{Q}_{use}} \quad \text{(eq. 28)}$$

The exergetic efficiency of solar sub-system is the ratio of the usefull exergy input to power cycle and exergy of heat obtained through absorber. It has been determined using eq. 29 given below[3-20].

$$\eta_{ex,S} = \frac{\dot{\psi}_{2'} - \dot{\psi}_{1'}}{\dot{Q}_{use}\left(1 - \frac{T_o}{T_{ref,sun}}\right)} \quad \text{(eq. 29)}$$

Where $T_{ref,sun}$ is apparent sun temperature as the equivalent heat source temperature (Tref, sun = 5739 K).

The exergy destruction of solar subsystem is the sum of destroyed exergy in intermediate heat exchanger and solar field. It has been estimated using the eq. 30 presented by[3]:

$$\dot{\psi}_{D,solar\ ss} = \dot{\psi}_{D,abs} + \dot{\psi}_{D,IHE} \quad \text{(eq. 30)}$$

B. Power cycle (Steam and Organic Rankine Cycle)

The following assumptions have been considered in the study of the power cycle**:**

- For turbines and pump in Rankine cycles , isentropic efficiencies are assumed as given in Table.
- The appropriate value of the efficiency for recuperator has been assumed as given in table.
- Pressure drop and losses inside of Rankine cycles are neglegible.

$\dot{\psi}_{2'} - \dot{\psi}_{1'}$ represents the usefull exergy input to the combined rakine cycle. Heat provided to power cycle is generated inside of IHE, it has been estimated using the expression given by eq.31[18].

$$\dot{Q}_{IHE} = \dot{m}_w(h_1 - h_{10}) = \dot{m}_f(h_{1'} - h_{2'}) \quad \text{(eq. 31)}$$

While the net output power work $\dot{W}_{net}$ of the combined Rankine cycle has been calculated using eq. 32[15].

$$\dot{W}_{net} = \left(\dot{W}_T - \dot{W}_{Pump}\right)_{SRC} + \left(\dot{W}_T - \dot{W}_{Pump}\right)_{ORC} \quad \text{(eq.32)}$$

Power generation unit converts thermal solar energy absorbed in imtermediate heat exchanger to the net power generated.Thus, the efficiency for both energetic and exergetic of power cycle have been estimated using the following eqs. 33 and 34 respectively[3, 20]:

$$\eta_{th,cc} = \frac{\dot{W}_{net}}{\dot{Q}_{IHE}} \quad \text{(eq. 33)}$$

$$\eta_{ex,cc} = \frac{\dot{W}_{net}}{\dot{\psi}_{2\prime} - \dot{\psi}_{1\prime}} \quad \text{(eq. 34)}$$

For the considered solar power plant the overall energy and exergy efficiency can be defined as ratio of the net output power to the energy or exergy input due to solar irradiation on parabolic collector field. More clearly, power plants overall can be expressed as product of solar field efficiency and power cycle efficiency.
The overall energetic efficiency of power plant has been calculated using eqs. 28 and 33[3]:

$$\eta_{th,PP} = \frac{\dot{W}_{net}}{\dot{Q}_{IHE}} * \frac{\dot{Q}_{IHE}}{\dot{Q}_{use}} \quad \text{(eq. 35)}$$

While the overall exergetic efficiency of power plant has been estimated using eqs. 29 and 34.

$$\eta_{ex,PP} = \frac{\dot{W}_{net}}{\dot{\psi}_{2\prime} - \dot{\psi}_{1\prime}} * \frac{\dot{\psi}_{2\prime} - \dot{\psi}_{1\prime}}{\dot{Q}_{use}\left(1 - \frac{T_o}{T_{ref,sun}}\right)} \quad \text{(eq. 35)}$$

Where $T_{ref,sun}$ is apparent sun temperature.

C. Absorption system analysis

In order to estimate the size of equipment and optimize single effect Water -Lithium bromide absorber cooler. The following assumptions and input values have been considered.

- Absorption system is operating in steady state and refrigerant is pure water.
- There are no pression variation, except through the flow restrictors and the pump (i.e pump and flow restrictors are considered as isentropic and adiabatic respectively).
- Environmental heat losses are neglegible.
- There are no jacket heat losses, and at points 20,17,22 and 24 there is only saturated state.

The cooling COP of absorption system is defined as the ratio of the heat load inside of evaporator and the heat load inside of generator and has beeen determined using expression 38 [22,23] :

$$COP_C = \frac{\dot{Q}_E}{\dot{Q}_G + \dot{W}_P} \quad \text{(eq. 38)}$$

$$= \frac{\dot{m}_{21}(h_{23} - h_{24})}{\dot{m}_{20}(h_{19} - h_{20}) + m_{21}h_{21} + \dot{m}_{17}h_{17} - \dot{m}_{18}h_{18}}$$

Where m is mass flow rate and h is the enthalpy of working fluid at each corresponding state point. The heating COP of absorption system is the ratio of combined heating capacity , obtained through absorber and condenser and heat load provided by an external source, specifically inside of generator calculated using eq.39 [22,23]:

$$COP_H = \frac{\dot{Q}_A + \dot{Q}_C}{\dot{Q}_G + \dot{W}_P} = 1 + COP_C \quad \text{(eq. 39)}$$

The exergetic efficiency of absorption system for cooling is exergetic ratio between chilled water at evaporator and heat source at the generator. Which has been calculated using eq.40 [24,25].

$$\psi_C = \frac{\dot{\psi}_{30} - \dot{\psi}_{31}}{(\dot{\psi}_4 - \dot{\psi}_5) + \dot{W}_P} \quad \text{(eq. 40)}$$

The exergetic efficiency of absorption system for heating is exergetic ratio of combined supply of hot water at absorber and condenser to heat source at the generator. Which can be expressed as given in eq.41 [26,27].

$$\psi_H = \frac{(\dot{\psi}_{29} - \dot{\psi}_{28}) + (\dot{\psi}_{33} - \dot{\psi}_{32})}{(\dot{\psi}_4 - \dot{\psi}_5) + \dot{W}_P} \quad \text{(eq. 41)}$$

The exergy destruction of absorption system is defined as the sum of destroyed exergy in each component and can be calculated using the following eq. 42 [28].

$$\dot{\psi}_{D,abs} = \dot{\psi}_{D,Gen} + \dot{\psi}_{D,Con} + \dot{\psi}_{D,\ Eva} + \dot{\psi}_{D,abs}\ \dot{\psi}_{D,she} + \dot{\psi}_{D,Val} \quad \text{(eq. 42)}$$

Table 1 : Energy and exergy balance

Components	Energy Q (kW)			Exergy destroyed I (kW)		
	#1	#2	#3	#1	#2	#3
Absorber	124.1	84.1	55	5.04	6.87	6.82
Generator	124.7	85	57.7	13.81	12.57	11.02

Total				**30.57**	**27.91**	**22.3**

4. Results and Discussion

4.1 Validation of PTSC assemblies

The SCA study is based on the pysical and optical characteristics of the parabolic collector used for its assembly. But for this study the parabolic collector used is the same for all the configurations, moreover we must know that the arrangement of the collectors is in series even if the size and the shape of the SCA show some differences. This validation of the SCA technology was based essentially on the Removal factor, thermal efficiency and thermal efficiency factor (0.85).

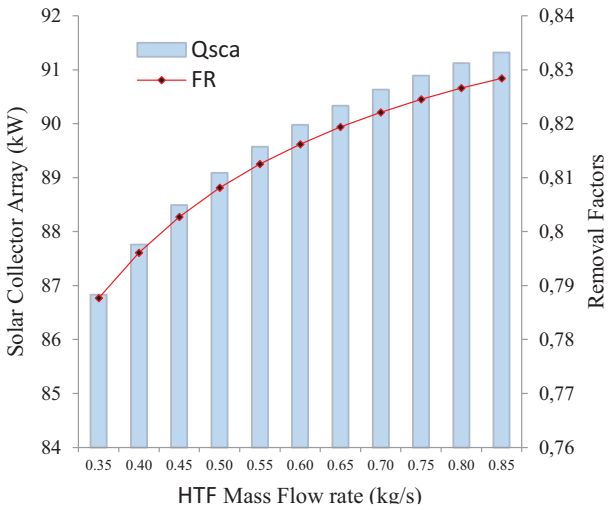

Fig.2: Absorbed energy and Removal factor of SCA. in configuration Type - A

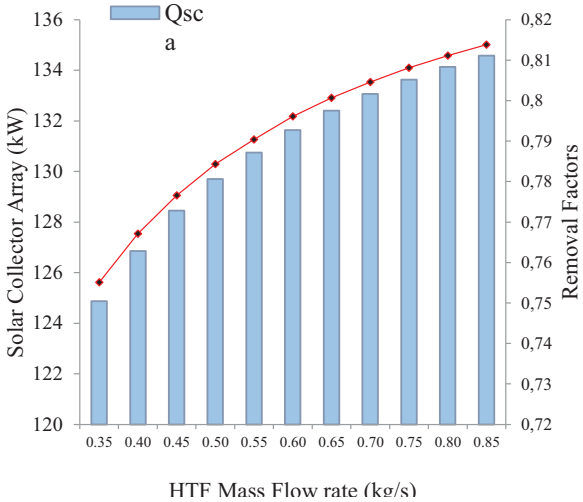

Fig.3: Absorbed energy and Removal factor of SCA. in configuration Type - C

The fig. 2 shows that the SCA used in the configuration type -A has a Removal factor of 0.812 and its energy absorbed of 89.9 kW, while Fig.3 presents a configuration type -B with a Removal factor of 0.791 and an energy absorbed of 131 kW when working with a mass flow rate of 0.55 kg/s. The configuration type-C not shown in this section has a Removal factor of 0.7543 and an energy absorbed of 249.46 kW working at a mass flow rate of 0.65 kg/s.

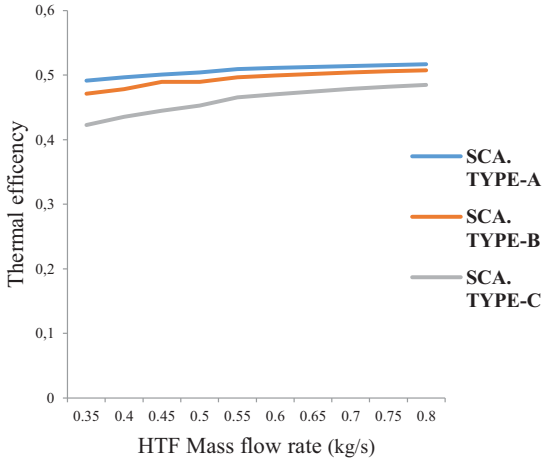

Fig. 4 : Effect of HTF mass flow rate on thermal efficiency.

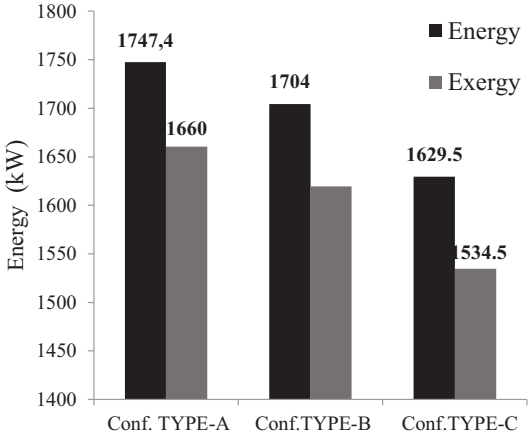

Fig.5: Effects of configuration type on Energy -exergy output

The fig.4 shows a negligible variation of the Thermal efficiency when the mass flow rate increases for the configuration type-A. On the other hand for the configuration type -C there is a considerable variation in the Thermal efficiency when there is a variation of the mass flow rate between 0.35 and 0.7 kg /s. For this study, a mass flow rate of 0.55kg/s will be used for Type-A and Type B configurations and 0.65kg/s for Type-C configuration

4.2 Validation of solar field configuration Type

Fig. 5 shows that the energy absorbed in the configuration type-A is greater than other configurations. It should be noted that the energy absorbed by the configuration of the solar field is closely related to the volume

of transfer fluid used to absorbe that energy. Futhermore outlet temperatures of the transfer fluid in the other types are significantly higher than configuration type-A.
In summary, we will say that the energy absorbed by the solar field changes inversely with the outlet temperature of the transfer fluid. The use of the ORC in the production of electricity does not influence the choice of the appropriate configuration. On the other hand, it contributes to the growth of electricity production in a significant way (Figures 6 and 7).

4.3 effects of configuration on power system performance

A comparative study of the results obtained in Tables 9, 10 and 11 between the CRC and SRC for different configurations shows a relative increase in electricity production according to the type of configuration. The configuration Type -A presents an increase of 5.05%, while configurations type -B and C show 3.1% and 1.95% increase in power generation respectively.

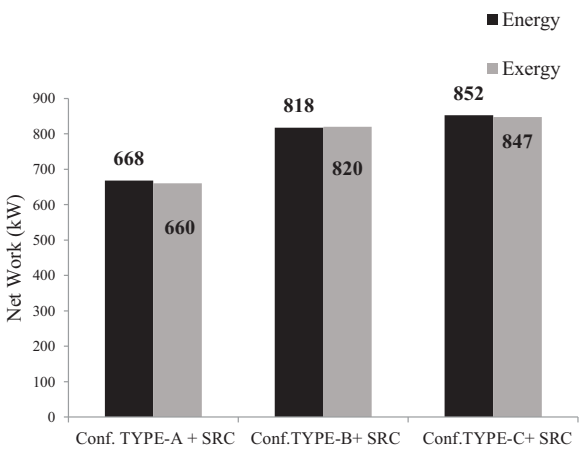

Fig.6: Net work of overall plant without ORC system

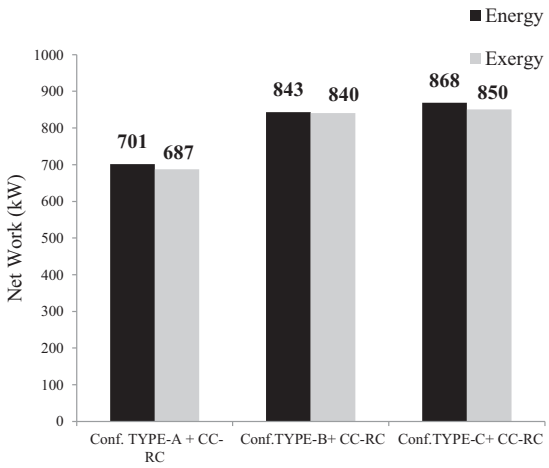

Fig.7: Effect of ORC on power system performance

4.4 effects of additive subsystem on system performance

The figures 8 et 9 show overall performance of studied configurations, configuration Type-C presente an higher performance with energy efficiency of 32.75%, exergy efficiency of 32.07% and lowest coefficient of performance for cooling and heating of 0.5751 and 1.5751 respectively.The configuration Type-C is followed by configuration Type -B, and configuration Type- A. The configuration Type- A has the lowest performance with energy efficiency of 26.45%, exergy efficiency of 25.91%, and highest coefficient of performance of cooling of 0.7706. The fig. 8 presents impact of both ORC and ARC in combined cooling power system analyzed.

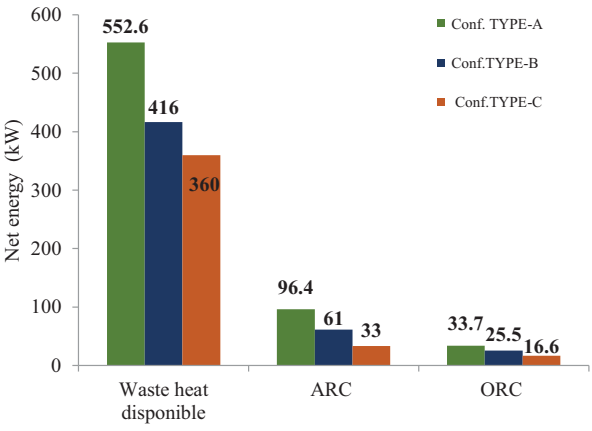

Fig.8: Effect of ARC and ORC on power system performance

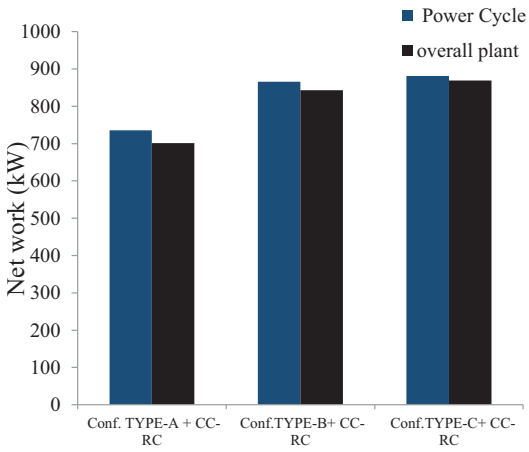

Fig.9: Effect of htf Pumping system on power system performance

Fig. 9 shows direct impact of htf pumping system of solar field configuration type on overall power plant. This study present configuration Type -A as a configuration which transfer 8.25 kg of Therminol oil per second too feed its piping network.

4.5 presentation of other results

Figure 10 presents a complete resume of this study through energy analysis of described system (fig.1). During this study optical, thermal conversion, transport and CCP losses has been analyzed for each solar plant configuration in order to show which of them is more efficiently and can be use to use provide power and cooling more suitably. fig.10.a shows repartition of these losses and overall plant production in configuration Type-A. The total losses evaluated for configuration is 68.62%, where optical losses contribute the highest value of 34.11%, followed by CCP production contributing 26.45% while cooling production contribute the second lowest value of 3.64% and external energy contribute the least lowest value of 1.29%.

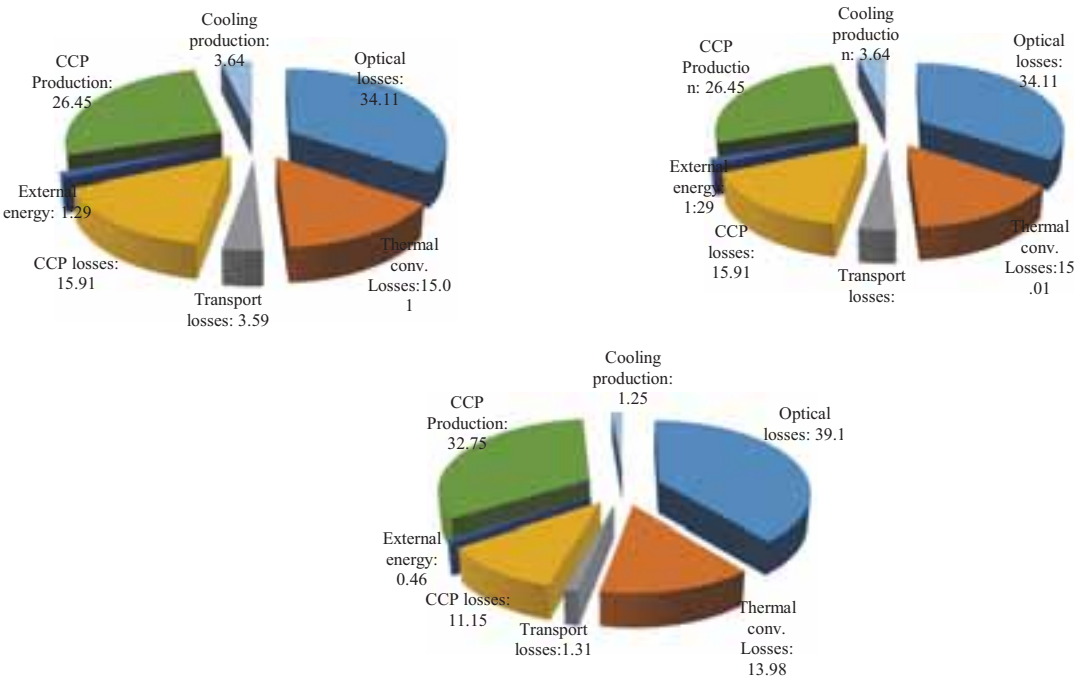

Figure 10: Repartition of energy losses of CCP in plant (a) configuration Type -A (b) configuration Type -B, (c) configuration Type -C

Fig.10.b shows the distribution of the total losses of configuration Type -B with the value of 65.54% , here CCP production contribute 32.75% of the total losses, while cooling production contribute 1.25% and external energy contribute the least value of 0.46%. It is worth to note that in all the configuration, optical losses contribute the highest to losses while external energy contribute the least. Furthermore, among the three configuration studied, configuration type-A had the highest losees followed by configuration type-B, while configuration type-C had the least.

In all the configurations presented, configuration type-C had a higher optical loss and lowest transport, thermal conversion and combined cycles power losses due to higher operating temperature, low mass flow rate of heat transfer fluid and short pipeline network.

5. Conclusion

The complete energy and exergy analysis on combined cooling power using combined Rankine cycles has been analyzed in this paper. This study has considered three differents configuration of same CSP system containing 120 modules. During this study effect of operating parameters such as temperatures, mass flow rates of working, transfer fluids are included, by a situable rate values of each one. Besides this, analysis of individual components of ecah subsystem is also done in order to improve global efficiency of system. This study shown that configuration type-C is more siutable for electricity produce in CSP commercial plant. This configuration despite working with higher temperature and lower mass flow rate, it has higher efficiency for power production. However, the system has lowest absorption refrigeration (AR) system efficiency due to lower exergy transfer by Steam Rankine cycle on the AR system. This study is important for identifying the performance uncertainties of various STC configurations using indirect stem generation (ISG) and selecting the most optimal configuration for small size plant in order to maximize the utilization of solar energy in CSP systems. Thus, its hoped that the results found in this study will be usefull for decision making regarding the selection of CSP systems configurations for optimal solar energy utilization.

3. Thermodynamic of working fluids

Exergy balance equations are expressed in eq.23a, b, and c given below have been used in this study[19]:

$$\dot{E}_{int} - \dot{E}_{out} = \Delta\dot{E}_{syst} \quad \text{(eq. 23a)}$$

$$\dot{\psi}_{int} - \dot{\psi}_{out} - \dot{\psi}_D = \Delta\dot{\psi}_{syst} \quad \text{(eq. 23bc)}$$

$$\dot{S}_{int} - \dot{S}_{out} + \dot{S}_{gen} = \Delta\dot{S}_{syst} \quad \text{(eq. 23c)}$$

For the first law of thermodynamics yields, energy balance of each component is given by eq.23 [19] :

$$\sum(\dot{m}h)_i - \sum(\dot{m}h)_o - \left[\sum Q_i - \sum Q_o\right] + W = 0$$

$$\dot{E} = \dot{m}h \quad \text{(eq. 24)}$$

The exergy of fluid has been estimated using the following expression

$$\psi = (h - h_o) - T_o(s - s_o) \quad \text{(eq. 24)}$$

The exergy destruction in each component has been calculated using :

$$\dot{\psi}_D = \dot{\psi}_{int} - \dot{\psi}_{out} - \left[\sum Q\,(1 - \tfrac{T_o}{T})_i - \sum Q\,(1 - \tfrac{T_o}{T})_o\right] + \sum W$$

$$\dot{\psi} = \dot{m}.\psi \quad \text{(eq. 25)}$$

The exergy destruction of system is the sum of destroyed exergy, can be presented by:

$$\dot{\psi}_{D,Total} = \sum_i \dot{\psi}_{D,i} \quad \text{(eq. 26)}$$

The system performance and optimatization has been done using the presented Thermodynamic law.

The equivalent heat source temperature is given by:

$$\dot{\psi}_{D,CC} = \sum_i \dot{\psi}_{D,T} + \sum_i \dot{\psi}_{D,P} + \dot{\psi}_{D,cond} + \dot{\psi}_{D,Eva} + \dot{\psi}_{D,rec}$$

The governing equations of mass and type of material conservation for a steady state and steady flow system are expressed by eqs. 36a and b[21]:

$$\sum \dot{m}_i - \sum \dot{m}_o = 0 \qquad \text{(eq. 36)}$$
$$\sum(\dot{m}x)_i - \sum(\dot{m}x)_o = 0$$

The heat exchanger efficiency has been estimated using eq. 37 as presented below[18].

$$\pi_{she} = \frac{T_{17}-T_{16}}{T_{17}-T_{19}} \qquad \text{(eq.37)}$$

Residential buildings retrofit: the role of solar technologies

Alessandro Bellini[1,2], Chiara Dipasquale[1] and Roberto Fedrizzi[1]

[1] Institute for Renewable Energy, Eurac Research, Bolzano (Italy)

[2] Free University of Bolzano, Bolzano (Italy)

Abstract

In line with the last European directives that boost actions for reducing the energy consumption in the residential sector, buildings refurbishment becomes key. On one hand, a deep building retrofit concerns actions aimed at reducing the building demands and the final energy consumption. In particular, the replacement of existing windows, the addition of an insulation layer on the external surfaces and the installation of a mechanical ventilation system with heat recovery (MVHR) help to drastically reduce the building demands. On the other hand, the installation of a system with improved performance can additionally decrease the final energy used for space heating and cooling (H&C) and Domestic Hot Water (DHW) preparation with respect to a traditional system. Once the retrofit measures have acted on improving the energy efficiency of both building envelope and HVAC system, an additional contribution can be given by solar technologies integrated in the building.

In this context, this paper wants to show the amount of final and primary energy consumption reduction through a deep renovation on existing buildings and the contribution that solar technologies gives in this perspective.

Keywords: Building retrofit, solar technologies, simulation-based analysis, residential buildings

1. Introduction

In line with the last European directives that boost actions for reducing the energy consumption in the residential sector, buildings refurbishment becomes key. The construction period of half of the existing European residential building stock dates back to before 1970. The average heating demand of these buildings over Europe is higher than 200 kWh/(m²y) (Birchall et al., 2014). This means a big potential for buildings refurbishment although up to now the yearly retrofit ratio is around 1-2%. For achieving high energy savings, what is needed is a deep building retrofit that involves both the envelope and the HVAC system of a building. The integration of solar technologies can even increase the reduction of energy consumption due to space Heating & Cooling (H&C) and Domestic Hot Water (DHW) preparation.

Deep building retrofit concerns actions aimed at reducing building demands and final energy consumption. On one hand, the replacement of existing windows, the addition of an insulation layer on the external surfaces and the installation of a mechanical ventilation system with heat recovery (MVHR) help drastically to reduce the building demands. On the other hand, the installation of a system with improved performance can contribute additionally to decrease the final energy needed for covering the building uses. Intervention on the envelope, in fact, are effective only if also the HVAC system is performing. The effect that one solution could have on another one and the contribution that solar thermal panels (ST) and photovoltaics (PV) without battery can have on the final energy consumption are not easy to be estimated during the design phase. For this purpose, dynamic simulations could help for accounting for the loads to be covered and production contemporaneity.

For the abovementioned reasons, this paper aims to present simulation-based results of renovation packages solutions applied to residential existing buildings. In particular, the paper reports building demands reduction due to envelope solutions, final energy consumption and HVAC system performance, solar fraction obtained with the integration of STC and PV production, self-consumption and energy fed into the grid. Simulations are carried out in the TRNSYS environment (Klein et al., 2011).

doi:10.18086/swc.2017.29.02 Available at http://proceedings.ises.org

The paper presents results collected in an online database (iNSPiRe, 2016) useful in a pre-design phase for giving an idea about energy and economic performance of market-available renovation packages solutions. The validity of this database concerns the possibility to consult easily renovation measures performance obtained through detailed models. The numerical models of the analysed cases take also into account the contemporaneity of available solar energy and building loads (thermal or electrical), the presence of thermal storages and the implementation of the system control. The analysis has been performed through seven European climates, seven building construction periods, four heating demand levels and five building typologies. Moreover, the database reports results on the investment, maintenance and running costs of each solution. For the scope of the paper, only a selection of these results is commented.

In this paper, in particular, the authors want to underline the impact that solar technologies have in a retrofit process for the reduction of the final and primary energy consumption. Additionally, the paper provides suggestions on the optimal solar field size to match the building needs and reduce stagnation hours in solar thermal field and fed-into-the-grid energy in PV installations.

2. Retrofit packages for residential buildings

The study refers to reference buildings individuated in a previous study developed within the iNSPiRe FP7 project (Birchall et al., 2014). Based on an extensive literature review through national statistics, public papers, other sources and previous European projects, two main building typologies, Single Family Houses (SFHs) and Multi Family Houses (MFHs) are identified. In addition, some variations of surface over volume (S/V) ratio through detached/row houses for SFHs and number of floors for MFHs, it was possible to have models that covered around 70% of the existing residential building stock in Europe.
Building typologies are classified based on information collected through the study: geometric and physic characteristics are defined by building typology, construction period and climate (Birchall et al., 2014). In particular, the SFH reference building is a two-storeys building with a total heated area of 96 m². Glazing ratio in the north façade is 10%, 12% in the east and west facades and 20% in the south façade. The building covering is a pitched roof; the ground floor bounds with a cellar. In order to enlarge the cases availability, together with the detached SFH, also row-houses are considered: east and west facades of the detached ones are taken as adiabatic surfaces instead of external. From detached to row-houses, the S/V ratio reduces from 0.87 to 0.58.
The MFH reference building here considered is a small MFH (s-MFH) composed by ten apartments distributed through five floors. Each dwelling is 50 m²; the staircase is embedded in the building between the two apartments. In this case, the roof is flat and the cellar is not present. In MFHs, the number of floors varied from three to seven in order to cover cases with S/V ratio from 0.48 to 0.61.
In the study, numerical models of the reference buildings were therefore developed and in particular, one model per building typology, construction period and climate were created. For each of these, the assessed heating and cooling demands were benchmarked with statistics data in order to prove the models validity (Dipasquale et al., 2014).
For the reference cases, energy consumption was calculated assuming that heating and DHW were provided by a gas boiler with efficiency of 0.8, while cooling demand was covered by a split unit with EER equal to 2.5. For the Primary Energy (PE) consumption calculation, conversion factors of 2.878 kWh_{PE}/kWh_{FE} for electricity and 1.194 kWh_{PE}/kWh_{FE} for gas are used (Malenkovic et al., 2012).

The abovementioned buildings models represent the reference cases for the retrofit solutions to be investigated.
The studied retrofit packages are defined with market-available products. In this way, the final user of the database, that could be the decision maker or a technician of the residential sector, can find in it a generic building similar to the specific case.
In this paper, the interventions of a deep renovation are studied in three steps: measures on the envelope, improvement of the HVAC system performance and integration of solar technologies.
The retrofit measures for the envelope concern the replacement of the existing windows with double or glazed windows, the installation of a mechanical ventilation machine with heat recovery (MVHR) with efficiency of 0.85 and the insulation of the external surfaces. The specific measure or insulation thickness are decided based on the climate (one of the seven, Nordic, Northern Continental, Continental, Oceanic, Southern Continental, Southern

Dry and Mediterranean) and the heating demand energy level (EL) to be achieved, 15, 25, 45 and 70 kWh/(m²y). Once defined the window quality, the presence of the MVHR system and, consequently, the new infiltration rate, the insulation thickness is calculated for achieving the targeted EL. For this study the insulation layer is an EPS (expanse polystyrene) with conductivity 0.039 W/(mK).
Details on the envelope renovation measures are reported in (Fedrizzi et al., 2016a) for SFHs and in (Fedrizzi et al., 2016b) for s-MFHs.

In the study, the existing generation and distribution system is supposed to be replaced with a more efficient HVAC system. Different configurations are studied with a modular approach that allows to investigate the performance of different devices for the energy generation and terminals using the same energy plant layout and working modes. Also for the HVAC system, the choice of the renovation solutions moves on the most common and promising market-available solutions. In particular, the investigated generation systems are: air-to-water heat pump, ground-source heat pump, condensing boiler and pellet boiler.
With regard to the distribution system, the different behavior and energy consumption of radiant panels, fan coils and radiators is taken into account.

Finally, the contribution of solar technologies is considered for even reducing the energy consumption. In the study, solar thermal collectors (STC) and photovoltaics (PV) fields were analysed accounting for the effect of either one of them or both together. Three different areas and two slopes, 30° on the roof and 90° on the façade, were studied. The below tables report the solar fields size for STC and PV.

Table 1: Solar thermal collectors field size

	Unit	SFH	s-MFH
STC_1	*m²*	4.6	18.4
STC_2	*m²*	9.2	27.6
STC_3	*m²*	13.8	36.8

Table 2: PV field size

	Unit	SFH	s-MFH
PV_1	*kWp*	1	3
PV_2	*kWp*	2	4
PV_3	*kWp*	3	5

3. Results and discussion

The abovementioned renovation measures aim at reducing the total energy consumption of the existing residential building stock keeping thermal comfort inside the dwellings. Each measure contributes differently: envelope solutions decrease the building demands, an efficient HVAC system reduce the final energy consumption and solar technologies contribute to the energy savings with the use of renewable energy.

Within all the cases presented in the database (iNSPiRe, 2016), in the following paragraphs only a selection of these will be reported. For the sake of clarity, extreme climates will be shown, that is Nordic, with reference weather conditions of Stockholm (STO), and Mediterranean – Rome (ROM). These two cases in fact represent a heating and a cooling dominated climates. For the generation systems, air-to-water heat pump (AWHP) only is chosen as one of the most common and innovative solution. Performance of this generation system is compared with the reference one. In terms of final energy consumption, ground-source heat pump differs from AWHP for a higher electricity consumption due to the hydraulic pump used in the source/sink side of the heat pump. However, exchanging with the ground instead of external air, the heat pump performance improves and consequently final energy consumption decreases keeping the same delivered thermal energy. A condensing boiler has higher efficiency than a normal boiler. The pellet boiler, since it has a smaller primary energy factor, outperforms the condensing boiler in terms of primary energy despite its performance is lower.

With regard to the distribution system, results refer to a system with radiant ceilings working with a supply temperature of 35°C. These units better suit the possibility to deliver heating and cooling with the same generation device working at low temperatures. Differently from the radiant panels, radiators and fan coils distribute heating/cooling with a lower radiative fraction. This means that with radiant panels the operative temperature in the zone is closer to the sensible temperature that is used by the thermostat. Consequently, more thermal energy, in a range of 3-5%, is required for keeping the internal set temperature and therefore balance the extra transmission losses due to surfaces higher temperature. However, fan coils consume additional electricity required by the fan

embedded in the device, while radiators, instead, cannot deliver cooling needing, therefore, another device for that purpose. In the case of boilers and radiators, space cooling is covered by split units.

3.1. Envelope renovation measures

The improvement of the envelope energy performance can allow important heating demand reductions.
In SFHs despite the different weather conditions of the Nordic and Mediterranean climates, the average heating demand for buildings built between 1945-1970 in both climates is around 170 kWh/(m²y). This behaviour is due to a better wall constructions adopted in the northern climates for the existing buildings. In the here reported case, the envelope measure aims at achieving a fixed heating demand of around 50 kWh/(m²y). For this energy level (EL) target, in the Nordic it is necessary to install a triple glazed window, a MVHR system, 8 cm of insulation on the external façade, 5 cm on the ground floor and 15 cm on the roof. In the Mediterranean, instead, the EL is reached by installing double glazed windows, 12 cm of insulation on the façade and 18 cm on the roof. These interventions on the envelope allow reducing the building heating demand of around 70% in both cases. A better quality window and the use of external shadings for both climates bring also a reduction of the cooling demand of 55% in Rome and 44% in Stockholm.
s-MFHs with same construction period as SFHs have heating demand around 86 and 95 kWh/(m²y) respectively in the warmer and colder climate. The lower demand is due to the lower S/V ratio. For this building typology for both climates, the EL target is achieved without the need of a MVHR system neither triple glazed windows. Regarding insulation, while in Rome only 5 cm are needed on the façade, in Stockholm it is required 10 cm on the façade and 10 cm on the roof. As shown, a small intervention on the envelope allows to reduce the heating demand of 40-45%. Differently with SFHs, the cooling demand in s-MFH slightly reduces (see Table 3).

Table 3: Heating and cooling demand before and after envelope renovation

Building	Space Heating [kWh/(m²y)]		Demand	Space cooling [kWh/(m²y)]		Demand
	Existing case	Post renovation	reduction [%]	Existing case	Post renovation	Reduction [%]
SFH_ Rome	171.2	53.7	68.6%	44.7	25.7	42.6%
SFH_Stockholm	173.9	51.3	70.5%	16.8	7.4	55.8%
sMFH_ Rome	86.3	55.1	36.2%	42.1	40.4	4.0%
sMFH_Stockholm	95.4	49.7	47.9%	14.7	14.5	1.4%

3.2. HVAC system renovation measures

A building with a good performance envelope is not enough for achieving important energy savings if also the HVAC system is not efficient. The replacement of the existing system with a more efficient one is able to bring relevant savings on the final energy consumption. Starting from the demands obtained after renovation (Table 3), Primary Energy consumption for space heating (SH) and space cooling (SC) is calculated considering the reference system (Reference) and the AWHP system (AWHP). The reference system is the one used for calculating the final energy for the existing buildings (see Par.2). Final energy consumption obtained after retrofit are instead calculated through simulations and are available on the database. The results reported in Table 4 show as an improvement of the HVAC system performance allows a PE reduction for SH of 44%-46% in Rome and 36-37% in Stockholm respectively for the SFH and s-MFH buildings. For SC the savings depend on a better EER of the cooling device bringing for Rome and Stockholm 23-27% of PE consumption in the SFHs and 33-36% in s-MFHs.

Table 4: Primary Energy consumption before and after HVAC system renovation

Building	PE heating [kWh/(m²y)]		PE for SH	PE cooling [kWh/(m²y)]		PE for SC
	Reference	AWHP	reduction [%]	Reference	AWHP	reduction [%]
SFH_ Rome	80.0	44.9	43.9%	29.6	21.6	27.0%
SFH_Stockholm	76.4	49.3	35.5%	8.5	6.5	23.4%
sMFH_ Rome	82.1	44.2	46.2%	46.5	31.2	32.9%
sMFH_Stockholm	74.0	46.3	37.4%	16.7	10.7	35.7%

Comparing the PE consumption for the cases before retrofit and the ones with the envelope renovation measures and the more efficient HVAC system, the energy savings that can be achieved amount to around 80% for the SH of the SFH and 66% for the SH of s-MFHs (regardless the climate). For the SC the percentage is lower due to also to the lower demand, but even not negligible: in the SFH, PE for SC is reduced of 58% in Rome and 66% in

Stockholm, while in the s-MFH the reduction is of around 36% in both climates (see Fig 1).

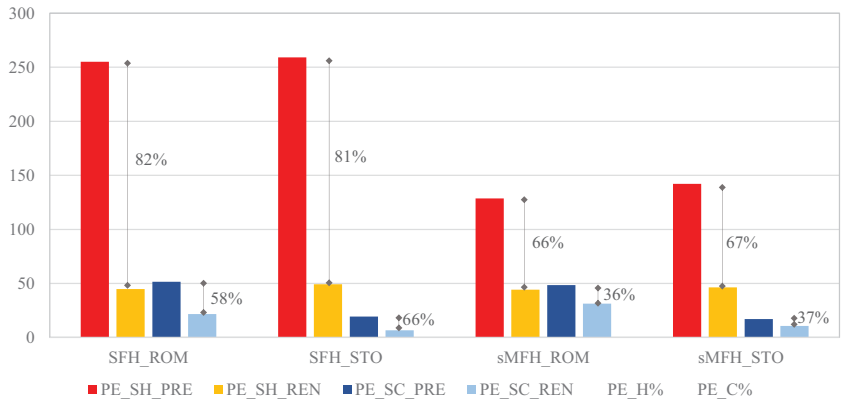

Fig 1 Primary Energy consumption of the two buildings typologies in the two climates before renovation (PRE) and after the envelope and HVAC system renovation (REN)

3.3 Solar technologies contribution

In a deep renovation process, a strongly reduction of the energy consumption is favoured by the installation of solar technologies as solar thermal panels (STC) and photovoltaics (PV). Depending on the building loads and climate, one or the other technology can have a higher impact on the total final consumption. However, even a small solar field can bring important savings against a small investment cost, with respect to the cost of the whole renovation.

Solar thermal collectors

In the following, results for cases STC_1 and STC_3 (see table 1) referred to SFHs and s-MFHs are reported.

In SFHs, a solar field of 4.6 m² installed on the roof is able to cover around 74% of the DHW load in the Mediterranean climate and 40% in the Nordic one. If the panels are installed on the façade (90°), the production is reduced respectively in the two climates of 18%-10%. This difference amounts to only 3 % if calculated over the whole heating production.

In the Mediterranean, a three times bigger solar field can double the solar fraction for the heating production (DHW demand and space heating) but the number of hours where the stagnation phenomena can occur drastically increases. To reduce this effect or even eliminate it, solar collectors can be installed on the façade with only 4% of solar fraction reduction with respect to the installation on the roof.

In a Nordic climate, the behavior is similar, moving from STC_1 to STC_3 the solar fraction for heating production almost double, but also stagnation hours occur. The installation of solar panels on the façade strongly limits the stagnation hours with only 1% less of solar fraction.

Accordingly, similar trend is observed also in the s-MFHs (see Table 5). The percentage of solar collectors over living are is smaller in s-MFH with respect to SFH because of the lower available surface. Despite this, a solar field of almost 37 m² on the roof causes the stagnation phenomena both in the Mediterranean and in the Nordic climate. Again in this case, stagnation disappears if the panels are installed on the façade with a solar fraction reduction of 3% (see Table 5).

Table 5: Solar fraction for heat production

AREA	Slope	ROM_SFH	STO_SFH	ROM_s-MFH	STO_s-MFH

		SF [%]	[hr]	SF [%]	[hr]	SF [%]	[hr]	SF [%]	[hr]
no ST	0	0%	0	0%	0	0%	0	0%	0
STC_1	*30°*	21%	101	12%	0	22%	37	13%	0
STC_3	*30°*	44%	1985	21%	374	34%	624	20%	68
STC_1	*90°*	17%	0	9%	0	17%	0	11%	0
STC_3	*90°*	40%	30	20%	0	31%	0	18%	0

In terms of final energy consumed for covering heating and DHW demands, the savings of using STC_1 amount to 26% in Rome – SFH and 12% in Stockholm - SFH. Despite the lower ratio of solar panels area over living area, same behavior is observed in the s-MFH. The STC_3 instead, that corresponds to around one fourth of the SFH roof surface, in the warmer climate can cover 43% of the heating production while in the colder one 20%. For the s-MFHs the final energy for heating production reduction with STC_3 amounts to 34% and 18% respectively in Rome and Stockholm (Fig. 2).

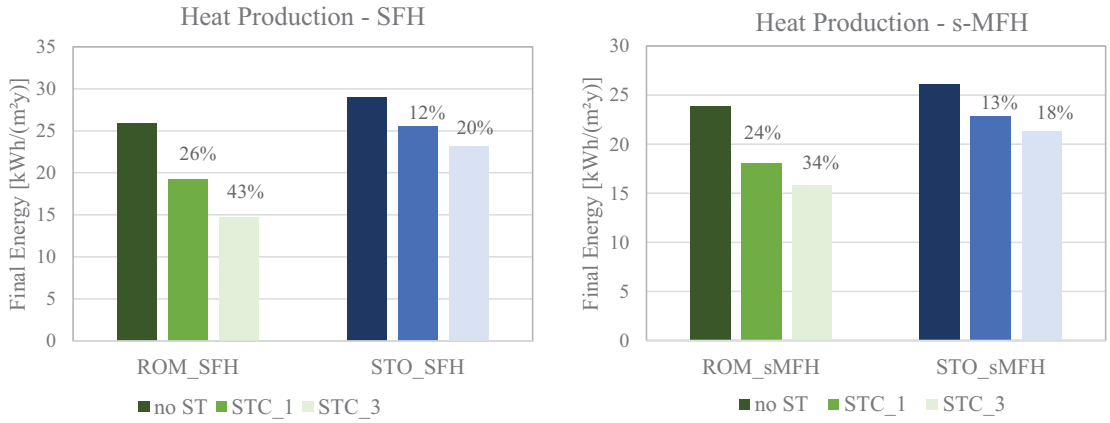

Fig 2 Final Energy consumption for heating production for two solar thermal fields in comparison with the case without thermal panels in SFH (left) and s-MFH (right)

In addition to two panels slope, the database contains also results for two different solar tank sizes, 50 l/m² and 100 l/m² of solar area. With respect to the final energy consumption for heating purposes, a slightly better performance is observed with the bigger storage, in the order of 2-3%.

Solar thermal panels influence only the consumption due to space heating and DHW consumption, so their contribution on the total building consumption depends on the share between the different uses. In particular for the cases here analysed, these quantities on the total energy consumption of a SFH for STC_1 and STC_3 fields amount to 20% and 33% in the Mediterranean, and 10% and 16% in the Nordic. In a s-MFH instead, the energy reduction due to the installation of a solar thermal field can achieve 23% in Rome and 16% in Stockholm if the biggest studied area is installed.

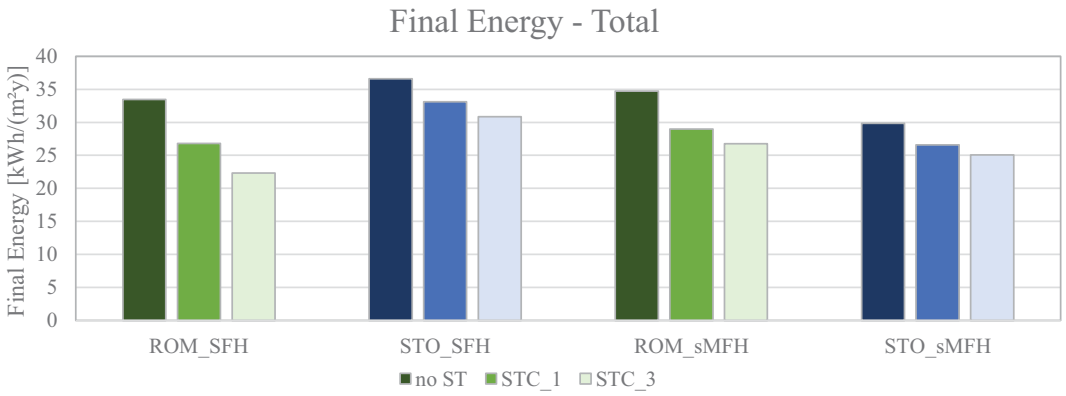

Fig. 3 Total Final Energy consumption for two solar thermal fields in comparison with the case without thermal panels

Photovoltaics

The analysis on the contribution that a photovoltaic field could give on the total energy consumption of a building focuses first on the share between self-consumption versus fed-into-the grid and then on the savings that this technology can bring to the building total final consumption.

Fig. 4 shows the share options of PV production between the energy used by the HVAC system (red bar), by other building uses like appliances (orange bar) and fed into the grid (yellow bar). The following comments do not consider any feed-in-tariff for the latter share option as every country has its own regulation that often changes.

In this contest, a solution that maximizes the auto-consumption is considered more favorable. Looking at the left graph of Fig. 4, the solution with only 1 kWp installed represents the best compromise between production and consumption. Most of renewable energy production is in fact used by the HVAC system itself or by other uses. Installing 3 kWp, instead, around 60% of the produced energy is not consumed by the building. This scenario becomes favorable only if convenient fees are foreseen. On the total PV production, the installation of the PV panels on the façade in place of on the roof brings less energy production of 24% in Rome and 13% in Stockholm. In the following it will be shown as the lower energy production has a minor effect on the single uses.

Different behavior is observed for the s-MFHs where, as for the STC, the percentage of PV area on the living area is lower than in the SFH. Electricity production of a 3 kWp PV field is used for 95% from the building uses. If instead 5 kWp of PV is installed, that means covering 6.5% of the roof area, the self-consumption amounts to around 85-90% both in the northern and in the southern climate.

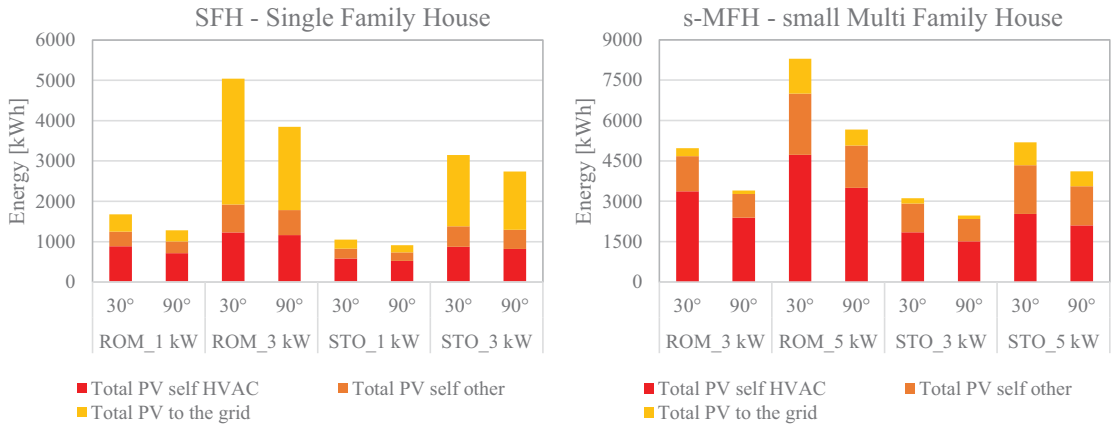

Fig.4 PV production and self-consumption for SFHs (left) and s-MFH (right) for two climates and two field sizes

Looking at the savings that the analysed solar fields bring on the different energy uses consumption, 1 kWp of PV in a SFH is able to reduce space heating consumption of 7% in Rome and 3% in Stockholm. If instead 3 kWp are installed, the reduction is respectively of 12% and 7%. The advantage in this case seems to be not relevant, but doing the same consideration for the cooling load, the reduction is higher than 80% in both climates. Together with the space heating and cooling, PV contributes also in the decrease of DHW preparation energy need. Looking at the total building consumption, we can observe that 1 kWp of PV field in a SFH reduces 27% of the total electricity in the southern climate and 16% in the northern one. A three times bigger field helps in achieving 38% and 24% lower electricity consumption respectively in the two climates (Fig. 5).

The above considerations refer to a PV field installed on the roof. If it is positioned on the south façade, the winter harvesting slightly decreases, in the order of 1-2%, but the summer harvesting increases. The yearly electricity reduction therefore amounts to 36% in the Mediterranean and 23% in the Nordic climate.

Although in s-MFHs the share of PV field over living area is lower than in SFHs, the higher percentage of self-consumed electricity makes the electricity savings similar in both building typologies. In particular, the bigger PV field – 5 kWp – brings 16% and 7% of energy reduction in winter for the two climates, Mediterranean and Nordic, while for the cooling the reduction amounts to 34% and 46%. Accounting for also the DHW production and the yearly behavior, the PV_3 field (Table 2) is able to reduce the total final consumption for the HVAC system of 30% in the Southern climate and almost 20% in the Northern one. If the PV field is installed on the façade, the total energy savings for the two climates reach respectively 23% and 16%.

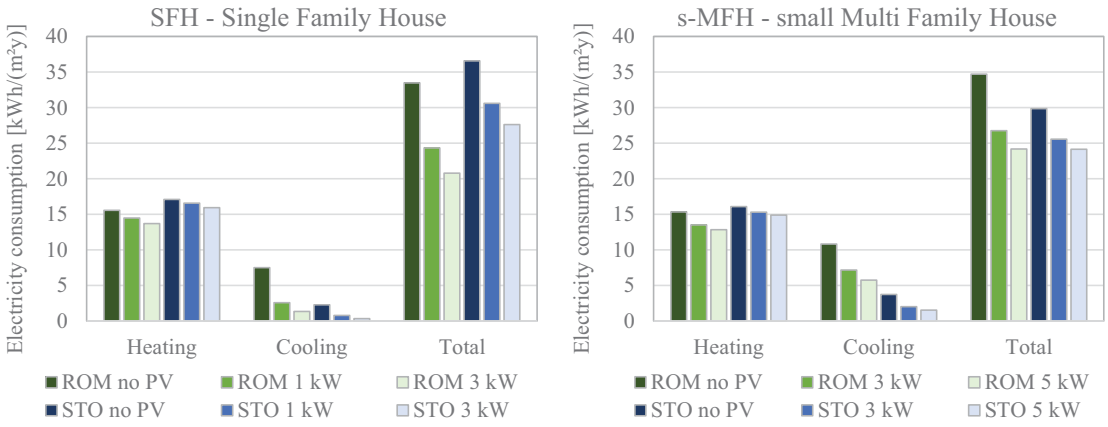

Fig.5 Final energy consumption for space heating, space cooling and total for SFH (left) and s-MFH (right) in two climates by different PV field sizes.

3.4 Retrofit solutions total savings

In the previous paragraphs, each retrofit measure has been analysed separately. In Fig.6 the initial PE consumption for space heating, space cooling and DHW preparation is compared with the PE savings that each measure gives to the total energy consumption. For the solar technologies, it has been considered the contribution of STC and PV together, considering the PV_3 size on the roof and STC_3 on the façade.

Table 6 summarizes the savings in percentage on the initial total primary energy consumption by each retrofit solution. The last line instead indicates the percentage of PE consumption after retrofit on the one before retrofit.

In the study, the retrofit measures for the envelope were decided once fixed the heating demand energy level. Consequently, depending on the initial building demand, the savings obtained by the envelope are larger where the initial building demand is higher. Buildings with same external surfaces thermal characteristics but different S/V ratio, i.e. SFH and s-MFH, can have heating demand one the double of the other. As a consequence for the studied cases, especially in SFH, the retrofit measures applied to the envelope are the ones that mostly contribute on the primary energy consumption reduction. An efficient HVAC system has a major impact on the heating production consumption than on the consumption for cooling because of the performance of the reference case. With this regard, the savings due to the HVAC system only amount to 32% and 23% in SFH respectively southern and northern climate and 38% and 31% in s-MFHs. This means that with respect to a boiler with 0.8 efficiency and split units with 2.5 EER, the final primary energy consumption can be reduced by around one third thanks to the use of a more efficient system composed by an air-to-water heat pump.

Additionally, even small surfaces of solar technologies as PV and thermal collectors, have an important impact on the total energy consumption. In fact in Southern climates as Rome, the combination of 3 kWp of PV and 6 panels in STC can almost halve the final consumption in SFHs. 5 kWp of PV and 16 panels of STC in s-MFH instead allow 43% of the total primary energy reduction. Due to climate conditions in the Northern climate the contribution of solar technologies on the total energy consumption is slightly lower, but still 34% in SFH and 29% in s-MFHs.

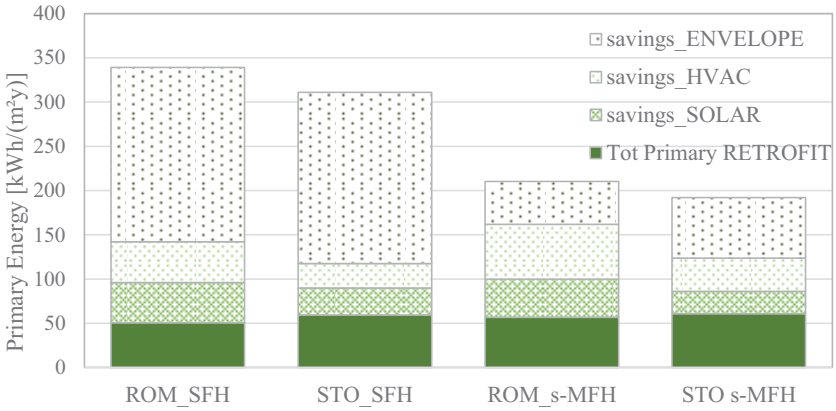

Fig. 6 Primary energy savings due to the retrofit solutions

Table 6: Energy savings of each retrofit solution on the total PE consumption pre-retrofit

Primary Energy	*Units*	SFH Mediterranean	SFH Nordic	s-MFH Mediterranean	s-MFH Nordic
savings_envelope	*kWh/(m²y)*	58%	62%	23%	36%
savings_HVAC syst	*kWh/(m²y)*	14%	9%	29%	20%
savings_PV+STC	*kWh/(m²y)*	13%	10%	21%	13%
Total PE retrofit	***kWh/(m²y)***	**15%**	**19%**	**27%**	**32%**

Finally, thanks to the interventions on the building envelope, HVAC system and use of renewable energies, primary energy consumption for space heating, cooling and DHW preparation of a SFH located in the Mediterranean climate is reduced up to 15% of the consumption before retrofit. Similarly, if the building is located in the Nordic climate, the PE consumption after retrofit amounts to 19%.

Due to the lower PE consumption already pre-retrofit of s-MFHs with respect to SFHs, the application of the renovation measures in this case reduces the primary energy consumption up to 27% in the southern climate and 32% in the northern one.

4. Conclusion

The large share of European residential buildings built before 1970 with high energy consumption requires measures that can contribute to the reduction of the final energy consumption. In this contest, this work wants to show how market-available solutions can drastically reduce the energy consumption for space heating, cooling and DHW of a building. In particular, the paper focuses on the contribution that solar technologies, e.g. photovoltaic and solar thermal collectors, gives on the final energy consumption reduction. In this contest, considerations are given with respect to the influence of each technology on the final uses, the installation position on the building and solar field size.

Regarding the panel position, both for PV and STC the installation on the façade obviously reduces the solar energy harvesting, but this does not mean a relevant difference on the final energy consumption. In fact, thanks to the solar radiation direction through the year, thermal panels vertically positioned become advantageous in reducing the stagnation hours in summer and in maximizing the winter harvesting. On the contrary, the PV contribution is mostly exploited during summer period due to the cooling demand that is covered by electricity. In this case, the difference on the solar radiation harvesting between the two positions is higher for the summer period. Despite that, even in the southern climate, the impact of the vertical position instead of on the roof on the total energy consumption is less than 10%.

Another important achievement of the study is that even small ratios of solar fields on living area can help on achieving relevant energy savings. In fact, looking at SFHs, solar thermal collectors of 2 to 6 panels can reduce the heating production (space heating and DHW preparation) of 26-43% in the southern climate and 12-20% in the northern. In s-MFHs due to the lower ratio between solar field versus living area, 8 to 16 panels contribute with 24-34% in the southern climate and 13-18% in the northern climate for the heating production reduction.

Regarding the PV, especially if it is not foreseen a feed-in-tariff policy, the solar field should be sized with the self-consumption capacity. From the study, 1 kWp for SFH and 3 kWp for s-MFH use respectively 80% and 95% of the PV production for self-consumption.

Concluding, in a deep renovation process of a residential building, in addition to retrofit measures on the envelope and HVAC system, even limited solar fields areas of PV and/or STC can contribute on an additional final energy consumption reduction. In fact, with respect to the case without solar technologies, these can allow additional energy savings of around 45% in the Mediterranean climate and 30% in the Nordic climate.

Abstract

The German energy transition must take place in the heat as well as in the power sector. In the field of solar energy, however, competition between solar-thermal systems and photovoltaic systems arises. A decreasing feed-in tariff leads to an increasing demand for solutions enabling self-consumption of energy. As a result, traditional heat generation systems, both fossil (e.g. gas heating boiler) and renewable (e.g. solar-thermal), enter a competition with systems being able to couple the electricity with the heat sector (e.g. photovoltaic + heat pump). The objective of this contribution is to analyze this competition and to evaluate the combination of solar-electric and solar-thermal systems in residential buildings. For this purpose, a linear optimization model is used. It also turns out that above all the investment costs for solar-thermal systems must fall, but also costs for battery storages are still too high. Only if several factors change, a combination of solar-thermal energy and photovoltaics becomes interesting from an economic point of view. For a reduction in emissions, the solar-thermal system competes with battery storage.

Keywords: solar systems, residential application, mathematical optimization, cost optimal

1. Introduction

The Paris climate agreement limits global warming to less than 2 °C, ideally less than 1.5 °C. To achieve this, a complete decarbonization is necessary by 2040 (Quaschning, 2016). Therefore, the share of renewable energy sources (RES) must be increased by a factor of 4 to 5 with respect to present values. In Germany, the implementation of RES primarily takes place in the electricity sector. This can mainly be determined by the coverage ratio. In 2016, the percentage of RES in electricity consumption was 32 % (Umweltbundesamt, 2017), while in final energy consumption it was only 12.6 % (BMWi, 2017). The integration of RES in the electricity system gets more and more difficult. Thus, the cost of redispatch in 2015 was 402.5 million euros (BDEW, 2017), because RES (predominantly wind power) had to be shut down in the north while conventional power plants had to be restarted in the south. This is due to grid bottlenecks, which do not permit enough power transfer from north to south or vice versa. This example shows that also the market is not always able to use the electricity sensibly.

One possible solution for dealing which such bottlenecks in the electricity grid is to couple different energy sectors, allowing more local self-consumption of the locally energy produced. Nevertheless, the question remains which sectors are best suitable to be coupled. In addition to mechanical energy (39 %), a large proportion of energy consumption in the domestic sector is attributable to space heating (27 %) and hot water preparation (5 %) (BMWi, 2017). Hence, there is great potential for coupling the electricity system with these sectors. A total of 56 % of the final energy consumption is due to heating demand (Quaschning, 2016). Thereby, the energy supply is still strongly based on fossil fuels. The share of fossil fuels in space heating is 75.1 % and in domestic hot water, it is 66.4 %. Only 13.7 % (space heating) respectively 9.3 % (domestic hot water) are covered by RES. The remaining demands are covered by district heating (9 % space heating, 4.4 % domestic hot water) and electricity (2.2 % space heating, 19.9 % domestic hot water) (Quaschning, 2016). Dominating RES for space heating and domestic hot water is still biomass (11 %). Solar-thermal systems as well as heat pumps are still less important, as the cover ratio of both technologies is only 1 % in 2014. Economic aspects prevent a stronger expansion of solar-thermal as well as geothermal systems (Quaschning, 2016). On the long term, efficient heat pumps must largely take over the supply of space heating and domestic hot water preparation, also due to the possibility of coupling with the electricity sector. However, the use of electric heaters can lead to more than double the current electricity requirement in Germany of 648 TWh in 2016 by an additional requirement of 770 TWh. This would be the case, if only gas heat pumps were used and the gas produced through power-to-gas (Quaschning, 2016). This in turn shows that the energy transition must take place both in the heat and power sector.

doi:10.18086/swc.2017.29.03 Available at http://proceedings.ises.org

In the field of solar energy supply, however, solar-thermal energy competes with photovoltaic systems, which is also due to the coupling of photovoltaics and heat pumps. Another aspect is the grid parity. This is the turning point where the use of self-produced PV power is more cost-effective then the consumption of grid electricity. Therefore, covering the heat demand with electric energy will become an interesting opportunity to increase self-consumption. The aim of this investigation is to analyze, under which conditions it may be useful to use a combination of solar-thermal and photovoltaic system and how the framework conditions would have to be changed, so that these systems can prove to be more cost-effective alternatives.

2. Simulation Model and Mathematical Description

To assess the research question stated above, the linear programming model urbs (lat.: city) (Dorfner and Hamacher, 2017) is used. The focus of the urbs model is to analyze urban energy systems. Amongst others, a low-carbon power system for Indonesia, Malaysia and Singapore was modelled (Stich et al., 2014). Currently, the model is used, in combination with the single-node variation of the model urbs, to optimize the energy supply of mixed use areas taking as example the Garching campus of TU Munich (Schweiger and Wedel, 2017). To answer the question concerning the competition of photovoltaic and solar-thermal systems, the original model, designed for the urban structures, was adapted to residential application.

2.1. Simulation Model

The urbs model (a mixed integer linear programming model (MILP)) is a simulation model for identifying cost-optimal system sizes and operation times for a portfolio of technologies and a given demand. The model consists of three main tuples[1], the commodities (*com*), the processes (*pro*) and the storages (*sto*). The commodities describe the different energy demands and external energy sources. Tab. 1 lists the implemented commodities.

Tab. 1: Different commodities implemented in urbs

commodity	***com***	**description**
Solar energy	solar	solar irradiation
Electricity	elec	electricity demand of the building
Heat	heat	heat demand of the building
Gas	gas	natural gas from the gas supply
CO_2	CO2	CO_2-emissions of the processes
Elec-buy	buy	electricity bought from the grid
Elec-sell	sell	electricity fed into the grid

With processes, it is possible to convert one commodity into another (e.g. electricity to heat by utilizing the process “heat pump”, cf. Tab. 2). These processes are defined by various parameters, e.g. input and output ratios, investment costs or the required roof area for solar energy systems. Tab. 2 shows the different investigated processes.

Tab. 2: Portfolio of processes in urbs

Process	***pro***	***com_in***		***com_out***
photovoltaic system	photovoltaic	solar	→	elec
solar-thermal system	solar-thermal	solar	→	heat
gas boiler	gas boiler	gas	→	heat
heat pump	heatpump	elec	→	heat
heating rod	rod	elec	→	heat
mini CHP	CHP	gas	→	elec
			→	heat
electrical grid	purchase	buy	→	elec
	feed-in	elec	→	sell

The last tuple, the storages, allows the time shift of different forms of energies and commodities. For residential buildings, there is a battery storage and a thermal energy storage (cf. Tab. 3).

[1] Ordered list of elements

Tab. 3: Considered storage types

storage	*sto*	description
Battery	elec	battery storage
Tank	heat	thermal energy storage

Fig. 1 shows the basic structure and layers of the urbs model. A detailed description of the individual parameters is given in the following sections.

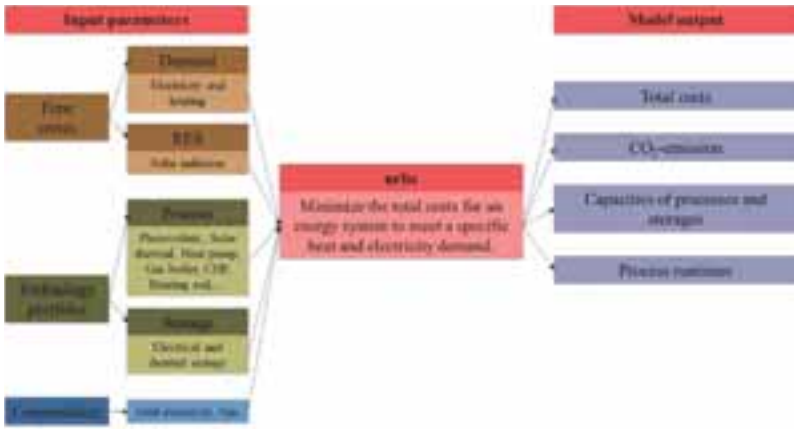

Fig. 1: Overview of the model urbs and the different components

2.2. Mathematical Formulation

The main aim of the model urbs is to minimize the total costs (c) for an energy system to meet a specific heat and electricity demand. These costs are composed of the investment costs $c_{pro,sto}^{invest}$, the variable costs $c_{pro,sto}^{var}$ (related to the operation of the system), the fixed costs $c_{pro,sto}^{fix}$ (independent from the operation of the system), the fuel costs $c_{pro,sto}^{fuel}$, the purchase costs $c_{pro,sto}^{purchase}$ (electricity costs), the startup costs $c_{pro,sto}^{startup}$ and the income from the feed-in $c_{pro,sto}^{revenue}$ for each process (*pro*) and storage (*sto*):

$$\min c = \min \sum_{pro,sto} [c_{pro,sto}^{invest} + c_{pro,sto}^{var} + c_{pro,sto}^{fix} + c_{pro,sto}^{fuel} + c_{pro,sto}^{purchase} + c_{pro,sto}^{startup} - c_{pro,sto}^{revenue}] \quad \text{(eq.1)}$$

(Dorfner and Hamacher, 2017) provide a detailed description of the objective function and the constraints. The essential constraint is that the power from processes (*pro*), storages (*sto*) and the electrical grid (*grid*) has to meet the thermal (d_{therm}) and electrical (d_{elec}) demand for every time step (t):

$$\sum_{pro} p_{pro,elec}(t) + \sum_{sto} p_{sto,elec}(t) + grid(t) \geq d_{elec}(t) \quad \text{(eq.2)}$$

$$\sum_{pro} p_{pro,therm}(t) + \sum_{sto} p_{sto,therm}(t) \geq d_{therm}(t) \quad \text{(eq.3)}$$

To use urbs for residential buildings means some changes. For urban structures, it is often possible to use several technologies, whereas in a residential building, besides solar-thermal systems, only one backup technology (e.g. heat pump or gas boiler) is used. Therefore, the number of back-up processes ($num_{pro,backup}$) is limited to one:

$$\sum_{pro} num_{pro,backup} \leq 1 \quad \text{(eq.4)}$$

The power demand and the power distribution in urban areas are much higher than in the domestic field. Hence, it is no problem to find the appropriate component sizes (cap_{pro}) on the market. For residential buildings, the necessary power would be partially below the power of available components, for example a heat pump with a thermal power less than 1 kW. Therefore, a minimum capacity ($cap_{pro,min}$) is defined, which the components must have at least:

$$cap_{pro} \geq cap_{pro,min} \quad \text{(eq.5)}$$

The thermal load for room heating and for domestic hot water specifies the minimum power required for the backup system:

$$cap_{pro,backup} = d_{therm,max} \quad \text{(eq.6)}$$

In addition, the step size of the possible extension of a process ($cap_{pro\text{-}new}$) is restricted, in other words, if the power is not sufficient, the next-largest component must be used. This is essential especially for the solar collectors, since here only the expansion by one collector is technically possible:

$$cap_{pro,new} \geq cap_{pro,new,min} \quad \text{(eq.7)}$$

Since the solar energy is free of charge for an installed capacity, it can be economic to 'destroy' surplus energy using the storage efficiency. This is not possible in a residential building, especially for thermal energy. For this reason, the storage must not be charged and discharged at the same time. This can be prevented by considering additional variable costs for the storage systems. The costs also show that turn-off is associated with higher maintenance costs.

Nevertheless, it can be useful to control the power distribution of the solar energy systems, especially in case of a solar-thermal system. For this reason, a process shunt is implemented which enables the solar process to be deactivated and to analyze how much energy is not used. Fig. 2 shows a comparison of a simulation with (c.f. Fig. 1, upper diagram) and without (c.f. Fig. 1, lower diagram) the shunt process for the month of May. It is seen that part of the solar-thermal generation is not used for economic reasons (green area), leading to a reduction of the thermal storage from approx. 100 kWh to approx. 10 kWh. It can also be seen that only the energy of the solar-thermal system is 'destroyed'.

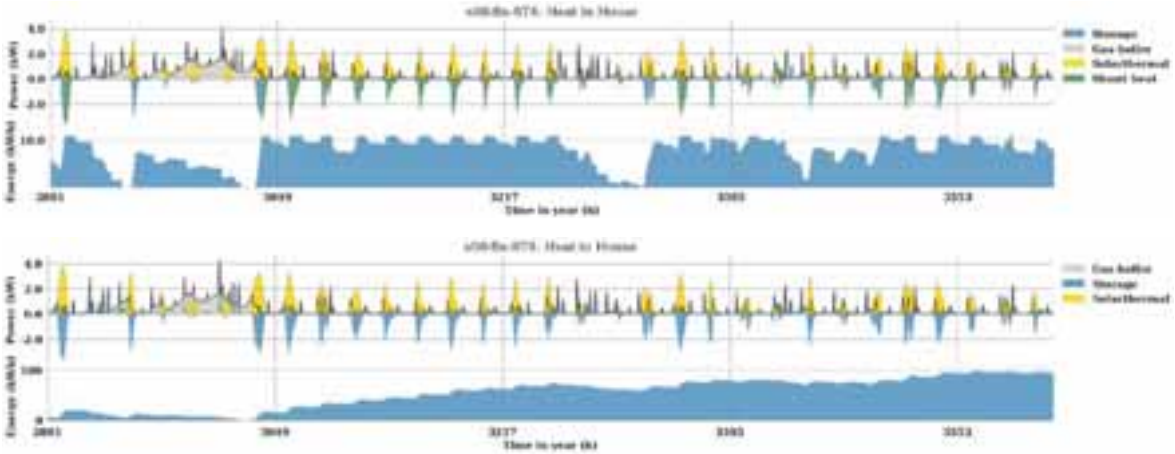

Fig. 2: Thermal energy flow with and without a shunt process for the month of May

3. Input Data

3.1. Technical and Economic Parameter

The different processes are defined with respect to their technical and economic parameters. The economic parameters are essentially the investment costs, the variable costs and the fixed costs. Added to this are the prices for the commodities/fuels.

The investment costs as well as the variable and fixed costs are stated in €/kW respectively €/kWh. Market surveys and data from scientific literature are used to determine the necessary investment costs. The costs of the solar-thermal system are composed of the costs for the flat-plate collector (320 €/m^2 (Sonne Wind & Wärme, 2017)), other component costs (90-160 €/m^2 (Kaltschmitt et al., 2014)) and installation costs (190 €/m^2 (Kaltschmitt et al., 2014)). This results in total system costs for the solar-thermal system of 620 €/m^2 (without storage). The specific solar yield for Germany is 425 kWh per square meter collector surface area (Eicker, 2012). By means of solar full-load hours, which amount to 1.140 h/a for the used weather data set (TRY Zone 13 (DWD, 2011)), the specific costs of the solar-thermal collector can be calculated (1,665 €/kW). The costs of photovoltaic systems are about 180 €/m^2 for the investigated sizes (5 m^2 -50 m^2), whereas a roof area of 8 m^2 is required for a capacity of 1 kW$_p$ (Solaranlagenportal, 2017). This results in costs of 1,440 €/kW$_p$ of the photovoltaic system. The cost of a thermal storage tank can vary between 1.50 €/l and 7.00 €/l (Kaltschmitt et al., 2014). This figures are in accordance with data available from an energy database, specifying an average cost of solar-thermal storages of 2.50€/l (Sonne Wind & Wärme, 2017). In

addition, installation costs of 0.50 €/l are taken into account. The usable temperature spread is 65°C for the thermal storage. The prices of the batteries are currently changing very fast. In the second half of 2015, the system prices were already down to around 1,300 €/kWh with an annual average price reduction of 18 % (Hegner, 2017). For this reason, a price of 1,066 €/kWh_{el} (a decrease of 18 % compared to the previous year) is assumed. The cost of the gas system is 600 €/kW_{therm} (Kilburg, 2015), of the air/water heat pump 900 €/kW_{therm} (Henning, 2012; Kilburg, 2015) and of the heating rod 75 €/kW_{therm} (Fuhs, 2015). For the heating rod costs for the installation of 25 €/kW_{therm} are added. The mini-CHP (combined heat and power) is the most expensive component with 6,430 €/kW_{el} (ASUE e.V., 2014). Every process converts the related commodities with a certain degree of efficiency. The interest rate of all technologies is 3 %.

The variable costs of a photovoltaic system are near-zero (Dorfner, 2016). The solar energy system has variable costs due to the power of the solar pump, these electricity costs amount to 3-5 % of solar-thermal gains (Weyres-Borchert et al., 2015). The considered variable costs of the other systems are taken from (EIA, 2014) and range between 1.5 % and 8 %. The fixed costs are mainly maintenance costs, typically specified as a percentage of the investment costs (Verein Deutscher Ingenieure, 2012). The prices of the commodities/fuel are average prices for the year 2016 (BMWi, 2016). Tab. 4 summarizes the assumed cost parameters. The current feed-in tariff of photovoltaic electricity is 12.3 ct/kWh (Bundesnetzagentur, 2017). The remuneration of the CHP will change as a function of the electricity prices on the European Power Exchange. On average, it is about 11.8 ct/kWh (Verbraucherzentrale, 2015). This value differs only slightly from the feed-in tariff of the photovoltaic system, which is why only one tariff is used for this calculation.

Tab. 4: Cost parameters for the considered different technologies (depreciation period: 20 years)

Process	*com*	Investment costs [€/kW]	Variable Costs [€/kWh]	Fixed Costs [$\%_{inv}$]	Fuel Costs [€/kWh]	Efficiency
photovoltaic system	solar	1,440	0	1,5	0	
solar-thermal system	solar	1,665	0.003	1,5	0	
gas boiler	gas	600	0.006	2	0.07	0.95
heat pump	elec	900	0.02	2	0.29	2.7 (COP)
heating rod	elec	100 €	0.005	3	0.29	0.99
mini CHP	gas	6,430 (elec)	0.5	8	0.07	0.23 elec 0.62 therm

Tank	heat	30	0.001	2		0.92
Purchase	buy	0	0	0	0.29	
Feed-in	sell	0	0	0	-0.123	

3.2 Time Series

The time series are an essential part of the model. There are two possible types. On the one hand, the model requires time series for the demand. For the residential building, these are the electricity (d_{elec}) and thermal energy demand (d_{therm}). This energy demand must be covered by every simulation time step (t). On the other hand, since solar processes cannot provide a constant power due to irradiation, an intermittent supply for this commodity (*solar*) must be defined. In contrast to the demand curves, which indicate the actual demand in kWh/h, the intermittent supply curve is normalized to a value of 1.This is because the output of these processes depends on the installed capacity, which is variable in the simulation model.

The VDI guideline (Verein Deutscher Ingenieure, 2008) defines an electrical load profile as a function of the building location, the day of the weak, the ambient temperature and the cloudiness, which serves as the basis for the annual simulations. For a 4-person household, an annual electricity requirement of 4,000 kWh is assumed. The VDI guideline also defines the hot water tapping profile with an overall annual demand of 2,000 kWh. The heating energy demand as well as the yields of the solar-thermal system are generated by means of parametric models, requiring only a limited amount of parameters (Dittmar, 2004). Characteristic parameters such as areas, window sizes and opaque elements for the building model are taken from IEA-SHC Task 44. This publication defines reference buildings for use in simulations, ensuring a fair comparison of different technological concepts (Dott et al., 2013). The SFH45 building standard represents current legal requirements of a renovated building with a building envelope

of good thermal quality, whereby SFH stands for **S**ingle **F**amily **H**ouse and 45 indicates the specific heating demand in kWh/m²a. With the used weather data set, the heat demand amounts to 8,000 kWh/a. The parameter model of the building is implemented in the simulation environment Matlab/Simulink and the additional CARNOT blockset (Hafner et al., 1999) to get the annual load curves as an input for the urbs model. In Simulink/CARNOT, a standard building, equipped with a boiler, a thermal storage and a solar-thermal system is implemented. The created load curves (Electricity and DHW) as well as the parameter model for the building are integrated in this model in order to get the necessary load curves for the subsequent linear optimization.

The annual simulation is used to get the necessary demand profiles for domestic hot water and space heating. Besides this, the simulation also enables to get the necessary input curves for the solar energy processes. The model urbs is a linear system. A large part of the examined components such as the photovoltaic system or the gas boiler can easily be linearly simulated and scaled. However, the solar-thermal system strongly depends on the ambient temperatures and supply temperature. In order to obtain a medium solar energy generation profile, simulations with 1-8 collectors were carried out in a Matlab/Simulink model. The area of a collector is 2.38 m^2. The storage size is adjusted according to the collector area and increased by 50 liters per square meter (Eicker, 2012). The volume flow is also increased linearly. Fig. 3. shows the annual yield of the various systems. The solar-thermal energy yields based on the number of collectors generally show logarithmic behavior. However, this behavior can be linearized for the collector areas as used in residential buildings (ca. 2–20 m^2). This is only possible for a small collector area, hence an extrapolation of the line leads to incorrect results.

In order to make a statement about the linear correlation, the Pearson correlation coefficient r and the coefficient of determination r^2 are calculated. With a correlation coefficient of 1, there is a completely linear coherence between the observed features. The correlation coefficient of the investigated systems is 0.988. The coefficient of determination is a quality measure for the linear adaption. The closer the coefficient of determination r^2 is to 1, the higher the probability of the linear coherence. Here the value is 0.976. These deviations are within the tolerance and a linearization and scaling of the solar-thermal system is possible without loss of accuracy. The normalized power curves of the 8 systems are averaged and act as input variables for the solar-thermal process.

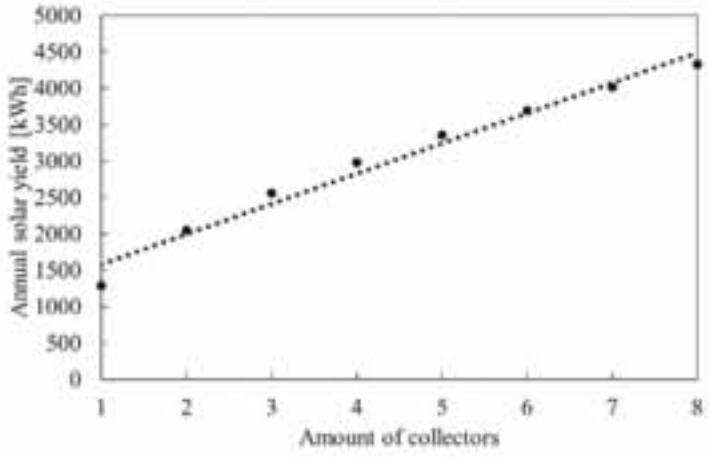

Fig. 3: Annual solar yields for 1-8 solar-thermal collector(s)

Fig. 4 shows a comparison of the solar-thermal performance for the parameter model in Matlab/Simulink and the linear model in urbs over a period of one week for two solar collectors. The results indicate that the generated solar-thermal power is nearly identical. The linear model produces a slightly higher peak load. However, the energy amounts are very low. The relative deviation between the CARNOT and the urbs model, as determined by eq. 8,

$$f = \frac{p_{CARNOT} - p_{urbs}}{p_{urbs}} * 100\ \% = \left(\frac{p_{CARNOT}}{p_{urbs}} - 1\right) * 100\ \% \qquad \text{(eq.8)}$$

is only 1.53 % for the solar-thermal power of an annual simulation. For the energy, the deviation is 0.17 % and thus even below one percent.

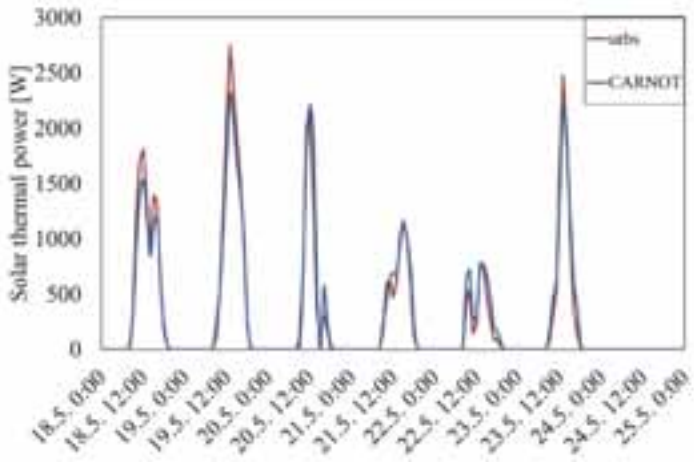

Fig. 4: Comparison of the generated solar power for the simulation models CARNOT and urbs

4. Scenario Results

This study is intended to show how solar-thermal and photovoltaic systems compete and under which conditions a joint use is economically reasonable. For that reason, various framework conditions are examined. On the one hand, the investment costs of individual technologies are modified and on the other hand, fuel prices and the remuneration are changed.

4.1. Variation of the Investment Costs

First, the study investigates the changes in system configurations for varying investment costs for the different processes. The investment costs for photovoltaic systems have declined in recent years (Wirth and Schneider, 2017). For this reason, one investigated scenario assumes drastically decreased investment costs of 50 % compared to today´s costs (s02). Solar-thermal systems have not experienced such a steep learning curve. Scenario s03 describes a potential cost reduction of solar-thermal systems by 50 %. A further scenario (s04) assumes even lower investment cost (75 % cost reduction compared to today`s cost level). The prices for batteries have also decreased in recent years. Similarly to the scenarios described above, a further cost reduction of 50 % compared to nowadays investment costs is assumed (s05). A technology that is currently too expensive for domestic applications is CHP. To make this technology competitive with the aforementioned, a cost reduction of 75 % is assumed (s06). Lastly, it is assumed that a solar-thermal system is already installed, on the one hand only for domestic hot water heating (2 solar collectors) (s07) and on the other hand for domestic hot water and space heating (4 solar collectors) (s08). All systems are compared with the base system as described before (s01).

Fig. 5 shows the results and the energy flows for the different investigated investment costs. The individual scenarios are listed vertically. This list shows the most cost-effective system for each scenario. Therefore, no comparison of the systems with one another is not possible. The annual costs for the different cost types are shown on the left. Revenue through feed-in is shown negative. The energy generation of the technologies used can be seen in the centre. Energy, which is not used by the building (feed-in, shunt process), is negative, too. This presentation allows a quick conclusion on how the system changes in the individual scenarios. On the right are the retrieved energies of the storages. It can be recognized, that the systems do not change with the investment costs. This is due to the low system costs for the gas boiler as well as the currently very low gas prices. The existing roof surface is completely covered with photovoltaic modules. If a solar-thermal system is already installed, a gas boiler is also used as the backup system. In this case, the thermal storage needs to be increased. However, because of the feed-in remuneration, this is economically more reasonable than buying a battery storage.

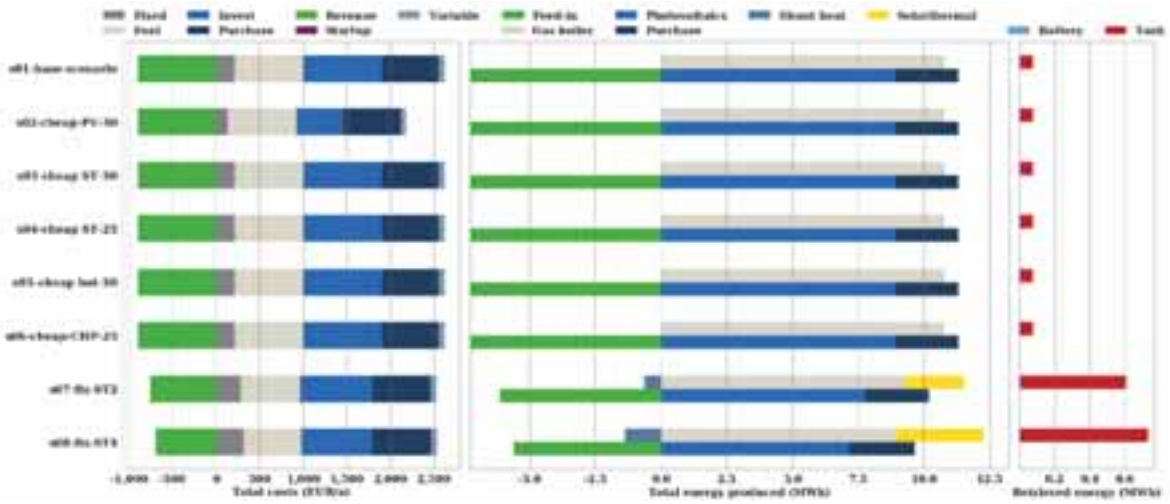

Fig. 5: Costs and energy flows for varying investment costs for the investigated systems

To account for a potential CO_2 tax, a CO_2-neutral energy demand of 15 % is assumed. This is in accordance with the requirements of the German Renewable Energies Heat Act (EEWärmeG). The different processes have a specific CO_2 emission per kWh. The basic system with gas boiler generates emissions of approx. 4,400 kg/a. The maximum annual CO_2 production is, therefore, limited to 3,750 kg.

Fig. 6 shows two essential findings. If there is no solar-thermal system, a battery storage must be installed to meet the emission limit. This reduces the emissions due to the purchase. At current prices, it is economically better to invest in a battery storage than in a solar-thermal system. Only in case of halved system costs, solar-thermal becomes competitive. A further cost reduction leads to the same result. In addition, the price of the battery storage does not affect the installed capacity.

The investigation with regard to the investment costs shows that these costs hardly affect the cost-optimal system configuration. Gas systems are the most economic at present prices. Only if CO_2 emissions are limited, some of the heat demand needs to be covered by the solar-thermal system. For this reason, the effect of the supply costs on the system is investigated, too.

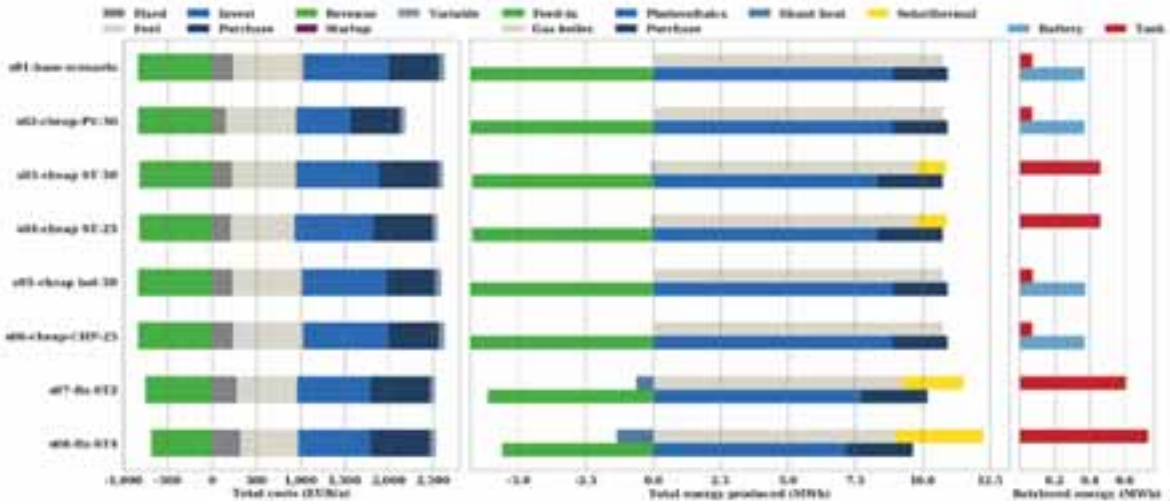

Fig. 6: Costs and energy flows for varying investment costs for the investigated systems and a CO_2 limit of 3,750 kg/a

4.2. Variation of Fuel Prices and Remuneration

In a further step, the energy supply costs and the remuneration are varied. In addition to an adjustment of the electricity costs with an increase (s09) as well as a decrease (s10) of 50 %, another gas price is also examined. The assumed gas prices represent a doubling (s11) and a tripling (s12) of current gas prices. This study also examines, what happens, when the remuneration is halved (s13) or when there is no longer any remuneration (s14).

Compared to the investment costs, it can be seen that the fuel prices have a much higher influence on the most economic system (cf. Fig. 7). A doubling of the electricity rate results in a battery storage being economically reasonable. If the electricity price is halved, the heat pump is more cost-effective than the gas boiler. This is also the case, if the gas price increases. For better economy of the heat pump, a doubling is already sufficient. Photovoltaic plants are economically unattractive with a reduction of the feed-in tariffs. The size is dimensioned in such a way that a high self-consumption can be reached. Thus, battery storages are again advantageous. The remaining roof area due to the small number of photovoltaic modules is, however, not used for a solar-thermal system.

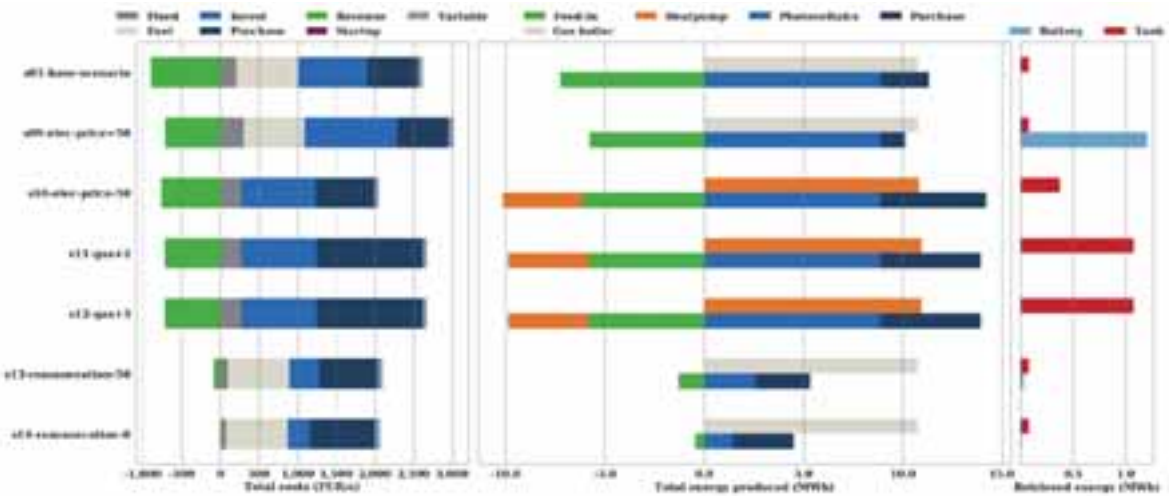

Fig. 7: Costs and energy flows for varying fuel prices and remuneration for the investigated systems

This shows that the decisive factor for a change in the energy systems is the price for the commodities. Investment costs have only a minor impact. A competition between photovoltaic system in combination with a heat pump and solar-thermal system cannot be observed. A reasonable combination of these three systems would require several boundary conditions to change at the same time.

5. Conclusions and Outlook

This study analyses the competition between photovoltaic and solar-thermal systems for residential applications. For this, the urbs model was adapted and extended for an application for single family houses. Due to the linearity of the model, it was shown that the yields of the solar-thermal system, which are strongly dependent on temperature, can be linearized with very high accuracy for the system sizes under investigation.

A major finding is that the cost-optimal system configuration is almost independent of the investment costs of the components. Gas-driven systems are currently the most economic ones. Only if the prices for electrical energy and gas vary, the system configuration changes. With a reduction in electricity prices as well as an increase in gas prices, the heat pump is more cost-effective than the gas system. An increase in the electricity price provokes an investment in a battery storage. A battery storage is also necessary if the CO_2 emissions are limited, whereby the size is independent of the investment costs. However, in the case of a reduction in the costs for solar-thermal systems, these are advantageous in comparison to the electrical storage. This shows that solar-thermal energy is an essential technology for decarbonisation.

However, there is no competition between photovoltaic and solar-thermal systems under current conditions. The combination of photovoltaic and heat pump is currently no more economic than a gas-driven system. This is due, on the one hand, to the feed-in tariff and, on the other, due to the currently low gas prices.

The aim of the study was to find the most economic system configuration for different boundary conditions. In this case, the solar-thermal system is disadvantageous compared to the photovoltaic system. However, not only economic optimization should be investigated. Further research must be conducted to answer how the different systems behave with different optimization objectives: (1) maximizing self-sufficiency, (2) maximizing self-consumption and (3) maximizing the use of solar energy. These questions will be addressed in further investigations.

Abstract

For holistic efficiency evaluation of solar-assisted heating systems in multi-family houses common system designs are tested with hardware-in-the-loop measurements. The experimental results provide the basis for the subsequent energetic and economic efficiency analysis. A previously introduced efficiency measure called "central performance factor of the heating facility" (CPF) is used to evaluate energetic efficiency of the overall heating system. Using this measure it can be explained, how system designs comprising low heat distribution losses (e.g. 2-pipe heat distribution networks or an ultrafiltration module in the DHW circulation return flow) feature the highest CPF. Cost analysis show, however, that such designs incorporate elevated levelized cost of heat compared to the other systems under investigation. Carbon abatement cost are combining the energetic and economic evaluation into one parameter. The results show that concepts with a bivalent heat storage tank and a fresh water unit connected to a 4-pipe heat distribution network, are leading to the lowest carbon abatement cost, at a minimum value of 46 €/tCO_2.

Keywords: solar combisystems, whole system testing, levelized cost of heat, carbon abatement cost

1. Introduction

There are various hydraulic design concepts for the integration of solar thermal energy into the heat supply of multi-family houses. Additionally, the control algorithms and the type of heat distribution network may vary. The variety of technical solutions therefor are hardly comparable for planners and installers due a lack of comprehensive system evaluation. This establishes a general obstacle for the application of solar thermal systems, especially in Germany, where solar thermal systems are used almost exclusively (97 %) for the heat supply of houses with one to three residential units (BSW, 2007), although more than 50 % of the apartments are situated in multi-family houses (IWU, 2010). In this paper selected solar-assisted heat supply concepts are evaluated in an energetic and cost-effective manner, in order to identify or derive optimal system concepts.

1.1 Evaluation method

Functional system evaluations (Helbig et.al, 2016) are carried out using a hardware-in-the-loop (HIL) test procedure (see Figure 1). For this purpose, the central components of the heat supply system (referred to "central heating facility" in the sequel) are implemented according to manufacturer´s instructions and tested under emulated, real operation conditions. Weather data and solar thermal collectors as well as the building with the heat distribution system are part of a dynamic simulation model in TRNSYS to ensure standardized and reproducible boundary conditions for system tests. The central heating facility is connected to thermostatic emulators during the tests, which supply the simulated heat gain or remove the required heat. The behavior of the emulators is calculated by means of real-time simulations in TRNSYS. With a time interval of one minute measured values are passed as input data to the simulation environment. Thus the HIL system can react dynamically to the behavior of the central heating facility. The test device allows the emulation of heating capacities sufficient for 20 residential units under central-European climate conditions and a solar thermal collector power of up to 60 kW.

doi:10.18086/swc.2017.29.04 Available at http://proceedings.ises.org

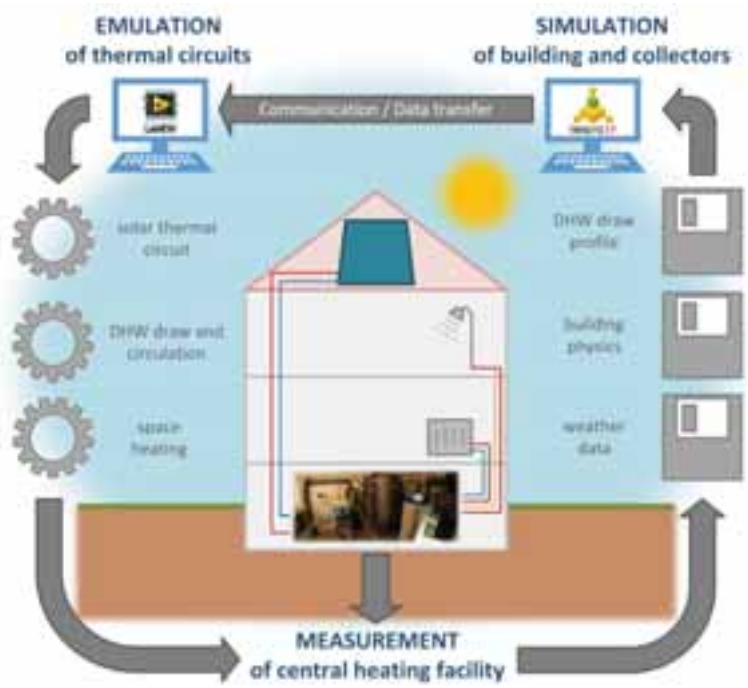

Fig. 1: Hardware-in-the-loop (HIL) test procedure for central heating facilities

The subsequent energetic evaluation is based on the results of high-resolution annual simulations of the solar-assisted heat supply systems under investigation. The simulation models are derived from the TRNSYS models of the HIL tests. Thereby, the performed measurements provide the data basis for model validations which allows a very precisely parametrization of the components of the central heating. While the HIL measurements are carried out for up to eight selected days, which generate all typical operation conditions within a year, the system simulations cover a complete year.

Finally, an economic analysis of the systems under investigation has been done. The economic evaluation is based on the results of the energetic system evaluation and a cost analysis of the single components of the central heating facility. Thereby two different evaluation parameter are used: levelized cost of heat (LCOH) and carbon abatement cost (AC_{CO2}).

1.2 Tested systems and applied boundary conditions

The tested solar-assisted heating systems for multi-family houses can be distinguished according to the type of heat distribution system, their solar heat storage and the hot water and boiler connection. In figure 2 the distinguishing features of the tested systems for the DHW preparation is shown. Additionally, all systems have solar support for space heating. The reference case has no solar support and is characterized by a domestic hot water storage and a 4-pipe distribution network.

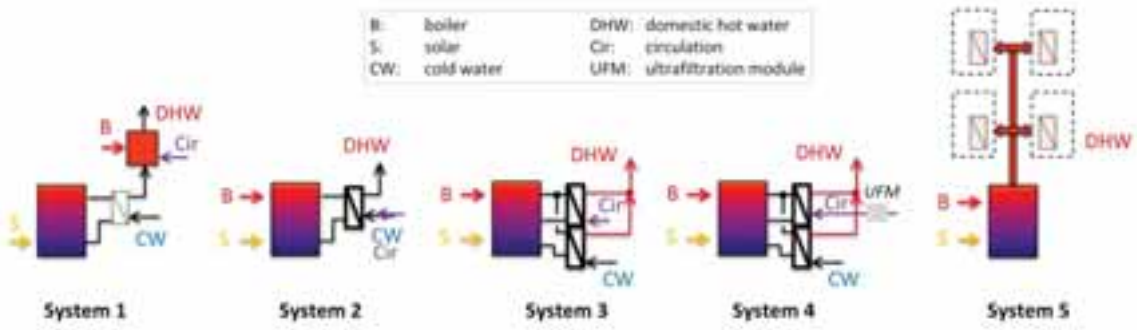

Fig. 2: Simplified hydraulic schemata for the DHW preparation of the tested systems (Adam et.al, 2016)

System 1 to System 4 are characterized by a 4-pipe distribution network, while System 5 has a 2-pipe distribution network. In system 1, solar heat is transferred exclusively to the monovalent solar heat storage tank.

The solar storage is used to preheat domestic hot water via a fresh water unit. Systems 2 to 4 differ in the number of heat exchangers in the fresh water unit. While system 2 has a common heat exchanger for heating both the domestic hot water (DHW) and the circulation return, the systems 3 and 4 have two separate heat exchangers for these tasks. System 4 is furthermore characterized by an ultrafiltration module in the circulation return. This provides a mechanical legionella treatment whereby the DHW flow line temperature can be lowered to little above the desired tap temperature (e.g., 47°C). System 5 has a bivalent heat storage tank from where the heat is distributed to the decentralized apartment transfer stations. The flow line temperature in the 2-pipe heat distribution network is constant at 50°C.

Tab.1: Boundary conditions for hardware-in-the-loop measurements and dynamic system simulation

	Description	Values
weather data	Meteonorm (version 5), location: Zurich, Switzerland	• days for HIL measurements: 38, 71, 99, 112, 175, (230), 250, (356)
solar thermal circuit	flat plate collectors as well as pipes between roof and central heating facility	• aperture area: between 14 m² and 33 m² • inclination: 45°, orientation: south • total pipe length: 53.5 m
space heating and distribution	multi-family house in Germany with a construction year between 1958 and 1968 and an energy-focused refurbishment according to the standards of EnEV 2009	• multi-zone simulation model (52 thermal zones) • number of apartments: 8 • detailed heat distribution network with more than 100 pipe sections • size of an apartment: 65 m² • heating system: radiators
domestic hot water draw	draw profile generated with DHWcalc (Jordan, Vajen, 2014)	• 55 litre per apartment and day (assumption of 1.8 inhabitants per flat)
domestic hot water circulation	constant circulation 24 hours a day	• 19 litre per hour and apartment (according to a maximum temperature difference in the flow line of 5 K)

2. Energetic efficiency evaluation

2.1. System boundaries and evaluation parameter

Figure 3 shows the system boundaries employed for balancing the energy fluxes of a solar assisted heat supply system for a multi-family house. Of particular interest is the boundary around the central heating facility with its energetic inputs and outputs. The central heat demand of the building ($Q_{central}$) combines the space heat demand and distribution losses as well as the heat demand for DHW and circulation. An efficiency measure previously introduced (Helbig et.al, 2016) is employed for the energetic evaluation of the investigated central heating facilities: the central performance factor of the heating facility (CPF). It represents the ratio of the central heat demand of the building as energetic benefit to final energy demand (E_{final}) as energetic expenditure:

$$CPF = \frac{Q_{central}}{E_{final}} [-] \quad \text{(eq. 1)}$$

For an overall evaluation of the energy conversion chain, the central performance factor of the heat supply chain (CPF_{plus}) is additionally introduced as an assessment parameter. In this case, the useful energy (Q_{use}) is set in relation to the primary energy (E_{prim}). The CPF_{plus} thus represents the reciprocal value of the plant effort (e_P) according to DIN V 4701:

$$CPF_{plus} = \frac{1}{e_P} = \frac{Q_{use}}{E_{prim}} [-] \quad \text{(eq. 2)}$$

In contrast to the CPF, the CPF_{plus} also allows the comparison of systems with different fossil energy sources and thus different primary energy factors. In addition, effects for reducing distribution heat losses can be assessed. However, a disadvantage of the CPF_{plus} is that both the useful energy and the primary energy are not measurable variables.

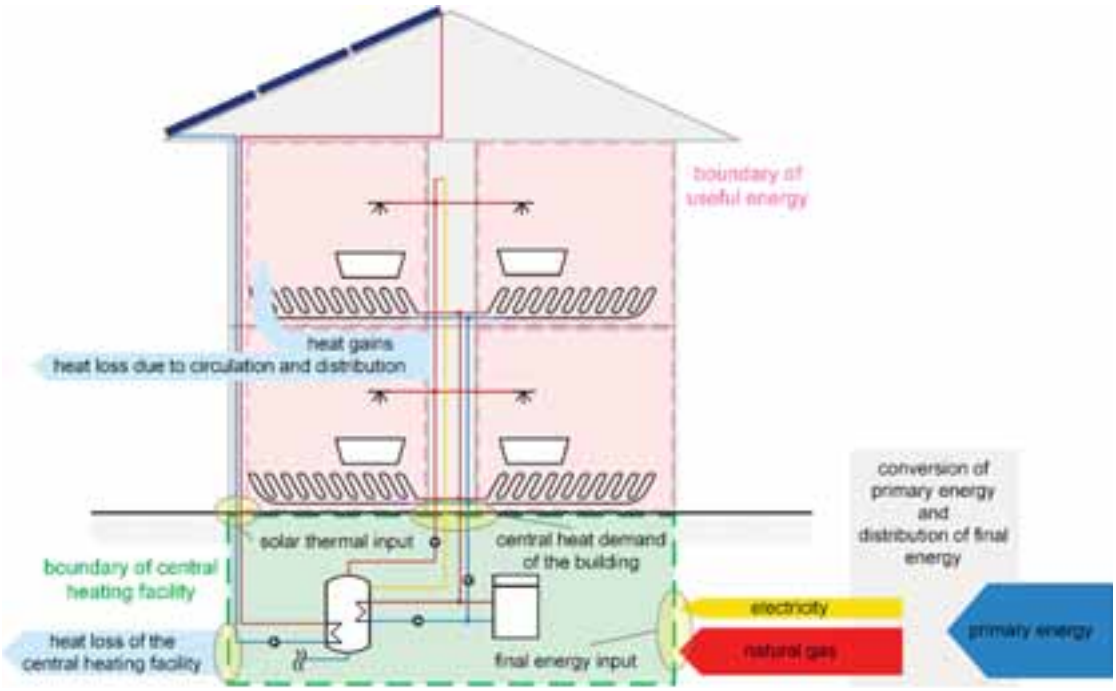

Fig. 3. Definition of system boundaries for the energetic efficiency evaluation (Helbig et.al, 2016)

Both the CPF and the CPF_{plus} are strongly dependent on the chosen boundary conditions (solar thermal collectors, weather and building characteristics, see Table 1). Accordingly, the demand-specific collector area (a_{dsc}) is selected as the reference parameter. It forms the quotient from the collector area (aperture) to the central heat demand of the building:

$$a_{dsc} = \frac{A_{col}}{Q_{central}} \left[\frac{m^2}{MWh}\right] \quad \text{(eq. 3)}$$

The benchmark procedure according to (Steinweg et.al, 2016) is used to calculate the maximum possible CPF or CPF_{plus} of an idealized central heating facility. For this purpose, the maximum collector circuit yield is determined by taking into account the temperature levels of the heat sinks in the monthly balance method. The central heating facility has no conversion losses from final energy to building energy. A comparison between the investigated systems and the benchmark makes it possible to determine the theoretical optimization potential of the individual systems (Helbig et.al, 2016).

2.2 Results

Figure 4 shows the CPF over the demand specific collector area for the systems 1 to 5, as well as for the reference system without solar support and the benchmark. It can clearly be seen that the central heating facilities 1 and 2 without solar support ($a_{dsc} = 0.0$) have identical energy efficiency (CPF) as the reference system. Systems 3 to 5, on the other hand, show an efficiency increase compared to the reference system without any solar support. The second heat exchanger in the fresh water unit (system 3 and 4) is leading to a better stratification of the heat storage tank whereas the ultrafiltration module in the circulation return (system 4) as well as the 2-pipe heat distribution network (system 5) are lowering the heat distribution losses. An increasing demand-specific collector area always leads to an increase in efficiency of the central heating facilities. For example, a solar support due to a demand specific collector area of 1.0 m² / MWh is leading to an efficiency increase of the central heating facilities of 15 to 37 %-points compared to the reference system. It can be seen that this increase in efficiency between the tested systems with solar support can differ by up to 22 %-points. However, system 5 as the most efficient of the systems under investigation still has a theoretical optimization potential of the CPF of a further 45 %-points (difference to the benchmark) with a demand-specific collector area of 1.0 m²/MWh. The theoretical optimization potential is made up of technical optimization measures and system idealization (Helbig et.al, 2016).

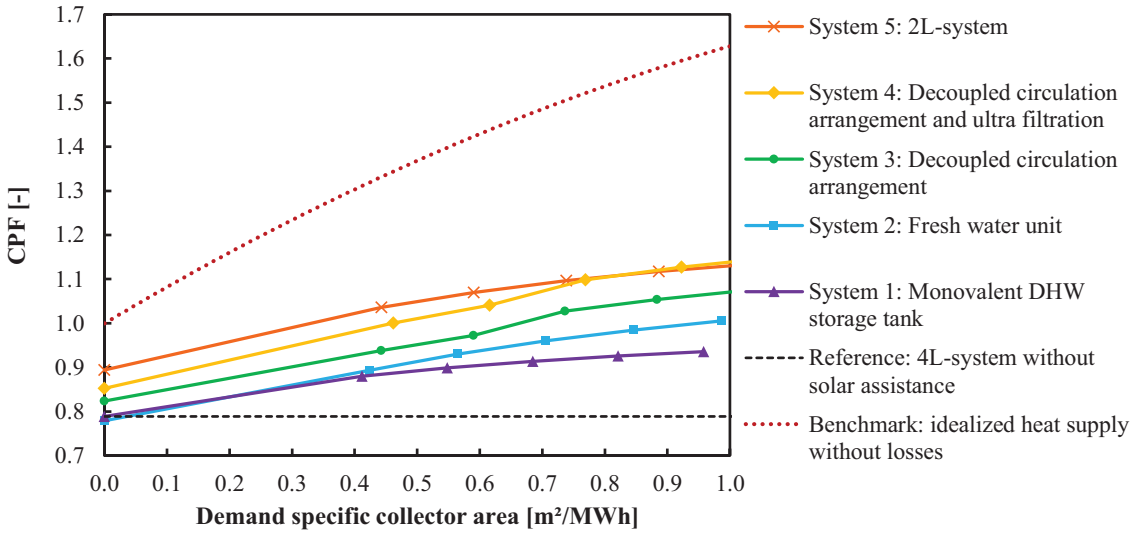

Fig. 4: Central performance factor of the heating facility over the demand specific collector area

Figure 5 shows the CPF_{plus} as a function of the demand-specific collector area. Since the CPF_{plus} evaluates a larger section of the energy conversion chain, its values always lie below those of the CPF.

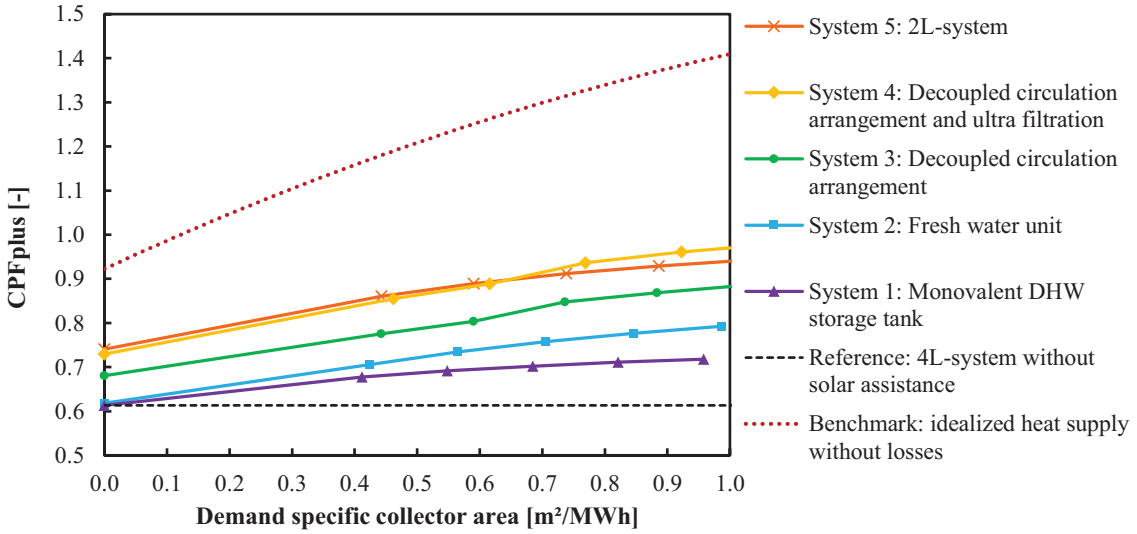

Fig. 5: Central performance factor of the heat supply chain over the demand specific collector area

A comparison between the CPF_{plus} in figure 5 and the CPF in figure 4 shows that both evaluation variables lead to a similar result in the efficiency assessment of the investigated systems. However, it can be seen in detail that the systems 4 and 5, compared to systems 1 to 3, have a relative efficiency increase in the heat supply which is attributable to lower heat distribution losses. In system 4 the reduction of those losses are a result of reduced DHW flow line temperatures because of the ultrafiltration module. The reduced heat distribution losses in system 5 are due to the application of a 2-pipe heat distribution network instead of a 4-pipe system. But it appears that the relative efficiency increase due to the ultrafiltration module is higher than the one due to the 2-pipe heat distribution network.

3. Economic efficiency evaluation

3.1 Evaluation parameter

In order to assess the economic efficiency of solar-assisted heating systems, levelized cost of heat (LCOH, see equation 5) as well as carbon abatement cost (AC_{CO2} see equation 6) are calculated and compared for the

systems under investigation. Both evaluation parameter rely on the calculation of the equivalent annual cost (EAC) which is determined by multiplying the annuity factor (a) with the net present value (NPV) (see VDI 2067):

$$\mathrm{EAC} = \mathrm{a} \cdot \mathrm{NPV} = \frac{i}{1-(1+i)^{-T}} \cdot \sum_{t=0}^{T} \frac{R_t}{(1+i)^t} \left[\frac{€}{a}\right] \quad \text{(eq. 4)}$$

where: i: annual interest rate [-]
T: observation period [a]
t: year [a]
R: net cash flow [€]

In the net cash flow (R) different types of costs (capital-related costs, demand-related costs, operation-related costs) as well as price change factors are considered. The investment costs as part of the capital-related costs come from real offers of an installation company for heating technology. The offers distinguish between component, delivery and assembly costs. Disbursements for replacements, which correspond to the depreciation period of the single components (VDI 2067), are also part of the capital-related costs as well as the possible payments by a residual value and incentives for thermal solar collectors of the German Federal Office of Economics and Export Control (BAFA, 2017a). The demand-related costs include the costs for electricity and natural gas. The operation-related costs are composed of the costs for maintenance, which were also selected according to the VDI 2067, as well as the costs for maintenance and inspection. The latter are from the offerings of the installation company, which contains a maintenance contract.

In addition to the offers for the systems under investigation, alternative offers were also made which have a quite similar hydraulic specification compared to the systems under investigation, but originate from another manufacturer. The alternative offers serve to assess the cost differences between the systems as well as between the manufacturers. The evaluation is done anonymously. It should be considered that to calculate the levelized cost of heat for the alternative manufacturers' systems, the respective energy efficiency of the systems under investigation is assumed. Accordingly, the levelized cost of heat of the alternative manufacturers are associated with additional uncertainty, which must be taken into account when interpreting and evaluating the results. Further boundary conditions for the economic efficiency calculation are summarized in table 2.

The levelized cost of heat describe the monetary expenditure for one heat unit. Therefor the equivalent annual cost are divided by the annual useful energy of the system:

$$LCOH = \frac{\mathrm{EAC}}{Q_{use}} \left[\frac{€}{kWh}\right] \quad \text{(eq. 5)}$$

Carbon abatement cost describe the additional cost for the carbon saving measure per unit CO_2 avoided. Consequently, for the calculation of abatement costs a reference system (ref) needs to be defined (see section 1.2). The annual CO_2 emissions caused by each system are determined by adding up the product of the carbon intensity per kilowatt-hour (CIPK) and the final energy demand for all energy sources used (n):

$$AC_{CO2} = \frac{\mathrm{EAC}_{Sys} - EAC_{ref}}{\left(\sum_{j=1}^{n} CIPK_j \cdot E_{final,j}\right)_{Sys} - \left(\sum_{j=1}^{n} CIPK_j \cdot E_{final,j}\right)_{ref}} \left[\frac{€}{tCO_2}\right] \quad \text{(eq. 6)}$$

Tab. 2: Applied boundary conditions for the economic efficiency analysis

annual interest rate	0,4 %
prices for energy	electricity: 29,7 €-cent/kWh and natural gas: 6,1 €-cent/kWh
price change factors	capital-related: 1,4 %/a and salary: 2,2 %/a electricity: 3,6 %/a and natural gas: 3,7%/a
observation period	20 years
CIPK	electricity: 526 gCO_2/kWh and natural gas: 202 gCO_2/kWh

3.1 Results

Figure 6 shows the LCOH and figure 7 the AC_{CO2} for the systems 1 to 5 and the reference system. The LCOH and AC_{CO2} for the benchmark are not shown, since this is not a real system. While the solid lines in figure 6 and 7 indicate the results for the systems tested in the HIL test, the dotted lines represent the results for systems with similar hydraulic specification, but from alternative manufacturers. In both figures the unsteady steps in the graphs of system 5 and system 1 (alternative offer) result from a nonfulfillment of a requirement for the incentives of solar thermal collectors from the German Federal Office of Economics and Export Control. The critical requirement states that the collector specific volume of the heat storage tank has to be larger than 40 l/m² (BAFA, 2017a). If it is clearly shown that a system has a solar support also for space heating and not just for the DHW preparation the limit of 40 l/m² can be undercut by 10 % (BAFA, 2017b). Nevertheless the systems 5 and 1 (alternative offer) do not fulfill the incentive requirement for all demand specific collector areas under investigation although the storage tanks have been replaced by similar models of the manufacturer with a larger volume as the collector surface area increases. However, a storage volume of 1500 liters was assumed as the upper limit, since the installation of even larger individual storage units in multi-family buildings is regarded as unrealistic and a possible storage cascading has so far not been used in the investigated systems.

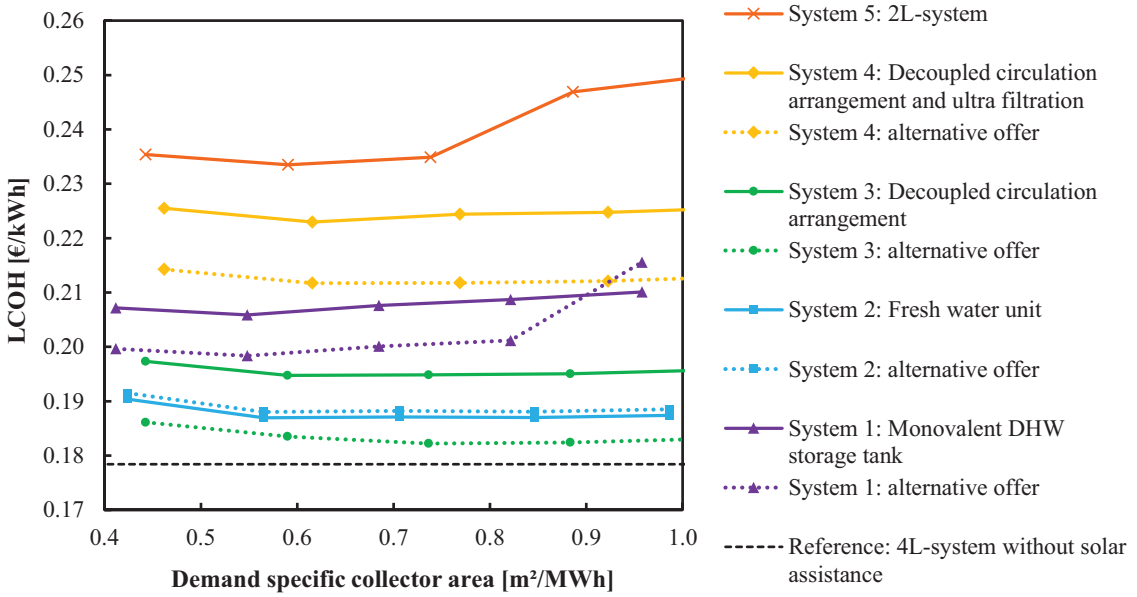

Fig. 6: Levelized cost of heat over the demand specific collector area for the investigated systems and alternative offers with a similar hydraulic specifications

It can be seen in figure 6 that all solar-assisted systems have higher levelized cost of heat than the reference system. When comparing the solar-assisted systems with each other, it appears that systems 2 and 3 have the lowest LCOH, with system 3 showing a greater difference between the considered manufacturers. In system 1, the large number of components and the low energy efficiency lead to high LCOH. The two most energy efficient systems under investigation are at the same time the ones with the highest LCOH. While for system 4 that is a result of the high costs for the ultrafiltration module, for system 5 the high costs for eight decentralized apartment transfer stations and their installation are leading to LCOH of more than 0.23 €/kWh.

Looking at figure 7 it appears that the systems with the lowest LCOH (systems 2 and 3) also feature the lowest AC_{CO2}. The alternative offer of system 3 is reaching 46 €/tCO_2 at its lowest point (at 0.74 m²/MWh). In contrast to that, system 1 shows to have the highest AC_{CO2} with over 1000 €/tCO_2 (at 0.4 m²/MWh). Although the AC_{CO2} is an economical parameter it is combining the energy efficiency analysis (CPF) and the economic efficiency assessment (LCOH). As a result, system 5 with the highest LCOH but also the highest CPF features lower AC_{CO2} than system 1 which is representing the most inefficient solar-assisted system under investigation.

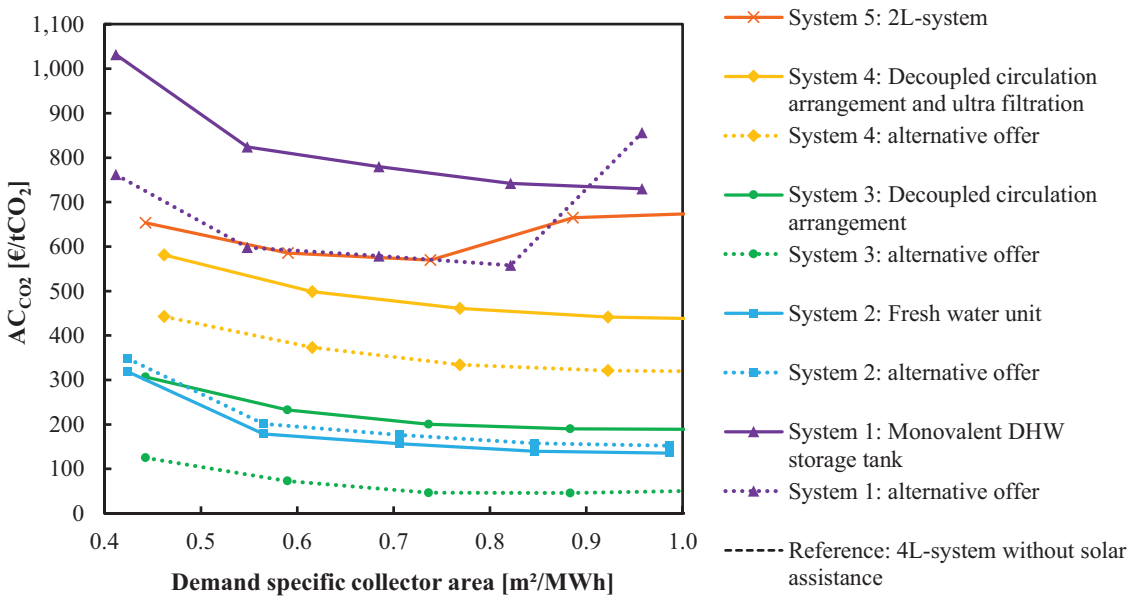

Fig. 7: Carbon abatement cost over the demand specific collector area for the investigated systems and alternative offers with similar hydraulic specifications

4. Conclusion

The overall assessment of solar-assisted heat supply concepts requires not only single component tests, but also tests of the entire system. The investigation shows that a significant increase in efficiency and utilization of the available solar heat can be achieved through compact installation (small number of components or short piping between components), the maintenance of the temperature layering in the heat storage tanks (e.g. stratified charging devices or circulation decoupling) and reduction heat distribution losses (e.g. 2-pipe heat distribution network or ultrafiltration module). The latter is not just reducing distribution heat losses within the building but also conversion losses within the central heating facility. Accordingly, systems that aim for reduced system temperatures show also a higher efficiency in the CPF and not just in the CPF_{plus}, which is explicitly considering distribution heat losses due to the chosen evaluation boundaries. In contrast to the CPF_{plus} the CPF can be easily determined in almost every building, since the input variables end energy and central heat demand of the building can be recorded without much effort with standard measuring technology.

The economic efficiency analysis shows that solar-assisted heat supply systems under investigation have higher levelized cost of heat than the reference system without solar support. A clear economic assessment of the systems is only possible to a limited extent, since the differences in the levelized cost of heat between the systems are roughly the same as the differences between the manufacturers. However, the increase in the number of components and therefore the complexity of the system also means that the levelized cost of heat are increasing.

The carbon abatement cost allows a combined energetic and economic evaluation of the systems and should therefore be the parameter used for the overall assessment of solar-assisted heat supply concepts. Moreover the carbon abatement cost offer the possibility to compare solar-assisted heat supply concepts with other activities where CO_2 emissions are avoided, like electricity production from photovoltaics or wind. The investigation presented in this paper disclosed large differences between the carbon abatement costs of the different solar-assisted heat supply concepts in multi-family houses. The carbon abatement cost moved in a span between 46 and over 1000 €/tCO_2. The most efficient systems in the meaning of a combined energetic and economic efficiency showed to be the systems 2 and 3 where the carbon abatement cost varied between 46 and 300 €/tCO_2 depending on the manufacturer and the demand specific collector area.

SOLAR THERMAL BASED NEW AND RENEWABLE ENERGY HYBRID SYSTEM FOR THE DISTRICT HEATING AND COOLING IN SOUTH KOREA

Jaehyeok Heo[1], Minhwi Kim[1] and Dong Won Lee[1,*]

[1] New and Renewable Energy Research Division, Korea Institute of Energy Research, Daejeon (Korea)

* corresponding author (dwlee@kier.re.kr)

Abstract

Considering the renewable energy ratio of only 4% in South Korea, the centralized renewable hybrid district heating and cooling demonstration complex would be new alternatives to expand new and renewable energy. In this paper, the current status of recently completed the first centralized renewable hybrid district heating and cooling demonstration complex is introduced. In addition, the methods for load estimation, installed capacities of installed new and renewable energy equipment, and control strategies with operation modes are simply explained.

Key-words: renewable hybrid, district heating, solar thermal system, seasonal thermal energy storage

1. Introduction

South Korea is one of the countries where the amount of energy usage is continuously increasing, but it imports about 95% of its energy sources from abroad because there are few natural energy resources available. Since more than 83% of the consumed primary energy is fossil energy, and with the dependency on nuclear power generation so high in the area of power generation, the ratio of renewable energy is only about 4% whereas the ratio of nuclear energy is about 12% as shown in Fig. 1.

Most of the new and renewable energy accounts for waste incineration and bio energy, and solar thermal energy and geothermal power are only about 1.2%. The reason why the spread of solar thermal energy is

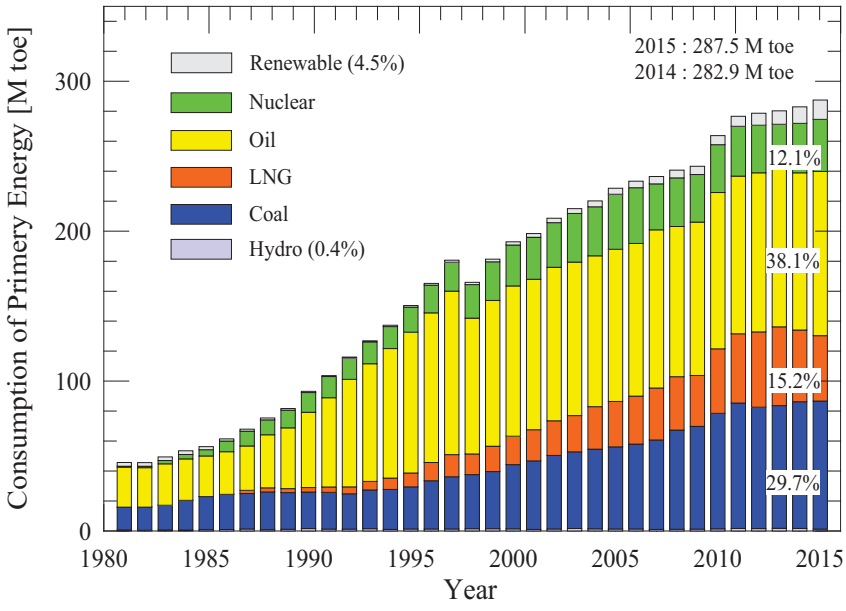

Fig. 1: Consumption of primary energy and the ratio with energy resource types in South Korea

(a)

(b)

Fig. 2: New and renewable energy hybrid system configuration (a) and current on-site pictures (b) of demonstration complex

slow is that the consumer confidence on the solar thermal system applied in the household is not high enough. Most companies related with solar thermal energy are small and follow-up service is not managed satisfactorily. In addition, relatively inexpensive cost of other heat energy sources is the one of the reason why consumers are reluctant to use solar thermal system. Therefore, in order to expand the use of solar energy, it is necessary to supply a large-scale solar thermal system that can be equipped with maintenance system in addition to a small domestic solar heater. The primary goal of this project is to construct a centralized renewable hybrid district heating and cooling demonstration complex based on a large-scale solar thermal system, targeting sewage treatment plants area and six public buildings (schools, libraries, etc.) located in Jincheon, Chungbuk Innovation City. The ultimate goal is to secure the necessary control technologies for the optimal hybrid operation while demonstrating the facilities, and establish a basis for expanding and distributing similar systems in the future.

2. Estimation of heating and cooling loads

In this project, it is aimed to build an energy independence demonstration complex that can provide annually stable heat and electric energy through the various new and renewable energy hybrid facilities. Seasonal thermal energy storage (STES) was applied for the stable thermal energy supply. The electric energy is produced by photovoltaic and fuel cell systems as much as the electricity demand in the demonstration complex for net energy independence, but it is connected to grid line to sell the produced electricity energy instead of self-consumption due to the economical factor. Initially, it was planned to supply only the heat energy necessary for heating and hot water supply. However, since the heat pump is used as an auxiliary system, it was decided to supply cold heat required for cooling to public buildings (except for a high school). In case of a high school, additional cooling system is installed, because the cooling load of high school is too much to be covered by the originally planned heat pump facilities.

In order to determine the capacity of the required renewable energy facility, the heating and cooling load of each public building was estimated first. The energy load is estimated based on the detailed building design and operating statistics on similar buildings (Lee et al., 2014). EnergyPlus was used for the heating load analysis. The thermal load of high school was estimated based on operating statistics of sites near high school, although exact load estimation was very difficult because operating circumstances are different in each school. Table 1 shows total annual heating and cooling load calculated based on the ambient temperature conditions of 24^{o}C and 26^{o}C in winter and summer, respectively. Total thermal energy load for heating and hot water supply were estimated as 761.5 MWh.

3. Capacity of installed new and renewable energy equipment and status

The capacities of new and renewable energy systems were determined based on the estimated thermal energy load and the TRNSYS-based simulation program. Due to field spatial limits, maximum installation area of solar thermal collector and size of STES were about 1,600 m^2 and 4,000 m^3, respectively. To cover the deficient thermal energy, water source heat pump (WSHP) of 350 kW and ground source heat pump (GSHP) of 175 kW were designed. In case of heating operation, totally 350 kW WSHP is operated to raise the residual heat in STES, and GSHP of 175 kW will be used as the auxiliary system. When the residual heat in STES is insufficient, sewage heat in the water purification center is used as the heat source. In case of cooling operation, alternating operation of WSHP would be possible with additional WSHP of 175 kW among 350 kW, because the cooling load of 4 public buildings can be covered by a GSHP of 175 kW and a WSHP of 175 kW. In addition, it is estimated that about 750 kW of photovoltaic power generation equipment is needed to produce about 850 MWh/year of electricity, which is expected to be consumed in public buildings in the demonstration complex.

Fig. 2 shows the new and renewable energy system configuration and current on-site pictures, respectively. All public buildings except for a youth center have been completed, and renewable energy facilities and seasonal thermal energy storage have been installed. The solar thermal systems were installed on the parking lot and the grounds where the geothermal heat exchanger was installed, and the photovoltaic systems were distributed on the installable space. The heat pump, the fuel cell, and the buffer storage tank were installed in the machine room including the monitoring center.

(a) (b)

Fig. 3: Operating options with heating (a) and cooling operations (b)

4. Operating methods

Operating options for new and renewable energy hybrid district heating system are divided into four operational methods as explained in section 4.1-4.4, and Fig. 3 shows the operation options with heating and cooling mode.

4.1. Operation based on solar thermal system

The heat energy produced in the flat plate and evacuated tube collectors is stored as hot water in the seasonal thermal energy storage through the heat exchanger. The stored hot water is supplied to public buildings for heating and hot water supply, and two separate heat exchangers were installed with purposes for separating the heat storage fluid in the STES and circulating fluid in the supply/return circulation pipe. At this time, the return temperature is controlled lower than 40^{o}C for the thermal stratification in STES by using both a variable speed pump and a 3-way valve. The return temperature will be preferentially controlled by the inverter pump, but 3-way valve might be additionally used according to the operation status by the inverter control. In the heating and hot water supply operation, the supply water is continuously circulated during business hours. When the heating and hot water load occur in public buildings, the temperature difference between supply and return water was observed. By this temperature difference detection, the heat energy in STES is supplied to the load. When the heat supply water temperature is less than 50^{o}C, operation mode is changed from the mode based on solar thermal system to the mode based on heat pump system because it can be considered that the thermal energy in STES is not available to supply to the load.

4.2. Operation for solar thermal overheating protection

In case that the STES is overheated by the over produced heat energy from solar collectors, overheating protection operation mode is provided to reduce the high temperature in STES. Except for summer season for cooling operation, the over produced heat is first released to underground through borehole heat exchangers, and the leftover heat is released to atmosphere by an additional cooling tower.

4.3. Heating operation based on heat pump system

Ground and sewage source heat pumps were installed as the auxiliary heating system. Besides, water source heat pump that uses residual heat less than 40^{o}C in STES as the heat source is also utilized. The hot water produced from heat pump is stored in the buffer storage tank and then supplied to the load. The reason why the buffer tank is used is to utilize the off-peak load time power. The operational cost can be reduced when hot water produced by heat pump operation during the night time is supplied to the load in day time. Of course, in case of heavy heating and hot water load, the heat pump should be operated during the day time.
It was checked that the capacities of heat pump and buffer storage tank can afford to respond to the maximum load of public buildings. The exchanger is installed for the separation between the heat storage fluid in the buffer storage tank and the circulating fluid in the supply / return circulation pipe. The heat pump operation in day time was set based on the temperature of hot water supplied to the load side.

4.4. Cooling operation based on heat pump system

In summer, cold heat is supplied to public buildings (except for a high school). Ground source and sewage source heat pumps are used as the cooling equipment, and the cold heat is supplied to the load side through

buffer storage tank. Buffer storage tank is applied for the utilization of the night time power as in the case in heating operation. In high school, additional direct-fired absorption chiller is used for the cooling. During the cooling operation, it is possible to supply hot water to the load side by using the stored heat in STES.

5. Conclusion

In November 2016, the first centralized renewable hybrid district heating and cooling demonstration complex based on a large-scale solar thermal system has been constructed in South Korea. The method for load estimation and capacities of installed new and renewable energy equipment were introduced, and the concept of major operation modes and control strategies were simply explained. While demonstrating the facilities, control technologies for the optimal hybrid operation will be improved and this experience will be a valuable basis for expanding and distributing similar systems in the South Korea.

High latitude solar heating using photovoltaic panels, air-source heat pumps and borehole thermal energy storage

Janne Hirvonen[1], Kai Sirén[1]

[1] Aalto University School of Engineering, Espoo (Finland)

Abstract

A solar community of 100 passive houses was designed for high latitude Finnish conditions. Typical solar thermal energy generation was replaced by solar electric system which was used to operate heat pumps. Short-term water-based thermal storage tanks were charged with an air-to-water heat pump and then discharged to a seasonal thermal storage system in the form of borehole thermal energy storage (BTES).

With total PV capacities of 240 to 600 kW, 78 to 97% of space heating and domestic hot water was provided by renewable energy from the local heating grid. Utilizing a water-to-water heat pump between low and high temperature water tanks increased the efficiency of the air-source heat pump. Varying the flow rate of borehole storage provided very minimal benefit.

Keywords: Solar community, seasonal thermal storage, solar electricity, heat pump,

1. Introduction

Solar energy availability varies between day and night and with seasons. The seasonal variability is different from country to country, with locations far from the equator experiencing larger changes in insolation. Finland is located above 60 °N latitude, which means that in summer the day can be 18 hours long, while in winter it might last only 6 hours. Correspondingly, energy demand for heating is greatest during winter, when there is little, if any, solar energy available. For this reason, conventional solar heating system with a short-term water storage is of limited utility in Finnish conditions. However, seasonal thermal storage may offer a solution.

Seasonal thermal storage allows the storage of heat for several months. The most popular seasonal storage methods are tank storage, aquifer storage, pit storage and borehole storage (Hesaraki, et al., 2015). Borehole thermal energy storage (BTES) consists of a grid of boreholes that have been drilled into the ground and fitted with heat transfer pipes (Lanahan & Tabares-Velasco, 2017). Hot fluid is circulated in the boreholes to heat the ground. If the size of the storage is large enough, thermal losses to the environment remain manageable and make it possible to provide a large fraction of heating by solar energy. Typically, the seasonal storage is heated by solar thermal collectors, which produce heat directly, as was the case in the Drake Landing Solar Community (Sibbitt, et al., 2012). Similar designs for Finnish conditions have been tested in an optimization study (Hirvonen, et al., 2017).

In Finland, the current market for solar thermal collectors is small, but installations of solar photovoltaic (PV) panels are accelerating and a new record for the country's largest PV system installation is set several times per year. Heat pumps are also replacing conventional district heating in many locations. Thus, combining these two technologies was considered in this paper. Solar electricity was used not only to meet the electric load of house appliances, but also to run an air-to-water heat pump to charge the seasonal thermal storage through a large water storage tank. The goal was to make an initial test of concept and find out the effect of different controls and solar generation capacity on the reduction of imported external energy.

2. Methodology and system description

This study looked at the energy matching in a virtual solar community of 100 single-family houses, located in Helsinki, Finland. The study was based on dynamic simulations performed with TRNSYS 17, using the weather data from Helsinki Test Reference Year 2010. The space heating (SH) demand in the houses was based on the

doi:10.18086/swc.2017.29.06 Available at http://proceedings.ises.org

simulated performance of a 100 m^2 passive level house with 25 kWh/m^2 annual energy demand according to heated floor area. The domestic hot water (DHW) demand was based on profiles gained from an IEA study (Jordan, 2001), normalized to 35 kWh/m^2. Electricity consumption of appliances was based on measured demand from 50 real district heated houses in the Helsinki region, normalized to 40 kWh/m^2.

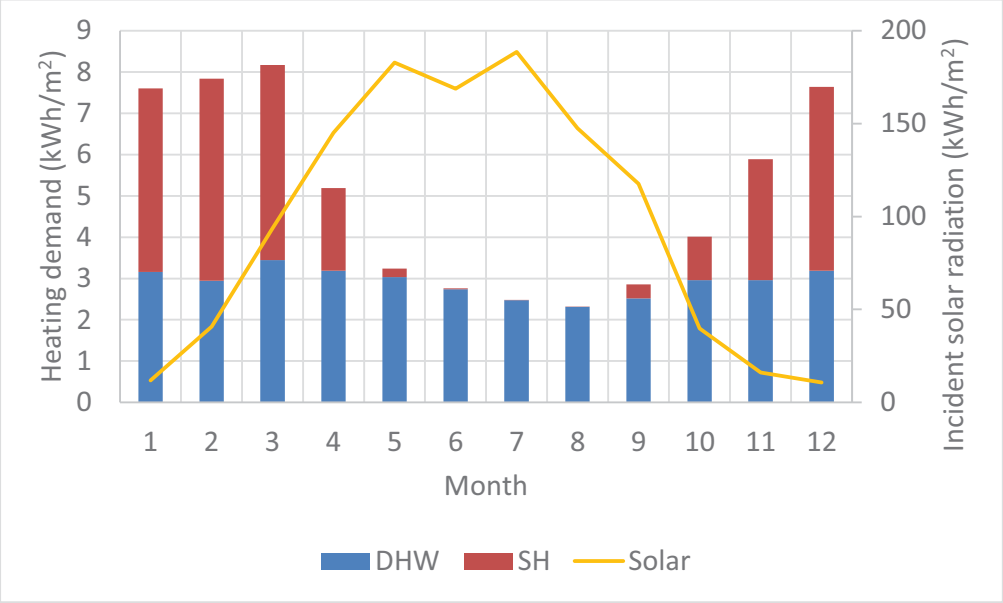

Figure 1: Monthly solar energy potential (vs. collector area) and heating demand in the houses of the community (vs. floor area).

The modeled energy system is shown in Figure 2. All the houses in the community were connected to a local heating grid that was fed from two large water storage tanks. The warm tank (300 m3) was used to supply space heating (SH) at 30 to 35 °C (floor heating) and to preheat the domestic hot water (DHW). The hot tank (150 m3) was used to superheat the DHW to the required temperature of 55 °C. The warm water tank was heated by an air-to-water heat pump (AW-HP, Figure 3) powered by solar photovoltaic (PV) panels, using ambient air as the heat source. The hot tank was heated by a water-to-water heat pump (WW-HP, Figure 4), using the warm tank as the heat source. Thus, the two heat pumps formed a type of cascade heat pump. Solar electricity was also used to run the house appliances. In case there was not enough solar power for all needs, the first priority of solar energy use was with the appliances, second priority with the WW-HP and third priority with the AW-HP. It was assumed that the heat pumps could be operated at any part-load between 10 and 100%. If solar electric power was not enough to run the AW-HP at the minimum part-load, the HP would not start. The ratios of the source-side (ambient air or warm water) and load-side flows (warm or hot water) in the heat pumps were kept constant. The flows adjusted according to heat pump power, to keep the load-side temperature change roughly constant at 12 °C.

If the warm tank cooled down and there was not enough solar energy available, it was be heated by discharging the seasonal storage. If the warm tank temperature rose above 50 °C by the use of the AW-HP, the extra heat was transferred to the seasonal storage. When the BTES temperature was above the tank temperature and the required SH temperature, energy from the ground was transferred back to the tank.

The seasonal storage was a borehole thermal energy storage system, contained in rock with thermal conductivity of 3.5 W/mK and total volume of 30 000 m3. There were 216 boreholes, each 37 m deep, evenly distributed along the BTES cross-section. The boreholes were connected in groups of 4, to generate a radial temperature distribution in the BTES. During charging, hot fluid entered from the center, flowed through 4 boreholes and exited at the edge of the BTES. During discharging, cold fluid entered from the edge and exited through the center. As it takes several years for a BTES system to reach stable conditions, a three-year simulation period was used. The results reported in this study were for the final year, on the assumption that long-term steady-state conditions had been achieved.

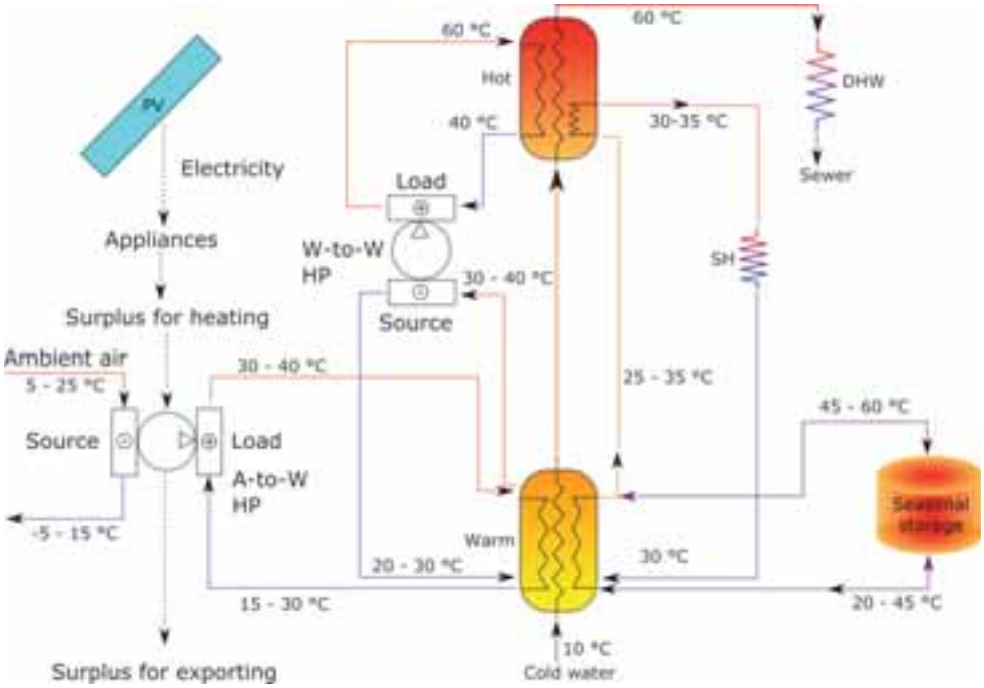

Figure 2: Energy system diagram.

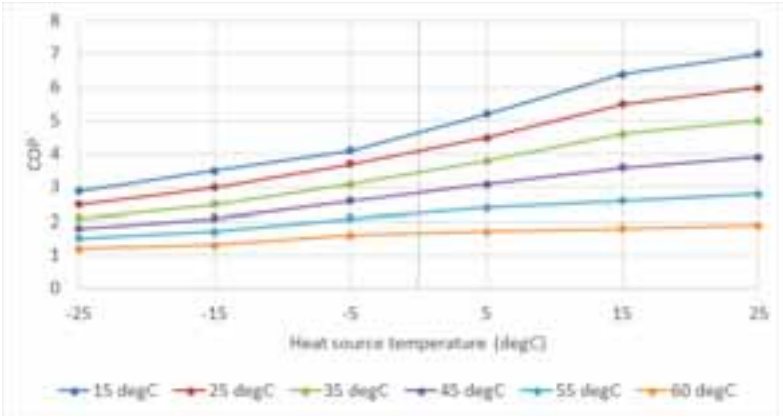

Figure 3: COP of the air-to-water heat pump with different load-side inlet temperatures. Based on model NIBE-2120.

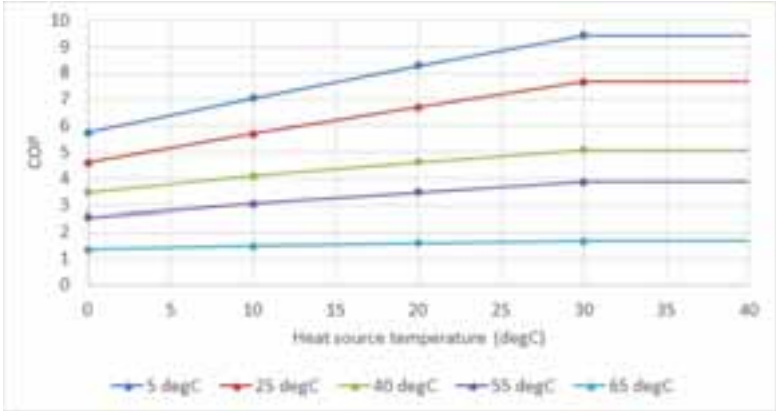

Figure 4: COP of the water-to-water heat pump with different load-side inlet temperatures. Based on model NIBE-F1345.

The total AW-HP thermal capacity was set to 960 kW, which corresponds to 240 kW electricity consumption in standard conditions. In addition, the WW-HP thermal capacity was set to 180 kW, which corresponds to 60 kW electricity consumption. Both heat pumps could be operated in part-load mode, with a minimum power of 10%. Actual ratio of thermal and electric ratio depended on the heat source temperature and load temperature, as shown in Figures 2 and 3.

2.1. Equations

Renewable energy fraction (REF) is the portion of end-use heat energy that is provided by the renewable energy of the local heating grid. Since electricity was the only external energy source, we can determine the REF indirectly

$$\mathrm{REF} = 1 - \frac{E_{imported\ heating\ elec}}{E_{SH}+E_{DHW}}, \qquad \text{(eq. 1)}$$

where $E_{\text{imported heating elec}}$ is the additional imported grid electricity needed for heating (heat pumps, backup system, pumps) after solar electricity has been accounted for, E_{SH} is the building-side space heating thermal energy demand and E_{DHW} is the building-side domestic hot water thermal energy demand. There was no electric energy storage, which limited the maximum amount of appliance related solar energy use. Thus, the REF only accounts for heating related energy, not electric appliances.

Efficiency of the seasonal storage is defined as the ratio of energy taken from the storage vs. the energy stored into the system

$$\eta_{\mathrm{BTES}} = \frac{E_{BTES\ discharge}}{E_{BTES\ charge}}. \qquad \text{(eq. 2)}$$

The PV system produces only electricity, but when connected to the heat pump the combined efficiency has the same meaning as the efficiency of a solar thermal collector. The combined thermal efficiency is defined as

$$\eta_{\mathrm{PV,thermal}} = COP_{HP}\frac{E_{PV,HP}}{G}, \qquad \text{(eq. 3)}$$

where COP_{HP} is the coefficient of performance for the heat pump, $E_{PV,HP}$ is the electricity consumed by the heat pump that was supplied by the PV system and G is the incident solar insolation on the solar panels.

2.2. Study parameters

To gain understanding of how the heating system and solar electricity interact, three parameters were chosen for analysis: PV capacity, BTES flow setting and WW-HP control mode.

PV capacity was selected as multiples of the nominal electricity consumption of the AW-HP (multiples 1, 1.5, 2, 2.5) to see how much excess capacity relative to the heating capacity is needed before there is enough power to both run the appliances and heat the BTES.

The BTES was operated in two different modes. In the Constant mode, all charging and discharging was done at a constant flowrate. In the Variable mode, the flowrate was changed according to the difference between the average BTES temperature and the temperature at the top of the warm tank. A high temperature difference corresponded to high flow and a low temperature difference to a low flow. The base flow rate for the BTES was 1600 kg/h per pipe loop. With a ΔT below 1, below 5, below 10 and above 10, the flow rate fraction was 25%, 50%, 75% and 100%, respectively.

The HP control setting decided whether the WW-HP was only run when the hot tank required recharging (setting 0) or if the hot tank was charged whenever there was available solar energy and the temperature at the top of the tank was less than 70 °C (setting 1). Additional use of the WW-HP lowers the temperature in the warm tank, thus increasing the COP of the air-to-water heat pump.

Table 1: Simulation parameters.

Case	PV capacity (kW)	BTES flow	HP control
0	0	-	0
1	240	Constant	0
2	240	Constant	1
3	240	Variable	0
4	240	Variable	1
5	360	Constant	0
6	360	Constant	1
7	360	Variable	0
8	360	Variable	1
9	480	Constant	0
10	480	Constant	1
11	480	Variable	0

13	600	Constant	0
14	600	Constant	1
15	600	Variable	0
16	600	Variable	1

3. Results

3.1. Renewable energy fraction

An important measure for energy system performance is the renewable energy fraction. Figure 5 shows the fraction of end-use heat energy that was met by the solar heating system. Even without any solar energy, 66% of heating was provided by the heat pump system alone. When solar capacity was set to 2.4 kW/house, which was equivalent to the maximum electricity use of the AW-HP, REF of heating was increased to 78%. Increasing the PV capacity to 3.6 kW/house, up to 88% REF was achieved. Increasing PV capacity further showed diminishing returns, as at 4.8 kW/house the maximum REF was 95% and at 6 kW/house it was 97%.

While PV capacity was the main determinant of REF, heat pump and BTES configurations also affected the results. With the smallest PV capacity (240 kW), increasing the WW-HP utilization during peak solar generation lowered REF compared to only running the WW-HP as needed by the hot tank. With all the larger solar generation capacities it had the opposite effect; increased use of WW-HP increased total REF. With a small PV capacity, the higher priority of the WW-HP prevented the operation of the AW-HP, since little extra solar energy was available for heating the warm tank and subsequently the BTES. With larger PV capacities there was enough energy to operate both the AW and WW heat pumps. In these cases, the WW heat pump cooled down the warm tank (which it used as an energy source), improving the COP of the AW-HP due to lower load-side temperatures. Increased use of WW-HP changed REF by -2.2%, +0.9%, +2,3% and +3.6% for the 240, 360, 480 and 600 kW cases, respectively. The effect of the variable BTES flow was less significant, though it was positive in all cases. The increase in heating REF was 0.2 to 0.6%, the largest gains found in the 360 kW case.

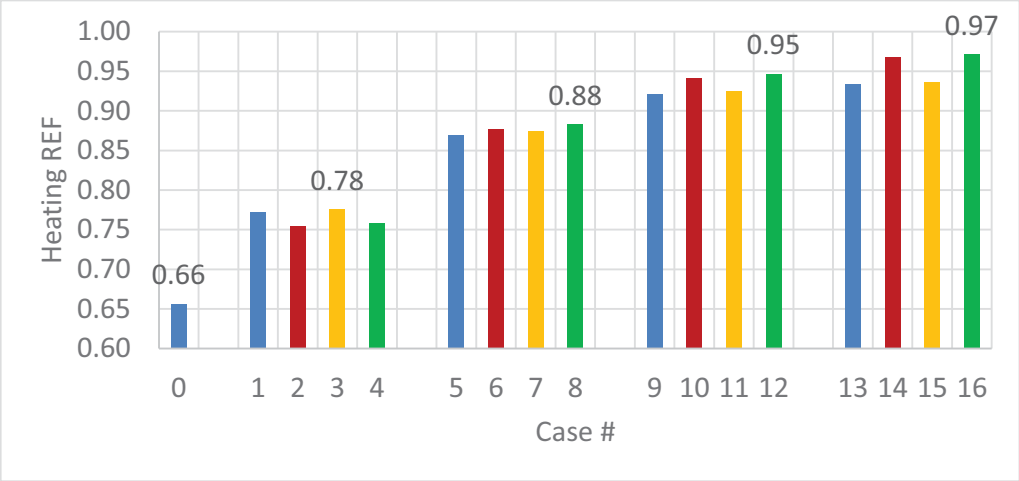

Figure 5: Annual renewable energy fraction of heating for the simulated cases. Bars with the same color have the same BTES and HP flow settings, but different PV capacity, as shown in Table 1. The numbers show the highest REF for each PV capacity.

3.2. Solar energy use

The solar energy generated by the PV panels was used for appliances, heat pumps and exporting. Increasing the PV capacity by 150% from 240 kW to 600 kW increased the PV use for appliances only by 25%, due to the mismatch in energy use and generation patterns. Most of the added solar energy generation was used by the AW-HP, as shown in Figure 6. Increasing the use of the WW-HP increased its electricity consumption by 230 to 420%, according to PV capacity. However, the total sum of the AW and WW heat pump electricity consumption remained practically constant in all the cases with the same PV capacity. In the cases with 240 and 360 kW PV capacity, 1% of PV generation was exported to the grid. With 480 and 600 kW, exports were 4 and 7% of PV generation.

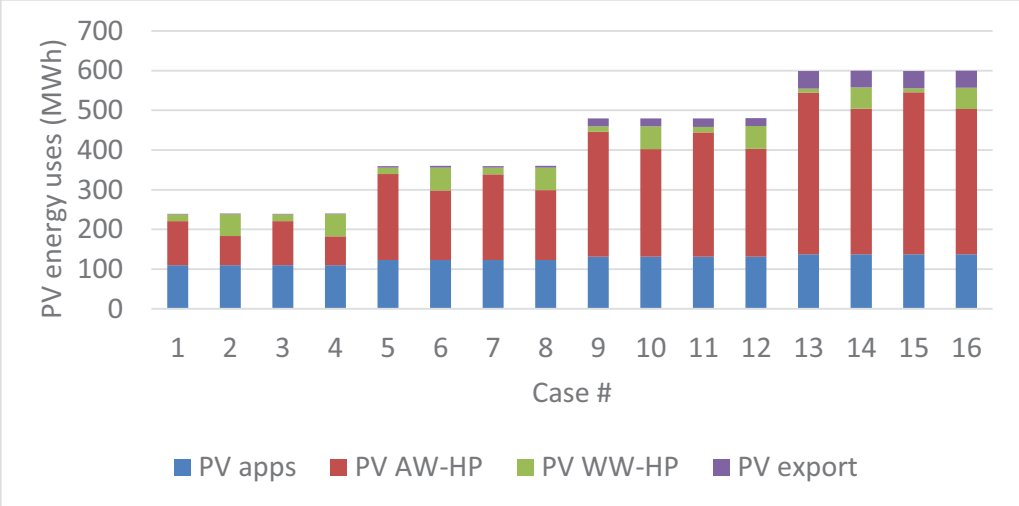

Figure 6: Annual distribution of PV generated energy for different uses.

3.3. Thermal efficiency of solar electric heat generation

Effective efficiency of solar panels when producing heat with heat pumps, hourly duration curve. Choose the best case of all PV sizes and put them in the same figure.

Since solar electricity was used to run the heat pumps, we can calculate the thermal efficiency of solar heat generation. Figure 7 shows the duration curves for the thermal efficiency of both heat pumps in the best cases of each PV capacity. The total running time of the AW heat pump was increased by adding more PV capacity, because after meeting appliance needs extra power was available more often. There was also a clear decrease in average efficiency as the PV capacity was increased. This is due to the AW HP operating at higher temperatures due to charging of the thermal storage tank. With WW HP, the longest running time and highest efficiency was

obtained in the 360 kW case. Conversely, the lowest efficiency was obtained with the 600 kW system.

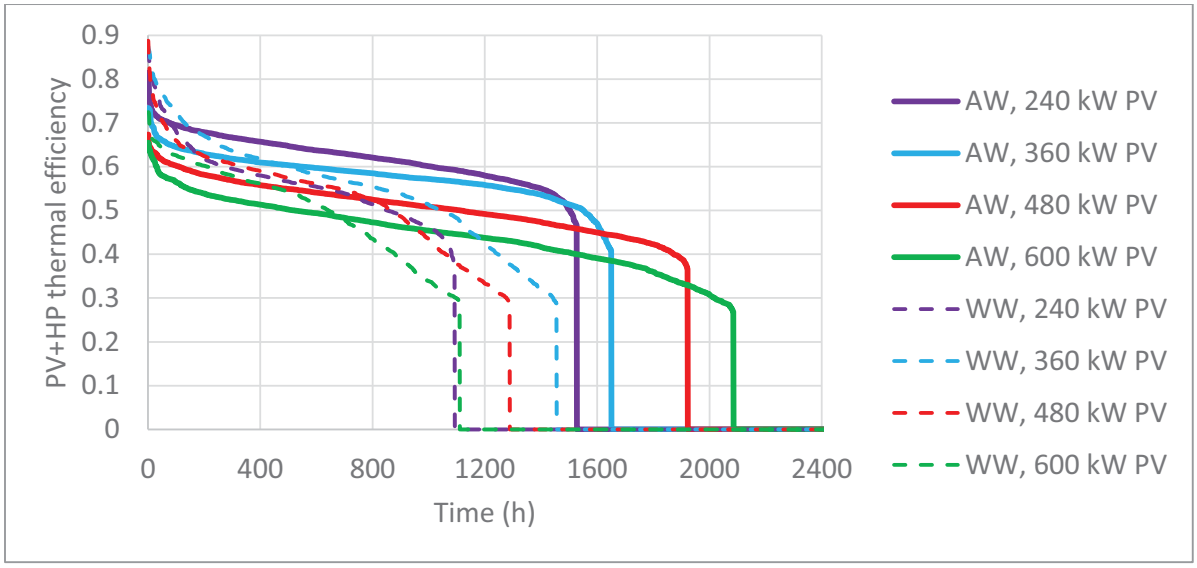

Figure 7: Duration curves of the thermal efficiency of heat pump energy generation using solar electricity.

3.4. BTES performance

Figure 8 shows the average temperature in the BTES during the seasonal cycle of the last simulated year. The bottom and top end of the bars represent the annual minimum and maximum temperatures, respectively. Also shown is the storage cycle efficiency. In the 240 kW PV cases, there was not enough energy to heat the BTES to the temperature levels required to meet space heating demand. The low temperature resulted in a very high cycle efficiency. Higher PV capacity raised the storage temperature.

The borehole flow setting had no practical effect on the temperature. The more active operation mode of the WW HP, however, decreased temperature and increased BTES efficiency for most cases. In the 360 kW cases, the lower temperature was also joined by lower efficiency.

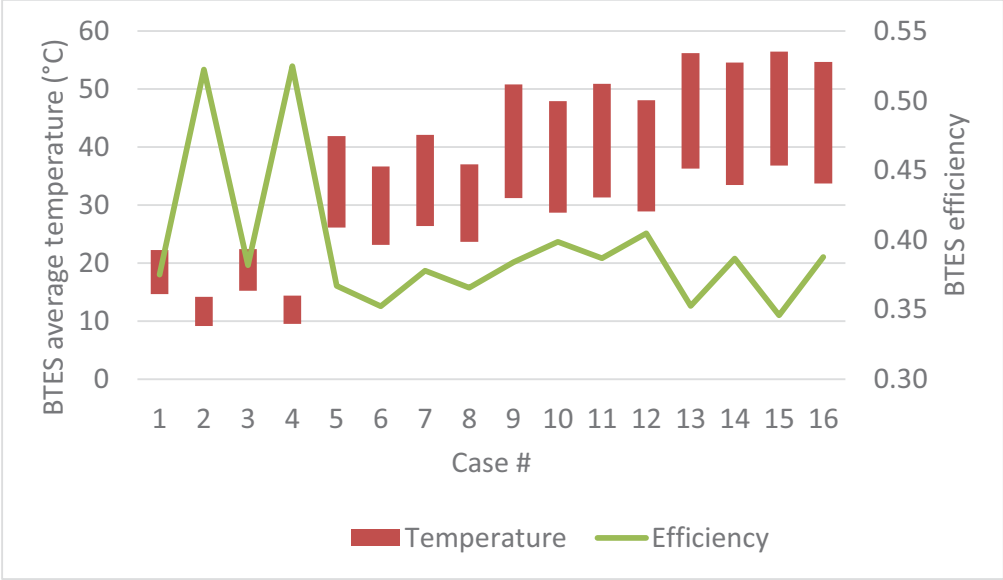

Figure 8: Range of average seasonal storage temperature and the annual seasonal storage efficiency.

3.5 Monthly comparison

Figure 9 shows the third year monthly electricity flows and seasonal storage temperatures in Case 1. Generation from the PV system was distributed between appliances, AW-HP and WW-HP. The minimum need for external energy happened in July, with 15 MWh of electricity imported. The maximum happened in December, with

66 MWh of electricity imported. The low amount of 2.4 kW solar panels per building didn't have enough excess energy to allow the charging of the seasonal storage. Thus, the maximum temperature achieved by the BTES was 22 °C, which was not enough to provide heating in winter.

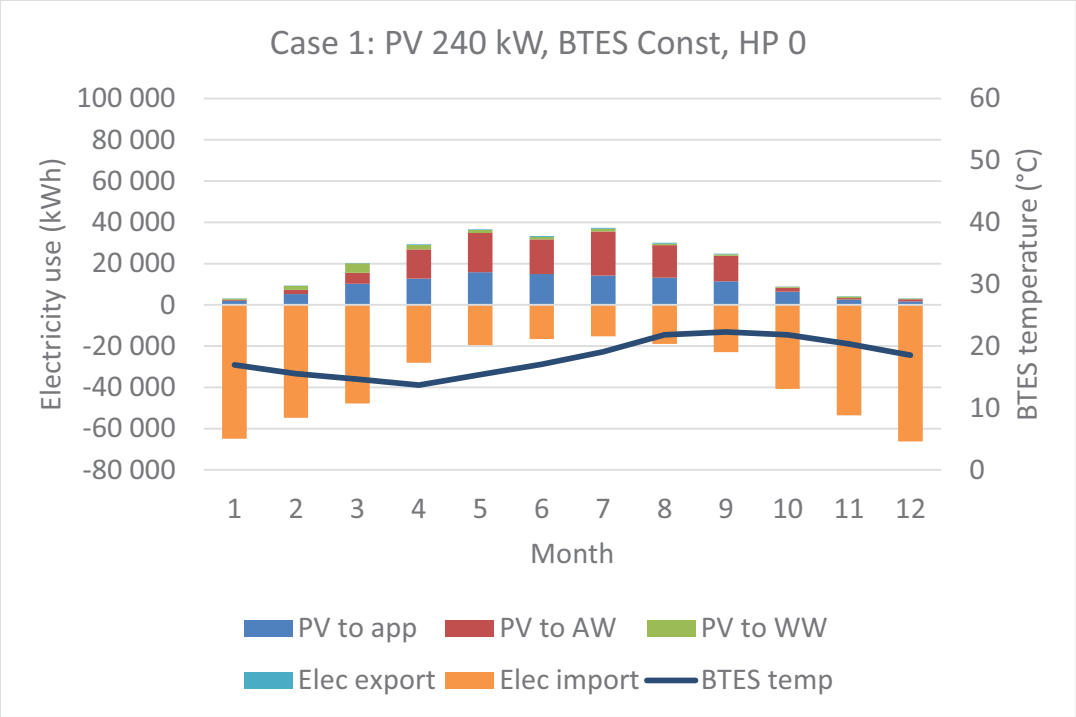

Figure 9: Electricity flows and seasonal storage temperatures in Case 1.

Figure 10 shows the third year monthly electricity flows and seasonal storage temperatures in Case 16. Now the higher solar capacity allowed diverting a large amount of solar electricity to the operation of the AW-HP. The extra heat was then used to charge the BTES up to 55 °C, while the annual cycle only dropped the temperature down to 34 °C. The need for imported energy was reduced compared to Case 1, as the minimum imports were 10 MWh in July and maximum 45 MWh in December. This highlights the difficulty of utilizing significant amounts of solar energy in high latitude conditions, which have a high seasonal mismatch in demand and generation. Increasing nominal solar energy capacity by 150%, compared to Case 1, reduced the need for external energy by only 32% during the peak month.

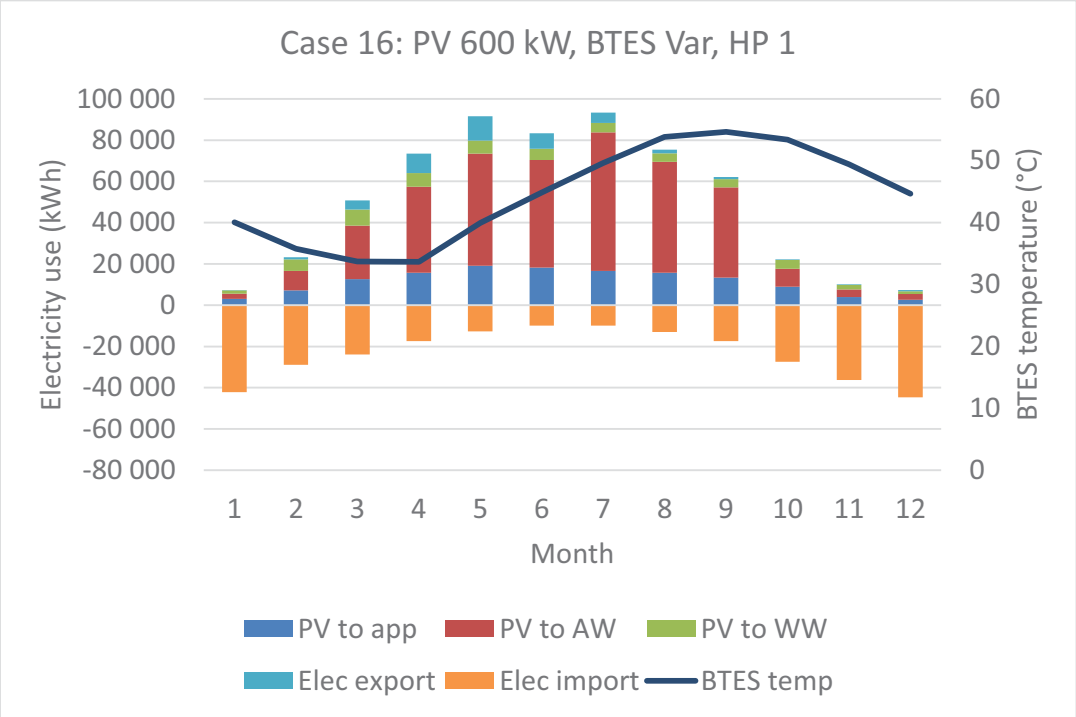

Figure 10: Electricity flows and seasonal storage temperatures in Case 16.

4. Discussion and conclusions

The heat pump based solar heating concept introduced in the paper worked well. A renewable energy fraction of up to 97% was achieved by having a nominal solar electric capacity of 600 kW. This was equal to 2.5 times the maximum electricity consumption of the air-to-water heat pump. However, even with a PV capacity of 360 kW, 1.5 times the maximum electric power of the AW-HP, the REF could be as high as 88%. Thus, with passive houses, a relatively low amount of PV generation per house was needed to achieve a high REF. Using the solar photovoltaic system simplifies the solar community design compared to a solar thermal collector design, because the same solar panels can supply both the heat and the electricity. In addition, no piping is required between the solar collectors and storage tanks.

Varying the BTES flowrate did not significantly influence the system performance. This implies that using a constant flow rate is effective enough, though the optimal flow rate could still be different than what was selected in this study.

Combined with the air-to-water heat pump, the average thermal efficiency of solar heat generation could be above 50%, even when heating REF was above 90%. The thermal efficiency of this electric heating system compared favorably to the 33% solar thermal efficiency obtained in the Drake Landing Solar Community (DLSC, 2012). Utilizing the water-to-water heat pump between the two buffer storage tanks increased total system efficiency by lowering the input temperature of the air-to-water heat pump, but only if PV capacity was large enough to also allow additional use of the AW heat pump. It should be noted that the ideal heat pump modeled here suffered no ill effects from part-load use or fast on-off behavior and could always adjust perfectly to the current solar conditions. A real-life system may face more difficulties in these aspects, which might lower total system efficiency.

A high REF solar community based on solar electricity and heat pumps was found to be technically feasible in a high latitude country like Finland. However, the seasonal energy mismatch and large losses in the seasonal thermal energy storage cause diminishing returns for increased solar capacities. Further optimization is needed to find out economical implementations of the basic design.

Abstract

A renewable hybrid energy system using seasonal thermal energy storage (STES) has been recently constructed in Jincheon, South Korea. The eco-friendly energy town was proposed and constructed in Jincheon to supply the heat from the solar thermal system and new and renewable hybrid energy systems with seasonal thermal energy storage (STES) to six buildings contained in town. In this research, the thermal behavior of the series connected solar thermal systems, which are flat-plate solar collectors and evacuated tube solar collectors, and the STES have been investigated. During the 21 days of trial operation period in January 2017, the ambient air conditions, irradiation, useful thermal energy gain, and internal thermal energy variation in STES were estimated by using measuring data. It was found that the efficiencies of solar thermal systems were 2.4 to 25.4%, and that of the STES were 90%, during the whole test period.

Keywords: solar thermal systems, seasonal thermal energy storage, control logic, experimental results, efficiency

1. Introduction

In South Korea, where the usage ratio of renewable energy among the national energy consumption is still low, the policies have been established to expanding the heat supply from renewable energy facilities including solar thermal systems. As part of these policies, the eco-friendly energy town constructed in Jincheon, South Korea has adopted a centralized heat supply system combined with various new and renewable hybrid energy systems, focusing on the solar thermal systems and seasonal thermal energy storage (STES).

This proposed eco-friendly energy town is the first case in South Korea that uses STES for stable heat supply to the buildings. The eco-friendly energy town contains six buildings with the new and renewable hybrid energy systems which includes a solar thermal system, STES, 3 heat pump systems which have different heat sources, buffer tank, and a district heating loop system. The six buildings are consisted of high school, library, youth center, child care center, public health center. Figure 1. shows the new and renewable energy hybrid system configuration installed in Jincheon. The two types of solar collectors are connected in series, and then the collected heat is stored in the STES through the whole year. The stored heat in the STES is supplied to the building for heating the space and supplying the hot water through the winter season. In the end of heating season, when the stored water temperature in STES is lower than the target supply heating water temperature, the heat pump system increases the supply water temperature with supplying the hot water in the STES to the source side of the heat pump. During the cooling season, two heat pumps which uses the ground heat source and sewage heat source, respectively, are operated to produce cooling water. The produced cooling water is stored during the nighttime in the buffer storage tank, and then the cooling water is sent to the district loop system to cool the buildings during the daytime.

Over the last decades, many researches have been conducted on seasonal heat storage and solar thermal systems focused on European countries. Schmidt et al. (2004) demonstrated the central solar heating plants using seasonal thermal storage. The demonstration plants that had been built up to this point through the government-funded research program, “Solarthermie2000” in Germany were presented in detail. Bauer et al. (2010) showed several central solar heating plants with seasonal storage in Germany while comparing and summarizing the results of

doi:10.18086/swc.2017.29.07 Available at http://proceedings.ises.org

extensive monitoring programs which were carried out within the framework of “Solarthermie2000”. Four different types of thermal energy storage were investigated, such as hot water, gravel-water, borehole, and aquifer. Novo et al. (2010) presented a review of technologies and conducted projects for central solar heating systems which employ seasonal sensible water storage. Different technologies for the storage of heat were available and researched. Xu et al. (2014) reviewed three forms of heat storage, namely sensible, latent and chemical heat storage. It was concluded that in comparison, sensible heat storage is most applicable for practical use whereas latent and chemical heat storage still need to be investigated and developed further.

In this study, we investigated the efficiency of solar thermal system and the thermal storage performance of the STES based on the measured data during the trial operation period.

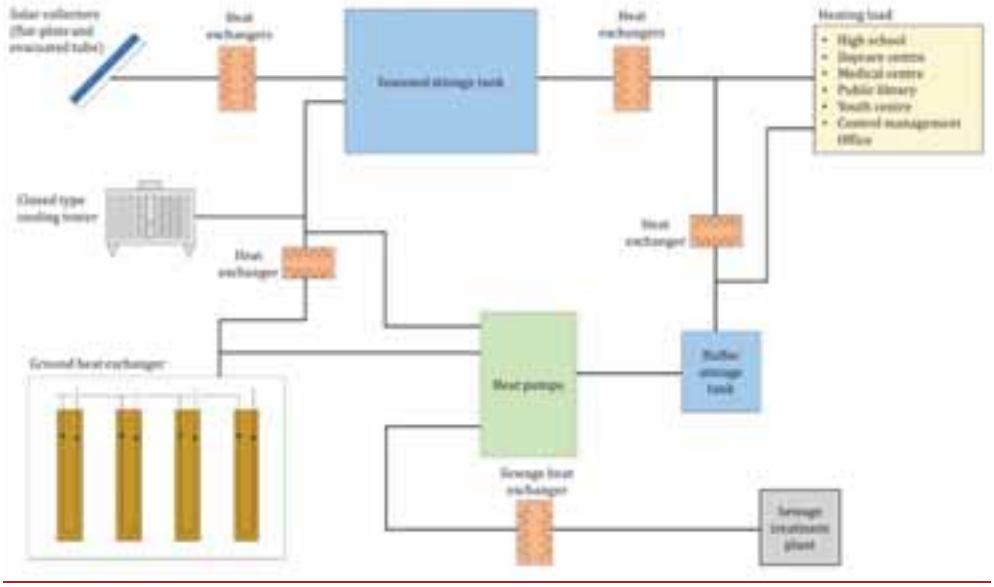

Fig. 1: New and renewable energy hybrid system configuration

2. System overview

The solar thermal systems in the proposed system consisted of 800 m2 of flat-plate type solar collectors, 800 m2 of evacuated type solar collectors, and 4000 m3 of a STES. As shown in Figure 2, the flat-plate type solar collectors and evacuated type solar collectors are connected in series. The solution that passes through the flat-plate type solar collectors is also heated by passing through the evacuated type solar collectors. The aqueous brine solution is used as a heat transfer medium for antifreeze. The collected thermal energy is transferred to the water, and then the water is used as a heat storage medium in STES. Figure 3 shows the installed solar collectors and STES in Jincheon.

The STES is a rectangular-shaped water tank. The STES consisted of concrete walls and a ceiling which are covered with a 700 mm thick insulation on the outside. The inside of the tank has a height of 10.3 m, a width of 16.7 m, and a length of 24.7 m. There is another concrete wall some distance away from the insulation surrounding the STES which creates a space that is filled with ambient air. For observing the stratification performance of the STES, nine temperature sensors are placed at the center of STES with 1 m different heights above the floor of the STES.

3. Estimation of system performance

3.1 Control logic of solar thermal systems

The hydraulic loop of the proposed system is divided into two parts: the solar thermal system loop and STES loop. The each loop of solar thermal system is closed-circuit with solution, and the water that used to storage heat in STES is firstly passing through the heat exchanger in the circuit of flat-plat type solar collectors, and then the heat exchanger in the circuit of evacuated type solar collectors heats the water. The heated water is distributed into the top of the STES, the water that located in the bottom of STES goes to the solar thermal systems. The each pump of solar thermal system loop is operated when the tilted solar radiation is reached at 400 W/m^2. And then, by comparing the middle or bottom of the water temperature of the STES, the pump of STES is operated. This control logic is primarily for maintaining the temperature stratification of STES. After that, the 3-way valve (VSM) is modulated to maintain the water temperature that higher than the water located in the top of the STES.

3.2 Efficiency of seasonal thermal energy storage (STES)

In order to observe the temperature stratification of STES, the nine temperature sensors were installed in the middle of STES. Each temperature sensor were located from the bottom to top of the tank, and the water inside the tank can be divided into nine sections. For simplifying estimation the efficiency of STES, the volume of the water inside the tank was divided into nine sections according to the nine temperature sensors, and it was assumed that the water temperature within a volume-section is constant and that it only changes with time. Each temperature sensor therefore displays the temperature of one volume-section.

The temperature variation were measured every 30 seconds. Based on the STES, the system can be divided by three circuits, that are the collector circuit, the load circuit, and the auxiliary circuit. For the collector circuit, the added energy is typically positive because heat is delivered from the solar collectors to the tank. When the temperature of STES was increased, the energy is added (i.e., positive) and it also can be mentioned that the more heat was collected from the solar thermal system than the used energy in the load side. On the other hands, when the energy delivered to the load circuit is larger than the energy collected from the solar thermal system, the temperature of STES should be decreased (i.e., negative). The energy added to the tank by the auxiliary circuit can either be positive or negative depending on the application. For the calculations presented in this article however, the auxiliary circuit does not contribute significantly to the results as it has not been activated during the time period from which the measured data was chosen. The energy added to the system through the collector circuit during time step n is calculated as follows.

$$\Delta Q_{\mathrm{C},n} = \dot{V}_{\mathrm{C},n}\left(\rho c_{\mathrm{p}} T_{\mathrm{C,in},n} - \rho c_{\mathrm{p}} T_{\mathrm{C,out},n}\right)\Delta t_n \qquad \text{(eq. 1)}$$

where $\dot{V}_{C,n}$ is the flow rate of the collector circuit in and out of the tank during time step n. $T_{C,\mathrm{in},n}$ and $T_{C,\mathrm{out},n}$ denote inlet and outlet temperature of the water stream, respectively. The length of the time step is denoted with Δt_n. Temperature-dependent values of water density ρ and heat capacity c_{P} have been used for the calculation. The energy added through the load and auxiliary circuits can be calculated in the same way as in Eq. (1):

$$\Delta Q_{\mathrm{L},n} = \dot{V}_{\mathrm{L},n}\left(\rho c_{\mathrm{p}} T_{\mathrm{L,in},n} - \rho c_{\mathrm{p}} T_{\mathrm{L,out},n}\right)\Delta t_n \qquad \text{(eq. 2)}$$

$$\Delta Q_{\mathrm{aux},n} = \dot{V}_{\mathrm{aux},n}\left(\rho c_{\mathrm{p}} T_{\mathrm{aux,in},n} - \rho c_{\mathrm{p}} T_{\mathrm{aux,out},n}\right)\Delta t_n \qquad \text{(eq. 3)}$$

The total energy added by the three circuits is the energy increase of the storage tank under ideal conditions, meaning when there is no heat loss to the environment. This energy increase is calculated as follows for one time step.

$$\Delta Q_{\mathrm{ideal},n} = \Delta Q_{\mathrm{C},n} + \Delta Q_{\mathrm{L},n} + \Delta Q_{\mathrm{aux},n} \qquad \text{(eq. 4)}$$

The change of internal energy in the tank is calculated based on the change in water temperature. For each of the nine sections the change in internal energy is calculated separately before it is added up to yield the change in internal energy for the whole storage tank. The change in internal energy is calculated directly from measurements from the first and last timestamp of the examined time period, which is typically one day. The change in internal energy for volume-section i over this time period is calculated with Eq. (5).

$$\Delta Q_{\mathrm{int},i} = V_i \rho c_{\mathrm{p}} (T_{\mathrm{S},N,i} - T_{\mathrm{S},n1,i}) \qquad \text{(eq. 5)}$$

The storage efficiency during charging is calculated by comparing the change of internal energy with the total added energy over the whole charging period:

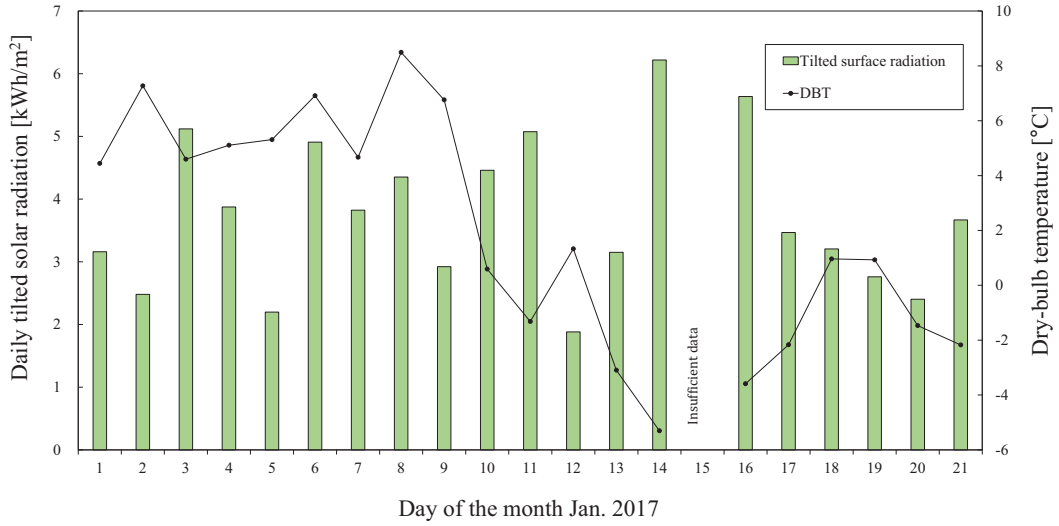
$$\eta_{\mathrm{s,chg}} = \frac{\Delta Q_{\mathrm{int},i}}{\Delta Q_{\mathrm{ideal},n}} \qquad \text{(eq. 6)}$$

4. Results

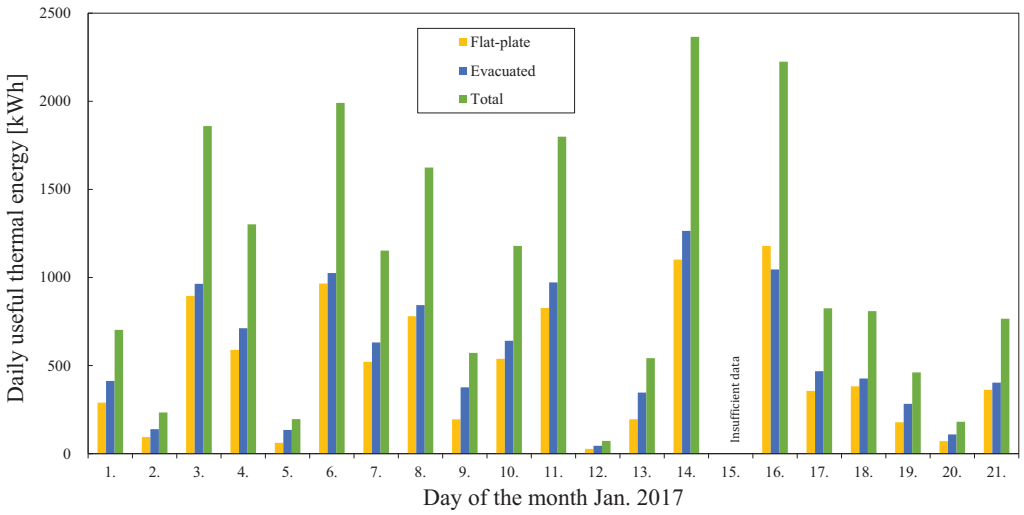
4.1 Efficiency of solar thermal collectors

The produced thermal energy difference from the solar collectors and stored thermal energy into the STES was caused by the operation time difference of the pumps in solar thermal system loop and that in STES loop. Therefore, the useful output thermal energy from the solar collectors was calculated using the water temperature difference between inlet of HH01 (TS1) and outlet of HH02 (TS3).

The trial operation test was conducted during the commissioning period. The tests were done in January 1st to 21th in 2017. As shown in Figure 4(a), during the test period, the average ambient air temperature, relative humidity, and tilted surface irradiation were ranged from -5.4 to 8.6°C, 42.1 to 75.8%, and 1.9 to 6.2 kWh/m^2, respectively. Figure 4(b) shows the produced useful thermal energy from the solar collectors in each day. One can see that the 72.5 to 2365.5 kWh of useful thermal energy could be obtained in each day. It also found that the efficiency of solar thermal collectors based on the useful thermal energy was from 2.4 to 25.4% in each day.



(a) Ambient conditions of test site

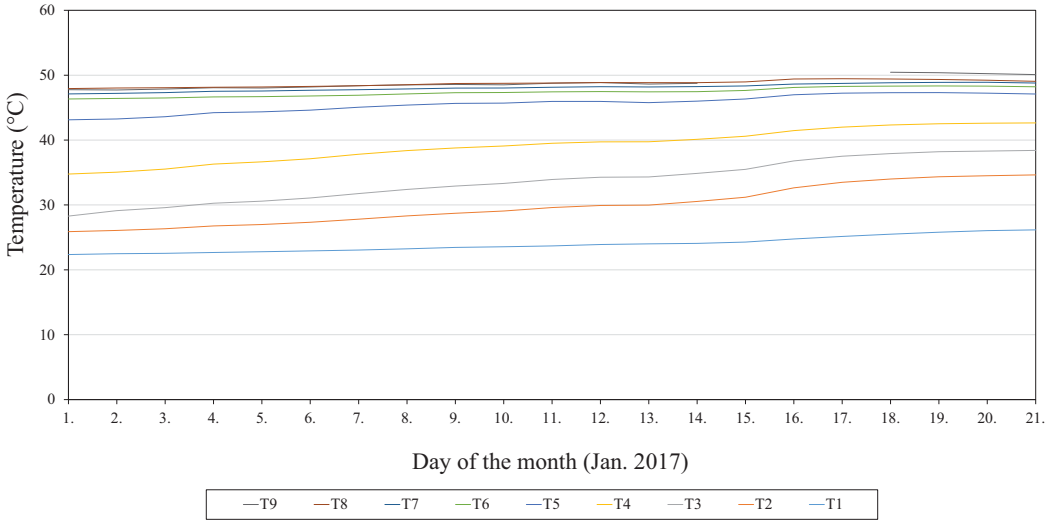


(b) Daily obtained heat energy

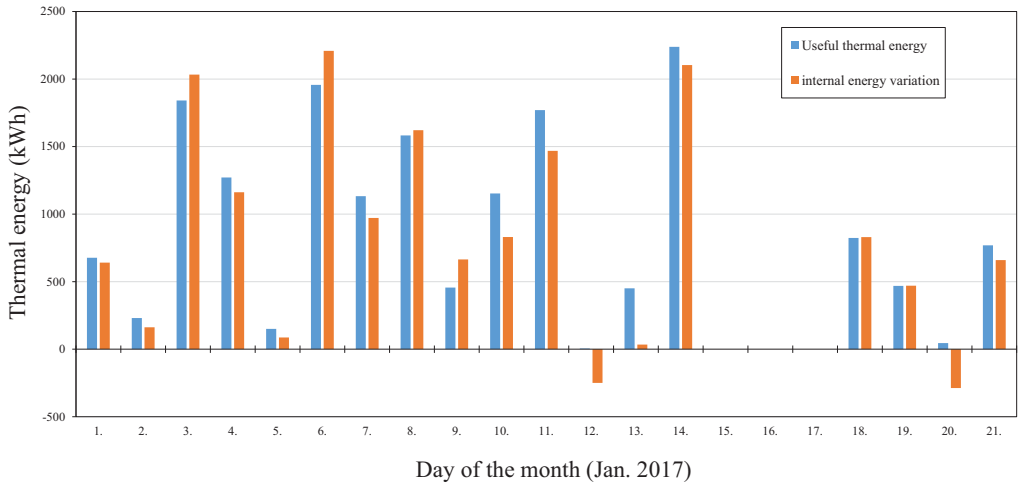
Fig. 4: Test results of solar collectors

4.2 Efficiency of seasonal thermal energy storage (STES)

Based on the produced thermal energy from the solar collectors and the internal energy variations of the STES, the efficiency of the STES was estimated. For estimating the internal energy variation, the installed nine temperature sensors were used, and the STES was divided into nine sections attributed to the nine temperature sensors. It was assumed that the water temperature within a volume-section is constant. The efficiency of STES was calculated by the change of internal energy variation in the STES over the useful thermal energy produced by the solar thermal systems. Figure 5(a) shows the comparison of the useful thermal energy and internal energy change in each day. One can see that the 90% of thermal energy storage efficiency was shown during the whole test period. As shown in Figure 5(b), the stratification of STES was well maintained during the test period.



(a) Daily heat gain compared to daily change in internal energy of the STES



(b) STES water temperatures and load circuit volume flow rate
Fig. 5: Test results of the STES

5. Conclusion

This research investigated the thermal performance of the proposed system, which was tried for the first time to use the STES in South Korea. For observing the thermal performance of the proposed system, the efficiency of solar thermal collectors and STES was estimated based on the experimental data during the commissioning period. It was found that the efficiency of solar thermal collectors based on the useful thermal energy was from 2.4 to 25.4% in each day. One can also see that 90% of thermal energy storage efficiency was shown during the whole test period.

Experimental Characterization of a Solar Combisystem with Seasonal Storage for a Single Detached House

Curtis Meister[1] and Ian Beausoleil Morrison[1]

[1] Carleton University, Ottawa (Canada)

Abstract

A solar combisystem with seasonal thermal energy storage has been designed and installed at the Urbandale Centre for Home Energy Research in Ottawa, Ontario, Canada. The system features a 28 m^2 evacuated tube solar array, 1350 litres of diurnal heat storage tanks, and a 37 m^3 buried water tank for seasonal heat storage. The single-detached research house is warmed through radiant floors supplied by either the diurnal or seasonal storage tanks, and domestic hot water is supplied with the diurnal tanks. This research aims to determine the performance of such a system over a full-scale one-year experiment, with the goal of demonstrating a high solar fraction. Preliminary results show that heat losses from the seasonal store exceed those expected from design values. Future experiments are identified.

Keywords: Solar thermal, solar combisystems, seasonal storage, solar domestic hot water

1. Introduction

The majority of energy consumed in cold-climate homes is used for space heating and domestic hot water (DHW). Our reliance on fossil fuels in the residential sector could be drastically reduced by replacing conventional space and hot water heating systems with solar combisystems. Solar combisystems provide space heating and hot water through solar-thermally-charged hot water storage tanks. Combisystems equipped with diurnal thermal energy storage (DTES) can be expected to achieve solar fractions (the fraction of energy demands met with solar energy alone) of 50-60% (Dincer and Rosen (2011), Edwards (2014)). For combisystems to achieve solar fractions approaching 100%, they will almost certainly require long term energy storage.

The focus of this research is an experimental facility equipped with a solar combisystem and seasonal storage in the form of a 37 m^3 buried water tank. In this paper, we describe the full-scale experiment that has been developed for this system and report on findings from preliminary heat loss tests. A high-level overview of the facility is given, followed by a detailed description of the system's instrumentation and control system. Finally, preliminary results of heat losses from the STES tank are presented and discussed.

2. Past Studies on Seasonal Storage

Thermal energy storage (TES) was studied extensively under Tasks 7 and 32 of the IEA (International Energy Agency) SHC (Solar Heating and Cooling) program. The programs explored many methods of thermal energy storage, including sensible, chemical and latent heat storage. Pinel et al. (2011) presented a comprehensive review of these methods for seasonal thermal energy storage, and concluded that for residential applications, sensible heat storage was currently the simplest, most cost effective and best-understood method. Indeed, most installed STES systems are simple sensible heat stores, using water or earth as a storage medium. This section briefly summarizes the relevant work in this area, particularly studies relating to STES for single homes.

2.1 Simulation Studies on Seasonal Storage

Simulation studies on STES have typically aimed to determine the optimum size of components in a solar combisystem with STES (array size, STES size). Sillman (1981) conducted simulation studies on buildings with long term heat storage, and determined that solar fractions increased with storage volume up until the "point of unconstrained operation", when all excess solar gained could be stored. Braun et. al (1981)'s simulations agreed that increasing STES volume for a constant array size led to higher solar fractions until all collected heat could be stored. Wills (2013) looked at larger STES tank volumes (80-130 m^3 for single detached homes) than the latter two studies, and found that larger tank volumes decreased solar fractions due to the lower quality of energy (exergy) that could be stored. Kemery (2017) simulated the as-built combisystem and STES tank presented in this study, and found that a high solar fraction (over 90%) could be achieved.

Losses from seasonal stores have been consistently identified as a source of uncertainty in STES models. This is largely due to the complexity involved in simulating the ground domain. Some tank models (TRNSYS Type 534, Thermal Energy System Specialists (2017)) take a simplified approach, imposing a constant boundary temperature on the tank's exterior wall. Other models, like those employed by Ochs (2009), Marazella(), and Wills (2013) employ 2D or 3D finite differencing to represent the ground temperature distribution. Pinel et al. (2011) point to a lack of consideration of a number of factors in ground heat transfer: humidity diffusion in soil, thermal coupling between the storage and house, and uncertainty in ground surface conditions. There are also uncertainties in the selection of material properties for models, particularly the thermal conductivity of insulating materials. This is treated in the next section.

2.2 Experimental Studies

Experimental facilities equipped with seasonal storage have mostly been limited to district scale systems, such as the heating system in Hannover, Germany (Ochs(2009), Raab(2005)) and Drake Landing (Sibitt et al. (2012)). However, there have been a few attempts to demonstrate STES on the single detached house scale. Most of these systems were designed for very low energy houses, and feature solar thermal arrays ranging from 10-42 m^2 and seasonal storage tanks ranging from 12-40 m^3. The interested reader is directed to the designs of Besant et al. (1979) and Esbensen and Korsgaard (1977), though neither present experimental results.

Colclough et al. (2011) present a STES system installed on a low energy home in Ireland. The system featured a 10.8 m^2 evacuated tube solar array, 300 litre DTES tank and a 23 m^3 STES tank. The system achieved solar fractions of 56% and 93% for space heating and domestic hot water, respectively. Heat losses from the STES tank were found to be more significant than predicted. The experimental heat loss coefficient found was approximately 10 W/K, despite calculations from nominal insulation properties giving 4.2 W/K (Clarke (2014)).

Other STES installations have shown higher heat losses than expected as well. Marazella's XST model was validated by Raab (2005) for the STES tank in Hannover. A parameter investigation based on measured data suggested that the thermal conductivity of the granular glass STES insulation must be approximately 0.10 W/mK. This was approximately 40% higher than the value found for dry granular glass (0.072 W/mK) when measured in a lab setting. The authors attribute this to moisture migration in the insulation and thermal bridging in the tank support materials. It is clear from the literature that care should be taken when using nominal insulation properties in designing and simulating STES tanks.

3. Experimental Setup

This section provides an overview of the design of the research home and solar thermal system, as well as its instrumentation and control system. The section concludes with a brief discussion of cooldown tests commenced to determine heat loss rates in the STES tank.

3.1 The Urbandale Centre for Home Energy Research

The Urbandale Centre for Home Energy Research (CHEeR) is an experimental research house built to study various innovative home energy systems. The house, pictured in Figure 1, contains a basement and two above-ground storeys with 149 square-meters of heated floor area. The house was intended to exceed current Canadian energy standards (i.e. R-2000) but to remain realistic under current building practices. The east, west and south walls have a nominal U-value of 0.21 W/m^{2}K, while the north walls are more heavily insulated at 0.12 W/m^{2}K. The attic is freely ventilated, and contains blown-in insulation with a U-value of 0.11 W/m^{2}K. The basement slab is insulated with rigid foam board with a U-value of 0.36 W/m^{2}K, and the basement walls have a U-value of 0.21 W/m^{2}K. The building's airtightness at 50 Pa depressurization was measured to be 1.3 ac/h. Almost all of the windows are placed on the south side of house to maximize solar gains. The total south-facing window area of the house is 20 m^2. All windows are triple-glazed with an argon fill and two low-emissivity coatings.

CHEeR has several redundant heating and cooling systems. An air-source heat pump connected to rock bed heat storage can heat or cool the house. An extensive hydronic network connects an evacuated tube solar array with one of two buried seasonal stores; a large insulated sandbox and a large buried water tank. The collectors can also charge a number of smaller hot water tanks for diurnal storage and to provide DHW. The hydronic network can supply either a radiant floor or a hydronic air handler.

The house is equipped with a large suite of instrumentation. Indoor air temperatures are measured at several locations on each storey using shielded, aspirated thermocouples. On the roof sits a weather station that can measure outdoor air temperature, humidity, and wind speed. A number of pyranometers measure direct and diffuse radiation on the horizontal, vertical and collector tilt (60°) planes.

3.2 Solar Combisystem with Seasonal Storage

The solar thermal system used in this research is shown schematically in Figure 2. The solar array consists of ten Apricus AP-30 evacuated tube collectors in two parallel lines of five. The collectors face south, and are tilted at 60° to bias solar collection towards winter. An antifreeze solution consisting of 60% Intercool Biogreen and 40% water is run through the collectors to prevent freezing in winter. Actuated valves allow the solar array to charge either the diurnal storage tanks or the seasonal storage tank. The antifreeze solution indirectly charges these loads through heat exchangers.

The diurnal store consists of three insulated 450-litre tanks. The primary diurnal tank, Tank A in Figure 2, is charged through an immersed-coil heat exchanger. A circulator pump can move hot water from the primary tank (A) to the secondary and tertiary tanks (B and C). Tank A is used to supply DHW to a load mimicry system, while Tanks B and C can provide hot water to the radiant floor. The seasonal storage tank is used only for space heating, and can heat the radiant floor through a heat exchanger.

Because the research home does not have mains water connection, domestic hot water draws must be mimicked experimentally. To do this, the solar collector loop is used to cool two 450 litre "DHW mimicry" tanks overnight. Flow in the collector loop is directed through heat dissipators mounted on the northern roof of the research house, which cools the DHW tanks through a heat exchanger. To mimic draws, water is exchanged between DTES Tank A and the DHW mimicry cool tanks. Hot water draws follow a typical Canadian hot water draw schedule developed by Edwards (2015)

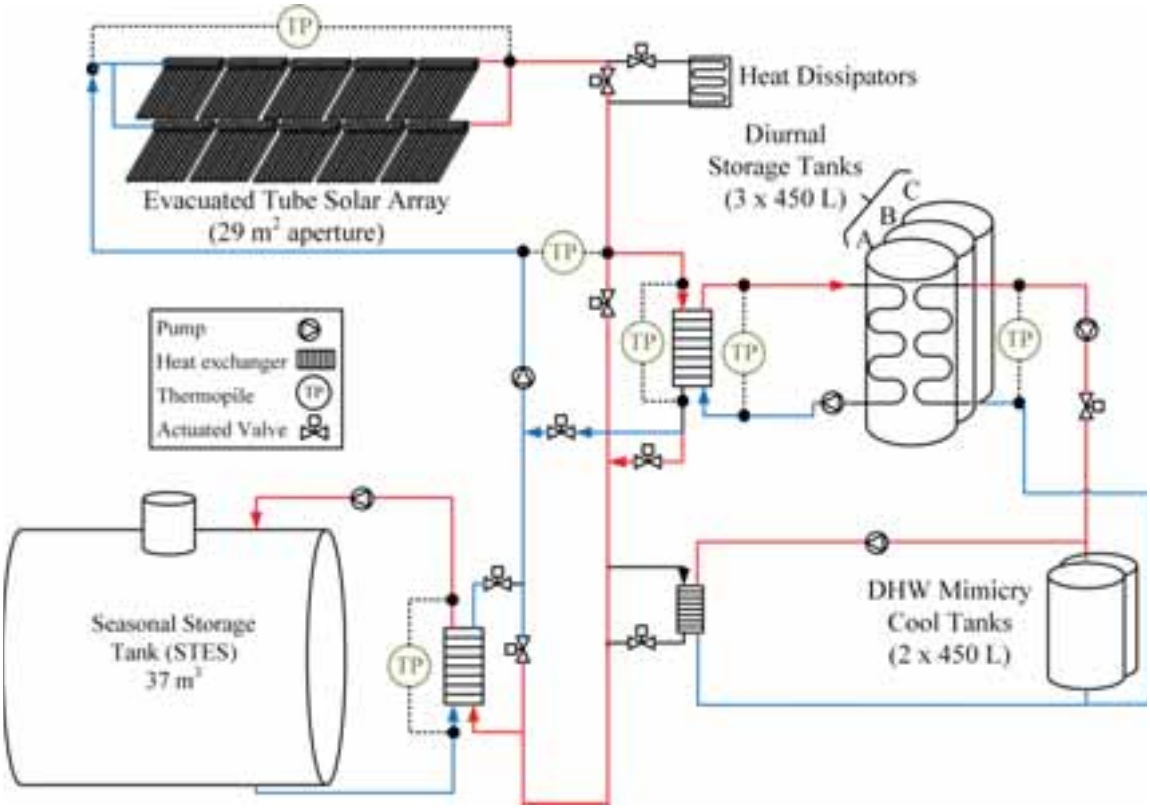

Fig. 2: Simplified schematic of CHEeR's solar thermal system with seasonal storage

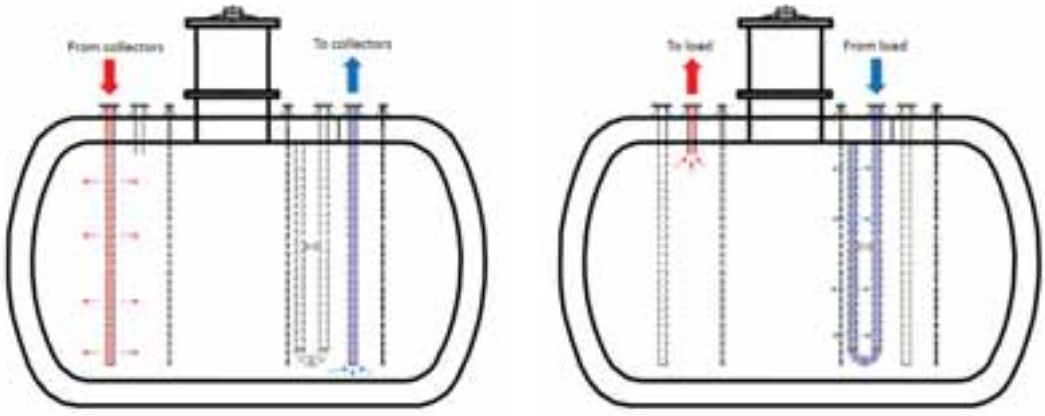
The seasonal storage tank (Figure 1.b) couples to the collector loop (Fig. 2) and radiant flooring loop (not pictured) through heat exchangers. The tank is approximately 37 m^3 in volume, and features two sets of inlets and outlets for charging and discharging (Figure 3). The tank inlets and outlets were designed to promote stratification in the tank; the pipes are 10 cm in diameter to produce low flow velocities, and the inlet tubes are perforated to encourage water to reach its appropriate temperature level. The perforations are 9.5 mm in diameter and spaced 5 cm apart vertically. The tank was insulated with 30.5 cm of spray-on polyurethane insulation, which gives it a nominal U-value of 0.075 W/m^2K.



a) b)

Fig. 3: Seasonal storage tank, with a) solar charging inlet and outlet, and b) space heating inlet and outlet

The tank's access hatch is above ground. To insulate the hatch, a small structure was created. Figure 4 shows a cross-sectional view of the hatch insulating structure. Five sheets of 7.6 cm rigid foamboard (nominally RSI 2.6 each) surround the hatch on each side. The cavity formed between the foamboard and hatch is stuffed with batt insulation (not shown). The foamboard pieces are affixed to one another with adhesive spray foam. The foamboard structure is surrounded by an air barrier, which is buried under a layer of soil. The design U-value of this structure is intended to match that of the tank's insulation (0.075 W/m^{2}K).

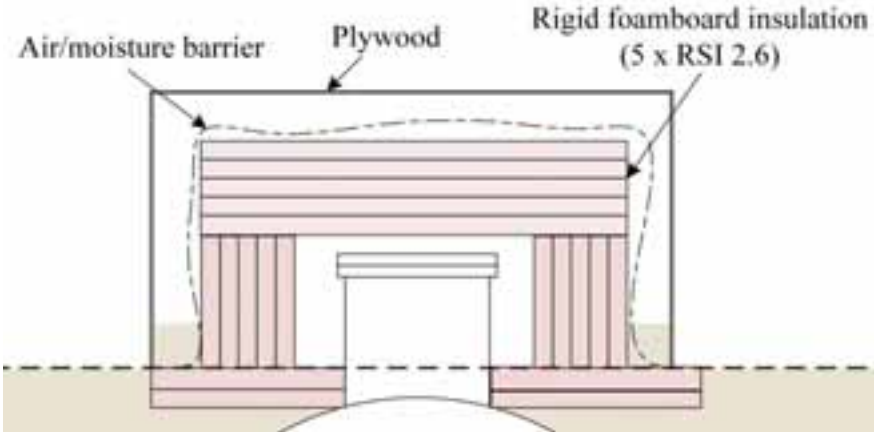


Fig. 4: Insulation of the STES access hatch

2.3 Instrumentation

We are primarily interested in measuring heat transfer rates within the solar thermal system. Heat transfer rates can be determined using the 1st law of thermodynamics and by treating the fluid (water or antifreeze) as an incompressible with constant density and specific heat:

$$\dot{Q} = (\rho c_p)\big|_T \dot{V} \Delta T \qquad \text{(eq.1)}$$

Where $\dot{V}$ is volumetric flow rate and ΔT the temperature rise in the fluid. Volumetric flow rates are measured by positive displacement oval gear flowmeters, which are manufacturer-calibrated to a bias error of ±1% of reading.

Temperature differences are measured with six-junction thermopiles. An example of a typical heat transfer station is shown in Figure 5.

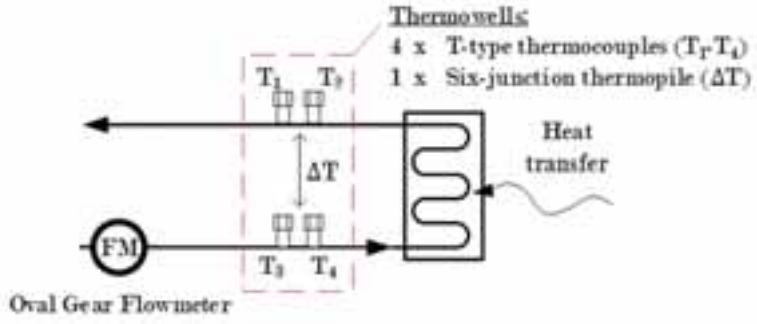

Fig. 5: Example of instrumentation on a heat transfer station

The thermopiles were calibrated using highly accurate platinum RTDs, and the bias error was calculated according to the methods detailed by Moffatt (1988) considering all sources of error. This included the voltage reading error of the data acquisition system, curve-fitting errors, and the bias error of the platinum RTDs themselves. Assuming negligible uncertainty is associated with material properties (density, specific heat), the total bias error for heat flows is less than 2% for temperature differences of 3°C and above. Some (but not all) thermopiles are shown on Figure 2. Eleven heat flows are monitored in total.

Stratification and heat loss performance of the seasonal storage tank can be inferred from three vertical racks of

25 T-Type thermocouples (Figure 3) that are immersed along the tank's vertical mid-plane. As with the thermopiles, a calibration was performed on the thermocouples. The bias error associated with a single thermocouple measurement was found to be 0.45°C when all sources of bias were considered.

2.4 Controls

The control scheme for the solar thermal system was designed to be similar to Wills (2013) and Kemery (2017). While it is almost certainly non-ideal, it was selected for its simplicity and ease of implementation in preliminary experimentation. Future work will examine optimum control configurations, for instance, the use of variable speed pumps to increase collector temperatures during low irradiance. The control algorithm is written in NI LabVIEW (National Instruments, (2017)) which runs in real-time on three NI data acquisition (DAQ) systems, which in turn actuate the pumps and valves in the system.

The control scheme for solar charging is given in Figure 6. When a given level of solar irradiation on the collector plane or sufficient collector temperature is sensed, the solar collector pump is triggered. If hot enough to charge the loads in the system (i.e. the collector outlet temperature T_{coll} exceeds the load temperature plus the "on" setting ΔT_{ON}), the algorithm selects a load to charge based on a pre-set priority list. The highest priority load is DTES Tank A. The tank is maintained at a set point T_{DHW} so that it can always supply domestic hot water. When charged in heating season, DTES B and C are prioritized over the seasonal store. If the system is charging the DTES, the temperature of the antifreeze after the DTES heat exchanger is sensed to see if it exceeds the mean seasonal store temperature. If so, the seasonal store is charged in series with the DTES. If the collector temperature falls below a certain level (determined by the load temperature plus setting ΔT_{OFF}), the solar pump is shut off.

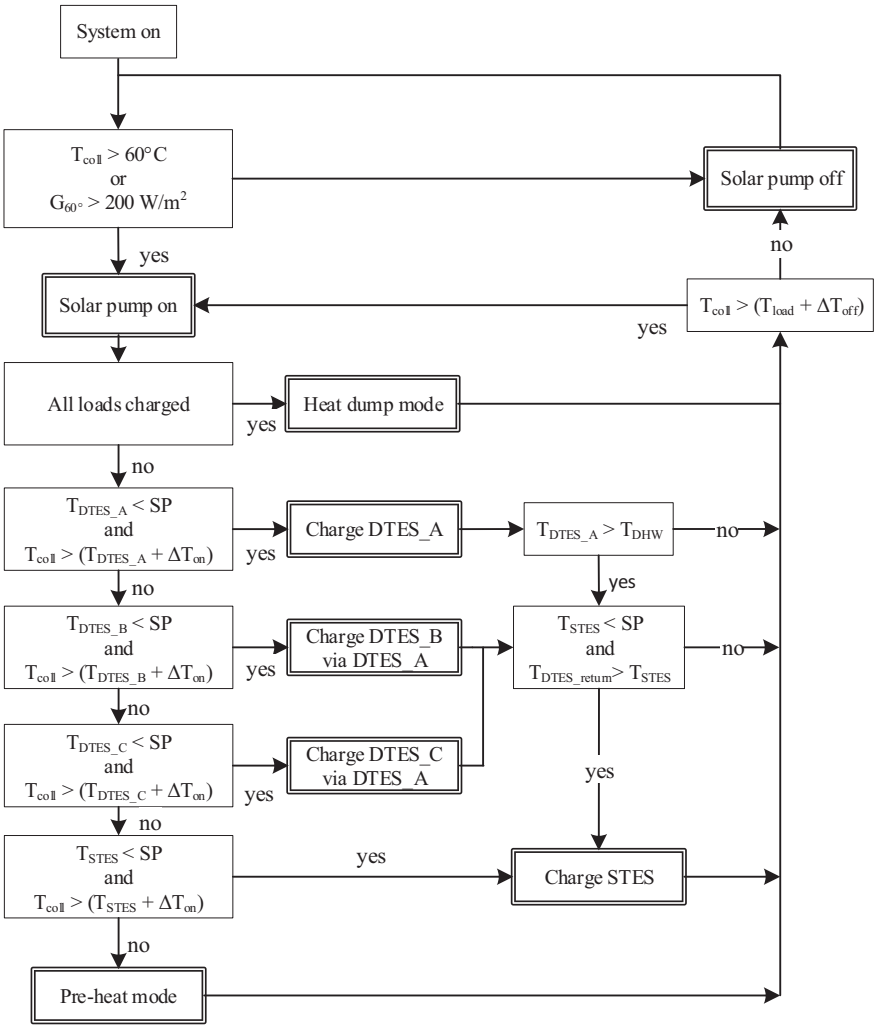

Fig. 6: Control strategy for charging the solar thermal system

A description of the control variables mentioned in Figure 6 are given in Table 1.

Tab. 1: Description of solar control parameters

Variable	Setting
T_{coll}	Temperature determined by an RTD placed on the solar collector
$G_{60°}$	Solar irradiance measured by a pyranometer on the collector plane
SP	Set point
T_{DTES_i}, T_{STES}	Temperature of a diurnal tank *i*, temperature of the seasonal storage tank
T_{load}	Temperature corresponding to the current load being charged

3.4 Cooldown Tests

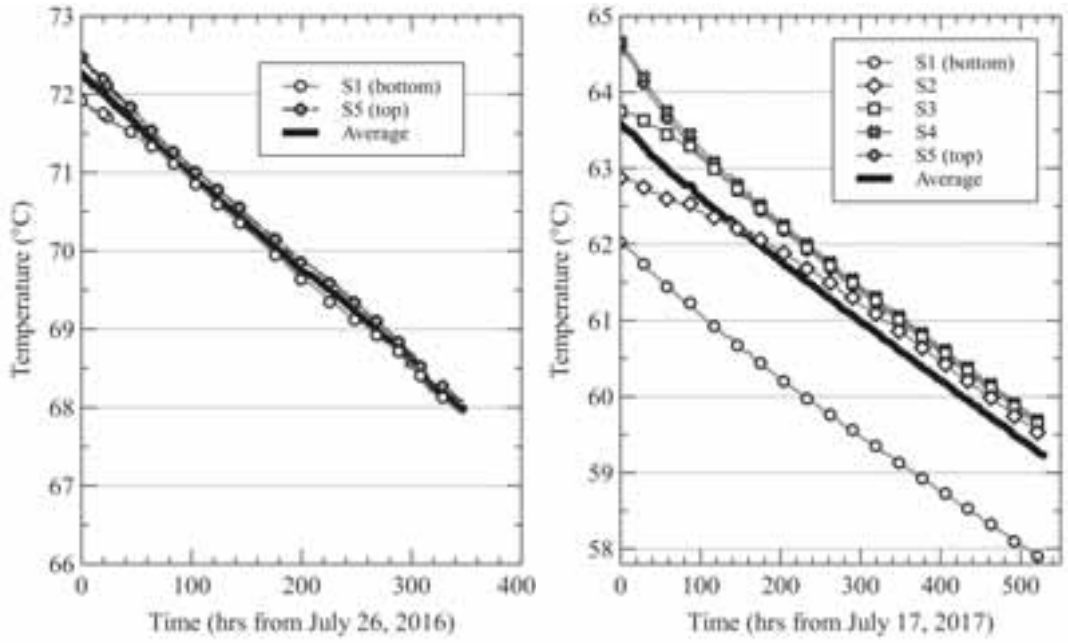
The ability of the seasonal storage to preserve thermal energy has obvious implications on its yearly performance. Two cooldown tests of the seasonal store, performed in July of 2016 and 2017 respectively, show early indications of the tank's heat loss performance. During the cooldowns, solar charging of the tank was ceased so that all energy transfer could be attributed to heat losses. The temperature distribution in the tank was then monitored over 2-3 weeks. During the July 2016 test, the tank began the test well-mixed at an average temperature of 72.2°C, while in 2017 the tank began approximately 5°C hotter at the top than bottom with an average temperature of 63.6°C. The results of these tests are given in the next section.

4. Results

Cooldown results for both tests are given in Figure 7. Results are given for the average temperature of 5 stratums within the tank, each containing 5 thermocouples (S1 through S5) from each of the three thermocouple racks. No significant temperature differences were found between the three thermocouple racks in the tank.

For the well-mixed test, the average heat loss rate was 530 W. No development of natural stratification due to heat loss is apparent during this time, and similar heat loss rates are seen in all layers of the tank. The stratified cooldown shows accelerated temperature loss at the top and bottom of the tank (S1, S5) relative to the middle layers. Destruction of stratification can be seen as layers S2 through S5 converge to a similar temperature around 300 hours. However, the bottom layer of the tank remained 5°C below the top layer throughout the test. The average late of heat loss for this test was approximately 350 W.

In both test cases, measured heat loss rates exceed expected values. According to Kemery (2016), even if a conservative ground temperature of 10°C is assumed, heat loss rates for a 72°C tank with 0.075 W/m^{2}K insulation should not exceed about 285 W. It is possible that these higher than expected losses are the result of heat loss from the tank's above-ground access hatch. It should be noted that during the 2016 tests, the foamboard sheets used to insulate the hatch did not extend underground as shown in Figure 4. Instead, they simply sat on the ground surface. The air barrier was also not installed until 2017. Hatch losses would not explain higher than expected losses from the bottom layer of the tank. Moisture migration in insulation is a typical cause for greater than expected losses, but this is deemed unlikely, as product specifications show the spray-foam insulation to be unaffected by moisture content. Further, the tank has a double-wall construction that should prevent moisture migration. Thermal bridges within the insulation are another possible explanation. Thermal bridges could be caused by either structural members within the tank or non-uniformities in the insulation coverage.



a) b)

Fig. 7: Temperature loss during seasonal storage cooldowns with a) well-mixed and b) 5°C stratified starting conditions

Regardless, as evidenced by the work of Colclough (2011) and Raab (2005) referenced earlier in this paper, excess losses appear to be a common trend with buried STES tanks, and may not indicate poor performance for the combisystem. Kemery (2016) performed a sensitivity study wherein the ground temperature was varied from 5 to 25°C. The ground temperature was used as a constant boundary temperature for the seasonal store. Simulation results showed that the solar thermal system's performance was not particularly sensitive to heat losses. This might be explained by the relatively high ratio of collector area to storage volume at CHEeR; lost heat can be quickly recovered by the large array. However, even with an imposed 5°C boundary temperature, predicted heat losses were less than those found through experiment. Predicted losses ranged from 6.9 to 9.5 GJ yearly. If we consider the experimental heat loss tests to represent typical average losses for the year, approximately 11 to 17 GJ of heat would be lost from the as-built tank yearly. That would represent 16 to 28% of the total solar energy collected by the solar array, based on Kemery's estimation of 60-70 GJ collected yearly. It should be noted that at the time of writing, the seasonal storage tank has only undergone one full annual charge and discharge cycle. It is possible that the surrounding ground is still in a transient state; that is, heat losses from the tank could be reduced as the ground warms up. Kemery (2016) notes that 4 years of simulation were required before the STES system reached a consistent cyclical behavior.

5. Conclusions and Future Work

This paper has presented an overview of the design of a solar combisystem with seasonal thermal energy storage. The system's components, instrumentation and control system were described. Preliminary results from heat loss tests show that the seasonal storage tank loses heat at faster rate than would be expected based on nominal properties of the insulation. Explanations for larger than expected losses are postulated, including losses through the access hatch and thermal bridging.

Future work will quantify the energy performance of the solar combisystem over a full heating and cooling season. A model of the as-built seasonal storage tank will be developed and validated in TRNSYS software (Thermal Energy Storage Specialists (2017)), and coupled to a full building model of the CHEeR house in ESP-r (Energy Systems Research Unit, University of Strathclyde (2017)), following the work of Wills (2013) and Kemery (2016). Parametric studies will re-examine the sizing and control of the solar combisystem, and multi-objective optimization will be performed for system performance and economic consideration.

Design and optimization of a De-centralized community sized solar heating system for Nordic Region

Hassam ur Rehman[1,*], Janne Hirvonen[1] and Kai Siren[1]

[1] Aalto University, School of Engineering, Department of Mechanical Engineering, HVAC group, PO Box PL 14400/Vi 351, 00760 Aalto, Finland

Abstract

There is a need to accelerate the application of advanced clean energy technologies to resolve the challenges of climate change. Solar heating is a feasible solution among clean energy technologies. These technologies are not yet highly used in high latitudes due to various challenges. This paper focuses on the community sized solar district heating system configuration for cold climates. The proposed configuration consists of a partially de-centralized heating system. Each individual house heat pump was connected between large centralized solar-charged low temperature tank and smaller de-centralized individual high temperature tank in each house. Additionally, the large centralized tank was directly charged by solar-charged borehole storage during winters. Dynamic simulation approach was used through TRNSYS software coupled with MOBO (multi-objective building optimizer) for NSGA-II optimization algorithm. The purchased electricity and investments were two objectives minimized. The impact of the energy system on the renewable energy fraction, purchased electricity and investments as a function of the building heating demand, collectors and photovoltaic areas, short-term tanks storages and boreholes volumes were evaluated. Results showed that purchased electricity varied 47 kWh/m^2/yr—25 kWh/m^2/yr and renewable energy fraction 75%—91%.

Keywords: De-centralized solar district heating, multi-objective optimization, cold climate, seasonal storage.

1. Introduction

Buildings are one of the largest consumers of the energy in European Union (EU). They consume around 40% of the total energy (Nielsen, 2012). Buildings in the urban and community setup play a significant role in the energy demand of the community. Furthermore, in Finland huge amount of energy is being used by space heating and domestic hot water for the residential buildings. This causes large emissions of CO_2 (Official Statistics of Finland (OSF), 2016). Therefore, with increase in the emissions, and interest on the environmental impact of residential areas, there is an increased interest in using of renewable energy for the buildings. Solar communities can provide a good alternative to the conventional communities that are being provided with fossil based heat energy. These community concepts have not been built at high latitudes in cold regions such as Finland. The cold temperature, demand and supply mismatch and expensive storage system does limit the operations of such systems in building heating requirements. On the contrary, solar thermal can be used effectively if designed properly. It is important to mention that designs and parameters cannot be used directly from other locations as each location has different conditions and climate (Flynn & K.Siren, 2015).

Solar district heating is a very promising alternative to fossil fuel district heating. Solar thermal (ST) systems are key technologies for achieving emission reduction goals. Their use is spreading in European countries. In Europe, there are around 141 heating plants which have more than 500 m^2 solar collector area (Dalenbäck & Werner, 2012). Since 1979 onwards several countries have participated in operating central solar heating plants with seasonal storage under IEA Task 7 to boost the progress of large scale heating technologies (International Energy Agency Solar Heating and Cooling Programme, IEA-SHC, Task 7, 2016). Since 1980s onwards, in Germany many plants have been built that provide district heating via solar thermal energy (Schmidt, et al., 2004). In Denmark, due to its competitive price in comparison to biomass and gas there is a boom in the solar district heating market (Nielsen, 2012). Similarly, many solar district networks are built in different parts of the Europe and North America. For instance, there are large scale pilot plants located in Norway, Denmark, Sweden, the Netherlands, Canada and the USA that uses solar energy with seasonal storage (Nielsen, 2012),

doi:10.18086/swc.2017.29.09 Available at http://proceedings.ises.org

(Solar District Heating, 2016), (Mangold, 2007), (M. Lundh, 2008), (Bauer, et al., 2010). It is found that community-scale solar energy systems are economical even without support payments. Community-scale allowed the use of seasonal thermal storage, which is a key technology for achieving a high degree of utilization of solar energy in Finland. However, no such community has been built in Finland yet. Instead of zero energy buildings, the focus should shift to developing zero energy communities, which can benefit from the best features of both distributed and centralized energy systems (Hirvonen, 2017). The reason and the challenges to build such community in Nordic region are: (a) the energy cost is still not yet competitive enough and (b) solar energy is not typically available when needed.

In community sized system, the energy storage plays an important role to improve the performance of the system. Moreover in Nordic conditions where the mismatch between the irradiation and demand is significant, seasonal storage is vital. Using thermal storage for viable solar energy utilization through solar thermal panels to meet building heat loads becomes an important discussion. Excess energy generated during long summer hours can be stored for seasonal periods (Kalaiselvam & Parameshwaran, 2014). Seasonal thermal storage stores thermal energy when solar radiation is abundant. The cost and size of the seasonal storage are important factors that influence the decision while choosing the type of seasonal storage to be used in such solar community concepts. Ground thermal energy storage has cost advantage due to its size and capacities compared to short term tanks storage (Fisch, et al., 1998), (Rad & Fung, 2016). However, ground storages have higher losses issues due to ground conductivity. Therefore, the properties of the ground, time of storage, temperature, location and geometry are critical (Nordell, 2000). Sensible thermal storage collects energy by increasing the temperature of a medium with finite heat capacitance (typically water) (V.Novo, et al., 2010). It is stored in a variety of medium for the use during winters. The most prominent modes of storage found in the literature are: (1) Hot Water Energy Storage (HWTES), (2) Gravel-Water Thermal Energy Storage (GWTES), (3) Aquifer Thermal Energy Storage (ATES), and (4) Borehole Thermal Energy Storage (BTES) (Schmidt, et al., 2004). Each method provides certain advantages such as location, capacity and cost. Among these four methods, BTES is the most flexible storage technique (Rehman, et al., 2017) and therefore is the primary focus of this analysis.

It is found that in most of the existing solar communities the focus is on space heating demand (SPH). This approach minimizes the heat losses in the seasonal storage (Chapuis & Bernier, 2009). This low grade temperature present in the seasonal storage can be increased using a heat pump. Heat pump (HP) can be used with the ground with any combination, i.e. regardless the ground is charged or not via solar energy. It is found that charging of the ground can improve the heat pump performance as the evaporator temperature increases. Hence, it improves the coefficient of performance (COP) of the heat pump (Rehman, et al., 2017). The heat pump can be integrated with the solar thermal system in multiple ways and with varying control strategies. The way and the strategy used to integrate the heat pump can also vary the overall solar thermal system performance and behaviour. In this study, a particular methodology is described to integrate HP with the solar thermal district network.

The novelty in the present study is the proposed partially de-centralized solar district heating system and the multi-objective optimization of such system. The proposed system has a centralized large tank that is at lower temperature and provides most of the space heating. While the de-centralized part consists of a small tank in each individual house that operates at higher temperature, it is being charged by the centralized tank and heat pump, and part of the space heating along with domestic hot water is provided through this tank. In this configuration the placement of the heat pump, hot short term storage tank and the overall control strategy is altered compared to the previous studies (Rehman, et al., 2017), (Sibbitt, et al., 2012). In the previous study carried out, the heat pump is centralized with the two large centralized short term storage tanks charged via solar energy and seasonal storage in parallel (Rehman, et al., 2017). These large tanks are divided into warm and hot tanks in order to meet the space heating (SPH) and domestic hot water demand (DHW) of the community respectively (Rehman, et al., 2017). Whereas in the present study, instead of a large centralized hot tank, a small tank is places in each of the 100 houses. Similarly, instead of a centralized large heat pump, 100 small sized heat pumps are distributed among the 100 houses to charge the small hot tank. Furthermore, only the large centralized warm tank is charged by the solar energy, and the small hot tank is charged via the heat pump directly instead of the solar energy. Likewise, the difference between the present study and the Drake Landing Solar Community, Canada is that for domestic hot water a dedicated individual collectors and natural gas heaters is installed to provide hot water (Sibbitt, et al., 2012). On the contrary in the present study, the individual

house hot tank is charged via heat pump using energy from the centralized solar heating network. The aim of this research is to design, optimize and assess the performance of such de-centralized solar thermal district heating system in Nordic location. The challenges mentioned above are addressed. The impact of the mentioned configuration of solar and ground loop on the annual energy consumption is evaluated. In particular the influence of varying solar thermal (ST) size, short-term storage tank volume, borehole (BTES) size, photovoltaic (PV) size, and building heating demand on the purchased electricity, investments and renewable energy fraction are evaluated. The energy system is designed by using dynamic simulation software i.e. TRNSYS (Thermal Energy System Specialists, LLC, 2012) and then optimized using multi-objective optimization algorithm (NSGA-II) where the purchased electricity and investments are minimized.

2. Methodology

The paper focuses on the modelling and the multi-objective optimization of the de-centralized community sized solar district heating system. Therefore the energy system is first design on dynamic simulation software i.e. TRNSYS (Thermal Energy System Specialists, LLC, 2012) and then the model is optimized using multi-objective optimization algorithm (NSGA-II) (Hirvonen, 2017) where purchased electricity and investments are minimized together. Renewable energy fraction (Hirvonen, 2017), (Rehman, et al., 2017), final purchased electricity, and investment costs (IC) are calculated to evaluate the system.

2.1. Energy system

The energy system consists of ST collectors, short-term tanks, boreholes, PV modules, heat pumps and buildings. The energy system is designed based on Drake Landing Solar Community (DLSC), Canada (Sibbitt, et al., 2012) as it has shown good performance in cold climatic conditions.

The solar energy system is used to provide DHW and SPH through the network and secondarily for charging the ground. The control is designed in a hierarchical pattern. Solar thermal pump draws the cold water from the large centralized low temperature tank bottom and into the heat exchanger to collect heat from solar collector loop. Meanwhile, heated water from collector transferred heat to the centralized tank directly via heat exchanger after attaining the desired temperature based on the set point. For this study, temperature tracking control mode is selected where the collectors typically aims for an outlet temperature that is one degree higher than the warm tank top temperature connection for charging (ur Rehman, et al., 2016).

If the large centralize tank temperature is lower than 40 ^{o}C, it is heated to 45 ^{o}C. Excess heat from solar collectors is transferred to BTES to avoid overheating of this large tank. Heat from storage tank is transferred when tank temperature reached 50 ^{o}C and stopped once the temperature dropped to 45 ^{o}C. If energy from solar collectors is not available, heat can be transferred back from BTES into the centralized tank directly. If the centralized tank temperature is less than 35 ^{o}C and the BTES average temperature is higher than the tank top temperature, the energy is transferred via BTES and tank is charged till 40 ^{o}C. The cold fluid entered from the cool outer edge of the BTES and exits from the hot centre. Low temperature is maintained in the collectors and centralized tank circuit to improve the collectors' efficiency. The energy from this centralized large tank is distributed in the low temperature space heating district heating network of the community. Moreover, the space heating return network is used by individual heat pump (NIBE, 2017) present in each of the 100 houses in the community to heat each of the small sized hot tanks present in each of the houses. If the hot tank temperature is lower than 60 ^{o}C, it is heated to 65 ^{o}C by the heat pump.

The space heating is provided by passing the space heating (SPH) water through the warm tank and then through the bottom node of the small hot tank. This heated water is then provided to the houses at temperature between 30 ^{o}C to 40 ^{o}C depending upon the outdoor temperature. Domestic hot water (DHW) is provided to houses by passing the cold water from the bottom of the hot tank and till the top of the tank until it reached the desired temperature of 60 ^{o}C. If the heat pump and solar energy are not enough to meet the temperature needs, backup heating is handled by direct electric heaters. A schematic representation of the system is shown in Fig. 1. The centralized section of the energy system i.e. solar thermal collectors, seasonal storage and warm tank along with de-centralized section of energy system i.e. the heat pump and the hot tank in each house is shown in Fig.1.

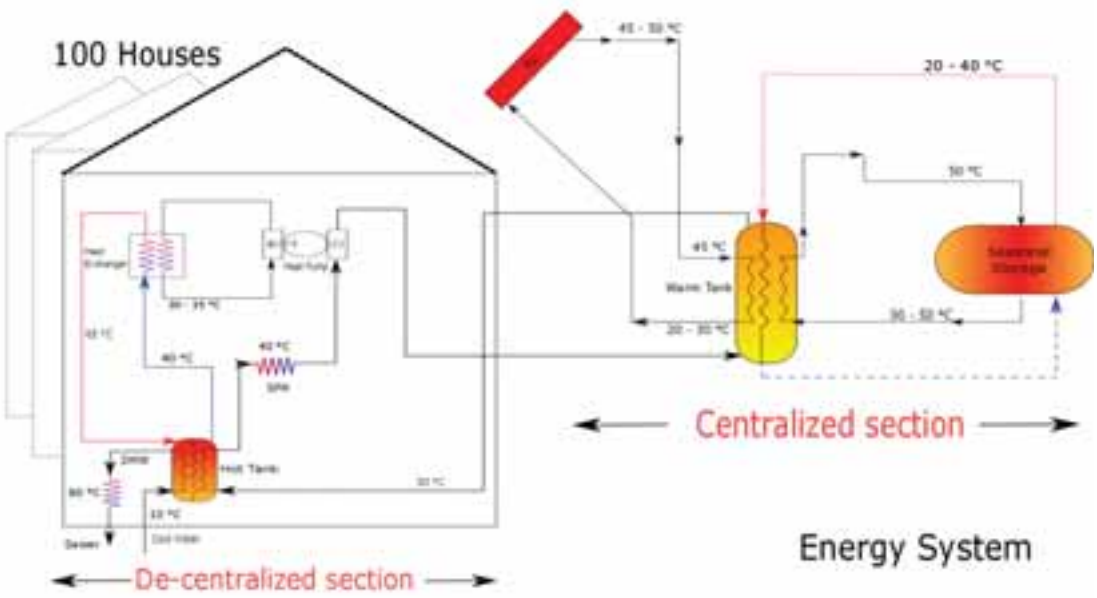

Fig. 1: Simple schematic representation of the partial centralized and de-centralized energy system.

2.2. Simulation environment

A 100-house community is studied, located in Helsinki, Finland. The system is simulated using TRNSYS simulation studio (Thermal Energy System Specialists, LLC, 2012). TRNSYS type 1b, type 543, type 557a, type 668, type 194 and type 15 are used for solar thermal collectors, buffer tanks, boreholes, heat pump, photovoltaic panels and weather data respectively (Rehman, et al., 2017). The buildings are built and simulated in TRNBuild (Thermal Energy System Specialists, LLC, 2012), a subroutine of TRNSYS that generated the thermal loads profile of the building. Each house is a single story house and has pitched roof with a tilted angle of 20°. Three different types of buildings with varying heating demands are selected for the study. Buildings with space heating demand (SPH) of 25, 37 and 50 kWh/m^2/yr are selected. The domestic hot water (DHW) demand is 45 kWh/m^2/yr and electricity appliances demand is 40 kWh/m^2/yr for all three building type cases (Hamdy, et al., 2013). For optimization, TRNSYS simulation model was integrated with the NSGA-II algorithm by optimization integrator software i.e. MOBO also known as multi-objective building optimizer (Hamdy, et al., 2011).

2.3. Optimization problem

In district heating system the optimization problem deals with multiple objectives of conflicting nature. Therefore, in this study the optimization problem consists of minimization of purchased electricity and the investments as both are of conflicting nature.

2.4. Objective functions

In this study, purchased electricity and investment costs (IC) are set as objective functions to be minimized. The purchased electricity and investments costs (IC) are of interest because purchased electricity is in the interest of the user and the investment is in the interest of the contractors and construction companies.

The solar energy system is simulated together with the houses energy demand. Two functions that are analysed are the purchased electricity and the investment costs (IC) together. It is given as:

Min, {F1 (x) = Purchased electricity, F2(x) = Investment cost(IC)} for all x= $[x_1, x_2, \dots, x_6]$,

where 'x' is the vector of the design variables (x_1, x_2, …, x_6) as defined above, F1 is the purchased electricity for the system and F2 is the investment cost of the system. In this problem, the number of considered design variables are six (i.e., x= $[x_1, x_2, \dots, x_6]$). MOBO is integrated with TRNSYS simulation to perform multi-objective optimization. NSGA-II algorithm is used to perform optimization.

The mathematical expression for purchased electricity is,

$$E_{PUR} = E_{PUMP} + E_{HP} + E_{BH} + E_{BUL} - E_{EXP,} \quad \text{(eq. 1)}$$

where E_{PUR} is the purchased electricity, E_{PUMP} is the energy consumed by all pumps, E_{HP} is the heat pump energy consumed to heat the hot tank, E_{BH} is the energy use of the direct electric backup heating, used to maintain the temperature in the space heating and domestic hot water network in case heat pump and solar energy is not sufficient, E_{BUL} is appliance electricity demand of buildings and E_{EXP} is the excess electricity that is produced by PV panels and exported.

The second function, investment cost is the sum of the present value of the investments cost of the system. It is expressed as,

$$IC = C_{ST}+C_{PV}+C_{BTES}+C_{WT}+C_{HT}+C_{B}, \quad \text{(eq. 2)}$$

where IC is the overall investment cost, C_{ST} is the solar collectors, C_{PV} is the photovoltaic, C_{BTES} is the borehole, C_{WT} is the warm tank, C_{HT} is the hot tank and C_B is the building costs. No maintenance costs are considered. The system is simulated and optimized in parallel for the three years to allow the slow temperature rise in the BTES to take effect.

2.5. Design variables

The energy performance of the energy systems may depend mostly upon the six parameters or design variables which are defined and considered in this paper (Idman, 2013). These are the parameters that can be altered by the designer. The importance of these parameters can vary depending upon the system configuration. The six parameters considered in the system are: (1) ST collectors area, (2) hot tank volume, (3) warm tank volume, (4) BTES volume, (5) photovoltaic area, and (6) building heating demand.

The values of all the design variables and investment costs of design variables are shown in Table 1 including the selected buildings. A constant unit price is used for some energy system components. On the other hand the costs of some design variables are assumed to vary depending upon its size. The cost of the collectors varied as found in the study, large collector field tends to be much cheaper compared to smaller field, caused by economies of scale (Mauthner & Herkel, 2016), (Ahola, 2015), (Dalenbäck & Werner, 2012), (Hirvonen, 2017). The collectors used in the study are roof mounted solar collectors which are expensive compared to ground mounted collectors (Mauthner & Herkel, 2016). Finnish market is still under development therefore higher prices can be assumed for the collectors, tanks and PV panels (including taxes). In Crailsheim, Germany borehole thermal energy storage (BTES) is used as seasonal storage therefore, same cost is used here for BTES cost (Schmidt & Miedaner, 2012). The cost of the BTES is assumed to be constant per unit volume (includes drilling, insulation, construction and taxes) as shown in Table 1. It is computationally expensive to explore all designs. Hence, a multi-objective non-dominated sorting genetic algorithm (NSGA-II) is used to perform the simulation (Hamdy, et al., 2013). MOBO uses NSGA-II algorithm with an initial population of 16 individual for 100 generations i.e. 16 x100 = 1600 simulation run.

Tab. 1: System configuration variations for the simulations and investment cost of the components used in energy systems.

Design variables	Type of variables	Ranges/ Values	Prices (€)	Options
Roof mounted solar thermal area (m^2)	Continuous	50—6000	1000—550 €/m^2	
Warm tank volume (m^3)	Continuous	300—500	825—810 €/m^3	
Hot tank volume /house (m^3)	Continuous	0.5—5	900—810 €/m^3	
BTES volume (m^3)	Continuous	10000—60000	17.19 €/m^3	
Photo voltaic area (m^2)	Continuous	50—6000	450—200 €//m^2	
Building configurations	Discrete	Type 1: space heating demand= 25kWh/m^2/yr	15 628€/building	3
		Type 2: space heating demand= 37kWh/m^2/yr	13 260 €/building	
		Type 3: space heating demand= 50kWh/m^2/yr	12 655 €/building	

2.6. Renewable energy fraction

The renewable energy fraction (REF_{heat}) for heating is defined as (Rehman, et al., 2017),

$$REF_{heat} = 1 - \frac{(HP+backup\ direct\ heating+pumping)electricity\ consumption\ per\ year}{SH\ demand\ per\ year+DHW\ demand\ per\ year}, \quad \text{(eq. 3)}$$

the above equation (eq.3) accounts the heat losses through the grid. The household appliances electricity demand is not included in the calculations.

2.7. On-site energy matching (OEM) and on-site energy fraction (OEF)

The onsite-energy matching (OEM) for electricity is defined as the ratio between exported electricity and total on-site electricity generated through photovoltaic panels (Cao, et al., 2013). The OEM provided the values that indicated the portion of the on-site generated electricity that is used in the local demand rather than being dumped or exported. The onsite-energy fraction (OEF) for electricity is defined as the ratio between annual purchased electricity and total electricity demand of the community (Cao, et al., 2013). The OEF provided the values that indicated the portion of the demand covered by the on-site generated electricity through photovoltaic panels. Higher the value of OEF and OEM better is the matching.

3. Results and discussion

The relationship between the purchased electricity and the investments costs of the non-dominated solutions are shown in Fig. 2. In total there are 132 non-dominated solutions for the energy system (red points). All the simulations results cloud is also shown in Fig. 2 (blue points).

The solutions on the Pareto front in Fig.2 (red points) are called non-dominated solutions. All simulations run (blue points) converged on the Pareto front (red points) as shown in Fig. 2. It shows that due to the increase in the investments there is a reduction in the purchased electricity. The solutions on the left side of the Fig.2 are less energy intensive compared to the solutions on the right (red points). The purchased electricity varied from 47.4 kWh/m^2/yr to 25.7 kWh/m^2/yr, this correspond to the investments cost (IC) from 180.7 €/m^2, floor area to 526 €/m^2, floor area. The solution shows that there are wide ranges of the optimal solution available which can be selected by the contactors and the end users based on their expectation and demand. It is found that the left most solutions contained a large photo voltaic and medium sized solar thermal areas. On the other hand the majority of the solutions on the right hand side in Fig.2 contained solutions with smaller photovoltaic panels and solar thermal area. Furthermore, other important design parameters that followed a certain trend on the Pareto front are building heating demand.

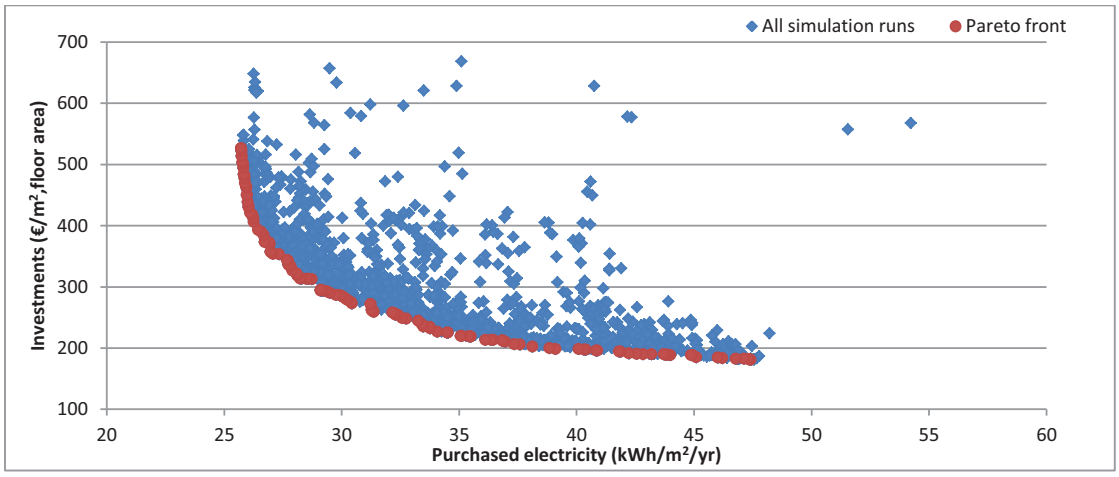

Fig. 2: Purchased electricity versus investments of the non-dominated optimal combinations of the design variables.

The cost breakdowns of the non-dominated solutions are shown in Fig.3.

The solutions on the left hand side of Fig.3 are the least expensive solutions. These solutions have higher purchased electricity. On the contrary the solutions on the right side of Fig.3 are expensive solutions and the corresponding purchased electricity is less.

It is observed that in Fig.3 photo voltaic area, solar thermal area, building heating demand and storage tanks volume played a significant role in the overall investments and also in the change in the purchased electricity. Due to the cheaper cost of the photovoltaics panels compared to the solar collectors, PV area is increased

initially by the algorithm to reduce the purchased electricity, and later solar collectors area is increased. Since hot tank is not charged by the solar thermal energy and it is only charged via the heat pump therefore, there is a large requirement of the electricity compared to the thermal energy. As a consequence, large photovoltaic area played significant role in reducing the purchased electricity compared to solar thermal area. Small-medium ST area is used to charge the warm tank at adequate level in all non-dominated solutions. Large PV panels area is used to provide electricity to the heat pump to charge the hot tank. Nevertheless if hot tank is charged by the solar thermal area then larger ST area would have been beneficial.

Furthermore, the solar thermal area also played important role in the reduction of the purchased electricity. The Fig.3 showed that on the left side, most of the cases has small solar thermal area of around 100—700 m^2. On the other hand, in the most expensive cases where the purchased electricity is less, the optimization algorithm selected medium sized solar thermal collectors of around 1000—2800 m^2. A very larger solar thermal area of around 3000 m^2 and above had minimal advantage in reducing the purchased electricity and also it is expensive, therefore the algorithm did not select a very large solar thermal collectors area. Hot tank is not charged by the solar energy therefore, large collector area had minimal advantage.

Building demand also contributed in improving the performance of the system. Initially, in most of the optimal cases building with heating demand of 50 kWh/m^2/yr are chosen because it is the cheapest option among others as shown in Fig.3 (left side). In the cases where the purchased electricity is less, on the right side of the Fig.3, the building with heating demand of 37 kWh/m^2/yr and 25 kWh/m^2/yr are chosen in majority. With higher investments, building demand could be reduced from 50 kWh/m^2/yr to 37 kWh/m^2/yr and up to 25 kWh/m^2/yr.

The size of the short term tanks also increased gradually from the least expensive to the expensive solution. This indicated that a large tank volume would improve the performance of the system. As this would provide the instantaneous energy needed for the system to meet the heating demand of the buildings. Larger the volume, large is the energy available. Larger tank volumes are also selected in high performing cases due to cheaper cost of the tank.

The solution on the right side of the Fig.3 shows that a combination of medium to large photovoltaic area, medium sized solar thermal area, and large volume of the tanks, energy efficient building and medium size of BTES volume could improve the performance of the energy system. On the other hand, this would have higher cost. A combination of small photovoltaic and solar thermal area, small BTES volume and building with highest heating demand would be the cheapest solution. This resulted in high purchased electricity by the system.

The solution with lowest solar thermal collectors area has minimal renewable energy fraction on left side in Fig.3. The renewable energy fraction increased with increase in the collectors area.

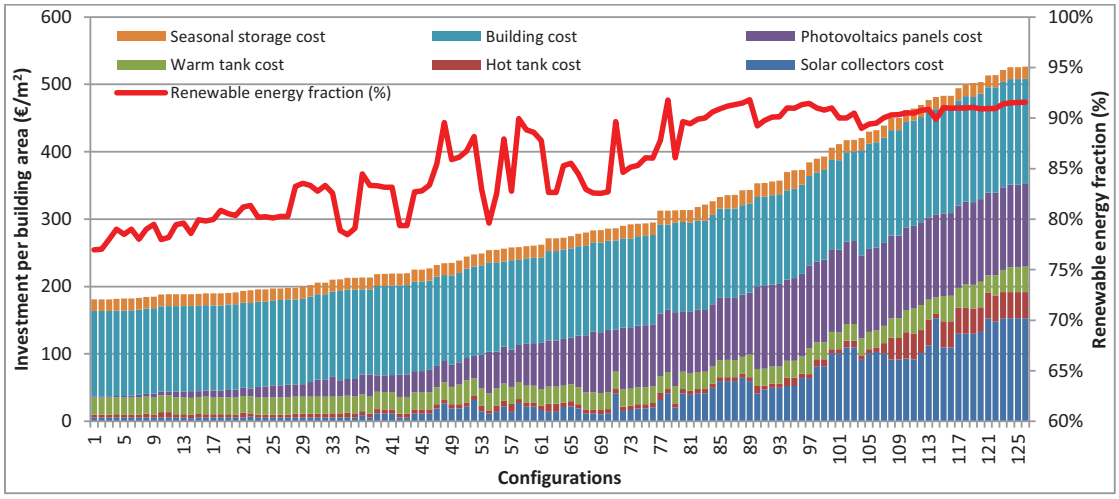

Fig. 3: The cost breakdown of the non-dominated optimal solutions.

The on-site energy fraction (OEF) varied between 2% and 38% as shown in Fig.4. This indicated that PV panels are able to meet 2%—38% of the local demand of the system, depending upon the PV panels size and annual electricity demand. The OEF is less when the PV panels area is less on the left side of the Fig.4, hence the on-

site generation of electricity is not enough to meet the high load. It improved until 38% when the PV and ST areas are large on the right side of Fig.4, resulting in large on-site electricity generation and lesser demand. The maximum OEF is 38% because of the mismatch between the generation and consumption and no electrical storage is considered. Since there is no electricity storage, therefore in the cases where the PV area is large the maximum OEM achieved is 20% as shown in Fig.4. This indicated that in highest performing cases 20% of the on-site generation by PV panels is used locally while the rest of the 80% is exported due to mismatch and lack of electricity storage in the system. On the other hand, the OEM is 100% when the PV area is small (no exported electricity), however this resulted in 2% OEF only.

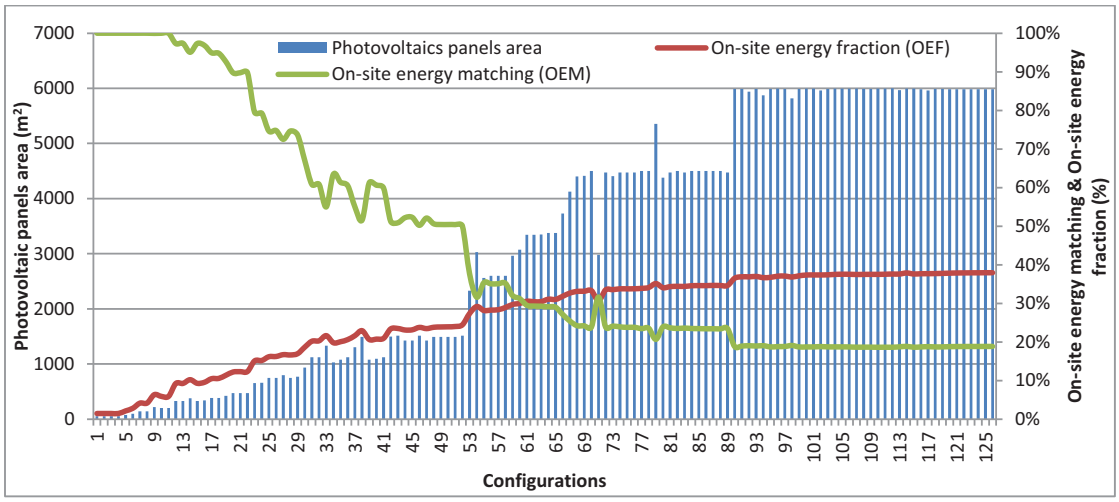

Fig. 4: The On-site energy fraction and On-site energy matching for electricity, correspond to the photovoltaic panels area.

3.1. The benefits of centralized space heating and de-centralized hot water

The simulation results provided some worthwhile findings. Firstly, size of the solar thermal area can be reduced in such system compared to the complete centralized system. It is found that in most of the optimized cases the size of the collectors ranged from 100— 2800 m^2. Large solar thermal area from 3000 m^2 onwards is not needed in such partial decentralized system. Because low temperature centralized tank can be charged with small-medium sized collectors and warm tank is used to preheat the space heating water therefore larger areas of collectors are not required. Furthermore, the decentralized hot tank is charged by the heat pump only and not via collectors. This also reduced the need of a larger collectors area in the optimized cases. Due to such partial centralized and decentralized configuration the size of the BTES is around 10700 m^3 in majority of the optimized cases. The discharge from the BTES is not significant in the cases where solar thermal capacity is less (cheapest cases), therefore in such cases BTES can be excluded from the system. Only in most expensive cases large volume of BTES (12000 m^3) is proposed that slightly improved the performance of the system. However large photovoltaic panels reduced the purchased electricity because hot tank is charged through electricity (heat pump) and not through solar thermal energy (collector) therefore large photovoltaic panels area are proposed.

Secondly, the partial decentralized system can be implemented at lower investment cost because the size of the solar thermal collectors and the BTES are less in most of the optimized cases. Since larger modules of both the solar collectors and BTES are not needed to improve the performance, hence the investment costs are less. Moreover, solar thermal collectors are the most expensive component in the solar community compared to photovoltaic panels. Hence lesser size of collectors is beneficial in terms of cost reduction.

Lastly, the results showed that by having de-centralized high temperature (domestic hot water) system inside houses, the losses through the piping reduced as the length of the high temperature pipe reduced from 4000 m (centralized) to 200 m (decentralized). The reduction in the losses through the domestic hot water piping is around 90%.

4. Conclusion

The goal of the research is to investigate the performance and optimize the solar district heating system for community in Nordic conditions. For this study de-centralized system is proposed. The proposed system

consists of individual house heat pump connected between large centralized solar-charged low temperature tank and smaller de-centralized individual high temperature tank in each house. Additionally, the large centralized tank is directly charged by solar-charged borehole storage during winters. The boreholes are charged by the centralized warm tank during summers. Multi-objective optimization is carried out in order to improve the performance of the system. The two objectives that are minimized are purchased electricity and investments cost.

Generally, it is found that solar energy can be used to provide both DHW and SPH, or also to charge the ground. Balancing the use of the solar energy throughout the year integrated with a HP is effective in energy system. In particular, storing energy in the seasonal storage increases the performance of the system by reducing the purchased electricity. The advantage of using the de-centralized system is that losses through the system and BTES are less. Since the size of the ST area is smaller therefore the temperatures in the seasonal storage is limited and it operates on lower temperature. Furthermore, the losses through the high temperature district heating grid are less compared to the centralized system because the high temperature tank is smaller in size and present inside the houses. This reduced the length of the piping from 4000 m to 200 m for 100 houses, as a consequence the losses through the high temperature DHW piping are reduced.

In terms of energy system, it is found that each component has varied effect on the performance of the system. In order to increase the performance of the system it is essential to have correct combinations of the system. The correct sizing of the design variables like: ST area, photovoltaic area, short-term storages tanks volume, BTES volume and the building heating demand is important. The analysis showed that the highest purchased electricity is 47.4 kWh/m^2/yr, on the contrary, the lowest purchased electricity is 25.7 kWh/m^2/yr. This is mainly caused by the variation in the heat pump consumption. The heat pump is used only to charge the small sized hot tank while taking energy from the space heating return line instead of the BTES. Hence, the source is relatively warmer on the evaporator side. The system can be implemented with the investments ranging from 180.7 €/m^2, floor area to 526 €/m^2, floor area. In most of the best cases, where purchased electricity is minimal, it is found that a combination of small-medium sized solar thermal collectors area, small-medium sized BTES and high energy intensive buildings are proposed in most of the optimal cases. However, purchased electricity can further be reduced by having a combination of medium solar thermal area, large volume of BTES and buildings with lowest heating demand. The results also showed that, photovoltaic area is vital for the overall system performance. Large photovoltaic area reduced the purchase electricity, however due to mismatch excess energy is exported to the grid. No electricity storage is considered in this study. As for the tank sizes, firstly it is beneficial to have small to medium sized decentralized hot tank in most of the optimal cases in each house. Secondly, it is beneficial to have large volume of centralized low temperature tank of around 300—460 m^3.

For the solar thermal collectors, a small to medium sized ST area is beneficial in most of the optimal cases. A large area of 3000—6000 m^2 is not selected in optimal cases. Large ST area had minimal benefit because high temperature is not needed in de-centralized system. In addition to that, the cost of the ST area played important role in selecting the solar thermal area, due to high cost of the collectors the algorithm selected small to medium sized collectors.

The on-site energy fraction (OEF) for electricity varied around 2%—38%. This correspond to the on-site energy matching (OEM) from 100%—20%. Both the OEF and OEM varied based on the PV panels area and the demand of the system. Large PV area and low purchased electricity resulted in higher OEF and low OEM. On the other hand, small PV area and high purchased electricity resulted in lower OEF and high OEM. PV panels installation is beneficial along with the ST collectors because without the PV panels the OEF for electricity would be zero and all the electricity has to be purchased via the grid. This would increase the purchased electricity and the operational cost of the community.

The renewable energy fraction varied from 75%—91%. This again illustrates the significance of the design variables and configuration on the system performance. This study clarified some important aspects of the energy system behaviour. It provides better in-depth understanding of the effect of each individual design variable on the system behaviour. This study gave the methodology and interactions between design variables for a proposed system configuration. In particular, their effect on the system performance in presented. An extended study could be made by changing the controls and other design variables, like the set points of the system in order to optimize the control algorithm. Additionally it is planned to include electricity price (operational cost) and emission price in the energy system optimization to show complete picture in the future

study. With increase in the popularity of the solar community concept in Nordic region, finding the best strategies and combinations would be important. This information is useful for the designers and contractors in making early stage decisions.

Solar Supported Agriculture in Desert Regions

Modeling of a solar dryer for fruit preservation in developing countries

Juliette Chaignon[1], Henrik Davidsson[1]
[1] Lunds Tekniska Högskola, Lund (Sweden)

Abstract

About 25,3 % of the Mozambican population is suffering from undernourishment even though a sufficient amount of food and specifically fruits are produced. Post-harvest losses are estimated to 25 % to 40 % and part of the production is not even harvested due to a short season. A solution has to be found to improve fruit preservation and allow the population to consume what is harvested later. Drying fruits is a solution to preserve them. However, juicy fruits are harder to dry than other fruits since they contain more water. One small-scale solution is drying juicy fruits in a specific membrane which allows water vapor to escape from the fruit and the fruit juice to dry. It is possible to couple these membranes with solar dryer technology to control parameters such as temperature, relative humidityand air velocit) in order to improve the drying process

Two types of solar dryers are tested and preseted in this paper: an indirect and a direct dryer. Both solar dryers are modeled using a CFD tool (COMSOL Multiphysics) and the modeling work is based on former research to elaborate a mathematical model of the dryer physics. The simulations results produced by COMSOL allow to study the influence of several parameters such as geometry of the solar dryers, ambient conditions and solar dryer materials in order to improve the design of the dryers. The results from the modeling are compared to on-site measurements, in Mozambique, in order to calibrate and validate the models. The models estimated temperatures and relative humidity with an average relative error inferior to 20 %.

Keywords: solar dryers, modeling, CFD, indirect solar dryer, direct solar dryer, fruit preservation

1. Introduction

1.1 Food insecurity and fruit preservation

Mozambique is a developing country which presents a high rate of undernourished people. Around 6,9 million inhabitants are undernourished which represents 25,3 % of the total population in Mozambique (Food Agricultural Organization of the United Nations, 2016). The situation is even more concerning for children since 43 % of the children under 5 years old suffer from chronic malnutrition and 6 % are considered as sharply malnourished (Instituto Nacional de Estatística, 2012).

Although an acceptable amount of food is grown, a significant part is not consumed due to harvest losses or spoilage before it can be consumed. Post-harvest losses are estimated between 25 % and 40 % in Mozambique and a large part of the fruit production is not even harvested due to a short season (Phinney, R. et al. , 2015).

A solution to cope with this issue is to provide a fruit processing technology to safely and cost-efficiently preserve fruits when they can be harvested in order to consume them later. Large-scale solutions such as canning or aseptic processing are economic but they also require a considerable amount of resources (clean water, energy, transport facilities) which are not necessarily available in developing countries like Mozambique.

1.2 Solar-assisted pervaporation

A small-scaled solution, solar-assisted pervaporation, is used to dry fruits in this work. It consists in putting fruit juice or fruit purée in a semipermeable membrane bags which allow water vapor to escape the bags but prevent it to enter back in it. A minimum temperature of 50 °C is required in order to avoid bacterial growth. The temperature also has to stay below 70 °C to avoid the degradation of acid ascorbic (Vitamin C) (Paul and Ghosh, 2011).

The criteria used to determine if a product has been dried enough and is suitable for conservation at room temperature is the water activity level a_w . The water activity corresponds to the ratio between the vapor pressure

doi:10.18086/swc.2017.30.01 Available at http://proceedings.ises.org

of the food, P_w, to the vapor pressure of water at the same temperature and pressure, P_{ws} (Phinney et al., 2015) and can also be expressed as the equilibrium relative humidity of the product divided by 100 (Singh, P. and Heldman, D.R. 2013). This relation is found in equation 1.

$$a_w = \frac{P_w}{P_{ws}} = \frac{RH}{100} \text{ (eq. 1)}$$

According to Phinney et al. (2015), several conclusions can be made concerning solar-assisted pervaporation pouches :

- The drying process using SAP-pouches allows to reach water activities below 0,7. For instance, the water activity in mango purée went from 1,0 to 0,48 after 45 hours of drying.
- Ambient relative humidity is a key parameter in the drying process and is related to the temperature. A lower relative humidity will provide a higher evaporation rate of the product inside the pouch.
- Ambient wind velocity that is the velocity of the air flow around the pouch decreases the drying time.

Given these conclusions, it is interesting to combine these SAP pouches with solar dryers.

1.3 Solar drying

Several types of solar dryers exist and this work aims to model two different types of them :

- A direct active solar dryer (Fig. 1)
- A tilted passive solar dryer (Fig. 2)

In a direct solar dryer, the drying product receives directly the solar radiations. In an active solar dryer, the heated fluid (air in this case) is forced to circulate by a fan, a blower or any equivalent. On the opposite, the drying product is not directly exposed to solar radiations in an indirect solar dryer and a passive solar dryer only relies on natural convection due to the temperature difference between the absorber and the air circulating in the solar dryer.

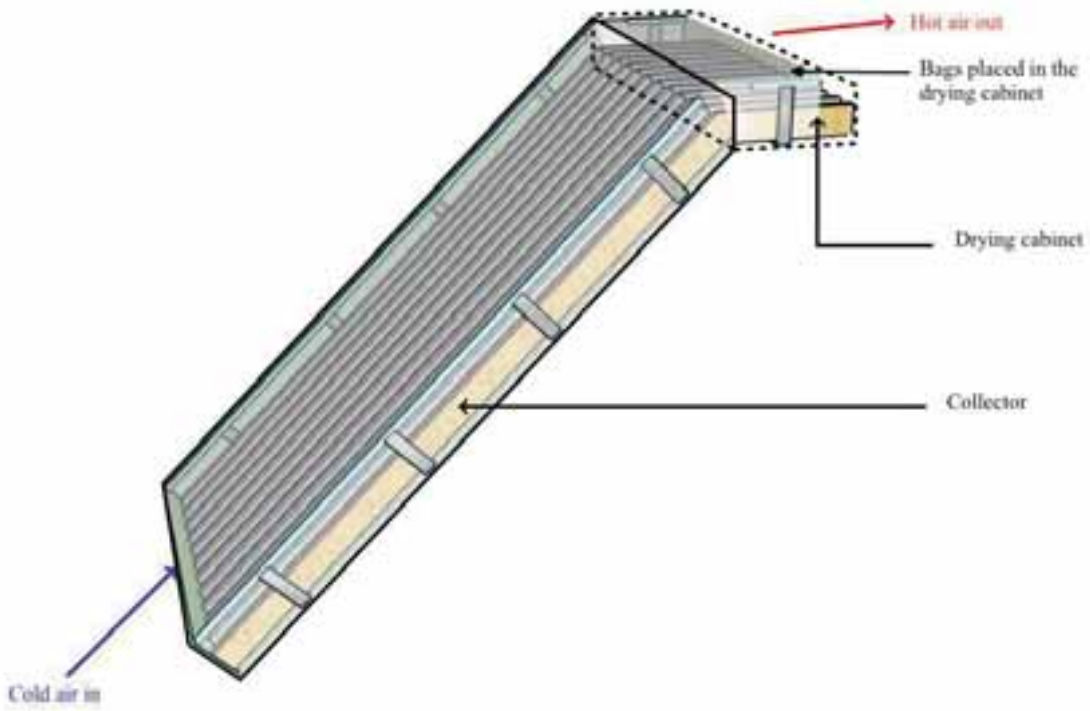

Figure 1 : Tilted passive solar dryer

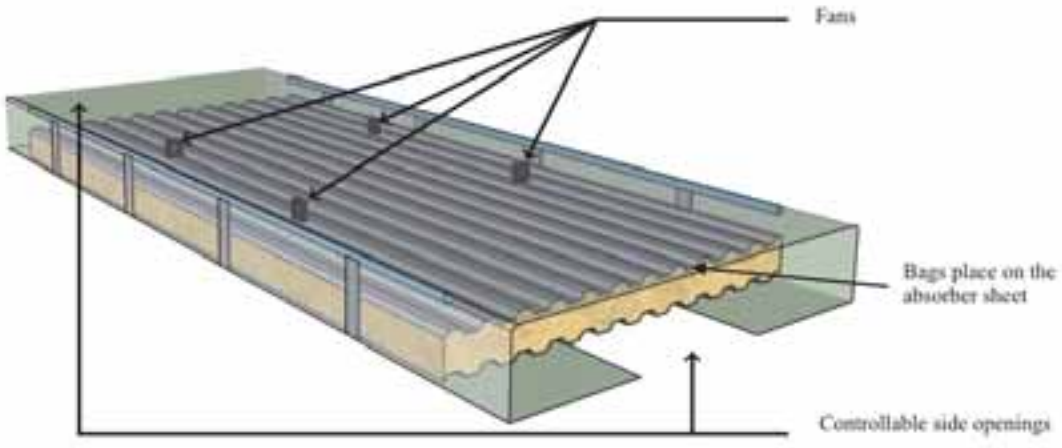

Figure 2 : Active direct solar dryer

2. Theory

The heat transfer exchanges in a solar dryer are presented on Figure 3. The solar radiation (1) is transmitted through a plastic sheet and absorbed by the absorber plate or on the fruit itself. Once the radiation is absorbed, part of it is emitted back to the plastic sheet. The rest is used to heat the air by convection on the absorber plate and the inner sides (4). The role of the absorber is thus to convert radiation in heat, by absorption and emission. Convection also happens on the plastic sheet (3) and the outer sides with the ambient air. Losses occur by radiation (2) from the plastic sheet from the sides of the solar dryer to the sky and from the bottom sheet of the collector to the ground. Finally, heat is transferred by conduction in the different materials.

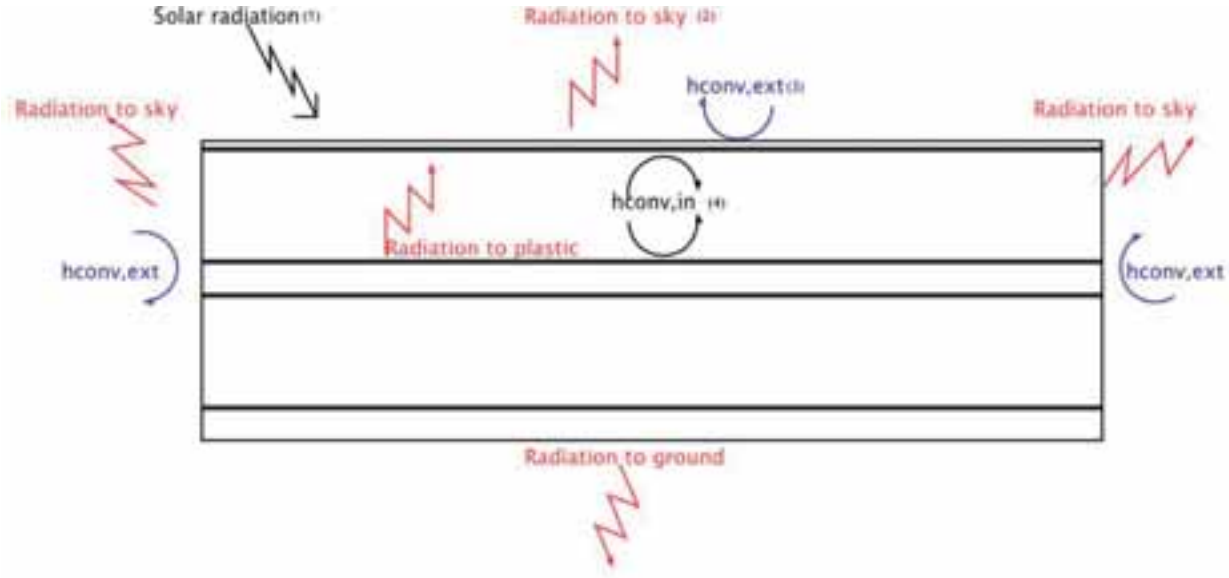

Figure 3 : Heat transfer in a solar dryer

3. Method

3.1 Models' description

The aim of this work is to model two types of solar dryers using the software COMSOL. The two main parameters taken into account in the studies are temperatues of the different elements of the solar dryers and relative humidity

of the air circulating in the solar dryers.

A first model, referred as Model 1, aims to represent the tilted collector, Figure 3, with a tilt angle of $\theta = 45°$. The computer model of this solar dryer enables to quantify heat transfer. In this model, the air inlet velocity is set to a constant value. This value is kept in the whole collector. In this model, the study focuses on the air characteristics circulating in the collector (temperature distribution, relative humidity). The velocity profile is not modeled using fluid dynamics equation. The airflow velocity value is used to calculate the Nusselt number and deduce the convective heat transfer occurring on the absorber plate.

A second model, referred as Model 2, represents an active flat dryer (Fig. 2) containing bags full of water. To create this model, the Heat Transfer Module is used in COMSOL. In this model, the solar dryer is the same as the indirect solar dryer, except that the direct solar dryer is flat and the bags are put directly in the solar dryer. The temperature distribution in the dryer and the relative humidity are the two main parameters studied.

3.2 Assumptions

The following assumptions are made to model the active direct solar dryer and the passive indirect solar dryer :

- The solar dryers' studies are steady state for a constant solar irradiation. This is an approximation since the solar irradiation varies with time and weather conditions (clouds).
- The calculations can be run on half of the solar dryer without affecting the accuracy of the results given the symmetry of the considered geometry.
- The solar dryers which are modeled are built with a black net put on top of the absorber. This net is neglected.
- The plastic sheet does not absorb visible radiation, $a_p = 0$.
- The outward radiation from the sides is assumed to be radiated toward the sky while the radiation from the bottom goes to the ground.
- The heat radiation between the absorber and the plastic sheet is taken into account and a view factor is calculated for this.
- The inner sides are assumed not to reflect radiation
- There are no air leakages

3.3 Model validation method

In order to validate the models created for the two solar dryers, the results obtained through the model calculations are compared to field measurements. The values compared are five temperatures, plastic sheet, inlet air, outlet air, absorber plate, rock-wool insulation, bottom sheet and the relative humidity of the outlet air. The experimental set-up is presented in Section 3.3.

The mathematical tool used to compare the values from the model and from measurements is the relative error, defined by equation 2.

$$\varepsilon = \frac{x_{model} - x_{measured}}{x_{measured}} \text{ (eq. 2).}$$

3.4 Experimental set-up

The measurements collected are temperatures and relative humidity at chosen points on the solar dryer (Figure below).

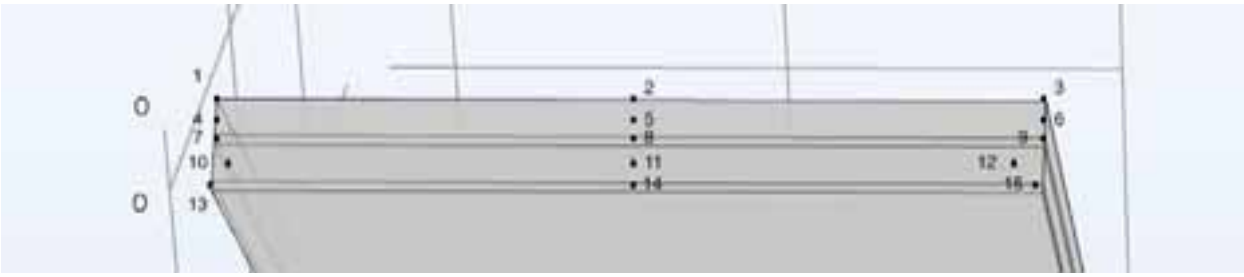

Figure 4 : Measurement points on the air outlet of the collector

The measurements collected are temperatures and relative humidity at chosen points on the solar dryer. To do so, two measurements tools have been used :

- four Vernier© sensors patched on strategic points on the solar dryer
- a Testo probe connected to a Testo435-2 logger, able to measure temperature and relative humidity

The measurements were taken during 30 minutes to reach stable values. The logs were stored on the Vernier© device and then transferred to a computer to be exploited on Excel. Each measurement has been done twice to deal with the repeatibility aspects of the experiments.

The ambient conditions were measured during 3 hours. Then, an average of the ambient temperature, ambient relative humidity and ambient solar irradiation has been done and used as intial values in the COMSOL models.

4. Results

4.1 Input data

The input data used for both the tilted passive and the flat active solar dryers is presented in the following table (Tab.1).

Tab. 1 : Input data

Parameter	Value	Unit
Collector width	1,1	m
Collector length	1,8	m
Insulation thickness	0,05	m
Global solar irradiation	916	W/m^2
Ambient temperature	31,6	°C
Ambient relative humidity	34,4	%

4.2 Model 1 : Tilted passive collector

The results from the computer model give the temperatures of the different elements of the solar dryer are given in Table 1 below. Here are presented the average temperature for each component of the tilted passive solar dryer.

Tab. 2 : Temperatures of the different elements of the titled passive solar dryer

Element	Temperature / (°C)
Plastic sheet	55,2
Outlet air	59,7
Absorber sheet	76,0
Insulation	43,0
Bottom sheet	33,2

The air temperature is above 50 °C and below 65 °C which means that the drying is performed in the correct range of temperatures to ensure the quality of the drying product, as shown on Figure 4. Less than 15 % of the collector length is necessary for the different elements to reach 80 % of the outlet temperature.

The value measured on-site for the ambient relative humidity is 34,4 % and is the one used in simulations. The calculations done by COMSOL show that at the outlet of the collector, the relative humidity drops to 10,1 % at

the center of the air outlet surface.

4.3 Model validation

In order to validate Model 1 (resp. Model 2) for the tilted passive (resp. flat active) solar dryer, the temperatues values and the relative humidity value of the air obtained through COMSOL calculations are compared to the measurements of the same values, done on-site.

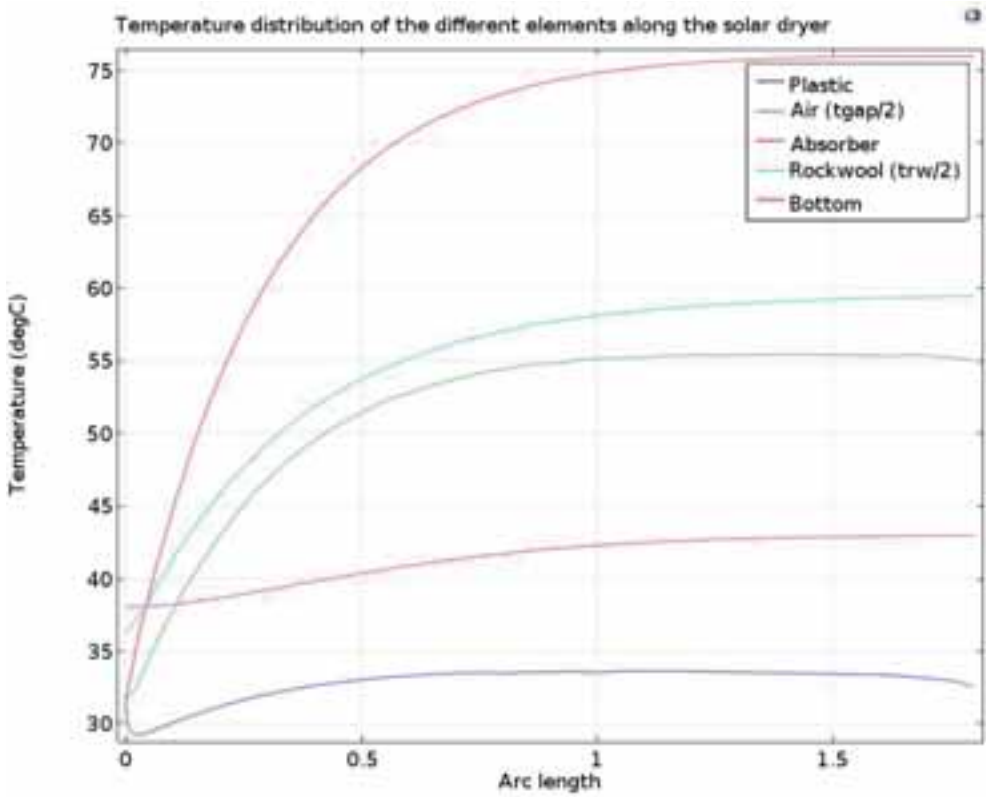

Figure 5 : Temperature of the different elements along the tilted passive solar dryer

For Model 1, the relative error for the temperatures given in Celsisus degrees varies from 2,6 % to 29,2 %. The average relative error for each element of the collector is given in Table 3 below, showing that the temperatures calculated by the model can be considered as accurate, except for the plastic sheet. For the relative humidity, a relative error of 8 % is obtained when the outlet air relative humidity measured is compared to the estimation from the computer model.

Tab. 3 : Relative errors for the temperature and relative humidity values – Model 1

Element	Average temperature measured on-site (°C)	Average temperature calculated by the model (°C)	Relative error on temperature
Plastic sheet	46	34	24 %
Outlet air	58	52	10 %
Absorber sheet	61	67	10 %
Insulation	61	55	11 %
Bottom sheet	40	41	3 %

The same is done with Model 2 and the relative error for the temperature values varies from 2,7 % to 33,2 %. The average relative error for each element of the collector is given in Table 4 below, showing again that the temperatures calculated by the model can be considered as accurate, except for the plastic sheet. For the relative humidity, a relative error of 8 % is obtained too when the outlet air relative humidity measured is compared to the estimation from the computer model.

Tab. 4: Relative errors for the temperature and relative humidity values – Model 2

Element	Temperature measured on-site (°C)	Temperature measured on-site (°C)	Relative error on temperature (°C)
Plastic sheet	41	28	32 %
Outlet air	49	43	12 %
Absorber sheet	44	51	17 %
Insulation	45	43	4 %
Bottom sheet	38	35	8 %

4.4 Parametric studies

The influence of the following parameters is studies through parametric studies in which all the parameters are fixed except the one studied.

The first parameter studied is the airflow velocity, which is constant in the solar dryer. The influence of the airflow velocity on the outlet temperatures, the internal convective heat transfer coefficient and the energy losses is studied. Six values of airflow velocity are studied : 0,1 ; 0,5 ; 1,0 ; 1,5 ; 2,0 ; 2,5 m/s. The higher the velocity, the lower the air temperature will be at the outlet. The same is observed for the absorber temperature at the outlet. This is due to the increased convection effects when increasing the airflow velocity. The air circulates faster in the absorber sheet and the heat will leave it faster. The relative humidity does not vary much as well and remains at about 10 % varying from 5 % for the lowest velocity to 12 % for the highest. Since the relative humidity depends on the temperature value, it is normal that a higher speed induces a higher relative humidity rate, because a higher airflow velocity is responsible for a lower temperature in the air. The internal convective heat transfer coefficient is affected by a change in the inlet airflow velocity. It is higher when the velocity is higher as shown on Figure 5. The range of values for this coefficient remains around [0,5; 2,0] $W/m^2/K$.

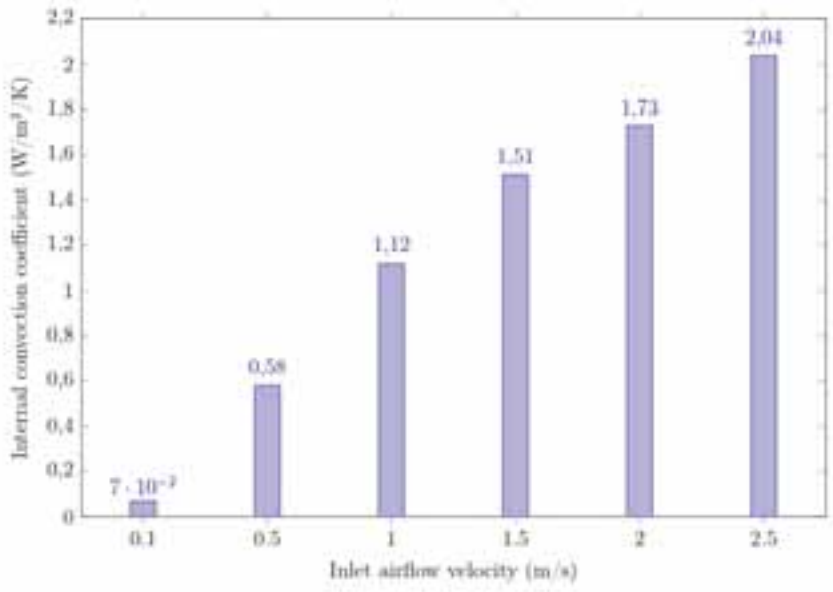

Figure 6 : Internal convection coefficient depending on the airflow velocity - Tilted passive collector

Then, the influence of the internal convection coefficient on the absorber plate is studied. The internal convective heat transfer coefficient on the absorber has a major influence on the outlet air temperature, the relative humidity and the outlet absorber temperature. When increasing the internal convective heat transfer coefficient on the absorber, the air at the outlet is at a higher temperature. For a constant velocity, increasing the internal convection coefficient on the absorber results in a lower relative humidity for the outlet air. The graph of the evolution of the outlet air temperature depending on the internal convective heat transfer coefficient is shown on Figure 6.

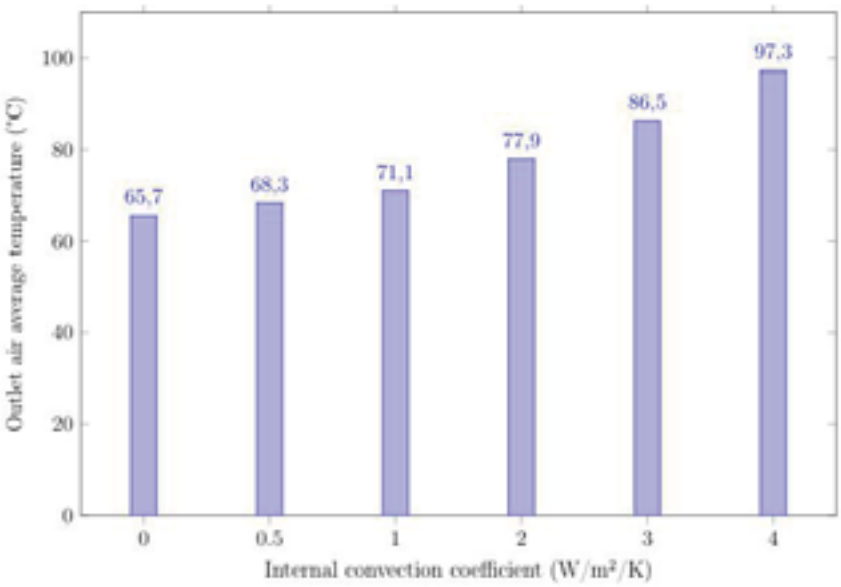

Figure 7 : Evolution of the outlet average air temperature depending on the internal convection coefficient for the tilted passive solar dryer

The radiative properties such as the transparency of the plastic sheet and of the absorptance and the emissivity of the absorber are some other important parameters which influence is studied. Simulations were run with the following values for the absorber emissivity : 0,1 ; 0,3 ; 0,5 ; 0,7 ; 1. The value of 1 corresponds to an ideal black body. The lower the emissivity, the higher the absorber temperature will be and thus the higher the air will be. A low emissivity means that the absorber is loosing less heat by radiation since it emits less thermal radiation (visible and infrared). This parameter is material-dependent.

Finally, the last parameters which influence is studied is the insulation thickness. The insulation thickness values tested are: 0.1 cm, 1 cm, 3 cm, 5 cm, 10 cm, 15 cm, 20 cm. Increasing the insulation thickness allows to get higher outlet air temperature to a certain point as shown on Figure 7. After 15 cm, the gain in the outlet air temperature is less perceptible. The temperature of the bottom part of the solar dryer is highly impacted by the insulation thickness.

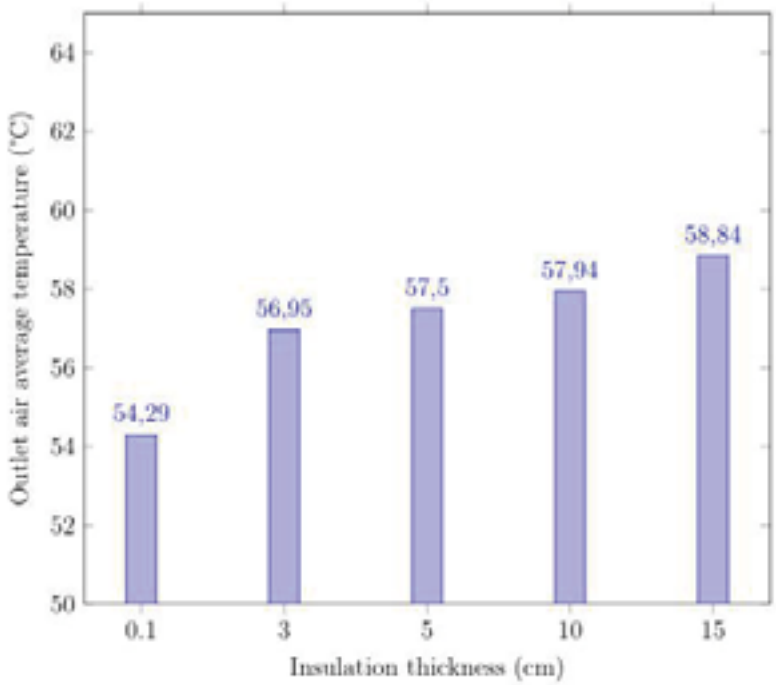

Figure 8 : Evolution of the outlet average air temperature depending on the insulation thickness for the tilted passive solar dryer

4.5 Design optimization

Some design optimization can be deduced from the previous parametrics. First of all, the insulation thickness needs to be chosen carefully. A too thick insulation layer is not useful but 5 cm seems to be a minimum value to limit the heat losses and keep the bottom part of the solar dryers at a reasonable temperature. Increasing the thickness of the insulation layer also increases the absorber temperature and in this case, even if more heat is transferred by convection to the air, the temperature difference between the absorber and the plastic sheet is higher and so are the radiative losses from the absorber to the plastic sheet. Finding the minimum thickness needed for the insulation layer allows also to reduce the price of the material needed.

The absorber material should be chosen carefully with the highest absorptance possible and the lowest emissivity. For this, low emitting coating absorbers would of course provide better drying performances. However, the quite high emittance of the absorber (0,8) used to build the solar dryers is sufficient to ensure an air temperature between 50°C and 65°C and thus food safety regarding the drying product. Since the solar dryers will be built and used in Mozambique, the emittance of the absorber is not a prior concern given the price difference between a classic corrugated metal sheet and a low-emitting coating. The plastic sheet material choice could be improved by choosing a more transparent material to increase the fraction of solar radiation transmitted to the absorber.

Then, increasing the convection on the absorber plate is a way of transferring more heat to the air. It can be done by increasing the surface of contact between the air and the absorber. Then, a better way of increasing the convective heat transfer is to increase the convective heat transfer coefficient, which means increasing the Nusselt number or the hydraulic diameter (the effective surface of the absorber). It could be possible to increase the natural convection thanks to a double-pass system with the air entering on the backside of the passive solar dryer and then going around the absorber plate and exiting the solar dryer on the opposite side to the one the air entered. The

convection around the bags is also very important. As explained by Phinney and Tivana (2016), the higher the airflow velocity around the bags, the higher the drying rate. One idea to increase the amount of air passing around the bags could be to have air passing above and under the bags. In the passive solar dryer, the bags should be put higher in the drying chamber joined to the collector. However, a balance has to be found because the driest air is located close to the absorber plate. In the active solar dryer, the fans already provide a good circulation of air around the bags. The point in this is also to avoid the moisture to stay on the bag so the relative humidity does not increase too consequently around the bags.

5. Discussion and conclusion

The model validation has been done by comparing measurements to values calculated by COMSOL. However, the tools used to take measurements are a source of error. In both models (passive tilted and flat active), the plastic sheet temperature is underestimated. This is an example of the difficulty to measure temperatures on certain elements of the solar dryer. Also, the model used to represent the solar dryers used an internal convective heat transfer coefficient based on a Nusselt number calculated using correlations. This is another source of error. One approximation has been done regarding the absorber plate shape. The material used in the solar dyers is a corrugated metal sheet. To simplify the problem, it is modeled as a flat sheet which thickness is equal to half of the height of the bumps of the corrugated metal sheet. When measuring the absorber temperature, it is always the temperature at the top of the bumps which is collected. A difference of 2,5 to 4°C is observed between the temperatures on the bumps or the hollows.

The internal convection in the solar dryer is one of the most delicate point in this modeling task. There are several solutions to do so. One solution is to determine an equivalent conductivity to the convection phenomenon. For the solar dryer, convection in the fluid would occurs in the case of an "horizontal cavity heated from below". COMSOL requires to give the dimension of the cavity (distance plastic sheet - absorber) and the temperature difference between the air and the horizontal plate heating the air. This solution might not be the best, first because knowing the temperatures of the air and absorber are one of the goal of the study and are not meant to be set. Also, the software uses some correlations that are not easily accessible. Another solution is to use another module in the software to model the flow behaviour. Thanks to the Boussinesq approximation for instance, it would be possible to model the natural convection inside a passive solar dryer (Motte et al., 2011). However, in this case, it is time consuming and it could not have been possible to carry out parametric studies with such a model. Finally, the chosen solution was to calculate the Nusselt number and give it as a parameter in the software. COMSOL allows to determine the different elements of the Nusselt number formula (specific heat at constant pressure, density, etc) depending on the temperature in each cell of the mesh of the air domain.

Finally, it could have been possible to model the airflow using the Navier-Stokes equations in the Non-Isothermal Flow Module available in COMSOL. However, this method is time-consuming, even using simplifications such as symmetry in the geometry. Some models have been built taking into account the fluid behavior. The results for the temperature and the relative humidity were close to the results given by the model not including the fluid behavior modeling.

To conclude, the models created in COMSOL Multiphysics give sufficient information regarding the temperatures and air relative humidity in several parts of both a direct and indirect solar dryer. Even if the exact temperatures might not be found, the models give correct approximation of it. The main purpose of these models is to study the effect of different parameters variation. The main conclusions of this work are that:

- COMSOL is a sufficient tool to build models. It will also allow to improve the modeling by including more phenomena (water vapor transport for instance).
- The models give a sufficient estimation of the temperature and relative humidity in a direct and in an indirect solar dryer with a maximum relative error of 10% for the outlet air temperature.
- The calculations of the external convective coefficient can be done with different formulas without changing the results in a significant way. However, the calculation of the internal convective coefficient is more important and the formula used to calculate requires to be chosen carefully depending on the flow characteristics (Reynolds and Prandtl numbers).
- It is possible to increase the performance of the two solar dryers tested by reducing the space between the absorber and the plastic sheet and by using an insulation layer of at least 5 cm.

- The choice of a low-emissivity material for the absorber is not of prime importance. However, the plastic sheet could be of higher quality with a higher transparency.

Abstract

The market for solar pumps is rapidly increasing due to rapidly declining costs and technology improvements that are replacing traditional manual (hand) pumps, mechanical windmills, and diesel engines around the globe. They are also reducing the demands on local and national power grids. Solar pumping has become a significant and growing niche for the solar energy industry. Solar pumps are an important way for smallholder farmers to increase crop yields through irrigation; fish farmers can increase fish yields through reliable water and improved aeration; and livestock herders can increase income through a reliable water supply for their animal's welfare. This paper details solar water pumping advances and example economic impacts that are making a real difference in the daily lives of rural Nepali farmers and communities.

1. Modern Solar Water Pumping

Solar photovoltaic water pumping (PVWP) systems are simple, reliable, cost competitive, and low maintenance. There is typically an excellent match between seasonal solar resource and seasonal water needs, when it is sunnier and hotter, is precisely when there is more solar energy to pump water (Foster, 2009). Small and medium scale solar water pumping systems are more econmical to operate than diesel or even many electric grid powered pumps, and provides a good return on investment. Their positive impact is most significant in rural communities like those in Nepal where conventional grid electrical power does not exist. Modern PVWP systems are characterized by their reliability, durability, and low maintenance. These qualities translate into a long-term lower cost when compared with other alternatives like diesel, not to mention the environmental benefits (they do not pollute the air or water, and operate queitly). In addition, PVWPs are easily automated and do not require an operator. PVWPs also provide system modularity, which provides the owner with the ability to flexibly meet specific need at any given moment.

There have been significant advances with solar water pumping systems over the past decade. PVWP systems costs have dropped by ~2/3 since 2000. Photovoltaic module prices have decreased by over 90 percent since 2010. As a result, solar water pumping system costs have declined significantly, from a high of over US$25 per peak Watt 20 years ago, to under US$5 a Watt today. Market estimates are that PV module prices may decrease by another 50 percent in only the next 5 or so years. There have also been improvements with pump system controllers using maximum power point tracking. Solar water pumping is now competitive with retail electric grid pumping costs (Kunen, 2015).

1.1. Centrifugal Solar Water Pumps

In Nepal, WI has been mostly deploying both DC and AC submersible and surface centrifugal water pumps. These pumps are readily available and affordable in the Nepalese Market. For a centrifugal pump, water enters at the center of the pump through a rotating impeller. The impeller spins the water, creating centrifugal force. The water gains both pressure and velocity as it flows through the impeller and is directed outward. A centrifugal pump can have multiple stages to increase its lift capacity. Each stage consists of one impeller with the output of the first stage feeding the input of the next. This is called a multi-stage centrifugal and may use up to about 20 stages to attain higher lifts. Each stage adds pressure, thus greater lift capacity. However, each stage also imposes friction, resulting in an efficiency loss of about 5 percent per stage.

Centrifugal pumps are especially efficient for higher flows > 40 lpm and for lifts of < 30 m. At lower flow rates and/or higher lifts, the efficiency is poor even under optimal conditions. To work efficiently, they need to run close to their full speed. Conventional power sources (grid or generator) provide stable power to maintain optimum rotational speed. Most solar pumps use variable power direct from a solar array; when power varies with the weather and the time of day, the speed of a pump will also vary (Foster, 2009). Centrifugal pumps are easily repairable locally in Nepal.

Any pump will have an optimum peak in its operating range, at which its energy efficiency is highest. Centrifugal pumps tend to have a narrow efficiency peak. A reduction in solar intensity reduces a centrifugal pump's performance disproportionately. This is because pressure is produced by centrifugal force, which is proportional to the square of the rotational speed. Thus, at half-speed, a centrifugal pump will produce only one-quarter pressure. Variation in water lift will also cause disproportionate drops in performance, if it falls outside the pump's range of efficiency. During late afternoon or early morning, or as cloud shadow appears, the pump may be spinning but the flow can stop completely.

A submersible pump is often simpler to install than a surface pump. It will not require intake piping or an intake valve. Nor will it require priming (being filled initially with water). It is less likely to be damaged from running dry due to pipe or valve leakage. Under ground and under water, it is protected from temperature extremes (e.g., freezing) and from human tampering.

Fig. 2: Pedrollo (Italian) surface centrifugal AC solar pump used in Odaltal village of Surkhet District for rice irrigation.

Horizontal submersible centrifugal pump installation (Fig. 3) is fine, but the lack of screen on the pump intake will cause the pump impellers to eventually clog from gravel and silt buildup that will require frequent cleaning of the pump stages. Pump intakes should be installed at least 1 meter from the bottom of well or river and with an intake screen to prevent large debris from entering. The community agreed to improve the pump setup.

Centrifugal pumps are useful for pumping large volumes of water and in situations of low head and are often the most efficient and economical. For example, in seeking a system to irrigate a large field requiring over 100 m3 per day, centrifugal pumps aer superior to positive displacement pumps.

Fig. 3: Grundfos submersible centrifugal pump used in a river for Taule village.

Fig. 4: Flood irrigation via a surface centrifugal solar water pump managed by Phattu Tharu of Bansgadhi, Bardiya.

The system above (Fig 4.) includes 8 TrinaSoar PV modules that are 315 Wp each (8 S X 1P configuration), directly powering a 1,800 W Italian Pedrollo AC surface centrifugal pump. The project irrigates rice and vegetables was implemented by the Hariyali Krishak Samuha farmer association in Bardiya in cooperation with the USAID Kisan project.

2. Accelerated Commercialization of Photovoltaic Water Pumping for Nepal

The USAID Accelerated Commercialization Solar Photovoltaic Water Pumping (AC-PVWP) project managed by Winrock Interational (WI) from 2015-17 is designed to expand the commercialization and adoption of PVWP systems for irrigation, livestock watering and community water supply in Nepal. The AC-PVWP project has worked closely with the USAID Knowledge-based Integrated Sustainable Agriculture and Nutrition (KISAN) Project in Nepal also managed by WI in supporting small scale farmers to transition from subsistence to commercial vegetable farming by helping implement new techniques and technologies such as solar water pumps, as well as the use of plastic houses and raised beds that replaced less effective traditional cultivation practices. Capacity building and market development activities have helped expanded commercialization and adoption of solar water pumping systems for irrigation, livestock watering, and community water supply. " Irrigation is a game changer for agricultural households in Nepal because they can grow during more seasons outside of the monsoon season and yields can be tremendously higher," states Phil Broughton, Chief of Party for the USAID

KISAN project (Warren, 2017).
The AC-PVWP project has been successful in establishing scalable and profitable business models. While higher upfront initial capital costs are always a barrier for the adoption of PVWP technology for rural communities and smallholder farmers in Nepal, the AC-PVWP project has worked closely with private suppliers, banks and financial institutions to develop business models such as credit financing, rent-to-own, water entrepreneurship, vendor financing to overcome this barrier and scale up installation of the technology. Furthermore, the project introduced new and affordable product with wide range of technology considering the need and affordability of the farmers for scaling up PVWP .market.

The first phase of the AC-PVWP project in 2016 installed over 69 pilot PVWP systems with installed capacity of 53.15 kWP benefiting 392 farmer groups in 16 districts as follows: Jhapa, Morang, Siraha, Rautahat, Makwanpur, Chitwan, Kathmandu, Kapilvastu, Syangja, Dang, Banke, Surkhet, Dailekh, Bardiya, Kailali and Kanachapurt. An additional ~120 replicated systems will be deployed in the second phase by the end of 2017. The business models employed and the district wise installations as shown below:

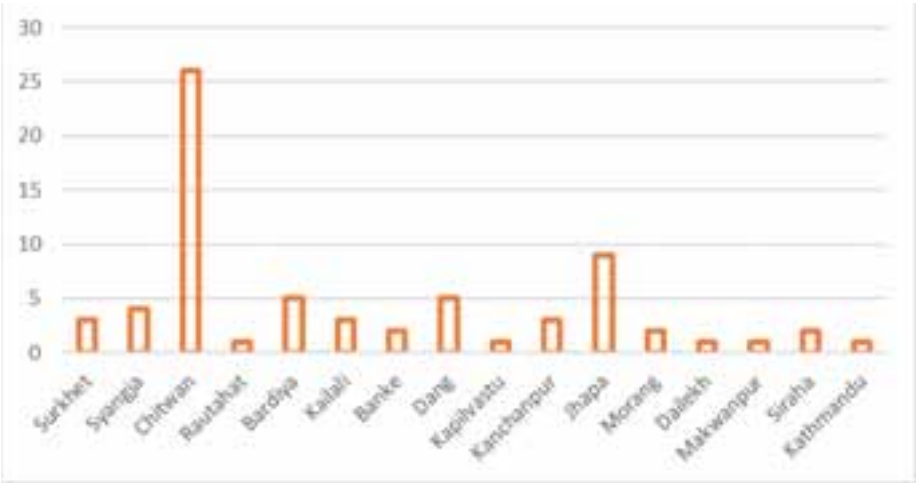

Fig. 5: Number of first phase AC-PVWP system installations by District in Nepal

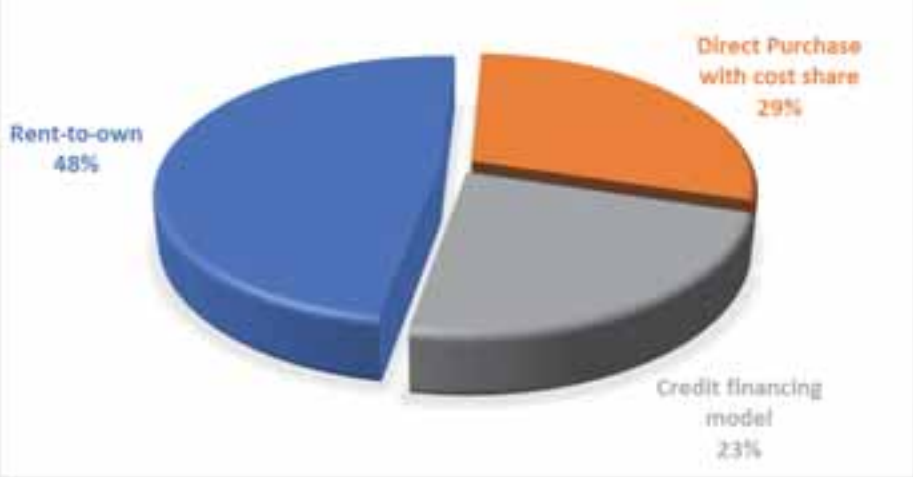

Fig. 6: Finance models for AC-PVWP projects installed in Nepal

3. Empowering Rural Women and Improving Livelihoods

"I can now earn enough to invest on the education of my children and I feel empowered" - Ms. Dila Gurung

Ms. Dila Gurung, 35 years old from the off-grid Taule village in Surkhet District, was in a difficult economic situation before acquiring a solar water pump which helped improve her livelihood. Even though she owned 5 Ropani (0.62 acres) of land, she was dependent on intermittent rainfed agriculture with no prospects for irrigation to increase productivity. WI approached the farmers about the potential to extend their ability to grow crops during the dry season through solar powered irrigation and that a solar-powered irrigation system would help transport 10,000 liters of water per day uphill from the nearby river to the fields where it was needed.

Her land is now green with high value commercial vegetables made possible with a PVWP system in collaboration with the Sitaram Agricultural Group. The financing for the PVWP was made accessible through the Small Farmer Saving and Credit Cooperative for commercial vegetable farming. Technical support was from WI from the USAID AC-PVWP project in collaboration with the Veri-Ganga municipality and USAID KISAN project.

The 1,260 Wp PVWP system installed at Taule-10 is primarily used for vegetable farming. The system includes 9 PV modules (140 Wp each) installed 9S X 1P. The mono-crystalline solar modules are manufactured by Ningbo Komaes Solar Technology Co. The system is community-based and owned by Sitaram Krishi Samuha benefiting 11 active farmers out of 16 members. The system pumps 10,000 liters per day of water at a total dynamic head (TDH) of 60 meters. The PVWP system was installed at a total cost of US$4,766 using a 1.26 kW SQF-3A10 manufactured by Grundfos. KISAN helped surmount that financial hurdle by arranging a cost-sharing agreement in which eight farmers took out a loan of $3,000 from a local farmers' cooperative, which would be paid back thanks to additional income from vegetable sales. In addition, Winrock, KISAN and the local Veri Ganga Municipal government contributed grants totaling $2,200. With labor supplied by the farmers and technical expertise from Winrock, the solar irrigation system was installed in May, 2015 (Warren, 2017).

Fig. 7: Solar water pumping array (9s x 1p) rated at 1.26 kWp used for irrigation by the Taule village farmers.

The difference consistent access to water has made in the amount of vegetables Gurung and his fellow farmers can grow has been dramatic. "After the solar pump the production has increased 70 or 80 percent," says Gurung. Household incomes have also risen between $300 and $2,750 annually, allowing the farmers to pay off the loan for the solar irrigation system (Warren, 2017).

The PVWP in Taule has completely changed Mrs. Gurung's lifestyle. She appreciates that the PVWP system has very low maintenance and running costs, quietly and reliably providing daily irrigation throughout the year. Her traditional subsistence farm was completely changed into a highly profitable enterprise based on using a PVWP systems for irrigation. She now harvests high value commercial vegetables and has seen a fivefold increase in her annual income from her former subsistence farming lifestyle. She grows cauliflower, cabbage, and red chilies and sells to the local markets. She is financially empowered and earned US$1,9145[1] last year from selling vegetables. She has better finances, improved self-esteem, and new technical skills attained from KISAN farmer trainings. "I feel socially, financially and technically empowered after commercial vegetable farming. I shared my journey of transition and boundless opportunities brought by the solar pump to Haree village to inspire women to switch to commercial vegetable farming." She looks forward to the returning of her husband from Qatar and she believes in their new potential to commercially grow vegetables together with no need for him to return to Qatar.

4. Case Study: Replacing Diesel Pumps for Solar Pumps for Fish Farming

"We are easily paying off the installation of our solar pump from the savings of diesel fuel costs" - Ms. Bhundi

[1] Exchange rate for 24 March, 2017: 1 US$=NPR 104.45

Chaudhary

Mrs. Bhundi Chaudhary, a 47 year old fish farmer from Maijui village of Chitwan district, whch is populated with indigenous Tharu residents whose main livelihood is fish farming. Mrs. Chaudhary decided to switch to solar water pumping system to fill her fish pond and aerate in order to eliminate the expense of her previous diesel powered water pump. Before installing solar water pumping system in her field, she used to fill the fish pond and irrigate her 13 Kattha (1.08 Acres) of land using an oversized 5 HP diesel water pump set. They used to operate diesel pump for 3 to 4 hours in every other day to meet their water requirements. They used to spend about US$ 81 per month for fuel to operate diesel pump.

Ms. Chaudhary learned about solar water pumping technology through a farmer's interaction program at Khareni, Chitwan organized by WI where she learned about a rent -to-own business financing program provided by Sun-Farmer Nepal. Leveraging the program, Ms. Chaudhary installed a 750 Wp solar pumping system that operates 0.8 HP submersible DC pump which pumps about 20,000 liters of water daily under this affordable financial model.

The PVWP was installed in December of 2015 at a total system installed cost of US$3,350, which included three years of vendor post-sales service. Since this was the first pilot in this region, and as incentive to buy down the technology risk for her as an early adopter, a subsidy of US$1,379 was provided jointly by WI and the Nepal Government Renewable Energy for Rural Livelihood project. As part of the subsidy agreement, she had to make her installation available as a demonstration for other area farmers. After providing equity of US$575 as up-front payment, NPR US$1,398 of the system and service cost was arranged under a rent-to -own business model through SunFarmer Nepal with a 3 years term. Under this scheme Ms. Chaudhary must pay monthly installment of US$39. Through productivity gains, she is paying back the installment from the savings of diesel fuel costs displaced. "Other farmers in the village were struggling to find diesel to run their diesel pump set during the Indian border blockade and were forced to buy diesel at higher price ranging up to NPR 350 (US$3.35) per liter. But, we were worry free as our solar water pump operated from the sun which was free from a blockade without incurring any cost and troubles" is Ms. Chaudhary's observation.

The 750 Wp Solar Water Pumping is used to draw water from an open-well to a canal to the pond. 3 panels each of 250 Wp are installed in configuration of 3 Sun-Worth PV models in series and 1 in parallel (3S X 1P). The pump is 600 W (48VDC submersible pump) from Solar Tech model SPM600C with a water output of 25,000 liters/day at 4.2-meter head for 6 kWh/m^2/day solar radiation. The system cost of the PVWP is NPR 350,000 (US$3,350.88). The system was installed under rent-to-model. In this model, the farmers provide a down payment upfront, and the remaining amount is financed by the company for a 3 years period. During the financed period, the PVWP vendor will be responsible for system operation and maintenance.

Fig. 8: Mrs. Chaudhary with her 750 Wp PV water pumping system in the background in between her aquaculture ponds

Besides the fish farm, Ms. Chaudhary also used water from solar pump to irrigate her land. She appreciates solar pump for several benefits such as minimal maintenance, effortless operation, minimal attention and continuous water supply compared to a diesel pump. The operation of diesel pump was not easy as it required physical strength to start and she had to look for help every time. She also had to remain standby to check the proper operation of diesel pump. Now, she is free as her solar pump is automated. The solar pump starts pumping water with the rising sun and stops as the sunset. She invests her saved time into productive works like vegetable farming, livestock rearing, and fencing her land. Her field is green with several types of vegetables. She is

growing green peas, cauliflower and other seasonal vegetables. She made profit of US$718 by selling of fish and US$287 by selling green peas and vegetables last year.

According to Ms. Chaudhary, "Installation of the solar pump was my sole decision and it feels good to be appreciated by my husband and family." She is now a model fish farmer in her village her self-confidence has been boosted from the interest and visits of other farmers to see her aquaculture operation and how they can also boost their productivity using a solar pump.

5. Case Study: Replacing Diesel Pumps for Solar Pumps for Fish Farming

"We no longer have to rely on rain to cultivate land. The barren land is now green with commercial vegetable farming" - Ms. Ganga Garanja

Ms. Ganga Garanja, 44 is a single mother of Pingale village of Pokharikada in Surkhet District who was a subsistence farmer who grew limited cereal crops to feed her family throughout the year. She owns 6 Ropani (0.75 acres) of mountain side land that was barren as irrigation was not feasible and she had to depend on inadequate rainfed agriculture compelling her to take out a loan just to feed her family. She along with her 2 daughters and a son were stuck in grinding poverty. Likewise, 29 other village households in Pingale were faced with a similar situation.

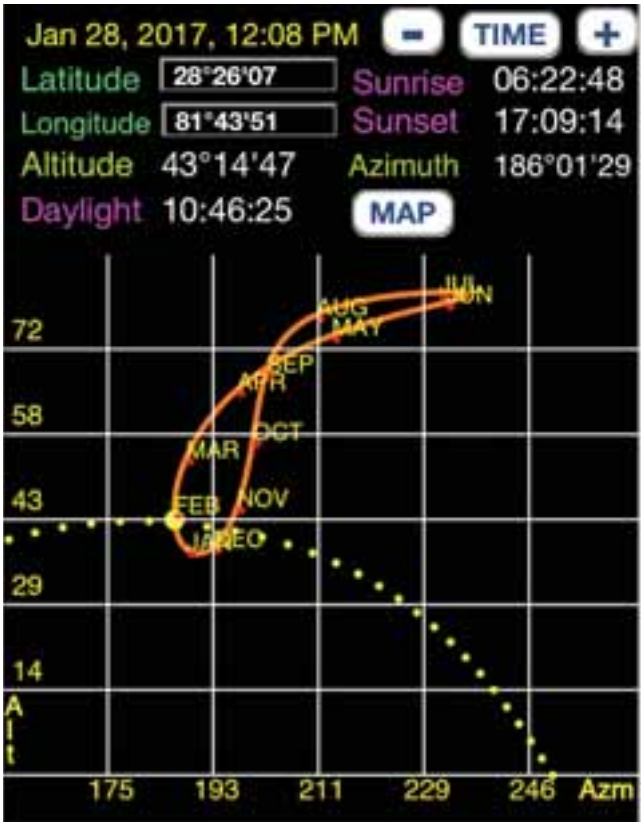

Fig. 9: Solar analemma near solar noon for Pokharikada (Solar Track App)

Despite owning land, the people of the village had to work as day laborers to survive. However, the money earned as day laborers was never sufficient to provide a good education and sufficient food for their children. Villagers intially tried to organize into a group named Milijuli Tarkari Utpadan Samuha to initiate commercial vegetable farming in 2009, but it was of no help as the group had no means for irrigation and depended on rain-fed agriculture.

Figure 10: Solar power array using German made Komaes140 Wp PV modules (9s x 1p) for t Pokharikada using a Grundfos submersible centrifugal solar water pump.

After 6 years in 2015, in collaboration with the AC-PVWP and KISAN projects, the Pingale village group installed a PVWP system for crop irrigation. The PVWP system helps farmers to irrigate throughout the year from a natural spring utilzing a spring catchment reservoir pumping to a higher altitude storage tank from where the water is distributed for irrigation. The villagers paid NPR. US$ 3,407 for the installation of the system. WI provided a pilot subsidy of US$1,436 through the AC-PVWP project and KISAN project provided US$192 to create a regional demonstration for other farmers in the district. Similarly, RISMFP and Pokharikanda VDC also provided grants of US$ 2,528 and US$ 1,292 for the installation of the system. .The system is managed and owned Milijuli Tarkari Utpadan Krishak Samuha farmer group.

Fig. 11: Pokharikada main water storage tank for solar water pumping from a spring for irrigation.

The PVWP helped the villagers make the transition from subsistence to commercial vegetable farming. The results for villagers has been life-changing from subsistence to commercial farming which has increased Ms. Granaja's income by 3-fold and enabled her to cultivate tomatoes and boost the quantity and quality of her crops. Now Ms. Granaja makes an annual profit of more than US$ 478.69 from tomatoes and US$ 287 from selling other seasonal vegetable and US$ 191 from livestock.

The technical skills provided by the KISAN project on commercial vegetable farming regarding the better seeds, vitamins, tillage, plant spacing, varieties and scheduling irrigation has been very effective. Mrs. Granaia

concludes that “The technical assistance from Winrock International has helped us to have received the solar water pump that requires less attention, effortless operation, and minimal maintenance.” The villagers now have a better financial status because of solar powered irrigation for commercial vegetable farming.

6. Commercial Rice Irrigation

A solar water pumping system was installed with WI assistance in the village of Odaltal of Surkhet District by Ghampower Pvt. Ltd. in November, 2016. The farmer group installed the distribution pipes and water storage tank in mid-2017. The system is managed by Jagaran Krishak Samuha, who is part of a 30 farmer cooperative group, whose chairperson is Ms. Tej Kumari Sunar.

The system consists of a 2,340 Wp array TrinaSolar modules from China (9S X 1 P configuration), each solar panel is 260 Wp. A 2,300 W Italian Pedrollo 2 HP AC surface pump is used to deliver water to the water storage tank from the spring reservoir. The total PVWP system cost was US$5,170, which excludes civil works such as the spring reservoir, storage tank, and distribution pipes. The irrigation system only became operational in mi-2017 and economic impacts for rice irrigation season have not yet been determined.

Figure 12: WI technicians measuring solar irradiance for the PVWP installed in Odaltal village of Surkhet District.

6.1. Rice and Vegetable Irrigation

A large solar water pump system was installed in November 2016 in Piparkoti, Valkachuha in Kailali District using a Trina Solar 3,120 kWp solar power array used for irrigation of rice and vegetables. The farmer group that uses this system was formed by USAID-KISAN project and has 20 members. The solar power system is owned and managed by Sirjana Krishak Samuha from the farmer group. The PV system is somewhat unique for solar water pumpoing in that it charges a battery bank to operate the solar pump and a crop grinder processing unit.

The battery bank is comprised of eight 150 Ah 12 V Asian batteries (made in Nepal) that are wired in a 4S X 2P configuration for a total capacity of 300 Ah at 48 V. (14,400 kWh). The battery bank is used to power a Chinese made 4 kW VOP Solar Hybrid Inverter model InfiSolar V 4000-48 operating at 220 V and 50 Hz. The PV power system operates an AC powered 1.5 HP Pedrollo AC surface centrifugal pump for irrigation. The total system cost of the PVWP was US$7,430 which includes the balance of system (batteries, inverter, etc.), as well as the crop grinder; it excludes civil works and power house costs.

Fig. 13: Piparkoti village inverter and controls for large scale rice irrigation

7. Lessons Learned

Solar water pumping technology ensures sustainable and effective access to water for irrigation, livestock watering and drinking water supply for smallholder farmers in Nepal. Easy access to water encourages smallholding farmers to carry out or increase their economic activity graduating them from subsistence farming to commercial farming. However, the key barriers for generating large scale commercial sales of solar water pumping systems are related to financial and market access issues, rather than technology which is reliable and mature. PVWP water pumping systems have dropped dramatically in price over the past decade, but still require a somewhat higher initial capital investment than diesel pumps. Experience in Nepal has shown that with access to financing, the challenges can be overcome by taking advantage of relative cost savings, increased reliability for both electricity and irrigation systems, increasing access to technology and technological assistance, and reduced greenhouse gas emissions, when compared with diesel pumps. Efforts to commercialize PVWP technology for irrigation are ongoing, by embedding the technologies in value chain projects which support farmers to increase income by growing off-season vegetables and fruits, fish, and livestock. Barriers include lack of awareness about the technology, high upfront costs, and absence of technical repair services can be overcome through demonstration projects, linkage with finance institutions, and partnerships with technology providers.

Abstract

Irrigation allows smallholder farmers to increase their yields and to grow two or even three crops of high-value vegetables and fruits a year, receiving higher commodity prices during the off-season. In Kenya in 2010, 2.5 million smallholders generated 80% of national horticulture production. Inexpensive diesel water pumps (US $200) are available, but fuel purchase and transport costs are significant (typically US $100–$300 per 3-month season for one acre); as a result farmers are conservative with, or cannot afford, diesel irrigation. Return on Investment case studies by Winrock International show an increase in gross profits of up to 186% within one to two crop seasons after purchase of a solar water pump (SWP). Between August 2015 and December 2016 Winrock demonstrated SWPs to more than 16,000 smallholder farmers in Kenya and found that despite strong demand, the lack of smallholder credit options for solar irrigation is a key obstacle preventing SWP sales from increasing rapidly; financial institutions and SWP retailers need technical assistance to facilitate smallholder access to credit.

Keywords: smallholder, solar irrigation, solar water pump, finance, return on investment, Kenya

1. Introduction

In Kenya in 2010, 2.5 million smallholders generated 80% of horticulture production. 80% of the country's land surface is classified as arid and semi-arid; the majority of people living in rural areas depend on rain-fed agriculture for their livelihoods. Historically, rains occurred in January, February, November and December, with dry conditions the rest of the year. Climate change is affecting rainfall patterns, which in turn is causing increased crop failures and lower yields. Expanding irrigation is a key mitigation strategy for smallholders (Karina 2011). Irrigation can assist in agricultural diversification, enhance food self-sufficiency, increase rural incomes, generate foreign exchange and provide employment opportunities when water is a constraint (Ngigi 2002). Irrigation can allow smallholder farmers to increase their yields and grow two or even three crops of high-value vegetables and fruits a year, receiving higher commodity prices in the dry seasons.

Winrock International is a non-profit organization that works to empower the disadvantaged, increase economic opportunity and sustain natural resources around the world. Winrock has been working to increase smallholder productivity and income through affordable on-farm solar technologies, including solar chillers and solar water pumps.

Solar water pumping is a mature, reliable, and economically attractive solution for off-grid irrigation, livestock water, and community water supply. A 2008 Rutgers University study showed that vegetable growing using solar irrigation is cost effective compared to grid-connected drip irrigation. Given that rural smallholders in Kenya have an increasing need for irrigation but limited access to conventional energy sources, solar water pumps (SWPs) are a critical tool for ensuring food security and decreasing poverty. However, smallholder adoption of solar irrigation is hampered by lack of awareness of affordable, high-quality solar pump products, and lack of access to finance for solar pump purchases.

2. Solar Water Pumps in Kenya: Supply and Demand

doi:10.18086/swc.2017.30.03 Available at http://proceedings.ises.org

In mid-2015, when Winrock International began demonstrating solar water pumps (SWPs) in Kenya under the USAID-funded Kenya Smallholder Solar Irrigation (KSSI) project, there were two high-quality, affordable small scale SWPs locally available. The US $450 SunFlower pump by Futurepump was designed to operate up to 10 meters Total Dynamic Head (TDH), and the US $2,200 SunCulture SP-300 pump was designed to operate up to 50 meters TDH (Kunen, 2015). SWP retailers were receiving individual pump orders but having difficulty aggregating purchases from smallholder farmers (<2 acres). During farmer field days attended by more than 16,000 farmers between August 2015 and December 2016, Winrock found very high interest in SWPs among farmers, but few had the cash needed to purchase a SWP. The most frequent comments from farmers were that the SWPs should be cheaper, and that financing would greatly facilitate purchases.

By early 2017 there were four high-quality affordable small scale SWPs locally available, including the new $350 Majipump MP 400 offered by Chloride Exide, and the $1,500 D3Solar offered by Davis & Shirtliff. The SunFlower had increased in price to US $650 and the SunCulture SP-300 pump had decreased to US $1,740. In October 2017 SunCulture launched the US $500 RainMaker pump, which claims to pump 7,000 liters per day at 100 meters total dynamic head, but has not yet been tested by Winrock. Given that the majority of the 5 million smallholder farmers in Kenya live in areas where TDH is between 10 and 50 meters (**Fig. 1**), Winrock estimates conservatively that 2 million smallholders in Kenya could achieve significant income benefits from the SWPs currently on the market. An efficient way to accelerate commercial sales of SWPs is through existing aggregation mechanisms targeting smallholder horticulture producers, including cooperatives, wholesale buyers, exporters, and processors.

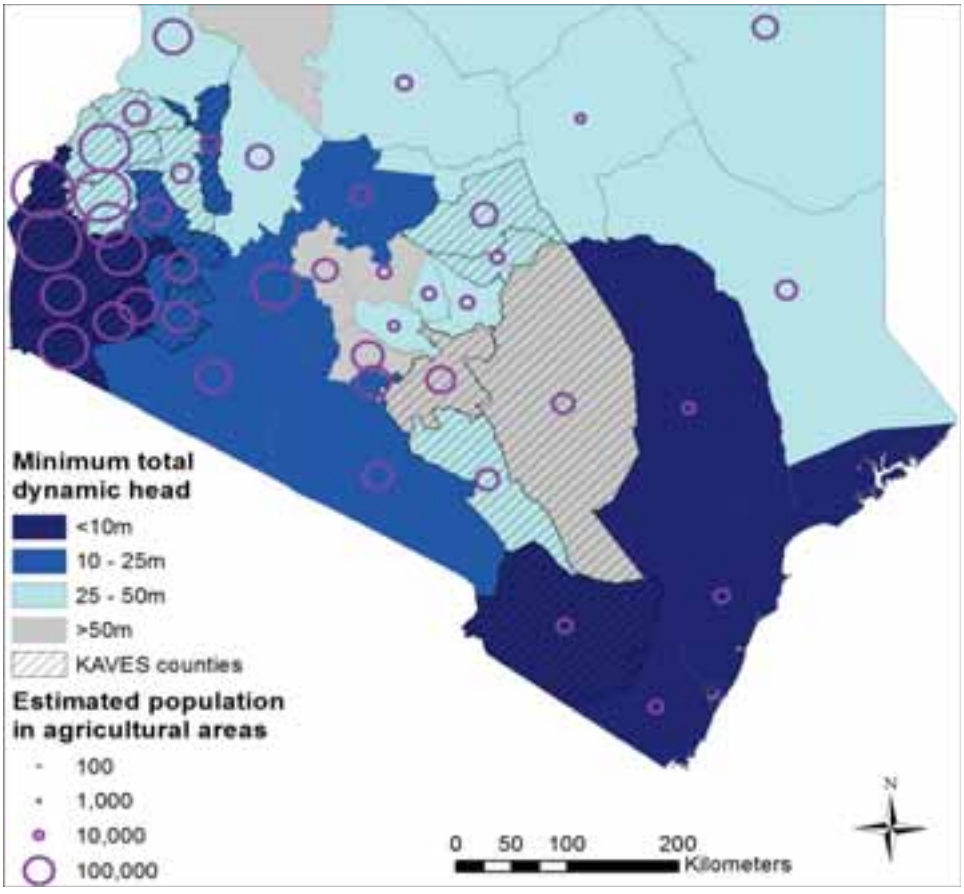

Fig. 1: Minimum total dynamic head vs estimated farmer population in Kenyan counties.

3. Smallholder Finance Options

Between August 2015 and May 2016, KSSI facilitated demonstrations of the Futurepump SWP at farmer

field days hosted by the Kenya Agricultural Value Chain Enterprises project. More than 8,000 farmers visited the Futurepump booth, yet only 9 SWPs were sold for cash during the events. In late 2015 Winrock began an effort to facilitate solar pump finance from Kenyan financial institutions (FIs). At the time Winrock could only identify one FI, Equity Bank Kenya, with an existing solar pump loan product for smallholders. Equity reported that, because of perceived high credit risk, they had rejected most of the 200 solar pump loan applications they had received since they created the loan product. Reasons included lack of farming experience or an alternative salaried income; lack of land ownership; and lack of required collateral.

Interviews with more than 20 Kenyan FIs showed that prevailing loan terms – if solar pumps were classified as agricultural loans – would be difficult for most smallholders to meet. Annual interest rates were 22% and up; a 20-30% down payment was required; and some FIs also required credit and crop insurance, which each added up to 10% in one-off interest fees. However, every FI interviewed by Winrock expressed interest in solar pumps as a way to mitigate risks of rainfall variability and drought, therefore lowering overall default rates in their existing agricultural portfolios. FIs acknowledged the high demand for solar pumps from their clients, but were hesitant to enter the market because of uncertainties about supply, performance, and cost of solar pump products.

Winrock selected five FIs as potential partners to create solar pump loan products. All five FIs had offices in areas with high solar pump demand and strong distribution and after-sales support from retailers. Three FIs – Juhudi Kilimo, ECLOF Kenya (through its affiliate Ecosmart Energy Limited, a renewable energy distributer), and the Kenya Union of Savings and Credit Co-operatives (KUSCCO) – moved forward with Winrock-supported loan pilots under the following terms:

- Commitment to lend to at least 50 SWPs over a period of 3 months;
- Affordability of credit to smallholder farmers, defined as owning less than 5 acres and having limited financial history and physical collateral;
- Availability of capital to put toward SWP loans;
- Willingness to share training costs;
- Strong senior management buy-in; and
- Readiness of systems and internal processes to lend into a new product.

Winrock served as a bridge between two FIs and a solar pump retailer, assisting them to negotiate terms for pricing, target sales volumes, demonstration pump units, distribution and after-sales support. FIs were reluctant to handle stock (which also results in a Value-Added Tax that they are not able to charge to loan clients), so an intermediary distributor or stockist was engaged near FI branch offices.

To decrease the risk perception of the FIs, Winrock provided data on farm-level return on investment case studies (**Section 5**), which showed payback times of 1.5 years or less; and on typical solar pump warranties (20 years for solar panels, 2 years for pumps). The warranty and payback periods match well with a 2-year loan tenor. Winrock advised the FIs to classify solar pump loans as asset financing, typically viewed as less risky, requiring less collateral and enabling better loan pricing. Winrock also provided solar pump technical training to FI senior management teams and branch loan officers.

During an initial loan marketing phase, issues that required troubleshooting from Winrock included miscommunication over pump delivery logistics, and adjustments to the marketing strategy to ensure that loan officers were targeting savings groups that had the capacity to take on new loans.

After 6 months, results included 5 solar pump loans made by Juhudi Kilimo, and 40 smallholders who had initiated savings with Ecosmart to qualify for a solar pump loan. One year later, the emergence of two lower-cost SWPs on the market has caused Juhudi Kilimo to adjust its SWP product offering, since many of its clients need a higher-powered pump than the one they had been offering. They plan to incresae the SWP loan size to include a water tank, piping and drip irrigation kit. Given the 2017 drought in Kenya they are also assessing other solutions including water conveyance and storage. Ecosmart is also seeking to offer one of the new lower-cost SWPs, as many of their clients felt the price of the original SWP product was too high. ECLOF's members have saved US $3,000 toward SWP loans.

Key lessons learned were:

- Co-guarantees in a group lending arrangement did alleviate prohibitive collateral requirements, but required a lead time of at least 3 months or more for existing loan groups to build up the required savings for credit disbursal. For new farmer groups the lead time was nearly double that of existing loan groups.

- Solar pump products must match smallholder needs in several key ways: the pump must perform at the required TDH; accessories must also be offered on credit if needed by farmers (e.g. pipes, water tank and/or irrigation drip kit); and smallholders must perceive that the SWP price is affordable.
- Aggregation mechanisms are an effective next step to gain scale and reduce costs when commercializing a new technology. Aggregation brings about volumes and bulk pricing discounts that eventually lead to lower prices for smallholders. For technical assistance providers, aggregation also offers economies of scale to reach thousands of farmers while minimizing program costs.

4. Pump Technologies Deployed

The KSSI project installed several types of solar water pumps for crop irrigation and aquaculture. There are two families of pump mechanisms with a range of options depending on water volume needs, pumping depth, and lift; thus there are two mechanical principles by which a pump can create pressure. Displacement pumps (also called positive displacement or volumetric pumps) move water by isolating it in sealed chambers, and applying mechanical action to force it upward. Displacement pumps work efficiently through wide ranges of speed and head. The KSSI project used mostly positive displacement pumps for small pumpig systems <2kW in both surface and submersible configurations as described in the following sections.

3.1 Reciprocating Displacement Pump

The SunFlower pump (**Fig. 2**), sold by Futurepump, is a portable solar irrigation pump manufactured in India. It raises a close-fitting piston in a submerged pipe to draw water up behind it to fill the vacuum which would otherwise occur; this works only up to a certain limit of the height water can be pulled by suction (~10 m maximum limit), see **Fig. 3**. The piston serves to create a vacuum and the water is actually displaced by atmospheric pressure pressing on its external surface. So water is displaced by "pulling." The KSSI project facilitated deployment of 172 SunFlower pumps, mostly in the Lake Victoria region of Kenya (**Section 5.2**).

Fig. 2: Futurepump SunFlower (SF1) is a micro-size piston pump for small-farm irrigation. To reduce cost and complexity, it uses a two-speed manual transmission instead of an electronic controller, and manual solar tracking. Photo: Winrock International Kenya.

4.2 D

iaphragm Pumps

Diaphragm pumps displace water by means of a diaphragm made from a flexible synthetic material (elastomer). Normally there are three or four pumping chambers, each with a check valve for the intake, and another for the outlet. Diaphragm pumps supply low volume water needs at high efficiency and low cost. A diaphragm pump may be used for solar pumping where the initial cost must be minimal, the water volume requirement is very low, and the future cost of maintenance frequent replacement is acceptable. Diaphragms normally need to be replaced after a two or three years of continuous use, due to normal material fatigue and wear. Manufacturers of these pumps provide replacement kits, or the entire pump may be replaced at low cost. Pumps that provide low lifts (the lower half of their capacity) can last longer than those operating at higher lifts. Diaphragm pumps are generally not a good choice for communal water pumping systems due to their higher maintenance requirements.

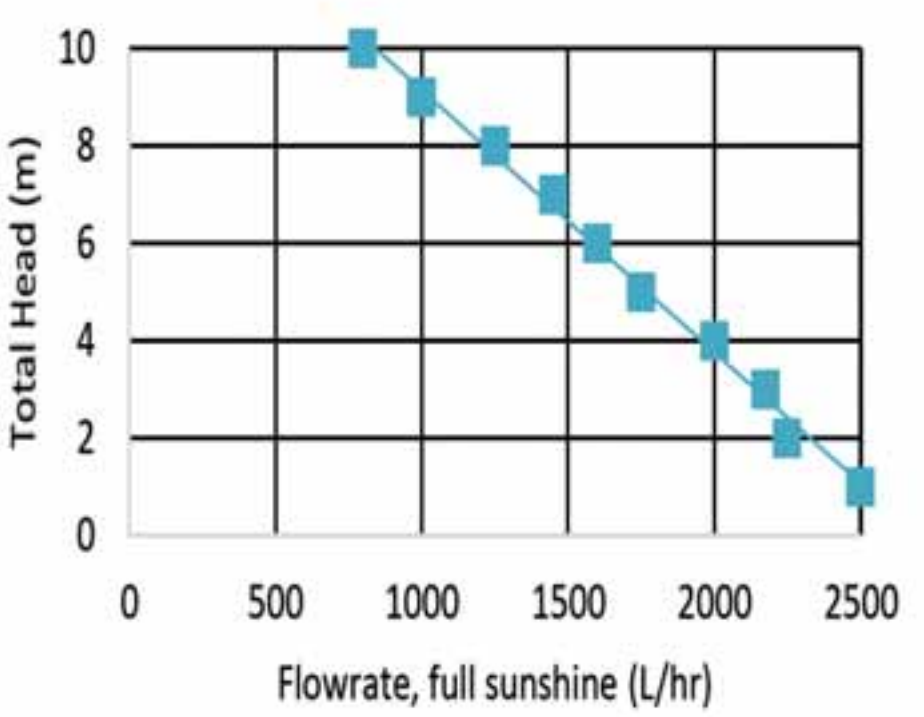

Fig. 3: As shown by the SunFlower pump manufacturer's performance curve, it can lift 2,000 lph at 4 m head at 1,000 W/m² irradiance using only an 80 Watt PV module. Courtesy: Futurepump

Diaphragm pumps are most appropriate for small volume requirements such as single-family drinking water or livestock pumping. If the pump is to be run every day, year-round, a HR pump should prove more economical in the long run.

Fig. 4: Winrock technicians inspecting two Ubink PV modules made in Kenya for the Machakos solar diaphragm pump system. The farmer brings her PV modules in at night for security reasons.

4.3 Helical Rotor Pumps

A helical rotor pump (HR) is a positive displacement pump that offers a wide range of volume and lift capacities at high efficiency. The pump end has only one moving part lubricated by water that produces continuous flow, free of pulsation (unlike a diaphragm pump) and requires no preventive maintenance. The HR pump has the best characteristics of any type of displacement pump due to its simplicity and reliability. It is optimum for flow ratesup to ~60 lpm for vertical lifts that exceed 20 m.

The HR pump's rotor is a helix made of stainless steel which fits precisely into a rubber stator (stationary outside tube), see **Fig. 5**. The inside surface of the stator is formed of two intertwined helixes, with an ovoid cross-section. The surfaces of the rotor and stator intersect to form a series of sealed cavities (hollow spaces). As a cavity forms at the intake end, it draws water in. As the rotor turns, the cavity seals and progresses upward (also called a progressive cavity pump). The pumped water lubricates the rotor. As with any pump, a high concentration of abrasive particles will cause premature wear of the rotor and stator.

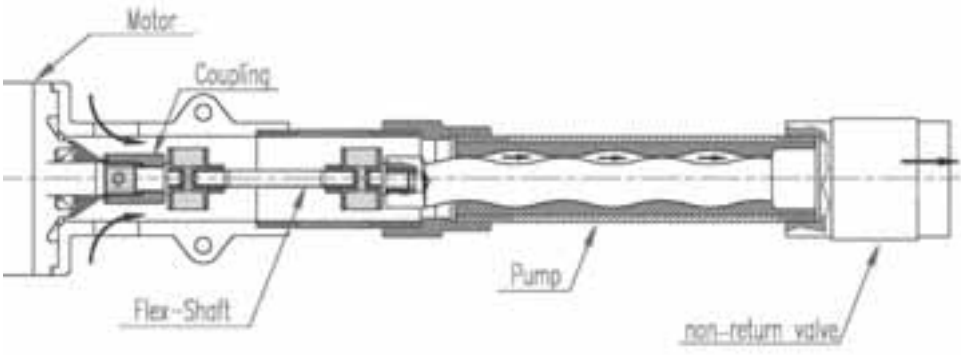

Fig. 5: Cross-section of typical helical rotor pump end (Foster et al, 2009).

A check valve at the pump's outlet prevents possible leakage downward when the pump is stopped. By relieving pressure, it tends to make the pump easier to start. The check valve closes only when the pump stops. Electronic controllers for HR pumps supply a boost of current, and precise control during startup. The KSSI project facilitated the installation of a relatively large solar pumping system in Nyandarua county, which uses an HR pump (**Fig. 6**).

Fig. 6: Lorentz helical rotor 8.1 kW_p solar water pumping system providing community and irrigation water supply to 500 farmers in Nyandarua County. The borehole is 230 meters.

5. Solar Pump Return on Investment Case Studies

Winrock conducted detailed farm-level return on investment case studies from 2015 to 2017. The case studies, which represent different pump price points, show strong returns within one to two crop seasons.

5.1 Solar drip irrigation in Machakos County

Mr. Shadrack Nzioka has farmed since 2006 in Muuani Village, Machakos County. He was using a diesel pump to transfer water to a pond, from which he irrigated 0.25 acre of onions with a treadle pump. In August 2015 Mr. Nzioka invested US $2,670 in a 27 meter borehole, a water tank, and land clearing. He purchased a US $2,500 SunCulture SWP and drip kit through a US $2,000 loan from Equity Bank at 18% interest; he will make a monthly loan payment of US $100 for two years. The helical rotor solar pump, which is powered by a 300 Wp solar module, automatically fills a water tank connected to drip irrigation (**Fig. 7**). During the first season after purchasing the SWP Mr. Nzioka irrigated 0.25 acres of onions. During the second season after purchasing the SWP Mr. Nzioka increased to a total of 0.875 acre: 0.25 acre of onions, 0.5 acre of passion fruit and 0.125 acre of tomatoes.

Fig. 7: Installation of water tank and drip lines at Shadrack Nzioka's farm.

The solar pump allowed Mr. Nzioka to increase his irrigated acreage from 0.25 to 0.875 acre, eliminate diesel fuel costs, and grow two crops per year instead of one. Using conservative estimates, he maintains his gross profit while paying off the two-year solar pump loan. Using conservative estimates, his gross profit is projected to increase by 100% after he pays off the loan. A profit and loss analysis for Mr. Nzioka is shown in **Table 1**.

5.2 Solar irrigation in Homa Bay county

Ms. Lilian Akinyi rents a farm in Homa Bay County near Luala Kambuya village. She was using a diesel pump to transfer water from a canal which is fed by the Sondu Miriu River. She hired the diesel pump one day a week for US $5.50, which included pump rental, petrol and transport. She irrigated 0.75 acre of tomatoes with the diesel pump and 0.25 acre of kale with a watering can. In September 2016 Ms. Akinyi purchased a Futurepump solar pump powered by a 80 Wp solar module and a 12-meter pipe (US $36) through Futurepump's Pay-As-You-Go program. She paid US $236 down, and will make a monthly loan payment of US $20 for 22 months. She stopped using the diesel pump as soon as she purchased the solar pump.

Fig. 8: Lilian Akinyi with her 0.75 acre maize crop, December 2016.

Ms. Akinyi no longer has diesel pump rental, fuel and transport costs, has increased her irrigated area from 1 to 1.25 acres, has added a maize crop (**Fig. 8**), and is irrigating more frequently than before. We assume she will increase to 1.5 acres by the second season after purchasing the solar pump. Using conservative estimates, her gross profit is projected to increase by 186% by her second season after purchasing the solar pump. A profit and loss analysis for Ms. Akinyi is shown in **Table 2**.

Abstract

It the current energy context it is necessary to implement highly efficient and cost-effective systems in order to reach indoor comfort conditions with minimum energy consumption. This paper aims to analyze the performance of an unglazed transpired solar collector (UTSC), which represents a building envelope element, and to assess the efficiency of two types of external metal cladding: with circular orifices and with lobed orifices. Several experimental campaigns were conducted using different approaches and the results are very interesting: the metal plate with lobed orifices increases the efficiency of the solar collector, providing an enhanced thermal transfer and higher exhaust temperatures. The use of lobed orifices rises the outlet air temperature with 10% more than in the case with circular orifices by enhancing the heat transfer between the metal plate and the air flow due to the more complex dynamic of the lobed flows near the metal absorber. The rise in temperature in case of using lobed orifices is 22.9°C and the metal plate temperature is 64.5°C. An experimental study regarding the implementation on phase changing materials (PCM) in transpired solar collectors was also conducted.

Keywords: Transpired solar collector, TSC, solar wall, energy efficiency, lobed orifices, circular orifices, PIV, phase changing materials, PCM

1. Introduction

Nowadays, the buildings sector is responsible for over one-third of the total energy consumption and CO_2 emissions, being the largest energy consuming sector in the world (IEA, 2013), while the requirements regarding energy use reduction and the CO_2 emissions are more and more strict (EU, 2015).

After the COP21 conference all the members of the UN agreed to limit the global warming even to 1.5°C above preindustrial level in next eighty years (Gütschow et al., 2015) and furthermore all the European Union states must reduce the CO_2 emissions with 20% until 2020 and 40% until 2030, and must reduce the primary energy consumption with 27% until 2030 (EU, 2014). Therefore, in order to reach these goals it is necessary to implement highly efficient systems and solutions by using renewable energy sources to obtain the indoor comfort parameters with minimum energy consumption.

One of the most promising strategies that could be used in this purpose is the use of the solar air collectors which can represent a cost-effective solution (Dymond and Kutscher, 1997, Gill et al., 2012). There are many types of solar collectors used in order to pre-heat the air (Shukla et al., 2012). Thermal solar walls can be classified in several types and categories (Hami et al., 2012) but the two main categories are: glazed solar collectors (GSC, e.g. Trombe walls) and unglazed transpired solar collectors (UTSC – usually used as façade elements). Transpired solar collector are more efficient than plane solar collectors (Belusko et al., 2008) and the efficiency can be even higher with 50% (Chan et al., 2014). According to the literature transpired solar

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2017.31.01 Available at http://proceedings.ises.org

collectors have lower investment costs and also lower operation costs, being an excellent cost-benefit, energy-efficient system (Nkwetta and Haghighat, 2014, Wang et al., 2017).

The UTSC usually presents a perforated metal plate which, together with the building wall, creates a cavity for the air flow. The metal plate is heated by the solar radiation and the energy is yielded to the air which is extracted from the top of the wall and afterwards, it is introduced in the building. The operating principle of the unglazed transpired solar collector which acts as a solar wall for the building envelope is highlighted in figure 1.

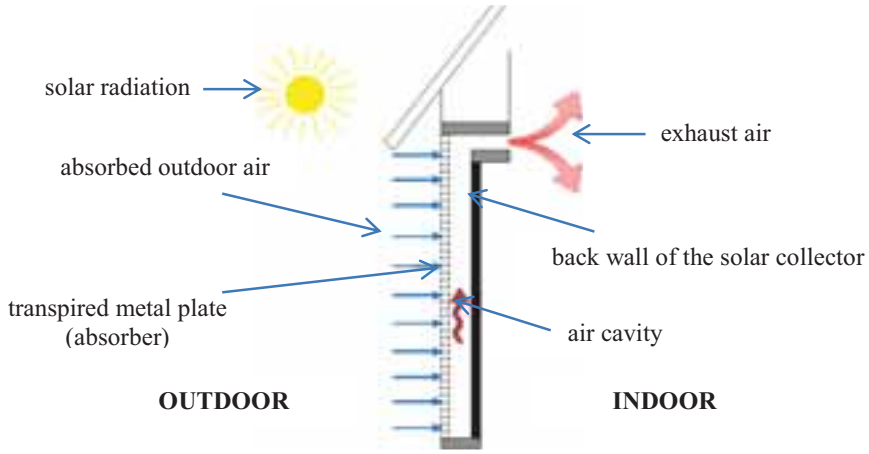

Fig. 1: The operating principle of an unglazed transpired solar collector acting as a solar wall

The solar radiation, ambient (outdoor) temperature, air flow, orifices geometry, pitch, collector geometry, solar absorber material are very important parameters which defines the efficiency of a solar collector (Zhang et al., 2016). Also in order to assess the impact of a transpired solar collector it is important to determine the rise in temperature (ΔT, difference between the outlet air temperature and ambient air temperature), the efficiency of the solar collector (η) and the efficiency of heat transfer or heat exchange effectiveness (η_t) (Van Decker et al., 2001, Leon and Kumar, 2007).

According to Wang et al. (2017) these parameters can be calculated with the following formula, where: c_{air} is specific heat capacity of air (J kg^{-1} K^{-1}), $\dot{m}_{air}$ is air mass flow rate (kg s^{-1}), $T_{air,out}$ is outlet air temperature (°C), T_a is the ambient air temperature (°C), G_s is the incident solar radiation on the collector (W m^{-2}), A_s is collector area (m^2) and T_p is the average absorber plate temperature (°C):

$$\eta = \frac{c_{air}\dot{m}_{air}(T_{air,out}-T_a)}{G_s A_s} \quad \text{(eq. 1)}$$

$$\Delta T = T_{air,out} - T_a \quad \text{(eq. 2)}$$

$$\eta_t = \frac{T_{air,out}-T_a}{T_p-T_a} \quad \text{(eq. 3)}$$

A very interesting study found in the literature emphasize that if the orifices diameter and the pitch have lower values, the heat transfer efficiency is enhanced (Leon and Kumar, 2007). An experimental study (Wang et al., 2017) shows that a transpired solar collector could reach a rise in temperature up to 31.16°C and an efficiency up to 74.93% depending on the input conditions (tests were made for solar radiation from 400 W m^{-2} to 1000 W m^{-2} and air flow between 80 (m^3 h^{-1}) and 200 (m^3 h^{-1})).

According the literature a UTSC could reach a rise in temperature between 6°C and 35°C, and an efficiency between 19% and 75% (Konttinen et al., 2005, Leon and Kumar, 2007, Cordeau and Barrington, 2011, Li, 2013, Perisoglou and Dixon, 2015, Wang et al., 2017). Even if there are many studies regarding the performance of the transpired solar collectors, very few authors focused their attention on the geometry of the orifices even if, according to the studies, 28% of the heat is transferred to the air in the orifice (Van Decker et al., 2001). Usually the metal plate orifices have circular shape. However, the lobed geometries studied before by researchers could improve the heat transfer because of the complex dynamics of the flows and streamwise vortices induced (Nastase et al., 2008, Nastase and Meslem, 2010).

The main objective of the present paper is to assess the impact of the geometry of orifices on the thermal efficiency of an UTSC in to cases (circular orifices plate and lobed orifices plate) and to determine new ways to improve the efficiency of the transpired solar collector.

2. Experimental setup and methodology

In order to achieve the objective presented above a physical model was built and tested. The graphical representation is emphasized in figure 2 and the physical experimental stand is pointed in figure 3 and figure 4.

The unglazed transpired solar collector proposed consists of a rectangular box with the following dimensions: 116x70x23 cm (figure 2). In addition to the UTSC built, the following materials and equipment were used for the experimental study (see figure 2, 3 and 4):

- Fan with variable flow (1)
- Interchangeable metal plates (2a – with circular orifices and 2b – with lobed orifices)
- Six halogen lamps (3) in order to simulate solar radiation (800 Wm^{-2}).

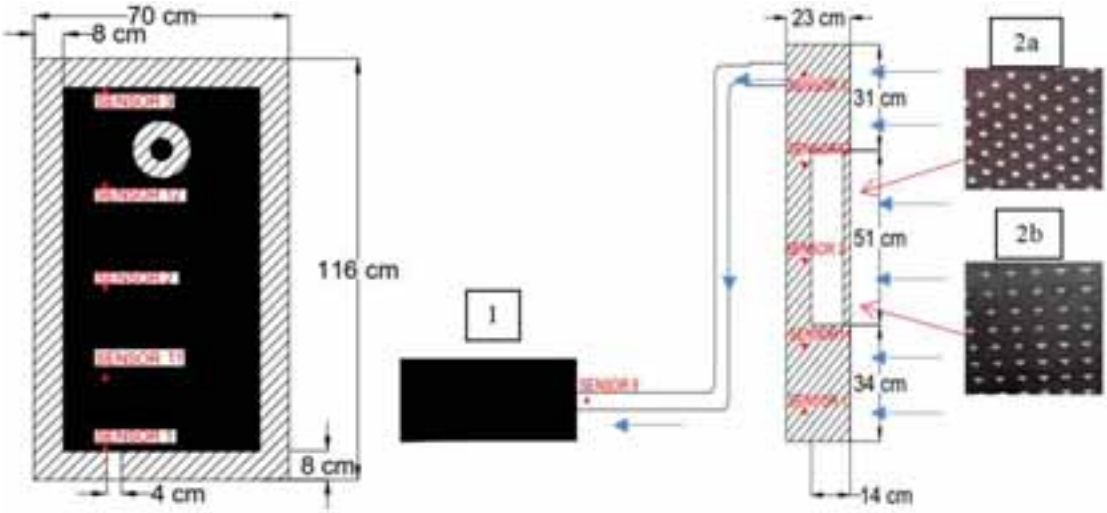

Fig. 2: Graphical representation of the UTSC (front and side view, dimensions, location of the temperature sensors)

The cavity formed between the metal plate and the back wall has 20 cm width and the wall is insulated with 5 cm of extruded polystyrene. The solar radiation is simulated by six halogen lamps placed on a stand 50 cm from the solar wall which generates 800 W m^{-2} (figure 4). Furthermore, the heat is embodied in the metal plate which acts as a solar absorber and then it is ceded to the air that passes through the orifices (circular or lobed). The heated air is extracted from the upper part of the UTSC through a 15cm hole using a fan with variable flow which forces the ambient air to pass through the transpired metal plate.

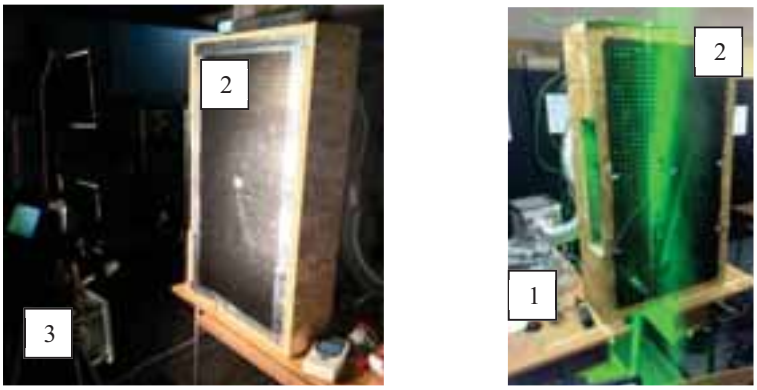

Fig. 3: Experimental setup of the UTSC during the measurements (temperature and velocity)

In order to measure the gradient of temperature within the UTSC, five sensors were placed inside the box in different places at 25 cm distance from each other (1, 11, 2, 12 and 3).

Other three sensors were used in order to assess the impact of the UTSC on the rise in temperature between ambient air extracted and the air exhausted:

- Thermocouple placed on the metal plate (sensor 4, T_p)
- Thermocouple located in ambient (sensor 14, T_a)
- Thermocouple placed on the exhaust/outlet duct (sensor 9, $T_{air,out}$).

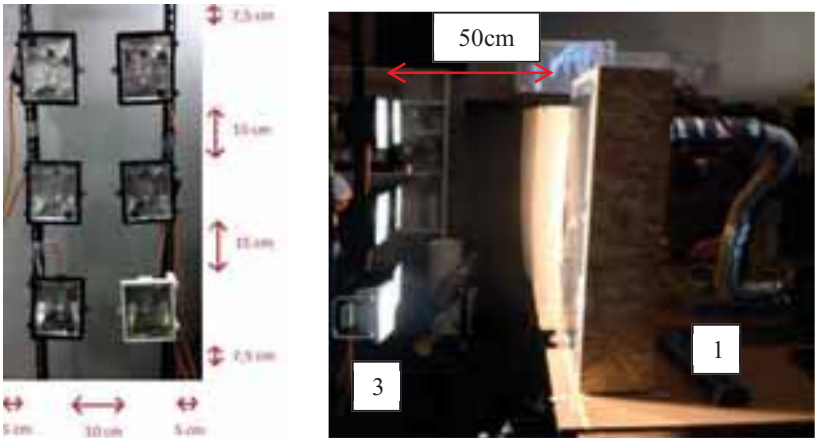

Fig. 4: Positioning of the halogen lamps in the experimental setup

All the data was collected using a very precise data logger. We also used the PIV measuring technique (Particle Image Velocimetry) in order to evaluate the velocity induced by the circular and lobed orifices (figure 3) and to determine the impact of the lobed geometry on the air flow, air mixing and efficiency of the solar collector.

3. Results and interpretations

Following the experimental campaigns conducted we have obtained interesting results. The measurements were made at different air flows and the most representative results are highlighted bellow for 29 (m^3 h^{-1}). Because the ambient temperature has a constant value, we waited for the other values to stabilize (metal plate temperature and exhaust temperature) and we collected the data which is presented below.

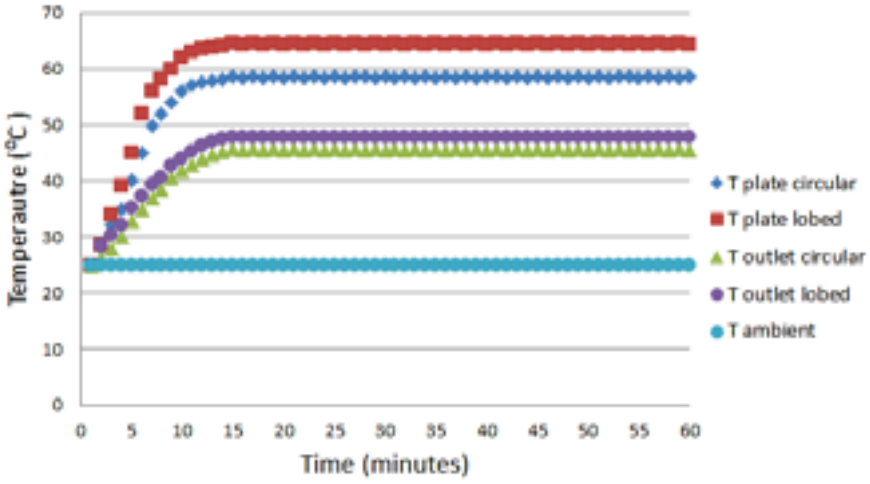

Fig. 6: Temperature variation inside the experimental setup for 29 (m^3 h^{-1})

As it can be observed in figure 6, the metal plate temperature stabilizes after almost 9 minutes of functioning

at approximately 58.5°C in case of the metal absorber with circular orifices and at almost 64.5°C in case of the metal plate with lobed orifices. Furthermore, the outlet air temperature stabilizes after 14 minutes of functioning at approximately 45.7°C in case of the metal absorber with circular orifices and at almost 47.9°C in case of the metal plate with lobed orifices.

The measurements conducted analyze the behavior of the unglazed transpired solar collector studied from two points of view: thermal and dynamic.

3.1. Thermal analysis

In figure 6 it is emphasized the variation of exhaust air temperature and also, the temperature on the metal plate, in both cases (metal plate with circular orifices and metal plate with lobed orifices). It can be observed that at the same ambient temperature (25°C), the temperature on the metal plate is 58.5°C in the case of using circular orifices and 64.5°C in case of using lobed shaped orifices. In this case, the temperature on the metal plate is higher with 6°C (which means almost 9.2% more) when using the plate with lobed orifices which clearly means that the geometry improves the heat exchange and the efficiency of the solar collector.

Moreover, it can be noticed from figure 6, that at the same ambient temperature (25°C), the exhaust temperature is with 2.2°C higher when using the plate with lobed orifices (47.9°C unlike 45.7°C), which means 5% more compared to the use of the metal plate with circular orifices. The rise in temperature in the case of the experimental study conducted with the plate with circular orifices is approximately 20.7°C and, in the second case, with the metal absorber with lobed orifices, the rise in temperature is approximately 22.9°C which means an increase of 10%.

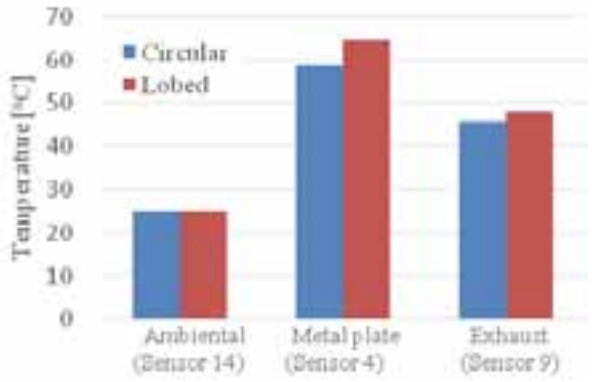

Fig. 6: Metal plate temperature variation and exhaust air variation for 29 (m^3 h^{-1})

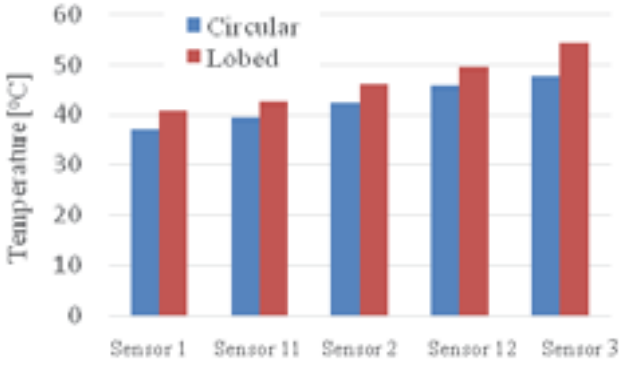

Fig. 7: Temperature measured in several points in the UTSC for 29 (m^3 h^{-1})

In figure 7 it is represented the vertical temperature variation inside the UTSC, also in both cases with circular and lobed orifices. It can be observed that the metal plate with lobed orifices enhances the heat transfer and air reaches a temperature of 54.3ºC at the top of the experimental setup (sensor 3), while in case of the metal plate with circular orifices, the air temperature reaches 47.6ºC, which means an increase in efficiency of 14%. Also, in every point where the sensors are placed, the temperature values are bigger in case of using the lobed orifices. Sensor 1 measures 40.5ºC in case of using lobed orifices unlike 37.5ºC in

case of using circular shaped orifices, sensor 11 measures 42.5ºC unlike 39.7ºC, sensor 2 measures 46.2ºC unlike 42.1ºC and sensor 12 measures 49.8ºC unlike 45.6ºC.

3.2. Dynamic analysis

Regarding the dynamical analysis, the plate with lobed orifices presents several advantages. From the results obtained using the PIV methodology, it can be noticed (figure 8) that the metal plate with lobed orifices provides higher velocities (in longitudinal section) and a uniform velocity variation. In case of using the plate with lobed orifices the maximum air flow velocity is 0.6 m s^{-1} and in case of using the plate with circular orifices the maximum air flow speed is 0.3 m s^{-1}. Moreover, the jet length is bigger for plate with lobed orifices (with 3.1 mm), resulting a better air mixing.

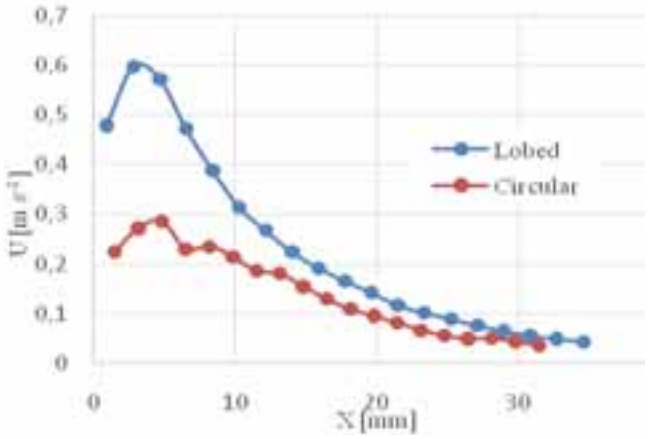

Fig. 8: Air flow velocity profile along the jets axis for airflow of 29 (m^3 h^{-1})

The difference between the jets and the flows in both cases can be seen in figure 9, which represents the velocity fields for the airflow of 29 (m^3 h^{-1}). As it can be observed, in case of using the lobed orifices it results a better air mixing and a stabilization of the jet flows inside the cavity determined by streamwise vortices created by this geometry. Moreover, because of the more complex dynamic of the lobed flows near the metal plate (absorber) the heat transfer is enhanced which determines a higher air temperature inside the cavity and a higher outlet air temperature, as it has been presented in the previous chapter.

With all these important results taken into account we can conclude that the lobed geometry provides a better flow profile and enhances the thermal transfer while increasing the efficiency of the unglazed transpired solar collector.

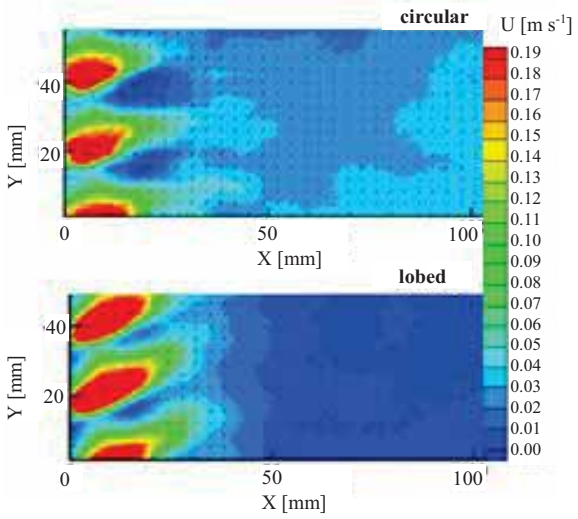

Fig. 9: Velocity fields of the circular and lobed jets extracted from PIV measurements (m^3 h^{-1})

3.3. Further studies and perspectives

According to the literature, the solar air collectors which are using renewable solar energy could be improved by adding thermal storage (Goyal et al., 1998, Khadiran et al., 2016). Thermal inertia can increase the operation time of the unglazed transpired solar collector, could stabilize the outlet air temperature (also increasing the comfort) and could increase its overall efficiency by overcoming the periods when the solar radiation is unstable/variable (during the day or during the night-time).

One of the most effective way to store energy is the use of latent heat storage materials or Phase Changing Materials (PCM) which can store 5 to 14 times more energy than classical materials (Kuznik et al., 2011).

In order to assess the impact of thermal inertia implemented in the solar collector we used the RT-25 phase change material from Rubitherm, an organic material (paraffin) with the following characteristics:

- Melting temperature: 22-26ºC
- Congealing area: 26-22ºC
- Heat storage capacity: 170 kJ kg^{-1}
- Specific heat capacity: 2 kJ kg^{-1} K^{-1}
- Heat conductivity: 0.2 W m^{-1} K^{-1}
- Density: 0.88 kg l^{-1} (solid), 0.76 kg l^{-1} (liquid).

The PCM was macro-encapsulated in four aluminum recipients with the following dimensions: 200x100x10 mm which were placed on the back wall of the UTSC presented in the previous chapters, with the same geometry and with the same conditions. For this experimental study we used the metal plate absorber with lobed orifices and the ambient temperature was 21ºC.

The study was conducted for two hours, respectively 7200 seconds. The test was divided in two equal steps: heating (the lamps are on, simulating solar radiation) and cooling (lamps are off, simulating cloudiness or night-time). As it can be observed in figure 10, the outlet air temperatures are stabilizing very quickly, after approximately 9 minutes. During the heating phase the outlet air temperature is lower in case of using PCM (with approximately 7ºC) which means that the materials store the heat. After the heating phase is over, the outlet air temperature drops also quickly (almost 15 minutes) but for the remaining time, the outlet air temperature is higher with 1.3ºC in case of using phase changing materials in the cavity of UTSC, which means that PCM are slowly releasing the heat stored.

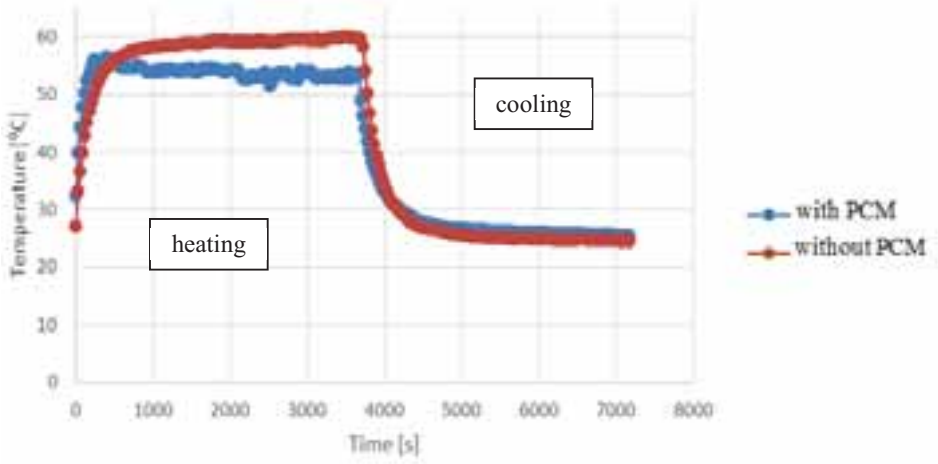

Fig. 10: Outlet air temperature variation in both cases: with and without PCM mounted on the back wall

This phenomenon still needs to be investigated and it opens new perspectives regarding the improvement of transpired solar collector efficiency by storing solar energy. More thermal storage could be added which can enhance the total capacity and a higher phase changing temperature is needed, near to the average temperature inside the cavity.

4. Conclusions

Transpired solar collectors are cost-benefit solutions which can significantly reduce the heating systems consumptions by heating or preheating the fresh air and could contribute to the reduction of CO_2 emissions around the world.

This paper is assessing a transpired solar collector performance by comparing and highlighting the importance of metal plate absorber by means of orifices geometry. Two types of orifices were studied: circular and lobed, and many interesting results were obtained.

After several experimental campaigns conducted we can conclude that:

- In case of using circular orifices the metal plate temperature is stabilized at 58.5ºC, while using lobed orifices the metal plate temperature is approximately 64.5ºC
- In case of using circular orifices the outlet air temperature is stabilized at 45.7°C, while using lobed orifices the outlet air temperature is approximately 47.9°C (5% more)
- The UTSC using metal plate with lobed orifices is more efficient, the temperature at the upper side of the UTSC being higher with 14% (6.7°C)
- The rise in temperature in case of the metal plate with lobed orifices is being higher with 10% (2.2°C)
- The rise in temperature in case of using lobed orifices is 22.9°C (unlike 20.7°C in the case of circular orifices)
- After the dynamic analysis we can observe that in case of using the lobed orifices it results a better air mixing and a stabilization of the jet flows inside the cavity determined by streamwise vortices created by this geometry
- In case of using the metal plate with lobed orifices the maximum air flow velocity is 0.6 m s^{-1} and in case of circular orifices the maximum is 0.3 m s^{-1} resulting a better air mixing (the jet length is also bigger with 3.1 mm)
- Because of the more complex dynamic of the lobed flows near the metal plate (absorber) the heat transfer is enhanced which determines a higher air temperature inside the cavity and a higher outlet air temperature.

We've also conducted studies with thermal inertia materials, such as phase changing materials and the preliminary results are promising. The thermal storage implemented in the transpired solar collector can increase the operation time of the unglazed transpired solar collector and could increase its overall efficiency by lagging the solar energy absorbed during the day-time and using it during the periods when the Sun is not available. During the heating period the PCM are storing the heat and the outlet air temperature is lower than in the case without PCM (with almost 7ºC) and furthermore, in the cooling stage, the heat stored is released slowly, the outlet temperature being higher with almost 1.3ºC.

The implementation of the PMC in UTSC needs to be further investigated. Further studies will be conducted with different types of thermal inertial elements which could improve the effect of the plate with lobed orifices implemented in a UTSC, with different phase change temperatures, different quantities and different orifices geometries.

Abstract

Polypropylene (PP) is increasingly considered as a material choice for pressurized components in solar-thermal systems. In these systems, the materials are exposed to superimposed mechanical and environmental loads. The objective of this research is the characterization of the mechanical behavior of three different black-pigmented polypropylene (PP) grades immersed for up to 750 h in chlorinated water (5 ppm chlorine content) at an elevated temperature of 60°C. Hence, values for strain-at-break and essential work of fracture were determined by tensile tests. For the strain-at-break values and for the essential work of fracture values a similar exposure dependence was obtained. Depending on the PP grade, time-to-embrittlement values of 250 h and 750 h were achieved. For one PP grade, both testing methods led to an identical time-to-embrittlement value of 750 h.

Keywords: polypropylene, solar-thermal collector, chlorinated water, aging, mechanical properties

1. Introduction

In novel pumped and non-pumped solar-thermal systems, a growing share of polyolefins, especially polypropylene (PP), is considered for pressurized component applications (Koehl et al., 2012). In conventional solar-thermal systems, polypropylene is mainly utilized for hot water piping applications, whereas in systems with overheat control, polypropylene can also be used as an absorber material (Koehl et al., 2012; Lang and Wallner, 2012; Meir et al., 2008; Wallner et al., 2012). In either configuration, all components are simultaneously loaded with elevated temperatures, mechanical stresses and different environmental media. While the outside of such components may be surrounded by air, the inside is part of the hot water supply system and is exposed to a liquid medium. Usually, water is used as the heat carrier fluid in single-loop solar-thermal collector system. In many regions of the world, water is polluted with bacteria, viruses and parasites. Disinfection of contaminated water is required as a prevention of waterborne diseases (WHO, 2011). Chlorine is the most widely utilized and the most affordable water disinfectant. Chlorine is easy to use and highly efficient against different kinds of waterborne pathogens (Deborde and von Gunten, 2008; WHO, 2011; WCC, 2008). The maximum allowed chlorine content in drinking water is 5 ppm (mg/l) to ensure no further risk for human health (WHO, 2011). Polyolefins exhibit a significant degree of aging when exposed to water disinfectants (Cosgriff et al., 2017; Fischer et al., 2016; Ge et al., 2012; Hassinen et al., 2004; Mitroka et al., 2013; Mittelman et al., 2008; Vibien et al., 2001). Hence, product lifetimes are substantially reduced and, in many cases, premature failure occurs. The structural performance of polymeric materials is dependent on the mechanical and environmental loading conditions (DeCoste et al., 1951; Krishnaswamy, 2005; Lang et al., 1997; Lang et al., 2005; Stern et al., 1998a; Stern et al., 1998b). Therefore, tests of plastics for solar-thermal applications should consider service relevant loading conditions. In previous research, polymer properties were investigated by tests of specimens which were affected by various environmental conditions (Altstaedt and Kausch, 2005; Brown, 1999; Cosgriff et al., 2017; DeCoste et al., 1951; Fischer et al., 2016; Freeman et al., 2005; Ge et al., 2012; Grabmayer, 2014; Lang et al., 1997; Povacz et al., 2016; Schoeffl, 2014; Stern et al., 1998a; Stern et al., 1998b).

This paper describes the characterization of the effect of aging in hot chlorinated water on the mechanical behavior of three different black-pigmented PP grades for solar-thermal applications. Micro-sized specimens of two commercial PP grades and one development PP grade were immersed in a water bath and were removed after

doi:10.18086/swc.2017.31.02 Available at http://proceedings.ises.org

different intervals. To ensure a constant environment, the temperature, the pH and the chlorine content of the water bath were controlled. The exposure time dependent values for strain-at-break and essential work of fracture were determined by tensile tests.

2. Experimental

Three polypropylene (PP) grades were characterized in terms of their aging behavior. While two materials are commercially available, black-pigmented PP pipe grades from two different manufacturers (PP-B1 and PP-B2), the third material represents a modified PP-B2 grade (PP-B2 mod) containing additional phenolic-based antioxidants (see Table 1). To investigate the aging effect of chlorinated water with a chlorine content of 5 ppm at an elevated temperature of 60°C, micro-sized specimens with a thickness of 0.1 mm (Grabmayer, 2014; Wallner et al., 2013) were immersed in a water bath with controlled temperature, pH and chlorine content (Cosgriff et al., 2017; Freeman et al., 2005; Ge et al., 2012). In order to achieve a range of degradation levels, the exposed micro-sized specimens were removed from the aging device at different intervals (0 h, 125 h, 250 h, 375 h, 500 h, 750 h).

Tab. 1: Material designation and material composition

Material designation	Matrix polymer	Stabilizer system
PP-B1	Polypropylene blockcopolymer	Basic stabilization
PP-B2	Polypropylene blockcopolymer	Basic stabilization
PP-B2 mod	Polypropylene blockcopolymer	Basic stabilization with additional phenolic-based antioxidants

Based on tensile tests, the strain-at-break values of the removed PP specimens were determined. The tensile tests were conducted with specimens with the dimensions 150 mm x 2 mm x 0.1 mm (length x width x thickness) to achieve the relevant stress-strain curves. The time-to-embrittlement was defined as that exposure time when the strain-at-break value of the exposed specimen dropped below the strain-at-yield value of the unexposed specimen.

Furthermore, to characterize the aging effect on the fracture behavior, the essential work of fracture (EWF) method was utilized. Therefore, tensile tests were carried out with specimens with the dimensions 80 mm x 30 mm x 0.1 mm (length x width x thickness). To obtain the EWF values, different ligament lengths (6 mm, 8 mm, 10 mm, 12 mm and 14 mm) are necessary (Bárány et al., 2010) and were realized with a unique cutting device. Based on the load-displacement curves the total work of fracture values were evaluated. EWF values were obtained by plotting the specific total work of fracture as a function of ligament length.

All tensile tests were conducted at 23°C using a screw-driven universal testing machine. The gauge length was 20 mm and the test speed was 50 mm/min.

3. Results and Discussion

Exposure of the three PP grades PP-B1, PP-B2 and PP-B2 mod to hot chlorinated water led to an oxidation induced material degradation indicated by significant changes in the stress-stain curves, which are illustrated in Fig. 1. The exposure time dependent values for strain-at-break and strength are depicted in Fig. 2.

Due to aging, a significant decrease of the strain-at-break and strength was obtained for all PP grades. The lowest initial strain-at-break (for the unexposed specimen) of 364 % was determined for PP-B1. After 250 h of exposure, this material reached the time-to-embrittlement, defined as the exposure time for which the strain-at-break value of the exposed specimen dropped below the strain-at-yield value of the unexposed specimen. PP-B2 and PP-B2 mod exhibit significantly higher initial strain-at-break values of 732% and 1177%, respectively. For both materials, a time-to-embrittlement of 750 h was measured. Up to an exposure time of 500 h for PP-B2 mod the highest strain-at-break values were determined, which indicates a positive effect of the additional stabilization

with the phenolic-based antioxidants. In terms of strength for PP-B1, PP-B2 and PP-B2 mod initial values of 31 MPa, 25 MPa and 30 MPa, respectively, were established. After 750 h of exposure, the strength dropped to 3.8 MPa, 6.1 MPa and 7.4 MPa, respectively. Comparing the strength of the three PP grades, the highest exposure time dependent values were obtained for PP-B2 mod.

For all three polypropylene grades, the exposure time dependent values of specific total work of fracture are depicted as a function of ligament lengths in Fig. 3. As alluded to above, exposure to hot chlorinated water led to oxidation induced degradation of the polymers and thus to a more brittle behavior at higher aging times. Hence, with increasing exposure times ligament yielding and crack initiation/growth were superposed. Thus, the EWF preconditions were not fully met. Nevertheless, up to certain exposure times, the EWF concept requirement of self-similar load-displacement curves was fulfilled (Bárány et al., 2010; Mai et al., 2000). For the EWF tests, the time-to-embrittlement was defined as that exposure time when no self-similarity of the load-displacement curves was obtainable. Above this aging time, the EWF preconditions were not met and thus the test conditions and furthermore the results were not valid.

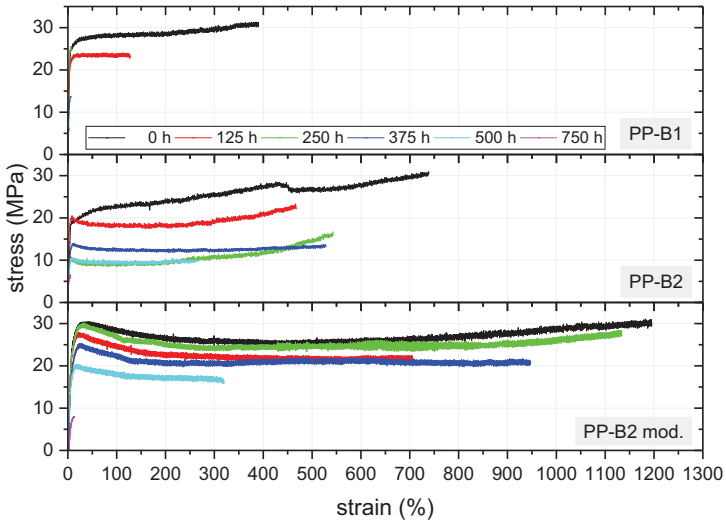

Fig. 1: Exposure time dependent stress-strain curves for the three PP grades.

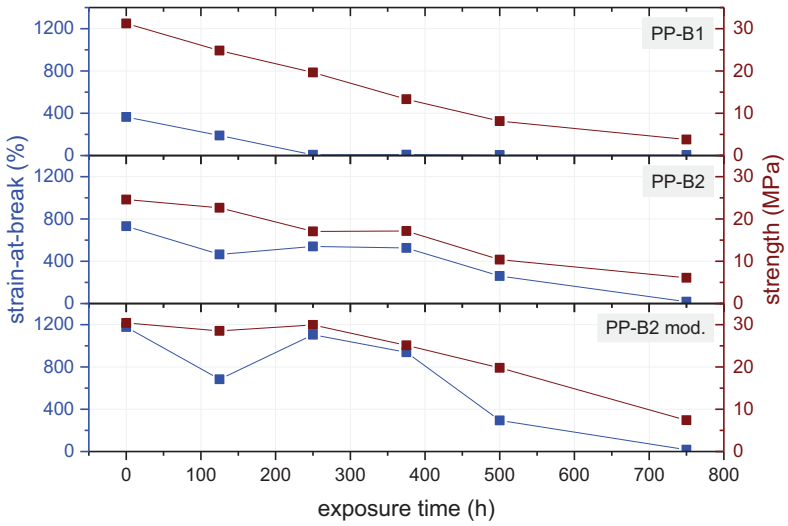

Fig. 2: Strain-at-break and strength as a function of exposure time for the three PP grades.

Based on the curves depicted in Fig. 3, the values for the specific non-essential work of fracture and for the specific essential work of fracture were evaluated. In Fig. 4, these values are plotted against the exposure times. Again, for all PP grades, the essential work of fracture decreased with increasing aging times. For the two commercial

PP pipe grades PP-B1 and PP-B2, the time-to-embrittlement was 375 h, for the additionally stabilized PP grade PP-B1 mod the time-to-embrittlement was 750 h. For PP-B2 and PP-B2 mod exposed up to 250 h, the aging dependent values of specific non-essential work of fracture and specific essential work of fracture are similar. However, due to the additional stabilization with phenolic-based antioxidants, the time-to-embrittlement was greatest for PP-B2 mod (500 h vs. 250 h for PP-B1 and PP-B2)

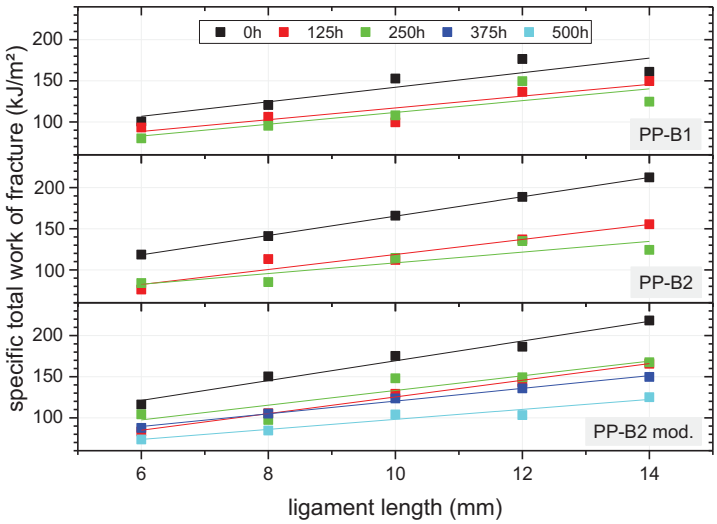

Fig. 3: Exposure time dependent curves of specific total work of fracture vs. ligament length for the three PP grades.

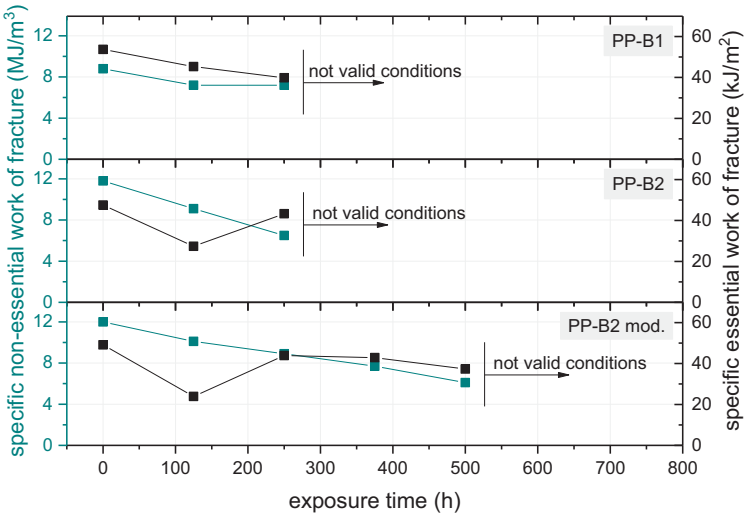

Fig. 4: Specific non-essential work of fracture and specific essential work of fracture as a function of exposure time for the three PP grades.

Exposure time dependent values for strain-at-break and specific essential work of fracture are illustrated in Fig. 5. For all PP grades, the strain-at-break curves exhibit similar aging effects as the EWF curves. Nevertheless, in terms of time-to-embrittlement, only for PP-B2 mod did both methods yield identical values. A comparison of the time-to-embrittlement data (all below 1000 h) with published data for similar materials tested in hot air and in hot heat carrier fluid (Povacz et al., 2016) reveals hot chlorinated water as the most aggressive environment.

Due to the simple specimen preparation and test procedure, the strain-at-break method is recommended for embrittlement tests. To receive further information on the fracture mechanism and the fracture toughness, the EWF method should be utilized.

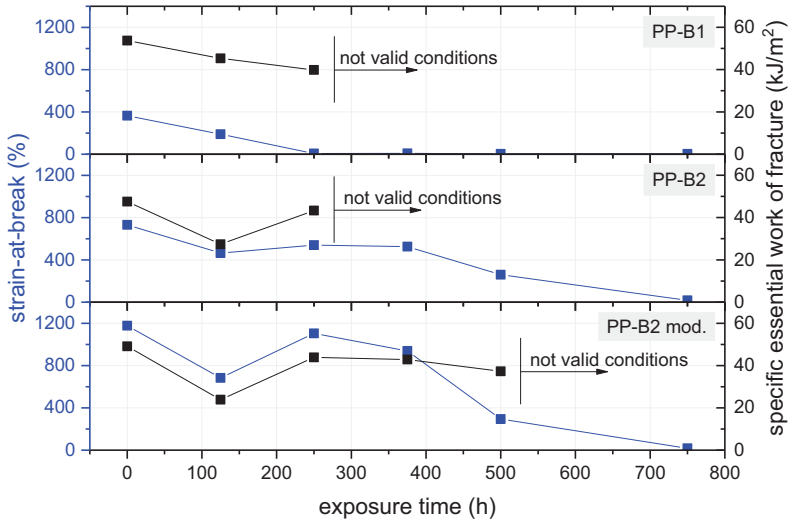

Fig. 5: Strain-at-break and specific essential work of fracture as a function of exposure time for the three PP grades.

4. Summary and Conclusions

Three different polypropylene grades were immersed for up to 750 h in a controlled water bath filled with chlorinated water (5 ppm chlorine content) at an elevated temperature of 60°C. To detect the extent of degradation over time, exposed specimens were removed at time intervals. Based on tensile tests on micro-sized specimens with method specific dimensions, values for strain-at-break and essential work of fracture were determined as a function of exposure time. The strain-at-break data exhibited a similar exposure time dependence as the essential work of fracture data. Depending on the PP grade, time-to-embrittlement ranged from 250 h to 750 h. For the PP grade that included additional phenolic-based antioxidants, the time-to-embrittlement was greatest at 750 h for both test methods.

Characterization of polymeric materials for solar-thermal collector mounting systems

Joerg Fischer[1], Patrick R. Bradler[1], Sandra Leitner[1], Gernot M. Wallner[1] and Reinhold W. Lang[1]

[1] Institute of Polymeric Materials and Testing / Johannes Kepler University, Linz (Austria)

Abstract

In this research, three unreinforced and two glass fiber reinforced plastics for the application in mounting systems of solar-thermal collectors were investigated comprehensively. Therefore, morphological, thermomechanical, mechanical and cyclic fracture mechanical tests were performed. Focus was given on the mechanical properties and the fatigue crack growth (FCG) resistance at service relevant temperatures. In the morphological characterization, for the five materials primarily homogenous material distributions were detected. However, the polymer blend ASA/PC showed a limited miscibility. This was confirmed by the separated glass transition temperatures, which were determined by dynamic mechanical analysis. In terms of mechanical properties, significantly higher values for Young's modulus and strength as well as lower strain-at-break values were obtained for the glass fiber reinforced polymer grades. Increasing temperatures led to decreasing Young's moduli and strengths as well as to higher strain-at-break values. The unreinforced plastics revealed an inferior FCG resistance. For all materials, temperature increase evoked a declining FCG behavior. The FCG resistance of the reinforced plastics was influenced by the fiber orientation.

Keywords: plastics, solar-thermal collectors, mounting systems, mechanical properties, fatigue crack growth

1. Introduction and scope

Currently, mounting systems of solar-thermal collectors are constructed from aluminum or stainless steel (Erfurth et al., 2001; Koehl et al., 2012). For the reduction of costs and weight, it is a common practice to replace conventional materials with advanced polymeric material solutions. For an appropriate material replacement, various aspects must be carefully considered. Materials for mounting and framing must withstand environmental loads (e.g., temperatures, environmental media) and mechanical loads (e.g., weight of the mounted solar-thermal collector, snow weight, wind load, hail) (Erfurth et al., 2001; Koehl et al., 2012). The loading conditions can adversely affect the structural performance of polymeric materials (Altstaedt, 2005; DeCoste et al., 1951; Fischer et al., 2016a; Lang et al., 1997; Lang et al., 2005; Stern et al. 1998a; Stern et. al. 1998b). A comprehensive understanding of the material behavior under service relevant loading conditions is of utmost importance. Thus, previous research focused on the effect of superimposed mechanical and environmental loads on the properties of polymeric materials (Bradler et al., 2016; Bradler et al., 2017; Fischer et al., 2016a; Fischer J. et al., 2016a; Schoeffl and Lang, 2015).

The main objective of this research was the characterization of the morphological, thermomechanical, mechanical and fatigue crack growth (FCG) behavior of polymeric materials for mounting systems of solar-thermal collectors under application relevant temperatures. Therefore, infrared spectroscopic microscopy, dynamic mechanical analysis, monotonic tensile tests and cyclic fracture mechanics tests were performed at three different temperatures (0°C, 23°C, 60°C) in air environment.

2. Background

The linear elastic fracture mechanics concept was used for the investigation of the fatigue crack growth (FCG) behavior of plastics (Anderson, 2017; Bradler et al., 2016; Bradler et al., 2017; Fischer et al., 2016a; Fischer J. et al., 2016b; Lang, 1980; Schoeffl and Lang, 2015). In this concept, the fatigue crack growth rate (da/dN) is plotted against the stress intensity factor range ΔK. While the crack growth rate indicates the crack growth per cycle, the

doi:10.18086/swc.2017.31.03 Available at http://proceedings.ises.org

ΔK_I-value, described in eq. 1, is the difference between maximum and minimum stress intensity factor ($K_{I,max}$-$K_{I,min}$) of a cycling loading profile in loading mode I (pure tensile loads). In this equation, "$\Delta\sigma$" describes the global loading, "a" the crack length and "Y" a factor which is dependent on the geometry of the specimen used.

$$\Delta K_I = \Delta\sigma \cdot \sqrt{a} \cdot Y \tag{1}$$

In the double-logarithmic fatigue crack growth kinetics curve, region II represents the stable crack growth of the material. In a comparison of different polymeric materials or of different test conditions, improved fatigue crack growth resistance is revealed by a shift of the FCG curve to higher ΔK-values. Additionally, also slope decrease of the FCG curve exhibits improved FCG behavior (Haager, 2004; Lang, 2005).

3. Experimental

Materials

An overview of all investigated materials is given in Table 1, comprising three unreinforced and two glass fiber reinforced plastics. These materials were characterized with different methods at service relevant temperatures (0°C, 23°C, 60°C). The unreinforced polymer grades contain an acrylic ester-styrene-acrylonitrile copolymer (ASA), a polymer blend of ASA and polycarbonate (ASA-PC) as well as a polymer blend of polybutylene terephthalate and polycarbonate (PBT-PC). The reinforced plastics include a short glass fiber reinforced polyamide grade with a fiber content of 30 w% (PA-GF30) and a long glass fiber reinforced polyamide grade with a fiber content of 40 w% (PA-LGF40).

Tab. 1: Material designation and material composition.

Material designation	Material	Reinforcement type	Reinforcement content
ASA	Acrylic ester-styrene-acrylonitrile copolymer	-	-
ASA-PC	Polymer blend of acrylic ester-styrene-acrylonitrile copolymer and polycarbonate	-	-
PBT-PC	Polymer blend of polybutylene terephthalate and polycarbonate	-	-
PA6-GF30	Polyamide 6	Short glass fibers	30 w%
PA6-LGF40	Polyamide 6	Long glass fibers	40 w%

Infrared spectroscopic microscopy

To analyze the morphology and the fiber orientation within the compounds, the specimens were characterized with an infrared spectroscopic microscope PerkinElmer Spotlight 400 FT-IR Imaging System (Perkin Elmer Inc., USA. Tests were carried out with an attenuated total reflection mode (ATR). The spectral range was 650 cm^{-1} to 4000 cm^{-1}.

Dynamic mechanical analysis

Dynamic mechanical analysis (DMA) measurements were performed on an Anton Paar Physica MCR 502 (Anton Paar GmbH, Austria) for determining the temperature dependency of the storage modulus and the loss factor. The loss factor can be calculated out of the ratio between the storage modulus and the loss modulus. All DMA tests were conducted in a temperature range of -70°C and 220°C with a heating rate of 3 K/min. The applied frequency was set to 1 Hz and a torsional loading mode was applied. The samples were cut from the parallel part of the 1B multi-purpose specimen (ISO 527) with the dimension 40 mm x 10 mm x 4 mm.

Tensile tests

The mechanical properties (Young's modulus, strength and strain-at-break) were examined with a universal testing machine Z020 (Zwick Roell, Germany) equipped with a multi-extensometer and a temperature chamber for test at 0°C, 23°C and 60°C. Test parameters and multi-purpose specimens were used according to ISO 527 with a traverse speed of 1 mm/min for Young's modulus determination until a strain of 0.25 % and 50 mm/min until failure.

Fatigue crack growth

In order to investigate the fatigue crack growth (FCG) behavior, all five materials were tested with an in-situ testing device (Schoeffl et al., 2014) allowing fatigue tests at different temperatures within service-relevant environmental environments. Therefore, an electro-dynamic testing machine of the type ElectroPuls E3000 (Instron Inc., USA) was used. Compact type (CT) specimens with an initial crack in mold direction and in cross direction were utilized for investigations of the crack growth (Fischer et al., 2016b). A sinusoidal loading profile with a frequency of 5 Hz and an R-ratio of 0.1 was applied. Characteristic double-logarithmic FCG kinetic curves were plotted providing the relation between the FCG rate, da/dN, and the stress intensity factor range, ΔK_I, describing the local crack tip stress field.

4. Results and discussion

In the morphological characterization via infrared spectroscopic microscopy, for the two blends (ASA/PC and PBT/PC), a predominantly homogenous color distribution was found (see Fig. 1), with a limited miscibility of the ASA/PC blend. The reinforced grades revealed in the middle of the specimen a clear fiber orientation in cross mold direction. Conversely, due to higher shear loads, a fiber orientation in mold direction was found on the surfaces of the specimens. Fischer et al. reported this effect before (Fischer et al., 2016).

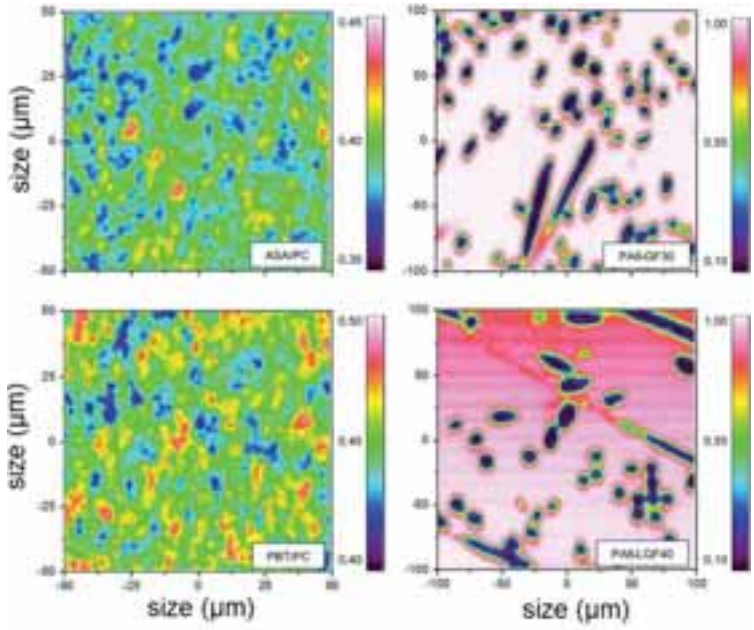

Fig. 1: Infrared spectroscopic map of the morphology of two polymer blends (left) and fiber orientation of two glass fiber reinforced polymers (right).

Curves of the storage modulus and the loss factor as a function of temperature (see Fig. 2) were attained via dynamic mechanical analysis (DMA). For the unreinforced materials, the highest storage moduli were exhibited for ASA and the lowest storage moduli for the PBT-PC blend. The glass transition temperature is depicted as a maximum of the loss factor curve. The ASA grade shows a peak at 124°C, for the ASA-PC compound two peaks are detectable, one for the ASA component at about 115°C, and a second at 149°C for the PC component. Hence, the limited miscibility obtained by infrared spectroscopic microscopy was assured. For the PBT-PC blend, a glass transition temperature of 140°C was found. The DMA data of the reinforced grades exhibit higher modulus values for the PA-grade PA6-LGF40 with 40 w% glass fiber reinforcement compared to the PA-grade PA6-GF30 with

30 w% glass fiber reinforcement. The glass transition temperatures of both PA-grades are similar (60°C for PA6-GF30 and 63°C for PA6-LGF40).

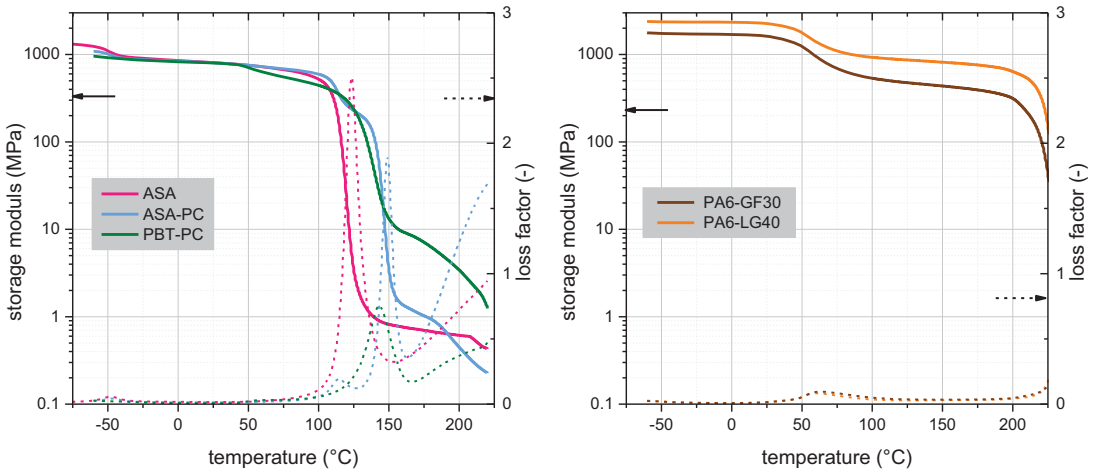

Fig. 2: Curves of the storage modulus and loss factor against temperature for unreinforced (left) and reinforced (right) plastics.

Storage moduli at the three application relevant temperatures 0°C, 23°C and 60°C are depicted in Fig. 3. Within each grade, highest moduli were obtained at 0°C. In the material comparison, at each temperature, the highest storage moduli were detected for the grade PA6-LGF40. At 60°C, the moduli of the grades ASA and ASA-PC are only moderate decreasing compared to 23°C. The PBT-PC compound shows a higher decrease, which is also visible in the DMA-curve (storage modulus against temperature) starting with diminishing storage moduli at 50°C. The reinforced grades PA6-GF30 and PA6-LGF40 exhibit a significant reduction of storage moduli between 23°C and 60°C. This is related to the immediate vicinity to the glass transition region of PA6.

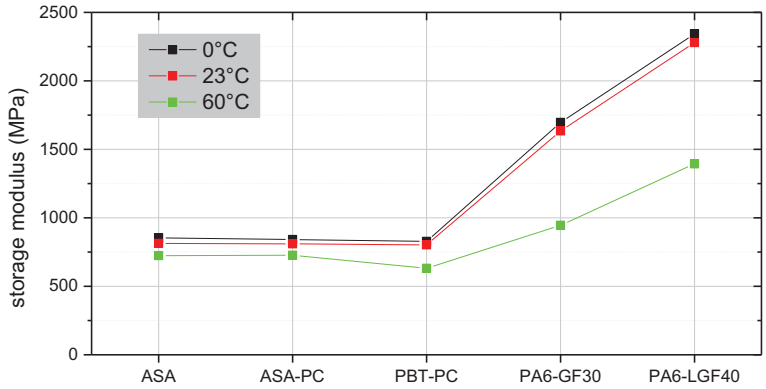

Fig. 3: Storage moduli at three different temperatures for three unreinforced and two reinforced plastics.

Temperature dependent stress-strain curves for the five plastics are plotted in Fig. 4. Based on the stress-strain curves, the values for Young's modulus, strength and strain-at-break were evaluated (see. Fig. 5). For all temperatures, the reinforced polymeric materials revealed significantly higher Young's moduli (factor 3 to 6) and strengths (factor 3 to 4). In contrast, the obtained strain-at-break values were much lower (factor 2 to 27). An increase in testing temperature led to declining Young's moduli and strengths. While the lowest values were determined for the polymer blend PBT-PC, for PA6-LGF40, the highest values were achieved. With a higher glass fiber content, an increase in Young's modulus was determined. Increasing temperatures led to higher strain-at-break values. The highest strain-at-break values were obtained for PBT-PC. For the glass fiber reinforced grades, a brittle failure and small strain-at-break values were received due to the dominating fiber influence.

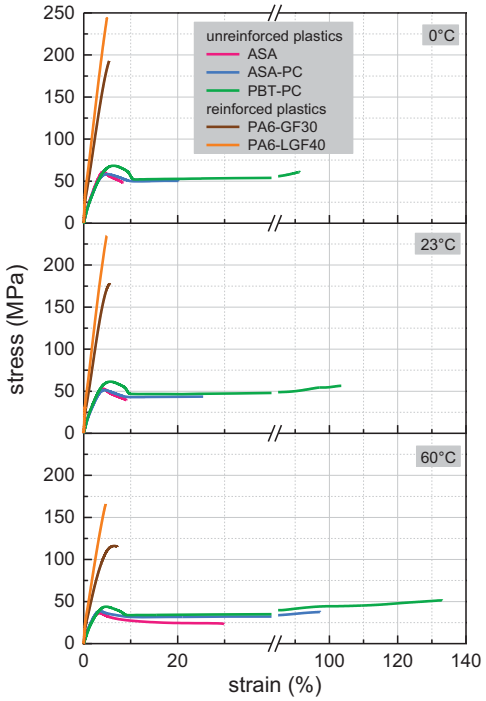

Fig. 4: Temperature dependent stress-strain curves for the three unreinforced and the two glass fiber reinforced plastics.

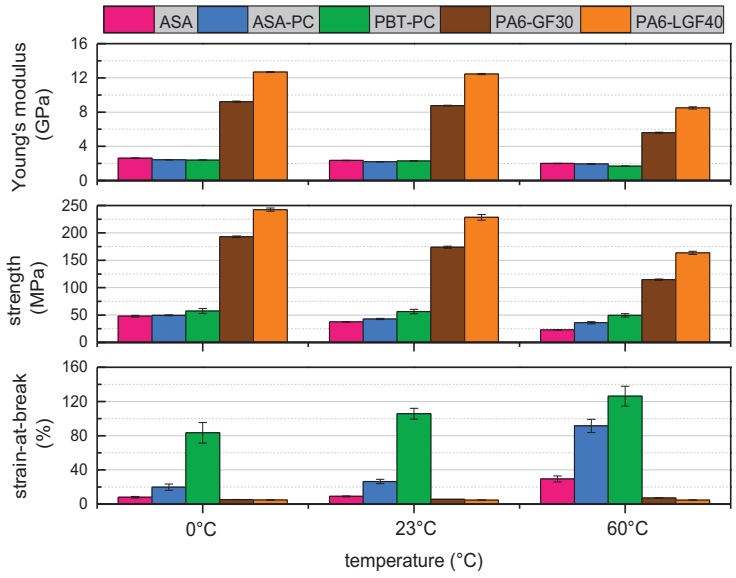

Fig. 5: Temperature dependent values of Young's modulus (top), strength (middle) and strain-at-break (bottom) for the five plastics.

In Fig. 6, the fatigue crack growth behavior of the five plastics for each testing temperature is depicted. Furthermore, the influence of different fiber orientation on the FCG resistance is revealed. For all materials, temperature increase led to a declining FCG resistance. In terms of the material comparison, for all temperatures, the glass fiber reinforced plastics revealed a significantly improved fatigue crack growth behavior. Conversely, the FCG resistance of ASA was inferior. In terms of fiber orientation, PA6-LGF40 and thus the PA grade with the long glass fiber reinforcement and the higher fiber content revealed an enhanced FCG behavior in the tests with the initial crack in mold direction. Nevertheless, tests with the initial crack in cross direction showed comparable FCG resistances for both glass fiber reinforced plastics.

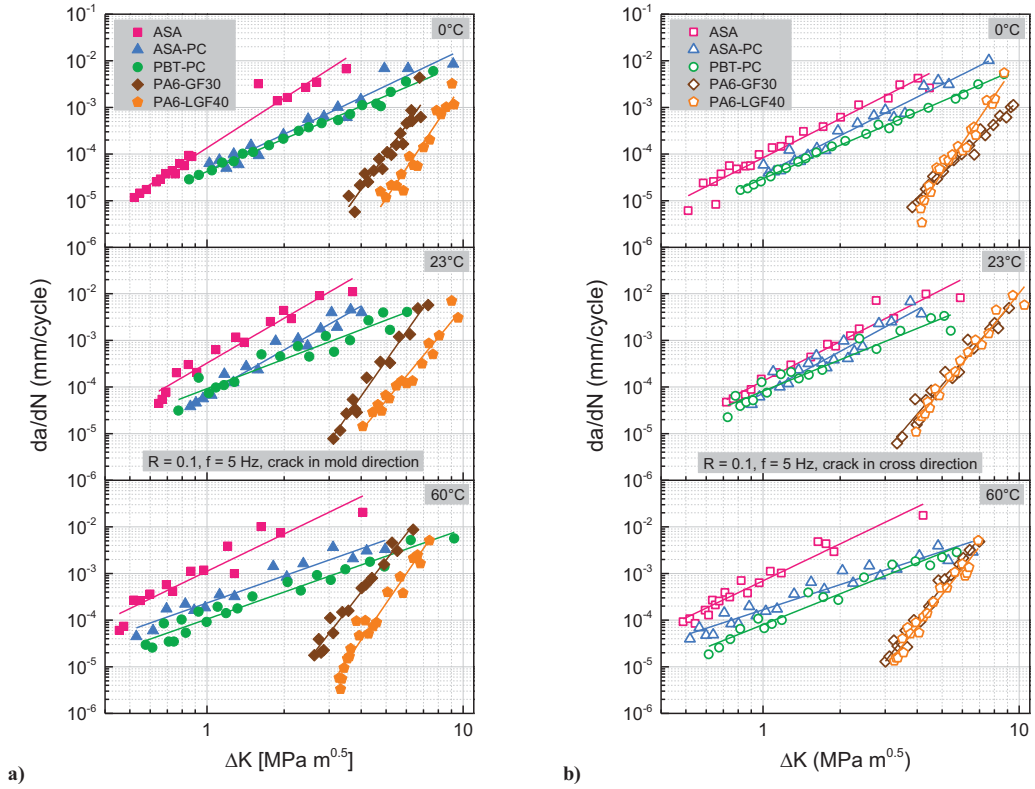

Fig. 6: Temperature dependent fatigue crack growth kinetics for the three unreinforced and the two glass fiber reinforced plastics tested with the crack in (a) mold direction and (b) cross direction.

5. Summary and conclusions

Three unreinforced and two glass fiber reinforced plastics for the application in mounting systems of solar-thermal collectors were characterized with regard to their morphological, thermomechanical, mechanical and fatigue crack growth (FCG) behavior. The three unreinforced polymeric materials included an elastomer-modified copolymer (acrylic ester-styrene-acrylonitrile, ASA) and two polymer blends (acrylic ester-styrene-acrylonitrile/polycarbonate, ASA/PC and polybutylene terephthalate/polycarbonate, PBT/PC). In the category of the reinforced materials one short glass fiber reinforced polyamide grade with a glass fiber content of 30 w% (PA6-GF30) and one long glass fiber reinforced polyamide grade with a glass fiber content of 40 w% (PA6-LGF40) were investigated. The morphological characterization revealed homogenous material distributions for all material grades. However, the polymer blend ASA/PC showed a limited miscibility leading to separated glass transition temperatures. For the three unreinforced plastics, significantly lower values for Young's modulus and strength were determined. A comparison between the strain-at-break values of the unreinforced and the reinforced plastics revealed higher values for the former materials. Decreasing Young's moduli and strengths as well as to higher strain-at-break values were detected with higher testing temperatures. At all temperatures, the reinforced plastics showed a superior FCG behavior. Increasing temperatures led to a diminishing FCG resistance. In order to investigate the effect of fiber orientation on the fatigue crack growth of the reinforced plastics, tests were carried out with specimens containing the initial crack in mold direction and in cross direction. While tests with the initial crack in cross direction revealed a similar FCG resistance, tests with the initial crack in mold direction showed a significantly better performance for the polymer with the higher fiber content.

Abstract

This paper represents an advanced methodology for the detailed modeling of the heat transfer and fluids dynamics phenomena in Linear Fresnel receivers. The present work aims at modeling Linear Fresnel elements (e.g. insulation material, glass cover, tube, pipe, etc.) by proposing a parallel modular object-oriented methodology. The heat conduction, natural convection, single & two-phase flow, and solar & thermal radiation are solved and coupled in an adequate manner. The Navier-Stokes 3D equations with incompressible and turbulent fluid hypotheses are used to solve the fluid inside the cavity by means of a CFD&HT coupling with thermal and solar radiation. The heat flux incident on the tube is analyzed by a 3D conduction model to determine the temperature distribution, single or multiphase models can be used for the HTF. A Monte Carlo Ray-tracing method is applied to obtain the estimated solar radiation source as a function of the altitude and azimuth solar angles. This work presents a comparison of three configurations, their optical behavior, the effects of the receiver height, the orientation of the mirrors and the shadows, temperature, velocity and thermal flow profiles are analyzed and presented hereafter.

Keywords: Linear Fresnel Receivers, CFD&HT, Numerical Model, TermoFluids.

1. Introduction

Many authors have carried out experiments on several prototypes with innovative design concepts and studied the performance characteristics of LFR for different optical and geometric parameters (Barale et al., 2010 [1]; Beltagy et al., 2017 [2]; Bernhard et al., 2008 [3]; Häberle et al., 2001[4]; Negi et al., 1989 [5]; Singh et al., 1999 [6]). Linear Fresnel reflectors usually employ a secondary concentrator that enlarges the target área for primary mirrors, and also acts as protective cover to reduce convective losses. A number of authors have been studied different types of receivers such as trapezoidal cavity with multiple absorber tubes (Facão and Oliveira, 2011 [7]) triangular, rectangular, arc-shaped and semi-circular cavity receivers (Lin et al., 2014 [8]), modified V-shaped cavity. Qiu et al. (2015) [9] investigated the thermal performance of LFR that employs a compound parabolic concentrator (CPC) with an evacuated absorber. They concluded that uniformity of flux distribution can be improved by choosing a proper slope error, but with a small sacrifice in the optical efficiency.

The present work develops an advanced model of LFR, through a modular platform that works each part of the system as a unique element with the capacity to transfer information between one element and another, this union is realized by coupling heat flow and temperature, which provides numerical stability. This modular system allows to apply different models for the various heat transport mechanics (solids are treated with a 3D conducting solver, the fluid inside the cavity is treated with a CFD & HT coupled with a solver of thermal and solar radiation, the HTF you can apply a single/two phase model depending on an industrial oil, molten salt or water vapor).

A scheme of the Linear Fresnel Collector (LFC) is given in Fig 1. The cavity receiver of LFC consists of an absorber tube and a secondary concentrator. The Fresnel cavity profile is defined by an equation from the literature [13]. The absorber is usually protected with glass cover at the bottom of the cavity to reduce heat losses. The primary mirror field reflects the direct normal radiation into the cavity and due to astigmatism and optical inaccuracies only part of the reflected radiation hits the absorber directly. A fraction of the radiation interacts with the secondary reflector and is redirected onto the absorber. While the absorber is being heated, it

doi:10.18086/swc.2017.31.04 Available at http://proceedings.ises.org

loses heat by long wavelength radiation and convection to the surroundings.

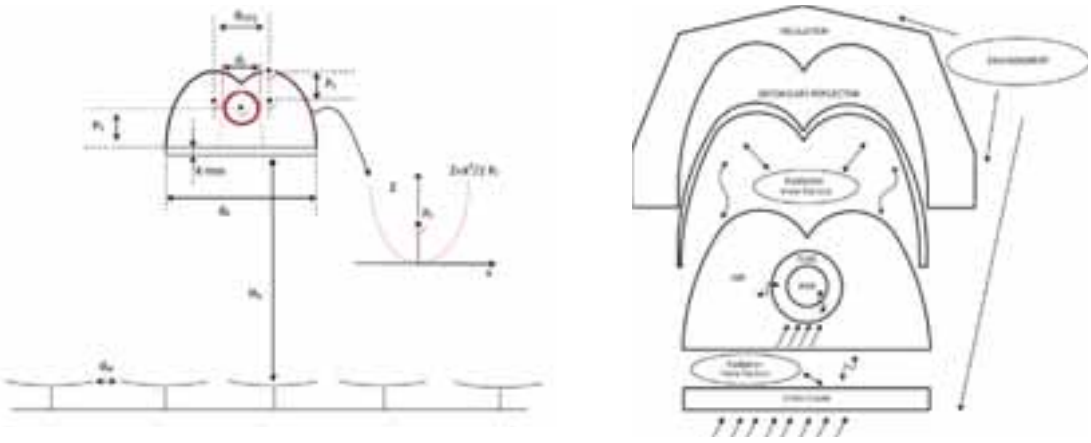

Fig. 1: NEST scheme of the modular system and Fresnel receiver

Nomenclature

c_p	Specific heat capacity, J kg^{-1} K^{-1}	Greek letters	
D_{in}	Internal diameter of the tube, m		
L_M	Width of mirror	ε	Thermal emissivity
f_M	Maximum deflection of the mirror	α	Sup. heat transfer coefficient, W m^{-2} K^{-1}
H_R	Receiver height	β	Thermal expansion coefficient, K^{-1}
d_R	Aperture of the receiver	η	Smallest turbulent scales of the flow, m
d_M	Distance between rows of mirrors	κ	Thermal diffusivity, m^2 s^{-1}
d_{F1F2}	distance between focal points	λ	Thermal conductivity, W m^{-1} K^{-1}
P_F	The focal parameter of the parabolic portions		
d_T	External tube diameter	μ	Dynamic viscosity, kg m^{-1} s^{-1}
P_T	Position of the tube in the cavity	ν	kinematic viscosity, m^2 s^{-1}
e_g	Thickness of the transparent glass	ξ	Turbulent kinetic energy dissipation rate, m^2 s^{-3}
η_{opt}	Optical efficincy	ρ	Density, kg m^{-3}
H	Height, m	σ	Stefan-Boltzmann constant, 5.67x10^{-8} W $m^{-2}K^{-4}$
g	Gravity vector, m s^{-2}	Γ_v	Stress tensor, m^{-2} s^{-2}
I	Identity matrix	Ω	volume, m^3
$\dot{m}$	Mass flow rate, kg s^{-1}	$\partial\Omega$	Surface which enclosed the volume **Ω**, m^2
Nu	Nusselt number	Δ	Magnitude increment
n	normal direction vector		
Pr	Prandlt number, $Pr = \mu c_p/\lambda$	Subscripts	
Pr_t	Turbulent Prandlt number, $Pr_t=\nu_{sgs}/\kappa_{sgs}$		
$\dot{Q}$	Heat losses, W	conv	Convection
$\dot{q}$	Specific heat flux, W m^{-2}	rad	Radiation
Ra	Rayleigh number, $Ra = g\beta\Delta TH^3/\nu\kappa$	cond	Conduction
S	Surface area, m^2	ins	Insulation
S_{ij}	Rate-of-strain, m^2	gc	Glass cover
$\bar{S}_{ij}$	Mean rate-of-strain fluctuations, s^{-1}	amb	Ambient conditions
T	Temperature, K	ref	Reflectors
t	time, s	tube	Tube
z	extruded direction, m	in	Inlet conditions
f(t)	Function of the time	out	Outlet conditions
u	velocity vector, m s^{-1}	sgs	Subgrid scales
g_k	Irradiosity on surface *k*, W m^{-2}	dir	Direct Radiation
j_k	Radiosity on surface *k*, W m^{-2}	max	Maximum
<u>	Average velocity u, m s^{-1}		
DNI	Direct Normal Irradiance		

A modular object-oriented methodology for the design and optimization of Linear Fresnel receivers is proposed (NEST platform [10]). This methodology considers the different parts of the Linear Fresnel receiver as independent models and the coupling between global models and advanced computational fluid dynamic and

heat transfer (CFD&HT) mainly based on large-eddy simulation (LES) techniques (TermoFluids[11]).

TermoFluids [11], a general purpose unstructured and parallel object-oriented CFD code developed to solve industrial flows, is used to optimize the optical and thermal performance of a defined system (geometry, optical and thermal properties of the materials).

The presented methodology was explained by Guadamud et al (2014), [12]. For each element of the receiver more than one model approach is considered depending on the desired accuracy. The use of a modular simulation allows that for the same element one-, two- or three-dimensional models can be used. At the same time, each element can receive a special treatment from the physical point of view.

The implementation of the Fresnel receiver methodology has been made within the existing NEST platform which allows the linking between different elements to perform a specific system or configuration. In the present implementation, Fresnel receiver is considered as the sum of different parts, e.g. insulation, glass cover, air inside the cavity, tube, pipe, etc., such as shown in Fig 1.

2. Geometry configurations and optimization

Three different configurations were selected; table 1 shows all the parameters.

Table 1. Different configurations for the Linear Fresnel receivers

Parameters	Configuration 1	Configuration 2	Configuration 3
L_M	12.5% H_R	5% H_R	10.5% H_R
d_{F1F2}	8.5% d_R	0% d_R	0% d_R
p_F	10.2% d_R	15% d_R	12% d_R

The H_R represents the height of the receiver, for optical analysis, this value will vary to determine its effect on optical performance, in the thermal analysis will set this value constant for all three configurations to a value in which its optical behavior is the most optimum. The d_R (aperture of the receiver) will be fixed constant in both analysis, based on this, various aspect ratios are obtained as shown in Table 1.

The procedure of the optimization consists in fixing certain parameters (taking into account some technical criteria) and calculating the others parameters by maximizing the optical efficiency (considered as the objective function).

The variation of the DNI during the day is simulated by a cosine expression:

$$DNI(t) = DNI_{max} * \cos\left(\left(-\frac{\pi}{12}\right) * t + \pi\right) \quad \text{(eq. 1)}$$

For the optical efficiency (η_{opt}) is evaluated by the total energy received by the tube during the day between the direct normal irradiance with the reflectors surface, the second optical efficiency (η'_{opt}) is the total energy received by the tube during the day between the direct normal irradiance with the total surface of the land requirements.

3. Mathematical Model

3.1 Heat conduction in the solid elements of the Fresnel receiver (tube, glass cover and insulation).

Transient conduction heat transfer can be solved directly from the governing equation. For the case of the transient heat conduction without volumetric sources, the energy transport equation can be written in integral from as:

$$\rho c_p \frac{\partial T}{\partial t} = \nabla \cdot (\lambda \nabla T) \quad \text{(eq. 2)}$$

where T represents temperature, t is the time, ρ is density, c_p is the specific heat and λ the thermal conductivity. In this work, a non-structured mesh and a uniform distribution has been used in some elements like the tube and

the glass cover, but due to the geometric singularity in the element insulation the mesh has been adapted to this form.

In TermoFluids, for the integration of the governing equations the finite volume method has been used. A modified least-square method has been chosen for the calculation of the gradients. The resulting system of equations is solved by means of the Conjugate Gradient method [15].

3.2 CFD&HT of the air inside the cavity receiver

The objectives for using a CFD&HT object for modeling the air inside the cavity are twofold: (i) due to the complex geometry of the cavity, there are not specific correlations for the heat transfer inside irregular cavities, thus results of such modeling would be used for proposing new correlations to be used in the global model for the convective process and (ii) it would shed some light into the complex physics presents in this kind of receivers. The CFD&HT air cavity object calls TermoFluids CFD&HT code [11] which is an object-oriented parallel and unstructured CFD&HT code for the resolution of industrial flows. In this object, the three-dimensional Navier-Stokes equations are spatially filtered. Therefore, some level of modelisation for the filtered non-linear convective terms is required. This approach is known as large-eddy simulation (LES) of the turbulent flow. In LES, all temporal scales of the flow together with the largest spatial scales are solved, and only the small scales of the flow are modeled by means of a sub-grid scale model (SGS).

The discretised continuity, momentum and energy filtered equations, assuming constant thermophysical properties and negligible viscous dissipation effects in the energy equation read,

$$M\vec{u} = 0 \qquad \text{(eq. 3)}$$

$$\Omega\frac{\partial\vec{u}}{\partial t} + C(\bar{u})\bar{u} + \nu D\bar{u} + \rho^{-1}\Omega\bar{\mathrm{p}} - f = C(\bar{u})\bar{u} - \overline{C(u)u} \approx -M\Gamma \qquad \text{(eq. 4)}$$

$$\Omega\frac{\partial\overline{\mathrm{T}}}{\partial \mathrm{t}} + C(\bar{u})\bar{T} + \frac{\nu}{Pr}D\bar{T} - \overline{\nabla\cdot q_{rad}} = C(\bar{u})\bar{T} - \bar{C}(u)T \approx -M\Gamma_T \qquad \text{(eq. 5)}$$

where $\vec{u} \in R^{3m}$, $\bar{p} \in R^m$ and $\bar{T} \in R^m$are the filtered velocity vector, pressure and temperature, respectively (here m applies for the total number of control volumes (CVs) of the discretised domain). $\Omega \in R^{3m}$ is a matrix with the cell control volumes. f are the body forces, $f = \beta(T - T_{ref})\boldsymbol{g}$. Convective and diffusive operators are given by $C(\vec{\boldsymbol{u}}) = (\vec{\boldsymbol{u}}\cdot\nabla) \in R^{3m\times m}$, $D = -\nabla^2 \in R^{3m\times 3m}$ respectively. Gradient and divergence (of a vector) operators are given by $G = \nabla \in R^{3m\times m}$ and $M = \nabla\cdot R^{m\times 3m}$ respectively.

The last term in Eqs. (6) and (7) indicate some modelisation of the filtered non-linear convective term. M represents the divergence operator of a tensor, and Γ is the sub-gird scale (SGS) stress tensor, which is defined as[4],

$$\Gamma = -2\upsilon_{sgs}\overline{S_{ij}} + (\Gamma{:}\,\mathrm{I})I/3 \qquad \text{(eq. 6)}$$

where $\overline{S_{ij}} = 1/2[G(\vec{\boldsymbol{u}}) + G^*(\vec{\boldsymbol{u}})]$, and G^* is the transpose of the gradient operator. Γ_T term is evaluated as in Γ term, but ν_{sgs} is substituted by ν_{sgs}/Pr_t, where $Pr_t$is the turbulent Prandlt. To close the formulation, a suitable expression for the subgrid-scale (SGS) viscosity, ν_{sgs}, must be introduced. The QR-model based on the invariants of the rate-of-strain tensor [15] has been used.

The governing equations used in TermoFluids CFD&HT code are discretised on a collocated unstructured grip arrangement by means of second-order conservative schemes [15], i.e. they preserve the kinetic energy equation which ensures stability and conservation of the kinetic-energy balance even at high Reynolds numbers and with coarse grids.

In the context of the large-eddy simulation of turbulent flows, the time advancement algorithm should be capable of solving all the relevant temporal scales while, at the same time, it should be kept within the stability domain. Different temporal schemes have been proposed in the literature to deal with time marching algorithm for turbulent flows (see for instance [16-18]). In this work, a two-step linear explicit scheme on a fractional-step method proposed by Trias and Lehmkuhl [19] is used. Its main advantage relies on its capacity of dynamically adapt the time step to the maximum possible value while at the same time it is kept within the stability limits. This strategy reduces the computational time required without lost accuracy. The method has been successfully

tested in different flows in [20-22].

3.3 Single phase flow

In this work, a one dimensional model has been chosen to represent the forced convection in the tube, solved by step by step method. The fact that this code is one dimensional makes difficult the communication between the fluid flow and the code for the tube heat conduction element. This problem has been solved by heat coupling between the tube and the pipe elements, evaluating the average heat flux of each n volume controls of the 3D tube element per plane of extrusion and passed to the pipe element, this average heat flux has been used to solve the fluid flow and a new temperature profile has been obtained, then this new temperature field has been used to evaluate the heat flow that has been send to the tube. A heat transfer coefficient has been calculated each time iteration considering the convective heat flux between the tube and the pipe in the extruded direction as:

$$\vec{q}_{tube-pipe,conv} = \sum_j \alpha_f \left(\bar{T}_{tube} - T_f^i\right) \frac{\pi D_{in}}{\Delta z} \qquad \text{(eq. 7)}$$

where α_f is the HTF convection heat coefficient at T_{tube} and is evaluated as a function of the Nusselt number Nu_{Din}, the Nusset number and the properties are evaluated at medium temperature between the temperature of the tube and the temperature of the fluid inside the tube. Due to the lack of specific correlations in literature for evacuation the Nusselt number taking into accont the temperature distribution of the tube, correlations for isothermal cylinders are considered. Specifically, the Gnielinski correlation [23] is used for turbulent and transitional flow (Re>3200) in circular ducts, which reads,

$$Nu_{D_{in}} = \frac{(C/2)\left(Re_{D_{in}} - 1000\right)Pr}{1+12\sqrt{C/8}\left(Pr^{2/3}-1\right)} \left(\frac{Pr}{Pr_w}\right)^{0.11} \qquad \text{(eq. 8)}$$

with $C = (1{,}82\log(Re_D)-1{,}64)^{-2}$.

A silicone HTF(Syltherm800)has been used, this fluid is normally used in CSP due to a highly stable at high temperature liquid phase operation. The thermo-physical properties of the syltherm 800 have been obtained from the datasheet [24], and the approaches have been made by a polynomial correlation, these properties correlation are presented in Table 2.

Table 2. Thermo-physical properties correlation of the Syltherm 800.

Property	Polynomial correlation
ρ	$1.269 \cdot 10^3 - 1.52\bar{T} + 1.8 \cdot 10^{-3}\bar{T}^2 - 2 \cdot 10^{-6}\bar{T}^3$
cp	$1.109 \cdot 10^3 + 1.7014\bar{T} + 1 \cdot 10^{-5}\bar{T}^2 - 9 \cdot 10^{-9}\bar{T}^3$
μ	$0.6527 - 6.451 \cdot 10^{-3}\bar{T}^3 + 2.552 \cdot 10^{-5}\bar{T}^2 - 5.023 \cdot 10^{-8}\bar{T}^3 + 4.905 \cdot 10^{-11}\bar{T}^4 - 1.9 \cdot 10^{-14}\bar{T}^5$
λ	$1.907 \cdot 10^{-1} - 2 \cdot 10^{-4}\bar{T} + 1 \cdot 10^{-8}\bar{T}^2 - 8 \cdot 10^{-12}\bar{T}^3$

3.4 Radiation

3.4.1 Solar Radiation from mirrors to receiver

The estimation of the incident solar energy was done by means of the Monte-Carlo Ray-tracing method, where a lightning sweep is performed on the various mirrors, the amount of energy incident on the tube is analyzed, and this amount of energy is saved for the different positions and is treated as a source term for the simulation of the system. The different matrixes obtained in the method will be loaded one by one each time it is considered suitable for which there has been a change of solar position and it is verified how it affects the Fresnel System.

a b

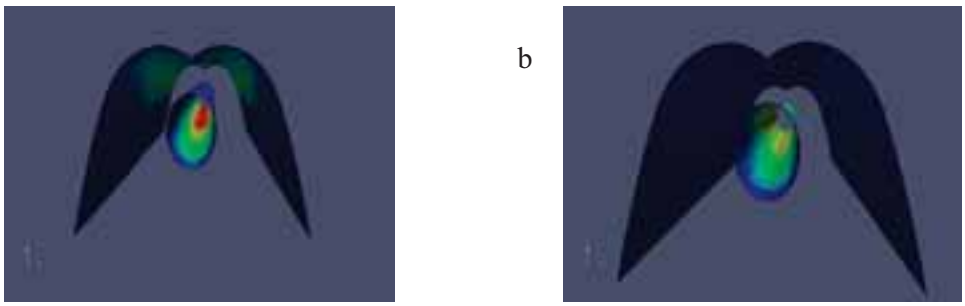

Fig. 2. Ray-tracing model obtained. (a) without a secondary reflector; (b) with a secondary reflector

Figure 2 shows the flux distribution of the incident solar radiation, comparing it qualitatively between a receiver without reflector (Fig. 2a) and with secondary reflector (Fig. 2b). In the first receiver the energy concentrates at lower part of the tube, losing many rays that go towards the upper part of the interior of the cavity, while having a secondary reflector distributes better the rays that do not directly affect the tube, and suffer second reflections increasing the optical performance of the system.

3.4.2 Thermal radiation inside the cavity

A Radiosity-Irradiosity method [25] has been applied to solve the non-participating media inside the cavity. The radiosity and the irradiosity can be expressed as:

$$j_k = \varepsilon_k E_{b,k} + \rho_k g_k \quad \text{(eq. 9)}$$

$$g_k = \sum_{l=1}^{N} F_{k\to l} j_l \quad \text{(eq. 10)}$$

For N surfaces, equations (11) and (12), define a linear system with N unknowns, the radiosities j_K. Once this system is solved, the toal heat flux, per unit area, is simply $q_K=j_K-g_K$. Considering the total heat flux $Q_K=A_K q_K$.

A Monte-Carlo Ray-tracing tool is applied to obtain the specular view factors needed, this factors are implemented on a Radiation model to solve a combined case with natural convection phenomena inside the cavity and their effects between the surfaces of the cavity and their surroundings.

4. Results

The need to analyze the behavior of a Fresnel Linear Receiver allows us to identify two important criteria, from the optical and thermal points of view.

The following is an intensive analysis of the various configurations, the parameters that determine its sensitivity, and has been compared with a commercial code such as OPSOL, obtaining very close results between those proposed by the RT-method of the CTTC and OPSOL [26]

Table 3. Optical efficiency comparison between this work and OPSOL code.

Parameters	Configuration 1	Configuration 2	Configuration 3
η_{opt}	*55%*	*57.5%*	*62.4%*
η'_{opt}	*39.5%*	*45.9%*	*48.4%*
η_{opt} **(OPSOL)**	*55%*	*60%*	*63%*
η'_{opt} **(OPSOL)**	*38.32%*	*46.8%*	*47.6%*

4.1 Optical performance of Linear Fresnel configuration

The instantaneous optical efficiency for the three configurations proposed was calculated for some day in April 2016 and based in Taroudant, Morocco. The analysis of the solar field behavior consisted on calculating the instantaneous power received by the tube during a whole day, from sunrise to sunset. The criteria to be optimized will be the effect of the receiver height, orientation of the mirrors, distribution of power in the symmetry plane, shadows basically.

4.1.1 Effect of receiver height.

It has been observed that increasing the height of the receiver results on a slightly higher performance. The reasons identified were: the orientation of the heliostats becomes more favorable, and the receiver being at a larger height casts less shadow on the mirrors.

4.1.2 Shadows

The shadows play a role in the efficiency of the system in two different ways. For the first and last hours of the day, when the sun altitude is low, some mirrors cast shadows onto other mirrors, thus decreasing the mirror surface area that reflects solar radiation to the receiver. On the other hand, when the sun is high in the sky, the receiver successively cast shadows one mirror by one mirror, thus also decreasing the effective area of the mirror. These two effects are illustrated in Figure 6.

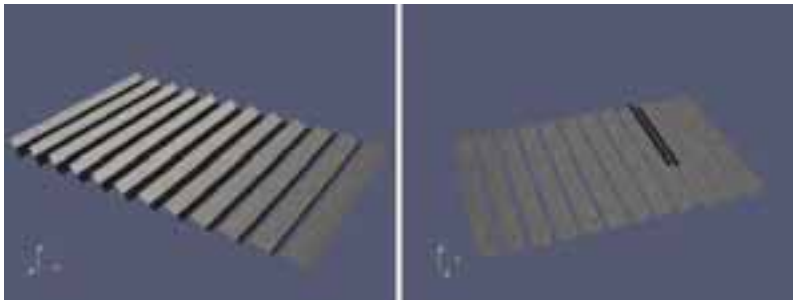

Fig. 6 Shadows cast on the mirrors are shown in black. Left: mirrors casting shadows on other mirrors when the sun is low in the sky. Right: receiver casting shadows on two mirrors when the sun is high in the sky.

It can be observed that the shadow casted by the receiver has less impact the higher the receiver is placed, because the shadow lasts for less time and covers less area of the mirrors. The fraction of the mirror that is illuminated during the course of the day, for several heights of the receiver, can be seen in Figure 7. The dents in the graphs correspond to the shadow of the receiver crossing the mirror, while the linear decrease at the end of the day (for outer mirror) and at both the beginning and end of the day (for the inner mirror) are due to the shadows cast by other mirrors. It is apparent from the figure that the effect of the shadows cast by the receiver is more detrimental for the configurations where the receiver is placed at lower a height. The effect of the shadows cast by other mirrors is (nearly) independent of the receiver height.

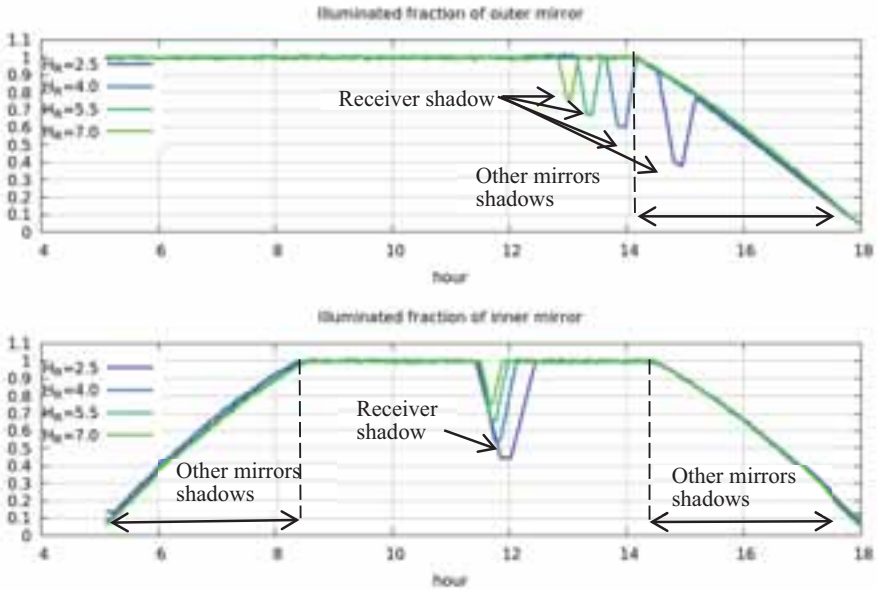

Fig. 7 Illuminated fraction of outer (top) and inner (bottom) mirrors, for several receiver heights.As the receiver height increases, both the size and duration of the shadow cast by the receiver decrease, making the mirror more effective.

4.1.3 Orientation of the mirrors

The orientation of the mirrors has an effect on the total power that can be reflected by the mirrors to the receiver and to the tube. Ideally, the mirrors should be facing a direction perpendicular to the direct solar radiation, but

there is a constraint that the orientation of the mirror is in fact determined by the point where it is supposed to focus the incoming solar radiation. Therefore, for a given receiver height and sun position, the orientation of the mirror is fixed. Looking at Fig. 3 one can expect that the orientation is more favorable the higher the receiver is placed, because the mirror will present a larger cross section to the solar radiation.

Fig. 3 Orientation of mirrors at noon. Blue mirrors: receiver height of 2m. White mirrors: receiver height of 8m. Taking into account that solar radiation at noon comes in Y direction (with some amount of Z component), clearly the higher the receiver height, the more effective area the mirrors present to the solar radiation. This effect is more important for the outer mirrors.

The influence of the orientation of the mirrors throughout the day is plotted in Figure 4. The inner mirror is the closest to the receiver, and the outer mirror is the furthest. The power reflected by the inner mirror due to its orientation is nearly independent of the receiver height. On the other hand, for the outer mirror the power reflected varies significantly with the receiver height.

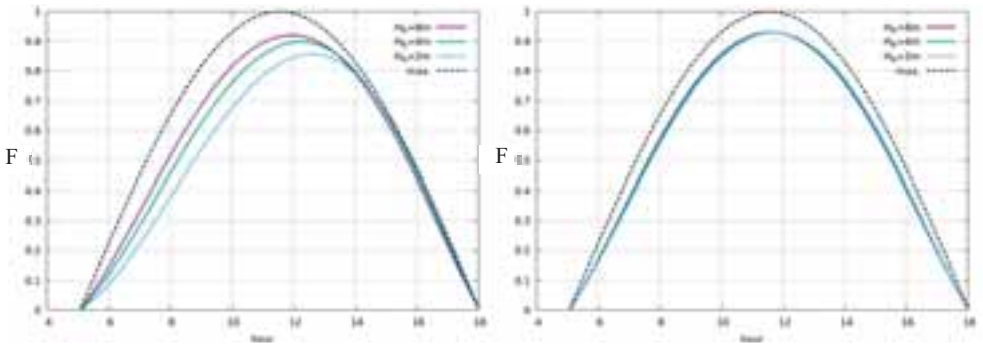

Fig. 4 Fraction of available solar power reflected by mirrors during the day. Geometric considerations only, i.e., the surface reflectivity of the mirror is not considered in these plots. Left: outer mirror (the higher the receiver, the more solar radiation is reflected). Right: inner mirror.

The daily integrated energy is shown in Figure 5. The closer the mirror is to the receiver (higher mirror index), the less influence the receiver height has on the power it can deliver. Note that the power reported is all of the power that is going to be reflected by the mirrors, without taking into account the distribution of this power in the zone near the receiver and the tube. In fact, not all of this power is going to be absorbed by the tube.

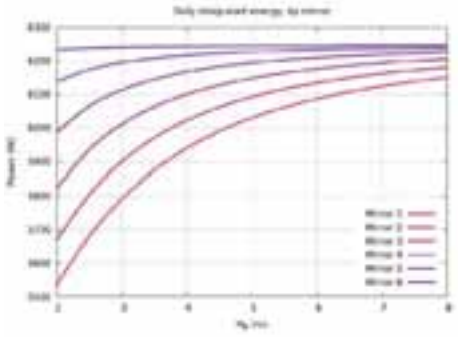

Fig. 5 Daily integrated energy for every mirror as a function of the receiver height. Inner mirror (6) is almost independent of H_R, while for outer mirrors (lower mirror index) the influence of H_R becomes noticeable.

4.1.4 Combination of all effects

To summarize, the receiver was collocated as high as possible so as to get less shadowing and higher cross section of the mirrors with respect to the incident solar radiation, but less power to the tube could available.

In Figure 8 the instantaneous power transferred to the tube is plotted for several heights of the receiver. It can be seen that the most optimal height roughly corresponds to that of the focal length of the parabolic mirrors. Also, the passage of the shadow of the receiver over the mirrors lasts less for higher heights (the wiggles start later and end before, and the time between two successive maxima is also shorter), and blocked area is smaller (the peak of variation is less pronounced).

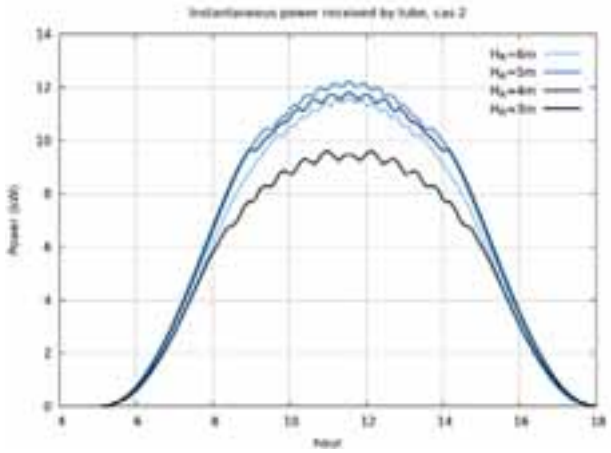

Fig. 8. Instantaneous power received by the tube in configuration "Cas 2" for several receiver heights.

4.2 CFD&HT modelling of the Fresnel receiver

4.2.1 CFD&HT modelling of the Fresnel receiver with radiation

The simulations were carried out with a direct intensity of variable radiation throughout the day. Similarities in the behavior and certain differences are presented in the different configurations. Due to the aspect ratio, visually there are differences, as shown in Figure 9. The first configuration has a double curve since there is a distance d_{F1F2} different from zero, whereas in the other two configurations only a single curve is presented. In the first configuration, the tube is situated at the vertical center of the cavity, in the second one is closer to the glass cover and in the third configuration; the tube is slightly higher than the vertical center of the cavity. At the energy level, the differences in position of the absorber tube, as well as the fact that there is a double parabola or only one, affect the temperature distribution. Higher values are observed in C1, than in the other two. Configurations 2 and 3 show similar temperatures.

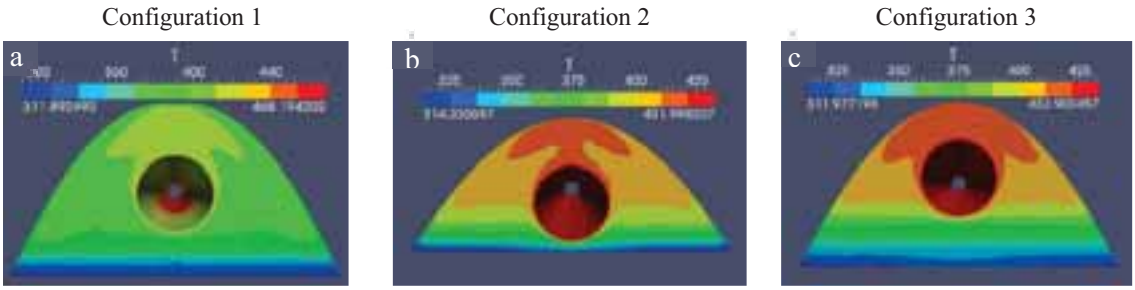

Fig. 9. Average air temperature (a) configuration 1; (b) configuration 2; (c) configuration 3

In the three configurations the tube with a higher temperature than its surroundings is observed, in configuration 3 there is a more closed concentration in the upper part of the cavity due to its closed curve, while in the two it is the more open, it is better distributed the temperature profile in this zone. In configuration 2, as the tube is closest to the glass cover, the Nusselt number is slightly higher, but the profile that reaches a higher peak is that of the first configuration. Figure 10 shows the distribution of the Nusselt number averaged in the air-tube absorber contact zone (Figure 10a) and in the air-insulation contact zone (Figure 10b). There is a change of trend in the Nusselt between the air and the insulation, because at the ends it is glued to the glass, where the air is at a lower temperature than that reached by the insulation, thus reversing the heat flow.

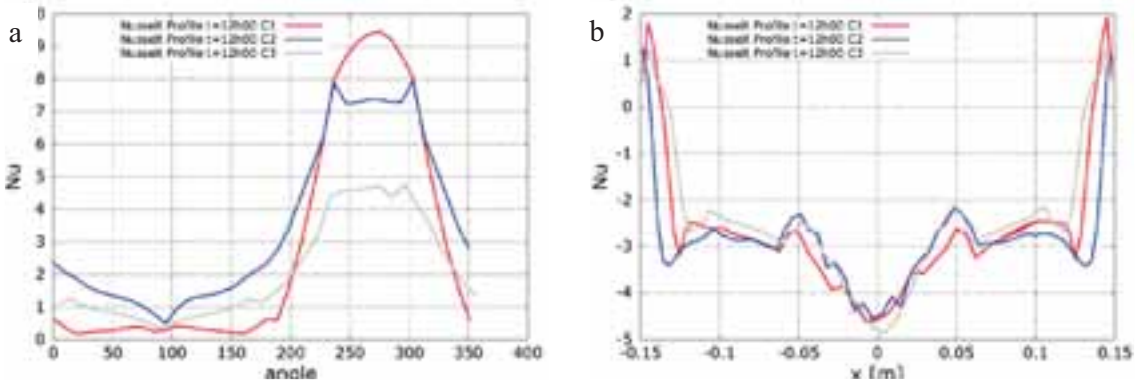

Fig. 10. Profiles of the average Nusselt number (a) boundary with tube; (b) boundary with insulation

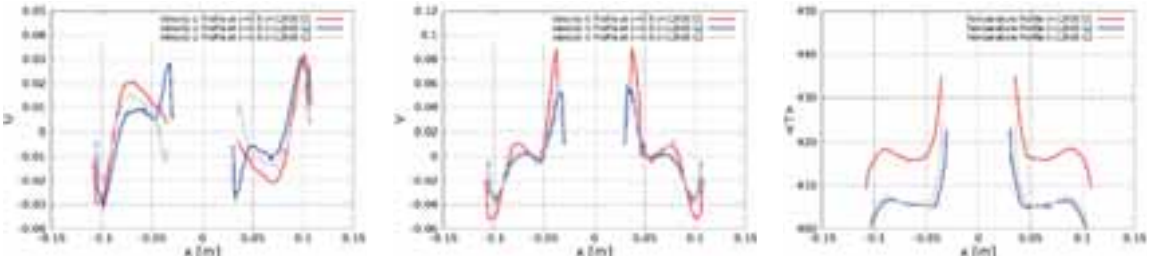

Fig. 11. Average profiles at middle of the cavity, plane z=1.0 (a) Velocity u profile from horizontal axis; (b) Velocity v profile from horizontal axis; (c) Temperature profile from horizontal axis.

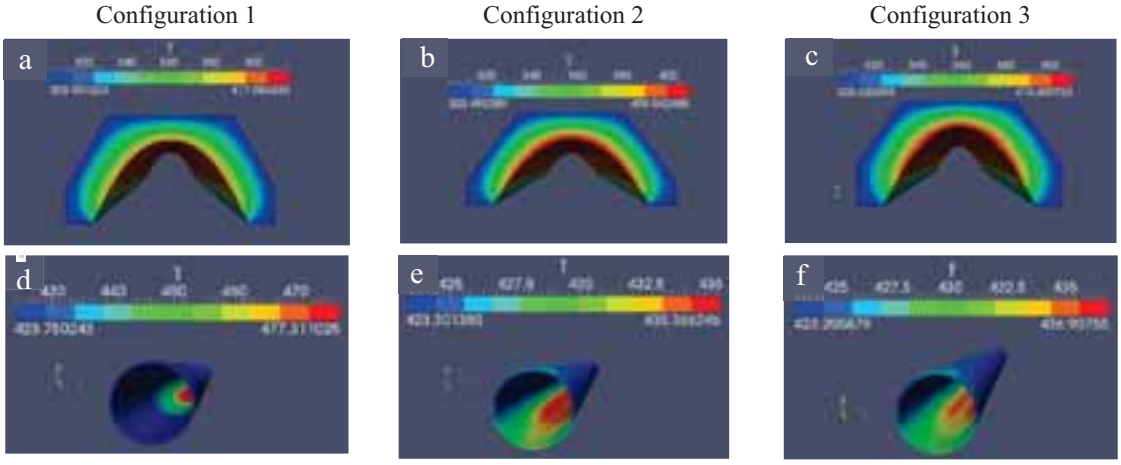
Figure 11 shows the velocity profile for the various configurations at 12:00 solar time and ate the middle plane of the geometry (located at z = 1.0) in a horizontal line (parallel to the x-axis). In Figure 11a., it can be observed that the horizontal velocity u has a symmetrical but inverted behavior due to the geometry. In configuration 2, a more pronounced peak of horizontal velocity (u) is shown in the zone of contact with the tube. The accelerated decay of the value of u is due to the boundary layer conditions. The other two configurations show a lighter decay but with the same tendency. Figure 11b- shows the vertical velocity profile (v), where the symmetry of the case is visualized with respect to the center of the cavity. It is observed that, for this component of the velocity, the configuration with the highest peak is in the first. Moving away from the center, the downward tendency of the air is observed, reaching 0 at the contact end with the insulation. Figure 11c shows the temperature profile across the cavity from the zone of contact with the tube towards the insulation. It can be seen that the temperature is higher in the area close to the tube and decrease as it moves away towards the insulation. These values of temperatures could enhance the thermal wear of the system configurations 2 and 3 are more interesting.

4.2.2 Heat Conduction (Tube, Insulation and Glass Cover) and HTF inside the tube.



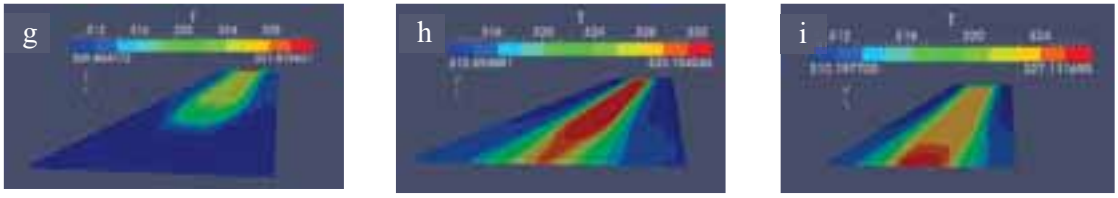


Fig. 12. Instantaneous distribution of the temperature, from top to bottom: insulation element, tube and glass cover. (a), (d), (g) configuration 1; (b), (e), (h) configuration 2; (c), (f), (i) configuration 3.

Figure 12 shows the instantaneous temperature profiles for each configuration and for each element of the system (insulation, absorber tube and glass cover). It is observed that the insulation has similar temperatures in the three configurations, even in the first case where a higher temperature is reached; it remains very similar, thermal expansion wear in this configuration must be taken into account. The absorber tube also has a high gradient between the inlet and the outlet, so it should be properly sized to withstand these temperatures and avoid thermal expansions that punish the element, configurations 2 and 3 exhibit similar behaviors with a variation of less than 2% of temperature in the tube and somewhat higher in the profile of the glass cover.

5. Conclusions

An advanced global model of a Fresnel linear system with couplings between natural convection, solar and thermal radiation, and its simultaneous multi-physics resolution allows us to estimate, study and analyze, the behavior of these systems in order to determine how is affected by the variation of the various parameters such as the height of the receiver, the shadows between mirrors, the orientation from the optical point of view. From the thermal point of view allows simulating diverse scenarios, to know maximum permissible temperatures. The coupled resolution also helps to determine the outlet temperature of the carrier heat fluid with a correct estimate, to test new materials, lighter or with lower optical properties, but to meet the energy requirements of these systems with the aim of reducing costs and making them more competitive with respect to other technologies of solar concentration.

The implementation of the system through a block where it can be varied of physical properties, the fluid carrier heat and the different models that are applied for its resolution, hypothesis, numerical approximations, etc., make this multidimensional model a versatile tool with many applications at industrial and energy sector level.

Abstract

Solar Chimney Power Plant (SCPP) is guided through natural draft utilizing solar radiant energy to impart ascending thrust to the flow of air and therefore, transforming the radiant energy to run the turbine. A simplified model for a solar chimney power plant aided with reflectors is developed and a comparative study is conducted with an SCPP model without reflectors. This paper presents the enhanced performance analysis of the SCPP model with the aid of reflectors by increasing the radiant energy incident onto the floor and presents its performance for Dhahran, Saudi Arabia. For solar radiation data of 2016, the reflector aided SCPP model can produce on average, around 331kW during daytime and has an average air mass flow rate of around 432 kg/s, when compared with traditional SCPP of same geometry which produces 123kW. The energetic efficiency and power output are found to increase by 40% and 167%, respectively. Moreover, power produced, energy efficiency, the variation of temperature for the floor, the variation of mass flow rate and inlet velocity of the turbine for each month of the year are reported.

Keywords: Solar Chimney Power Plant (SCPP), Reflectors, Energy, Efficiency.

1. Introduction

SCPP is an agglomeration of three traditional mechanisms: the green house, the lengthened chimney at the center, and the wind turbine seated within the chimney. This setup fulfills the effort of transformation into electrical energy from the radiant energy of sun. This transformation involves two steps. During the first step, air flowing radially inwards under the collector transforms the radiant energy into thermal energy and this stride is fulfilled by the greenhouse effect. During the next step, the chimney transforms the developed thermal potential into kinetic energy and finally into electricity through the generator connected to the wind turbine.

In the simple model, the collector is built with the film of glass or plastic cover drawn out evenly and advanced on the top of the ground, thus the cover fulfills the objective of trapping the heated air, and in turn allows the radiation of the smaller wavelength from sun and on the other side below arresting the radiation of smaller wavelength emanated from the ground. Consequently, temperature above the ground rises up, which in turn heats the air flowing beneath the film. The elevation of the collector cover, just above the ground increases evenly towards the middle of the SCPP. This accommodates continuous smooth passage of the hot air flowing through the long tubular chimney and therefore, downsizing the disturbance within the flow and thereby diminishing the eddy loss. A flat collector of these characteristics can transform a considerable fraction of the radiant energy into thermal energy.

The idea of SCPP was conceived by (Schlaich Jorg 1995) and (Haaf et al. 1983) in the 1970s. The very first operational 36 kW pilot plant was constructed in Manzanares which is near Madrid in Spain. The concept of SCPP was developed gradually over the years, several research issues argued distinct facets of the SCPP, in which intricate mechanism of heat transfer and fluid mechanics appear. But a very few attempts have been reported to enhance the performance of the system.

One of the technique was to introduce water filled tubes for thermal storage as reported by (Kreetz, H. 1997), water filled tubes are placed on the ground upon which radiation is incident, thermal energy is stored during day time and during night time when there is no solar radiation, temperature of air in the collector drops. Then water inside the tubes releases the heat that is stored during the day. But in the extended study of (Bernardes 2004) it is reported that the power produced during the peak hours of sunshine is decreased as the heat is absorbed by the water filled tubes.

doi:10.18086/swc.2017.31.05 Available at http://proceedings.ises.org

Anyhow, uniform power output is produced throughout day and night i.e., approximately 40% of the peak power of a traditional SCPP without water tubes is produced depending upon the depth of water stored.

Later (Pasumarthi and Sherif 1997, 1998a, 1998b) developed mathematical model, performed theoretical and experimental analysis. They suggested two designs, one is to elongate the sloped collector and the other was to introduce absorber plate in between ground and glass cover, both the designs were found to enhance the energy output by 10-15% compared with previous designs. Considering the first design suggested by (Pasumarthi and Sherif 1997, 1998a, 1998b) with the increase in the elongated sloped collector would surely increase the area subjected to solar radiation, but due to geometric constraints owing to negative draft it will also increase the height of chimney which is not desirable from construction and functioning aspect of SCPP.

(Bilgen and Rheault 2005) designed sloped SCPP for hills at high latitudes and evaluated its performance. As natural hills are used as collector field, the chimney height is reduced by 90%, which reduces the construction and maintenance cost. But construction of sloped collector increases the cost as it involves much civil work. Anyhow the authors claimed the efficiency of 0.48%, which is slightly better than the traditional SCPP. (Zhou et al. 2009) proposed a novel concept for producing energy by integrating a solar collector with a man-made mountain hollow. The mountain hollow, formed by excavation in a large elevation mountain, can avoid the issues of concrete chimneys which could reduce the usage of material and construction cost.

(Islamuddin et al. 2013a, 2013b) proposed a new idea of providing an external heat source to the SCPP by placing the hollow rectangular channels beneath the collector cover and passing the exhaust gases (flue gases) through it. They developed the mathematical model and investigated the numerical simulation, they validated their result with the analytical model of (Petela 2009c). But increase in overall efficiency of the system is found to be 1.14%. Anyhow, short coming of this hybrid technique is that flue gas is to be transported to the location of SCPP or thermal power plant should be in the vicinity of SCPP.

It can be observed from the literature review that no technique is able to enhance the efficiency of SCPP by more than 1.5%. In this article, study on new technique is emphasized, keeping the geometric parameters of SCPP same as that mentioned in the literature, an effort has been made to increase the radiation incident on solar collector with the aid of reflectors. Enhancement in the performance of SCPP was observed which is described in detail by performing energy analysis for Dhahran, Saudi Arabia. The results of the current research will be a valuable reference for researchers extending their studies for enhancing the efficiency of SCPP.

2. System Description

Air enters the collector through (point 0) via a gap of H_e. The floor of the collector is of diameter D_f, which is under the transparent cover which rises proportionally to ensure a constant radial cross-section area of flow for the radially directed air. The assumption of a constant radial cross-section implies

$$\pi \, x \, D_f \, x \, H_e \; = \; \pi \, x \, D_1 \, x \, H_1 \; = \; \pi \, x \, D_1^2/4 \qquad \text{(eq. 1)}$$

The values of H_e and D_f allows to determine inlet turbine diameter and height.

$$D_1 \; = \; \left(4 \, x H_e \, x D_f \right)^{\frac{1}{2}} \qquad \text{(eq. 2)}$$

$$H_1 = \frac{D_1}{4} \qquad \text{(eq. 3)}$$

The Collector floor heats the air from state 0 to a state 1. Heated air expands in the turbine to state 2. The inlet and outlet diameters of the turbine are D_1 and D_2, respectively. Height of the turbine is H_T; ($H_1 + H_T = H_2$). Air after expansion leaves the SCPP through the top of chimney of height H_3. Fig. 1 depicts the schematic representation of the SCPP taken into consideration for the present study.

Tab. 1: Dimensions of SCPP considered for present study

Geometric Parameter	Dimensions in Meter
D_f (Diameter of floor surface)	240
H_3 (Height of Chimney)	195
H_e (Height of Deck at Point 0)	0.3

The above dimensions from Tab.1 are substituted in afore mentioned geometric correlations to obtain overall dimensions of SCPP, owing to the fact to keep constant radial cross sectional area throughout the flow.

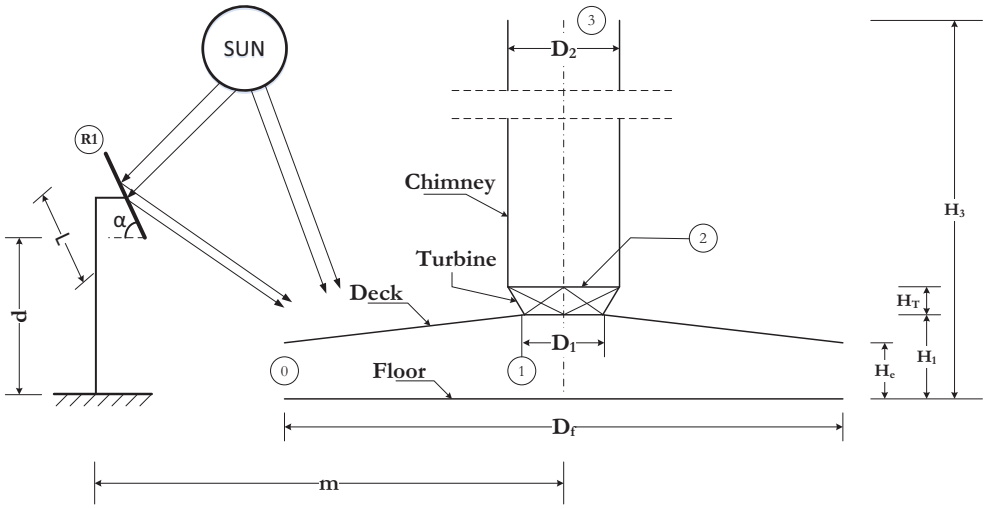

Fig. 1: Schematic Diagram of Solar Chimney aided with reflector

Once the geometric parameters of SCPP are determined then the location of reflectors is set such that the radiation incident on the mirror is reflected on to the collector field. Here, m denotes the distance of mirror from the center of SCPP, d, denotes the height between lower edges of mirror to the ground, L, denotes the length of mirror placed at an angle α. Since the mirrors are placed around the deck in concentric pattern, in our analysis, we consider the location of mirror along the mean position of the mirror field.

The ratio of reflection of mirror on deck to each mirror area is assumed to be one, which implies total area of mirrors required is equal to area of deck.

$$Number\ of\ mirrors = \frac{Total\ area\ of\ deck}{Area\ of\ each\ mirror} \qquad \text{(eq. 4)}$$

The dimensions of SCPP and positioning of mirror with respect to SCPP evaluated in this study are provided in Tab.2.

Tab. 2: The dimensions of the SCPP aided with reflectors under evaluation

Geometric Parameter	Dimensions
Area of each mirror	4 m2
Number of mirrors	11260
m	150 m
L	2 m
d	10 m
Alpha	70^0

3. Mathematical Modeling

First geometric modelling of SCPP is performed which is followed by energy analysis of the SCPP. The thermodynamic equations are derived by obtaining the correlation between the solar input energy, energy losses at various locations, and final output power. Then, it is followed by analyzing SCPP model for Dhahran conditions depending up on the solar irradiation data. Once all the correlations between energy input and final output are obtained, all the equations are solved simultaneously using EES.

3.1. Energy Analysis

Energy conservation principle using control volume approach is applied to each part of the SCPP. The energies are represented by E and the six energy balance equations are used considering the floor surface, collector (includes floor, air and deck), turbine, air in collector, chimney as presented by (Hussain and Al-Sulaiman 2016).

$$E_{s-f} + S_R = E_{f-a} + E_{f-d} \quad \text{(eq. 5)}$$

$$E_{f-a} + E_{d-a} = E_{a1} + E_{w1} + E_{p1} \quad \text{(eq. 6)}$$

$$E_{S-f} = E_{a1} + E_{w1} + E_{p1} + E_{d-sky} + E_{d-amb} + E_{d-ch} \quad \text{(eq. 7)}$$

$$E_{a1} + E_{w1} + E_{p1} = E_{a2} + E_{w2} + E_{p2} + E_{Power} \quad \text{(eq. 8)}$$

$$E_{a2} + E_{w2} + E_{p2} + E_{d-ch} = E_{a3} + E_{w3} + E_{p3} + E_{ch-amb} + E_{ch-sky} + E_{ch-gr} \quad \text{(eq. 9)}$$

$$E_{a-ch} + E_{d-ch} = E_{ch-amb} + E_{ch-sky} + E_{ch-gr} \quad \text{(eq. 10)}$$

Subscripts used in the above equations have the following definitions:

Tab. 3: Definition of subscripts in the above equations (5)-(10).

Subscript	Definition	Subscript	Definition
S-f	The solar radiation reaching the floor.	S_R	Radiant energy obtained by reflectors.
f-a	Heat transfer by convection from floor to air. .	ch-sky	Heat transfer by radiation from chimney to sky.
f-d	Heat transfer by radiation from floor to deck.	ch-gr	Heat transfer by radiation from chimney to ground.
d-a	Heat transfer by convection from deck to air.	a-ch	Heat transferred from the air in chimney to the surface of chimney.
d-ch	Heat transfer by radiation from deck to chimney.	a1, a2, a3	Enthalpy of air at different points.
d-sky	Heat transfer by radiation from deck to sky.	w1,w2, w3	Kinetic energy of air at different points.
d-amb	Heat transfer by convection from deck to atmosphere.	p1, p2, p3	Potential energy of air at different points.
ch-amb	Heat transfer by convection from chimney to atmosphere.	P	Power generated by turbine.

The Kinetic energies are calculated using the well-known formula:

$$E_w = m \times w^2/2 \quad \text{(eq. 11)}$$

The mass flow rate m is calculated as:

$$m = 0.25 \times \pi \times D_1^2 \times w_1 \times \rho_{a1} \quad \text{(eq. 12)}$$

Where, w represents velocity and ρ represents density.

Enthalpy of air is calculated using the formula:

$$E_a = m \times c_p \times (T_a - T_0) \quad \text{(eq. 13)}$$

The potential energies of air are calculated using the formula derived by (Petela 2009b):

$$E_p = m\left\{-\frac{1}{\rho}\left[\frac{b}{6d}(\rho - e)^3 + \frac{a}{2}(\rho - e)^2\right]\right\} \quad \text{(eq. 14)}$$

Where, a, b, d and e are constants having a particular value, given by (Petela 1964, 2003, 2008a, 2008b, 2009a).

The solar energy received by the floor of the collector is given as:

$$E_{S-f} = \tau_d \varepsilon_f I A_d \quad \text{(eq. 15)}$$

Where, I is the incident solar radiation on the earth surface, τ_d is the transmissivity of deck, and ε_f is the emissivity of the collector floor, A_d is the floor surface area, which receives the solar radiation and defined as:

$$A_d = \pi(D_f^2 - D_1^2)/4 \quad \text{(eq. 16)}$$

The additional solar energy S_R received by the floor with the aid of reflectors is defined as:

$$S_R = r_1 \tau_d \varepsilon_d I A_d \quad \text{(eq. 17)}$$

Where r_1 represents the reflectance of reflector R1, and was assumed to be 0.9, τ_d is the transmissivity of deck, and ε_f is the emissivity of the collector floor reflectors are assumed to be of same area as of floor surface area.

The energy radiated by the deck to chimney is calculated as:

$$E_{d-ch} = \varepsilon_d \frac{\pi}{4}\left[D_f^2 - (c_D D_2)^2\right]\sigma(T_{dE}^4 - T_{ch}^4) \quad \text{(eq. 18)}$$

T_{dE} is the effective temperature of the deck, c_D is factor which is used to account for the thickness of the chimney wall. The shape factor for radiation from the deck to the chimney ϕ_{d-ch} can be calculated as:

$$\phi_{d-ch}\frac{\pi}{4}\left[D_f^2 - (c_D D_2)^2\right] = \phi_{ch-d}\pi c_D D_2(H_3 - H_2) \quad \text{(eq. 19)}$$

Where, ϕ_{ch-d} can be determined from

$\phi_{ch-d} = 0.5 \times (90 - \beta)/90$, the value for β is found from $\tan\beta = 2 \times H_3/D_f$

Energy radiated from the floor to the deck is given by:

$$E_{f-d} = A_d \sigma(T_{fE}^4 - T_{dE}^4) \quad \text{(eq. 20)}$$

Where, T_{fE} is the effective temperature of the floor.

Energy transfer from the floor to air by convection is given as:

$$E_{f-a} = A_d h_{f-a}(T_{fE} - T_{aE}) \quad \text{(eq. 21)}$$

Energy transfer from the deck to air by convection is given as:

$$E_{d-a} = A_d h_{d-a}(T_{dE} - T_{aE}) \quad \text{(eq. 22)}$$

Energy transfer from the deck to ambient by convection is given as:

$$E_{d-amb} = A_d h_{d-amb}(T_{dE} - T_{amb}) \quad \text{(eq. 23)}$$

Energy transfer from the chimney to environment by convection is given as:

$$E_{ch-amb} = A_{ch} h_{ch-amb}(T_{ch} - T_{amb}) \quad \text{(eq. 24)}$$

Energy transfer from air inside the chimney to the chimney wall by convection is given as:

$$E_{a-ch} = \pi D_2(H_3 - H_2) h_{a-ch}\left(\frac{T_{a2}+T_{a3}}{2} - T_{ch}\right) \quad \text{(eq. 25)}$$

In the above equations h is the convective heat transfer coefficient for the respective pair of the surfaces, and the chimney surface area is defined as:

$$A_{ch} = \pi \times c_D \times D_2 \times (H_3 - H_2) \quad \text{(eq. 26)}$$

The convective heat transfer coefficient h_{a-ch} can be determined as, $h_{a-ch} = Nu \times k/D_2$. The Nusselt number is calculated from $Nu = 0.023 \times Re^{0.8} \times Pr^{0.4}$. Here Reynolds number is calculated as $Re = w_2 D_2/\nu$, and the Prandtl number (Pr) is taken as constant for air, Pr=0.7.The convective heat transfer coefficient h_{f-a} is determined considering forced convection. The calculations for h_{f-a} is made using Reynold's Number, instead of Grashoff Number. For this the average flow velocity of the air is assumed. Energy radiated from the deck to the chimney is given as:

$$E_{d-ch} = \phi_{d-ch} A_d \sigma (T_{dE}^4 - T_{ch}^4) \quad \text{(eq. 27)}$$

Energy radiated from the deck to sky is given as:

$$E_{d-sky} = \phi_{d-sky} A_d \sigma (T_{dE}^4 - T_{sky}^4) \quad \text{(eq. 28)}$$

Energy radiated from the chimney to sky is given as:

$$E_{ch-sky} = \phi_{ch-sky} A_{ch} \sigma (T_{ch}^4 - T_{sky}^4) \quad \text{(eq. 29)}$$

Energy radiated from the chimney to the ground which is not a part of the collector is given as:

$$E_{ch-gr} = \phi_{ch-gr} A_{ch} \sigma (T_{ch}^4 - T_{gr}^4) \quad \text{(eq. 30)}$$

The shape factor relations are as follows:

$$\phi_{d-sky} + \phi_{d-ch} = 1 \quad \text{(eq. 31)}$$

$$\phi_{ch-sky} + \phi_{ch-d} + \phi_{ch-gr} = 1 \quad \text{(eq. 32)}$$

Where, $\phi_{ch-sky} = 0.5$.

Temperature T_{a2} is calculated using the equation for isentropic expansion in turbine, which is defined as

$$\frac{T_{a2}}{T_{a1}} = \left(\frac{p_2}{p_1}\right)^{\frac{\kappa}{\kappa-1}} \quad \text{(eq. 33)}$$

Where κ for air is 1.4. Internal efficiency of turbine is η_T. Energy is converted into electric power at an overall efficiency η_0, which also includes mechanical and electrical efficiencies of the turbine generator. Further as mentioned in (Petela 2009b, 2009c), the temperature drop in the chimney can be estimated using eq. 34.

$$T_{a2} - T_{a3} = 0.154 \times D_2 \times H_3/m \quad \text{(eq. 34)}$$

Air distribution inside the collector was assumed to be linear. Therefore, the average temperature of air inside the collector was calculated as:

$$T_{aE} = (T_{amb} + T_{a1})/2 \quad \text{(eq. 35)}$$

Relative pressure drop across the chimney for maximum fluid power was given by (Backstrom and Fluri 2006) as:

$$\frac{P_1 - P_2}{P_1 - P_3} = \frac{2}{3} \quad \text{(eq. 36)}$$

The energetic efficiency of an SCPP aided with reflectors is described as below.

$$\eta_{energy} = \frac{E_{power}}{E_{sf} + S_R} * 100 \quad \text{(eq. 37)}$$

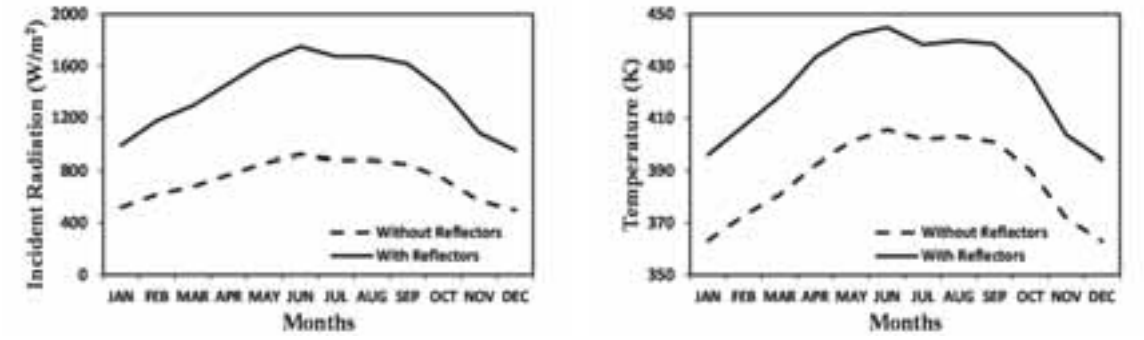
The following assumptions are used:

$T_{gr} = T_{amb}$, $c_D = 1.015$, $c_p = 1000 \frac{J}{kg} K$, $\kappa = 1.4$, $\eta_T = 0.7$, $H_T = 1\ m$, $h_{ch-amb} = 7 \frac{W}{m^2} K$, $h_{d-amb} = 5 \frac{W}{m^2} K$, $H_0 = 0.3\ m$

4. Results and Discussion

All the above formulated energy equations have been solved using sufficient and necessary assumptions with the help of EES software simultaneously, considering all the losses into account which eased in determining the theoretical final power output and hence forth the theoretical efficiency as well. Taking monthly average data into consideration, energy output and efficiency were determined for the SCPP model with and without reflectors for Dhahran, Saudi Arabia. The direct relationship between the energy output and the efficiency could not be drawn as they are dependent on many inter-dependent parameters, such as solar insolation, wind speed, atmospheric temperature. Furthermore, the geometry of the solar chimney model plays a vital role, which was clearly depicted in the results below. All the required data such as average insolation, wind speed, and atmospheric temperature for Dhahran, Saudi Arabia, was taken from NASA metrological website for the year 2016 which has a record of data for past 22 years.

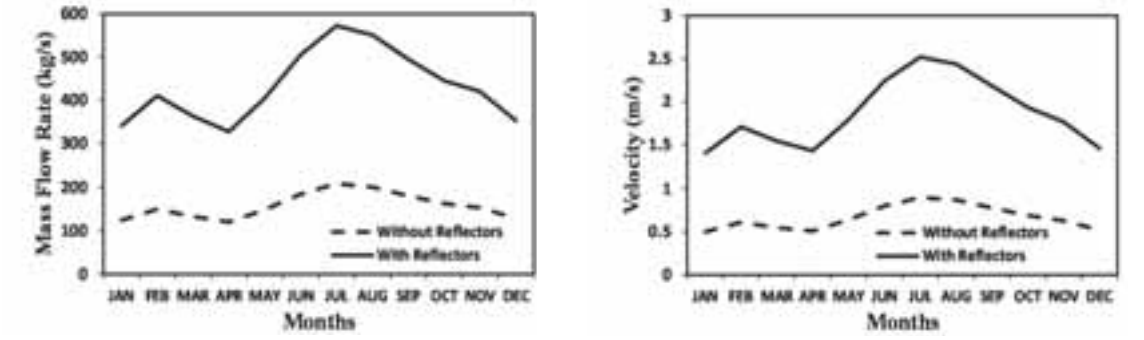
From Fig. 2(a). With the aid of reflectors it is evident that there was increase in amount of irradiation incident on collector surface area by 90.25%, maximum intensity is found during the summer months vice versa along the winter months it is found to be minimum. It followed the same pattern as that of the available solar radiation over a period of one year. Fig. 2(b). Depicts the temperature of the floor upon which solar radiation is incident. The average ambient temperature for Dhahran is 297K, average floor temperature for SCPP model with and without reflectors are found to be 423K and 387K. Increase in floor surface temperature when aided with reflectors is found to be 9.3%, the higher floor temperature causes the density variation in air which in turn moves air towards the center i.e., low density area which helps in driving the turbine. The maximum temperatures were found to be for the summer months, which also correspond to maximum power generated. Across the winter months the temperatures were observed to be lower which corresponds to a lower power output as well.



2 (a) **2 (b)**

Fig. 2: (a) Variation of incident radiation on SCPP model at Dhahran, Saudi Arabia. (b) Variation of floor temperature.

Variation of Mass flow rate and velocity at the inlet of the turbine are summarized in Fig. 3. The highest velocity and greater mass flow rate are observed for the month of July and August which has the highest incident solar radiation, as well as, higher energy output. With the aid of reflectors, average increase in velocity and mass flow rate are found to be 180% and 172% respectively.

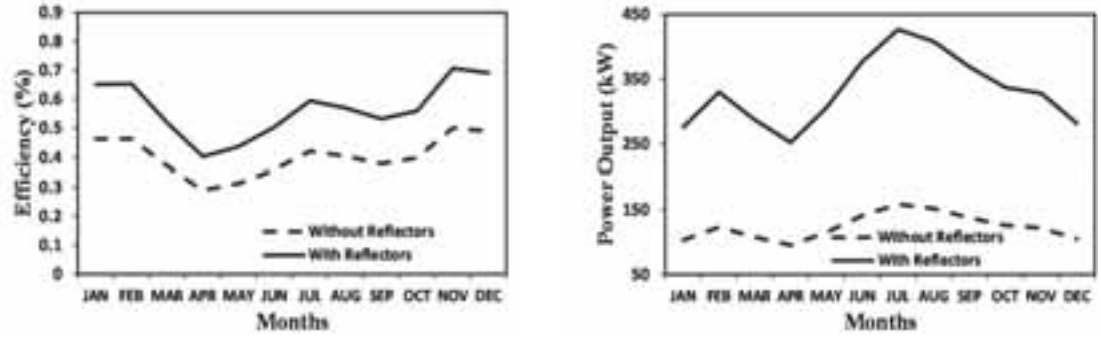


3 (a) **3 (b)**

Fig. 3: (a) Variation of mass flow rate. (b) Variation of velocity at the inlet of turbine.

Theoretical power output and efficiency of SCPP model for both the cases are determined and summarized in Fig. 4. Increase in power output due to reflectors is found to be 167% whereas efficiency was increased by 40%, which is much higher than the design suggested by Pasumarthi and sherif (Pasumarthi and Sherif 1997, 1998a, 1998b).

From Fig. 2(a). Fig. 4(a). Fig. 4(b). an important conclusion can be drawn though the energy output was found to be less for the months of January and December, but SCPP model is found to have a maximum efficiency during this period, it is because of the fact that the velocities obtained are less which increases the duration of contact between air and floor in which air absorbs more heat from floor, when compared with summer months; thereby making the system more efficient for the winter months but less energy output because of lower solar irradiation.



4 (a) **4 (b)**

Fig. 4: (a) Variation of efficiency. (b) Variation of energy output of the SCPP model.

5. Conclusions

This paper presents the enhanced performance analysis of the SCPP model with the aid of reflectors by increasing the radiant energy incident on to the floor and presents its performance for Dhahran, Saudi Arabia.

- It can be concluded that, the energy output is nearly directly dependent on the mass flow rate, which in turn is dependent on the geometry of the model, wind speed, and density.
- The reflector aided SCPP has an average air mass flow rate of around 432 kg/s, when compared with traditional SCPP which has an air mass flow rate of 158 kg/s.
- The SCPP aided with reflector is found to increase floor temperature by 9.3%.
- The reflector aided SCPP can produce on average, around 331kW during daytime when compared with traditional SCPP of same geometry which produces 123kW.
- The energetic efficiency found to increase by 40% and energy output is increased by 167%.

Abstract

The low-temperature-caused freezing of outdoor pipes and solar collectors in winter night is one of the most serious problems in solar thermal system. Studying the heat loss characteristic of the solar connector groups in nighttime is greatly significant for solar collector groups anti-freezing and maintaining system safety. In this paper, a heat loss mathematical model was established and validated through on-site measurement, to investigate the heat loss characteristic of the flat plate solar collectors (FPC) groups. Furthermore, the anti-freezing critical flow rate was analyzed when outdoor temperature and inlet water temperature vary. As an illustrative example, the anti-freezing analysis for Harbin, a northern city in China, was conducted. The results show that, the front heat loss and connecting pipes constituted the main heat loss of the solar collector group in nighttime, which accounted for 63.32% and 15.53% respectively. Besides, making anti-freezing flow rate equal to daytime working design flow rate is not suitable. Hence, the flow rate should be reduced through the water pump frequency conversion methods. Moreover, winter minimum temperature in China severe cold area can be 28.7℃. On that occasion, a single set of solar connector group should keep the inlet temperature higher than 15℃, while the flow rate larger than 0.5L/min.

Keywords: flat plate solar collectors, nighttime heat loss, heat loss mathematical model, anti-freezing

1. Introduction

With the extensive use of fossil fuels, global pollution problem is getting increasingly serious. The use of renewable energy has been paid more and more attention to by many countries around the world, in which the solar energy is promoted for the similarity to that of traditional energy maneuverability and adaptability (F. Dinter and Mayorga Gonzalez, 2014; Xiaolei Li et al., 2017) . Solar energy utilization can be either photovoltaic or photothermal. While the hot water system, which is a kind of photothermal, is of high working stability and easy for thermal energy storage, making it suitable for heating in winter (BillyAnak Sup et al., 2014; CJ Porras-Prieto et al., 2014; L.M. Ayompe et al., 2011). However, in severely cold areas, the freezing of outdoor pipes and collectors is one of the most serious problems, which, to a certain degree, limits the utilization of solar energy and decreases the system economic performance (Huifang Liu et al., 2015). As a result, studying the heat loss characteristic of the solar connector groups at night to avoid frost crack and maintain the system working safe and stable really makes a great difference.

According to available literatures, many scholars studied the solar connector anti-freezing. The conventional measures include the use of antifreeze fluid, electric tracing tapes, draining water from the collectors and using the hot water in a thermal storage tank to heat the outdoor pipes by circulation (BV Bourke, 1995; HMS Hussein et al., 1999; M Smyth et al, 2001; PW Cronin et al., 1997; R.H. Lewis and JB Carr, 1981). For FPC, KLEINS (S.A. Klein, 1975) proposed a method to calculate the heat loss coefficient, and respectively, put forward the top, bottom and side heat loss coefficient calculation method. Gao Liuhua (Gao Liuhua et al., 2014) proposed a one-dimensional steady state mathematic model of single FPC. He took overall heat loss coefficient of collector as a variable quantity. And absorber plate thickness and tube spacing of copper-aluminum FPC were optimized based on efficiency factor and metal consumption of collector. Th Beikircher (Th. Beikircher et al., 2014) studied heat loss measurements without insolation and a novel conversion towards daytime conditions. This research thought a broader application and test of the new method for further types of solar collectors by independent researchers is desirable. Fan Zhou (Fan Zhou et al., 2017) did experimental and numerical study of the freezing process of

doi:10.18086/swc.2017.31.06 Available at http://proceedings.ises.org

FPC, finding that narrowing the pipe space, increasing the pipe diameter or header diameter and reducing the emissivity of absorber and glass-cover are the effective ways of enhancing the antifreeze performance of flat-plate collector. But the reported studies rarely analyze the influence of the environment temperature, the inlet temperature, and the flow rate to a FPC group anti-freezing.

In this paper, a heat loss mathematical model was established and validated through on-site measurement, to study the heat loss characteristic of the FPC groups. Furthermore, the anti-freezing critical flow rate was analyzed when outdoor temperature and inlet water temperature vary. And we had an anti-freezing analyze of Harbin as a typical case. This study can provide meaningful references for practical engineering.

2. Experimental System

In order to study the heat loss characteristic of FPC groups in nighttime, we built a test bench at Sichuan University, which is at east longitude 30.67° and north latitude 104.06°. Fig.1 is the schematic diagram of the experiment system. From the figure, the test bench includes two FPC groups, which can control the flow rate independently. Besides, each FPC group is set up by two pieces of 2000mm×1000mm×700mm FPCs in parallel. The FPCs is facing south while the installation angle is 40°. Within each FPC group, the connecting pipes between two FPC is 74mm long and is made of copper.

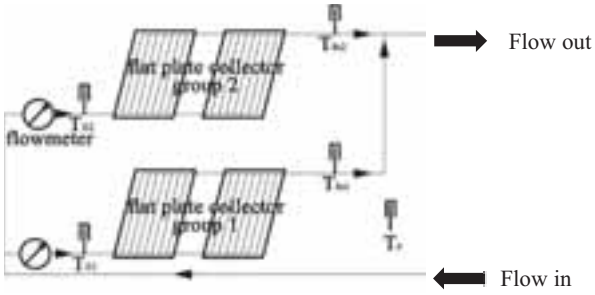

Fig.1 experiment system diagram

Fig.2 is the FPC configuration diagram, which shows the PFC comprises glass cover-plate, sheet absorber, pipe, insulating layer and housing. The sheet absorber is made of pure aluminum anodic oxide film plating. The insulating layer is made of polyurethane foam. And the pipe is made of copper. The heat loss of FPC can be divided into front heat loss, bottom heat loss, and side heat loss. Tab.1 shows detailed parameters for the FPC and connecting pipes.

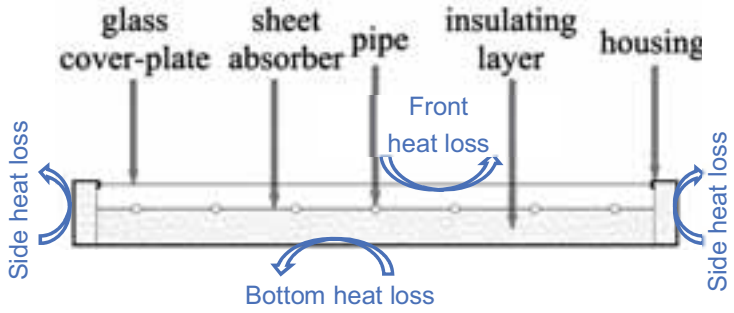

Fig.2: FPC configuration diagram

Tab. 1: Detailed parameters for the FPC and connecting pipe

Item	Value	Item	Value
FPC length /mm	2000	Connecting pipe number	2
FPC width/mm	1000	Connecting pipe length/m	0.074
FPC thickness/mm	70	Connecting pipe thermal	386.4

		conductivity/W·(m·K)$^{-1}$	
FPC lighting area /m2	1.85	FPC pipe outer diameter / mm	8
Sheet absorber length/mm	1940	FPC pipe wall thickness /mm	0.5
Sheet absorber width/mm	950	FPC pipe thermal conductivity / W·(m·K)$^{-1}$	386.4
Sheet absorber thickness/mm	0.4	Glass cover-plate emissivity	0.9
Sheet absorber emissivity	0.09	Glass cover-plate number	1
Sheet absorber absorptivity	0.95	Insulating layer thermal conductivity / W·(m·K)$^{-1}$	0.023
Sheet absorber thermal conductivity /W·(m·K)$^{-1}$	202.8	Bottom insulating layer thickness /mm	20
Connecting pipe outer diameter / mm	22	Side insulating layer thickness /mm	20
Connecting pipe wall thickness /mm	0.6		

The pipe between temperature measuring point and inlet or outlet water gates for FPC group is short and has a good thermal insulation, so it is assumed that the tested temperature is the temperature of water inlet or outlet gates for FPC group. T-type thermocouples (with accuracy of 2%) were used to measure the inlet temperature and outlet temperature of each groups, as well as the ambient temperature. All measurement data is collected by a JTRG-II building thermal temperature automatic tester. And flow meters (with accuracy of 5%) were used to measure the flow of every FPC group. Testing started from 20:15 Mar. 11 to 7:00 Mar. 12, with 1 min recording interval.

3. Heat Loss Mathematical Model

In this paper, one group of FPCs in Fig.1 is the studying object for the heat loss mathematical model, which includes two pieces of FPCs and two pieces of connecting pipes.

3.1 Heat Loss Mathematical Model for the FPC

In nighttime, the total heat loss of FPC group equals the FPC heat loss plus the connecting pipes heat loss plus the FPC group heat storage change. The heat loss equation can be written as Eq. (1):

$$Q_u = Q_{lh} + Q_p + \triangle Q_s \quad \text{(eq. 1)}$$

Where Q_u is the total heat loss of FPC group, W; Q_{lh}, Q_p and $\triangle Q_s$ denote the FPC heat loss, the connecting pipes heat loss, and the FPC group heat storage change, W. The FPC group heat storage is negligible, so we make an assumption that $\triangle Q_s = 0$.

The FPC heat loss can be calculated by the FPC lighting area, the total heat loss coefficient, the sheet absorber temperature and environment temperature (Eq. (2)).

$$Q_{lh} = A_a U_L (T_a - T_e) \quad \text{(eq. 2)}$$

Where the A_a is the FPC lighting area, m^2. The U_L is the total heat loss coefficient, W/m^2·K. The T_a and T_e are the sheet absorber temperature and environment temperature，K。

The total heat loss coefficient is a comprehensive and equivalent value that integrate the front heat loss coefficient, the bottom heat loss coefficient, and the side heat loss coefficient (Eq. (3)).

$$U_L = U_t + U_b + \frac{A_e}{A_a} U_e \quad \text{(eq. 3)}$$

Where the U_t、U_b、U_e denote the front, bottom and side heat loss coefficient, W/m^2·K. The A_e denote the FPC side area, m^2.

The U_t is calculated by the formula (Eq. (4)-Eq. (7)) put forward by Klein (S.A. Klein, 1975), which has

considered the heat loss caused by cold radiation of the sky. And the error of the formula can be controlled in ± 0.3W/(m2 • K)。

$$U_t=\left[\frac{N}{\left(\frac{c}{T_p}\right)\left(\frac{T_a-T_e}{N+f}\right)^e}+\frac{1}{h_w}\right]^{-1}+\frac{\sigma\left(T_a^2+T_e^2\right)\left(T_a+T_e\right)}{\left(\varepsilon_p+0.00591Nh_w\right)^{-1}+\frac{2N+f-1+0.133\varepsilon_p}{\varepsilon_g}-N} \quad \text{(eq. 4)}$$

$$f=\left(1+0.089h_w-0.1166h_w\varepsilon_p\right)\left(1+0.07866N\right) \quad \text{(eq. 5)}$$

$$C=520\left(1-0.000051s^2\right) \quad \text{(eq. 6)}$$

$$e=0.43\left(1-100/T_a\right) \quad \text{(eq. 7)}$$

Where the N is the glass cover-plate number. The h_w is the convective heat transfer coefficient between the air and the surface. The ε_p and ε_g are the sheet and glass cover-plate absorber emissivity. The s is the installation angle of FPC.

The U_b and U_e can be calculated by Eq. (8) and Eq. (9).

$$U_b=1\Big/\left(\frac{1}{h_b}+\frac{1}{h_w+h_r}\right) \quad \text{(eq. 8)}$$

$$U_e=1\Big/\left(\frac{1}{h_e}+\frac{1}{h_w+h_r}\right) \quad \text{(eq. 9)}$$

Where the h_b, h_e and h_r are bottom, side, and radiation heat loss heat transfer coefficient, W/ m^2·K. We made the assumption that $h_r \approx 0$ (Y. Lu et al., 2013). The h_w can be achieved by outdoor wind speed (Li Ming, 2004), which is 1m/s according to Chengdu Tianqi net (Chengdu weather net, 2017).

$$h_w=5.7+3.8v \quad \text{(eq. 10)}$$

Because the sheet absorber is too big and has a non-uniform distribution of temperature, we introduce efficiency factor *F'* for modification (JA Duffie et al., 1980), in order to use the inlet and outlet average temperature instead of the sheet absorber temperature (Eq. (11)).

$$Q_{lh}^{'}=A_aU_LF'(T_f-T_e) \quad \text{(eq. 11)}$$

Where the T_f is the inlet and outlet average temperature (Eq. (12)).

$$T_f=\frac{T_{fi}+T_{fo}}{2} \quad \text{(eq. 12)}$$

Where the T_{fi} and the T_{fo} denote the inlet and outlet temperature.

FPC pipe and sheet absorber has three kinds of welding method, welding way adopted in the experiment are shown in figure 2. The *F'* for this kind of welding can be got through Eq. (13).

$$F'=1\Big/\left(\frac{WU_L}{h_i\pi D_i}+\frac{W}{D_o+(W-D_o)F}\right) \quad \text{(eq. 13)}$$

Where the W, D_i and D_o denote the sheet absorber width, the FPC pipe inner diameter and outer diameter, m.

The h_i is the convective heat transfer coefficient between the water and the FPC pipe wall, W/ m^2·K. The F is the sheet absorber efficiency. And the h_i has a connection with the inlet and outlet average temperature, the flow velocity, and the FPC pipe inner diameter (Eq. (14)) (Badescu V, 2006).

$$h_i = \left(1430 + 23.3T_f - 0.048T_f^2\right) v_w^{0.8} D_i^{-0.2} \quad \text{(eq. 14)}$$

Where the v_w is the flow velocity for FPC pipes, m/s. The F can be got through Eq. (15).

$$F = th\left[\frac{\sqrt{U_L/\lambda_a\delta}(W-D_o)}{2}\right] \Big/ \frac{\sqrt{U_L/\lambda_a\delta}(W-D_o)}{2} \quad \text{(eq. 15)}$$

Where the λ_a is the sheet absorber thermal conductivity, W/m·K . The δ is the Sheet absorber thickness.

3.2 Heat Loss Mathematical Model for the connecting pipes

The two connecting pipes are symmetrical in the PFC group, so it is assumed that the inlet and outlet average temperature is equal to the average temperature for connecting pipes. The connecting pipes heat loss can be calculated by Eq. (16)

$$Q_p = q_l l \quad \text{(eq. 16)}$$

Where the q_l is the heat loss of unit length, W/m. The l is the length of connecting pipes. The q_l can be got by the formula of thermal conductivity for a cylindrical wall (Eq. (17)).

$$q_l = (T_f - T_e) / \left(\frac{1}{h_i' D_i' \pi} + \frac{1}{2\pi\lambda} + \frac{1}{h_w D_o' \pi}\right) \quad \text{(eq. 17)}$$

Where the D_i' and D_o' denote the connecting pipe inner diameter and outer diameter, m. The v_w' denote the flow velocity for connecting pipes, m/s. The λ is the connecting pipe wall thermal conductivity, W/m·K. The h_i' is the convective heat transfer coefficient between the water and the connecting pipe wall, and can be obtained by Eq. (18).

$$h_i' = \left(1430 + 23.3T_f - 0.048T_f^2\right) v_w'^{0.8} D_i^{-0.2} \quad \text{(eq. 18)}$$

3.3 Heat Loss Mathematical Model for the working fluid

The heat loss for working fluid circulating within the FPC group can be calculated by the flow rate and the inlet and outlet temperatures (Eq. (19)), which are obtained directly by the experiment.

$$Q_u' = \rho c V (T_{fi} - T_{fo}) \quad \text{(eq. 19)}$$

Where the ρ and c are the density(kg/m^3) and specific heat capacity of water(J/(kg·K)). The V is the flow rate of the connect pipe.

3.4 Anti- freezing Analysis Method

According to the energy conservation law, the heat loss for heat carrying fluid flowing through the FPC group is equals to the total heat change of FPC group (20).

$$Q_u' = Q_u \quad \text{(eq. 20)}$$

From the Eq. (1)-Eq. (20), We can get the relationship among all the major parameters, which include the T_e, the T_{fi}, the T_{fo}, and the flow rate of FPCs. If we set outlet temperature equal to 0 as the critical condition of pipe freezing, we can obtain the critical flow rate in different environment temperature and inlet temperature.

4. Results and Discussion

4.1 Experimental Results

During the experiment, the flow rate for FPC group 1 and 2 were 3.09L/min and 1.67 L/min. The T_{fi} and T_{fo} for each group and the T_e are showed in Fig. 3. The Fig. 3 indicates that the inlet temperatures for the two group were similar, while the outlet temperature for FPC group 1 was higher than that for FPC group 2. It was because the flow rate for FPC group 1 was higher than that for FPC group 2, making heat transfer time shorter for every unit of fluid.

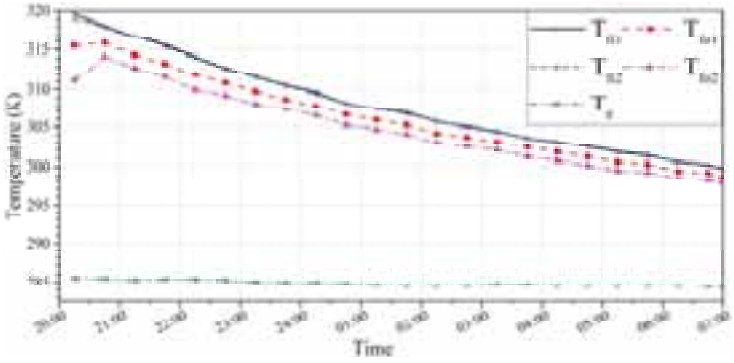

Fig. 3: Environment temperature, inlet temperature, and outlet temperature for every minute

In general, heat storage water tank has a limited capacity. With the operation of the anti-freezing working at nighttime, the inlet temperature become lower and lower, calling for a higher flow rate. So, it makes a difference to investigate the critical flow rate, which leads to the system antifreeze, in different environment temperature and inlet temperature.

Fig.4 shows the proportions of the PFC group front, bottom, side heat loss, and the connecting pipe heat loss. The front part of the PFC group occupied 62.32% of the heat loss, which constitutes the dominant part, because the cold radiation was large at night, and the top surface was large and has no heat insulation layer. The side part of the PFC group accounted for 3.57% of the heat loss, which serves as the smallest part, because the side surface was small and had a good heat insulation layer. The bottom part of the PFC group accounted for 18.57% of the heat loss, which was much smaller than the front part but had the same surface area as the front part. It was because of the bottom surface had a good heat insulating, substantiating the importance of heat insulating measures. The connecting pipes of the PFC group accounted for 15.53% of the heat loss, which was higher than the side part but lower than underside part. It was because of the connect pipe has no heat insulating layer, and was made by copper which had a high absorber thermal conductivity. In summary, reducing the heat loss in front part and making insulation layer for connecting pipes in practical engineering are very important, otherwise, the high heat loss of PFC groups will cause the outlet temperature too small, inevitably increasing the risk of system freezing.

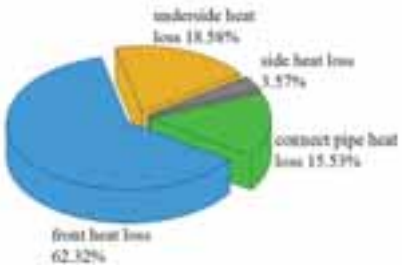

Fig. 4: The proportions of the PFC group front, bottom, side heat loss, and the connecting pipe heat loss

4.2 model verification

To verify the aforementioned heat loss mathematical model, we use Eq. (20) to compare the total heat loss of FPC (Q_u) with the heat loss for heat carrying fluid flowing through the FPC group (Q'_u).

Fig. 5 is the minutely variation of the Q_u and the Q'_u for the two groups. The Q_u and the Q'_u decrease gradually along the process of FPC groups dissipating heat at night. While the Q_{u1} is higher than Q_{u2} in most time, implying that the flow rate will be higher with the increase of the heat loss of the FPC group. Besides, since the Q_{u1} is always close and fit well to Q'_{u1}, so does the Q_{u2} to Q'_{u2}, the heat loss mathematical model can well describe the FPC group cooling process.

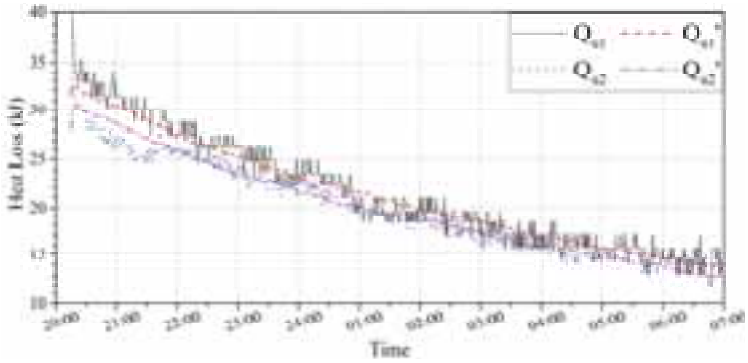

Fig. 5: The minutely variation of the Q_u and the Q'_u for the two groups

Fig. 6 is the cumulative variation of the Q_u and the Q'_u for the two groups. The $\sum Q_{u1}$ for one time is the cumulative Q_u before the time, so does the $\sum Q_{u2}, \sum Q'_{u1}, \sum Q'_{u2}$ to Q_{u2}, Q'_{u1}, Q'_{u2}. The $\sum Q_{u1}$ and the $\sum Q_{u2}$ increase gradually along the process of FPC groups dissipating heat at night. While the $\sum Q_{u1}$ is higher than $\sum Q_{u2}$ in most time, implying that the flow rate will be higher with the increase of the heat loss of the FPC group. Besides, the $\sum Q_{u1}$ is always close and fit well to $\sum Q'_{u1}$ with an error of only 1%, so does the $\sum Q_{u2}$ to $\sum Q'_{u2}$, so the heat loss mathematical model can well describe the FPC group cooling process, and the model can be used to study the heat loss of FPC group anti-freezing process.

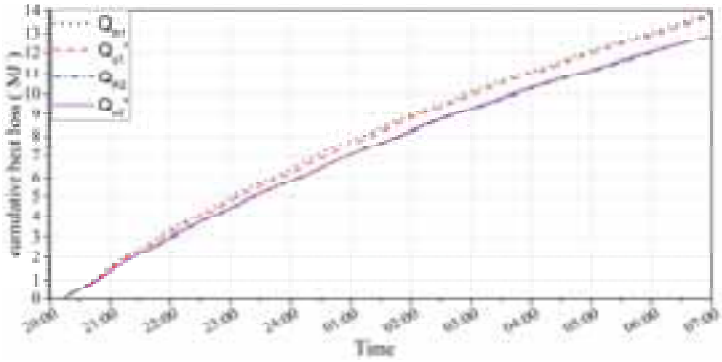

Fig. 6: The cumulative variation of the Q_u and the Q'_u for the two groups

4.3 Anti-freezing analysis for FPC group

In practical engineering, when the PFC group outlet temperature is lower than 0℃, the water in the system will be frozen. We define the flow rate of the system leading to 0℃ outlet temperature as the anti-freezing critical flow rate. When the inlet and ambient temperatures are constant, the heat loss increases with increasing flow rate, so the outlet temperature will be higher than 0℃ when the flow rate is higher than the anti-freezing critical flow rate.

Fig. 7 shows the anti-freezing critical flow rate varies with the ambient temperature and the inlet temperature. When the ambient temperature is constant, with the increase of inlet temperature, the anti-freezing critical flow rate is decreased fast when the inlet temperature is lower than 15℃ and is decreased slowly when the inlet temperature is higher than 15℃. When the inlet temperature is constant, with the increase of environment temperature, the anti-freezing critical flow rate is decreased fast when the inlet temperature is small and is decreased slowly when the inlet temperature is large. When the inlet temperature is 5℃, the anti-freezing critical

flow rate is decreased by 0.2L/min when the environment temperature is increased by 5℃. While when the inlet temperature is 30℃, the anti-freezing critical flow rate is decreased very slow when the environment temperature is increased.

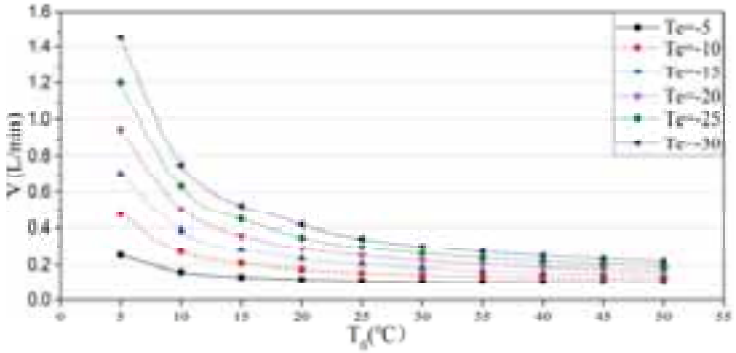

Fig. 7: The anti-freezing critical flow rate varies with the environment temperature and the inlet temperature

According to the standard (Hu Hanxin, 2016), the flow rate of the FPC group in daytime working is 4.8L/min, which is three times higher than the maximum anti-freezing critical flow rate in Fig. 7. In other words, the anti-freezing critical flow rate at night is much lower than the flow rate in daytime, so making anti-freezing flow rate equal to daytime working design flow rate is not a reasonable and desirable choice. By contrast, the flow rate should be reduced through the water pump frequency conversion methods.

4.4 Illustrative Example

We choose Harbin as a case of typical anti-freezing analyzing city, which is located in severe cold area of China and has the minimum temperature of -28.7℃ (U.S. Department of Energy and Lawrence Berkeley National Laboratory, 2017) in winter. Studying the anti-freezing critical flow rate in the winter extreme temperature of Harbin can provide meaningful references for practical engineering.

Fig.8 is the outlet temperature varies with the inlet temperature and flow rate in the winter extreme temperature. When the outlet temperature equals 0℃, the flow rate is the anti-freezing critical flow rate. Firstly, when the inlet temperature is constant, as the flow rate is increased, the outlet temperature is increased faster. Besides, when the flow rate is constant, as the inlet temperature is increased, the outlet temperature is increased. And when the flow rate is 1.5L/min, the outlet temperature is increased by 8℃ when the inlet temperature is increased by 5℃. Furthermore, when the inlet temperature ranges from 5℃ to 15℃, the anti-freezing critical flow rate is increased very fast when then inlet temperature is decreased, which is unfavorable for the anti-freezing flow rate control. So, in that situation, the inlet temperature should be higher than 15℃, and the anti-freezing flow rate should be higher than 0.5L/min.

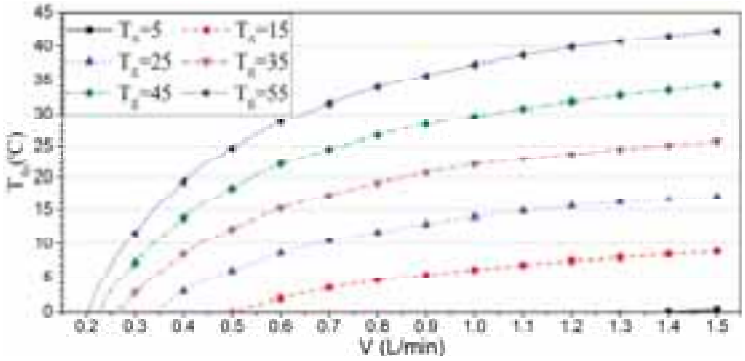

Fig. 8: The outlet temperature varies with the inlet temperature and flow rate in the winter extreme temperature

4. Conclusion

This paper studied the heat loss characteristic of the solar connector groups in nighttime through a heat loss mathematical model. A test bench which included two FPC groups has been built and solved analytically. The measured data well validated the analytical model. And main conclusions of this paper are as follows:

Firstly, when the FPC groups is anti-freezing working at night and the inlet temperature is constant, the outlet temperature increased when the flow rate increased, which keeps the system from freeze. But heat loss of FPC groups also increased when the flow rate increased. Secondly, the front part of the PFC group and connect pipes respectively accounted for 62.32% and 15.53% of the total heat loss, so reducing the heat loss in front part and making insulation layer for connecting pipes in practical engineering can make sense. But there is a pity that the front heat loss coefficient (Eq. (4)) did not independently show the radiant heat loss and the heat conduction, which is worth a further study. Besides, making anti-freezing flow rate equal to daytime working design flow rate is not suitable. By contrast, the flow rate should be reduced through the water pump frequency conversion methods. Furthermore, in the winter extreme temperature of Harbin, where the minimum temperature is -28.7℃, the input temperature should be higher than 15℃, and the anti-freezing flow rate should be higher than 0.5L/min.

This study can provide meaningful references for practical PFC groups anti-freezing engineering.

Abstract

The present work addresses a flat plate solar collector with transparent insulation material (TIM) and high temperature protection system. The design and optimization of the collector have been numerically carried out by means of a parallel object-oriented simulation tool which is capable of simulating all the entities constituting the system as a whole, using efficient coupling between the elements. Three variants of the design are chosen to first test them under laboratory conditions. These collectors then are mounted in the roof of a hospital building, where their performance are comparatively tested along with a conventional flat plate solar collector, under real meteorological conditions and during long periods of time. Thus, due to long term exposure of the collectors, aspects such as reliability, durability, energy performance, correct functioning of the protection system will be analyzed, with the objective of improving the detected shortcomings for the future generations of the present design.

Keywords: Flat plate solar collector, thermal insulation material, thermal protection system, collector testing

1. Introduction

Flat plate solar collectors are generally designed for working temperatures between 40 and 60 ºC, which makes them ideal for their application in domestic hot water systems. Despite the variety of the products which have appeared in the market dedicated to the solar energy capturing, flat plate solar collectors have a privileged share in the market due to their simplicity, relatively lower cost, ease to manufacture, and the capability to collect radiation being stationary in any roof. By using highly selective absorbers, these collectors can work at temperatures up to 80 ºC with good efficiency (Kalogirou, 2003). To extend the application of these devices to higher working temperature, thus making them more available for applications such as food, drying of wood, crops, fruits, distillation, desalination, solar cooling (Nkwetta and Smith, 2012; Sharma et al., 2017), the transparent insulation materials (TIM) between two transparent covers or between absorber and outer glazing were used (Rommel and Wagner, 1992; Platzer, 1992). In some of these works, glass capillary tubes were considered, which despite their good resistance to temperature, increased the cost and weight of the collectors considerably. For commercial solar collectors, plastic TIM is potentially a good solution due to its advantage over glass capillary tube solution in terms of cost and weight. The main drawback is its vulnerability under the stagnation conditions. To overcome this problem, different solutions were proposed. Martínez et al. (2013) proposed a thermoelectric self-cooling system designed to dissipate the excess heat. A flat plate collector with plastic TIM and passive overheating system based on closed loop heat-pipe was recently introduced to the market showing good thermal performances (Adel, 2013).

In the present work, a flat plate solar collector with transparent insulation material is addressed. The scheme of the collector is shown in Fig. 1. The collector aims at delivering heat at the range from 80 to 110 ºC. The losses due to natural convection between the absorber plate and the cover glass is expected to be reduced due to employment of a layer of cellulose triacetate honeycomb TIM. According to the TIM manufacturer, this material can typically withstand a temperature of 140ºC, which can easily be reached under stagnation conditions. Indeed, yellowing and embrittlement can already be observed at temperatures above 100°C, well below the expected temperatures according to manufacturer's data. Moreover, outgassing, which affects both the optical efficiency and the appearance of the

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2017.31.07 Available at http://proceedings.ises.org

collector, may occur at temperatures below 100 °C (Giovannetti et al., 2011). Thus, to protect TIM, the collector involves a ventilation channel between the absorber and back insulation, which operates thanks to a thermally actuating door which uses a shape memory alloy. When the system reaches high temperatures, the door opens, thus ventilating the collector to safer temperature levels. The collector is designed by means of a numerical model based on the numerical resolution of different components of the collector in the framework of a modular, object-oriented platform. The design is first tested in laboratory conditions, where the correct functioning of the system is tested and the characteristic curve of the collector is obtained. During the laboratory tests, different issues related with TIM and overheating protection system are identified and improved. The tested prototypes are then installed in the roof of a hospital building, where they are used along with the conventional flat plate solar collectors to cover the domestic hot water and space heating demand of the building. The site is properly instrumentalized so as to compare both developed and commercial collectors in terms of energy performance. Moreover, the prolonged exposure of the prototype under real climatic and working conditions constitutes a useful test for the reliability and durability of the design.

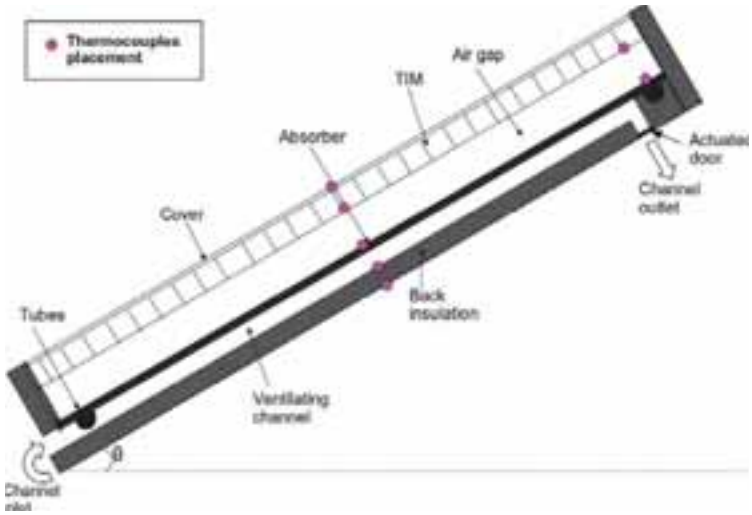

Fig. 1 Schematic view of the flat plate solar collector with TIM and ventilation channel.

2. Mathematical and numerical method

A mathematical model was developed (Kessentini et al., 2014b) where the flat plate solar collector with TIM and thermal protection can be numerically studied. In this model, the thermal and fluid dynamic phenomena taking place in each of the components that make up the prototype, i.e., glass cover, TIM, air gap, absorber plate, working fluid, ventilation channel, opaque insulation material, are numerically resolved considering different levels of complexity. In Figure 2, the detail of the mathematical model and the heat flux terms considered in the cross-section of the prototype and the absorber are schematically depicted.

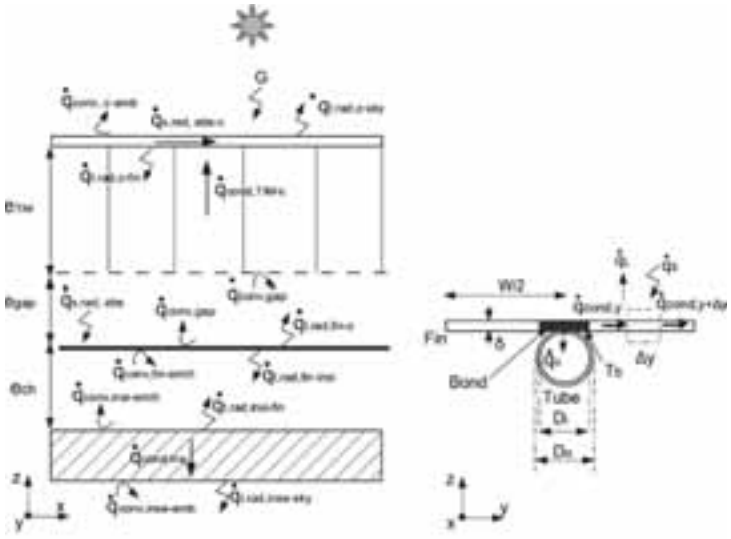

Fig 2. Detail of the heat flux terms. A cross section of the collector with TIM (left) and heat transfer at the absorber (right).

The object-oriented platform, called NEST (López et al., 2012), enables proper interaction between related components. The components, which can be treated as independent objects, can be linked with other related components through a global resolution algorithm. The numerical platform allows for efficient communications between the components (see Figure 3). Depending on the desired level of detail in the resolution of a particular element, even a high-level CFD object can be employed in the resolution of parts of the system. Given the computationally demanding nature of such a system composed of one or more CFD objects, the NEST framework provides parallelization to distribute the available computational power depending on the demands of each component, thus reducing computational time. Besides the active solar energy systems, like flat plate solar collectors (Kessentini et al., 2014a), this framework was also employed in the study of passive systems (Kizildag et al., 2014). Further details of the mathematical and numerical model used in this study are presented in Kessentini et al., 2014b.

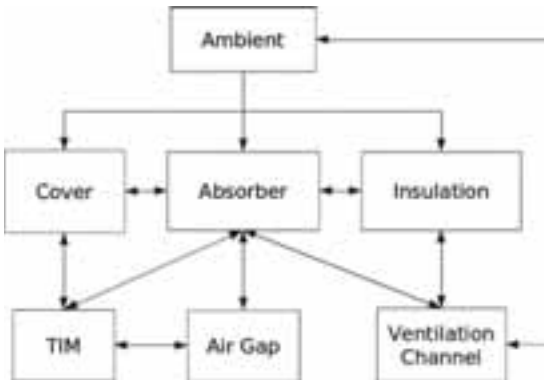

Fig. 3 Representation of the system composed of different components and their communications between each other.

3. Lab-scale testing and improvements

In line with the outcomes of the predesign performed using the numerical tool, prototypes with different TIM layer thicknesses were initially considered to observe their influence on the overall performance. In order to perform the characterization of the optical properties of the selected options, a set of preliminary glass-TIM configurations were initially tested under real outdoor conditions, as shown in Figure 4.

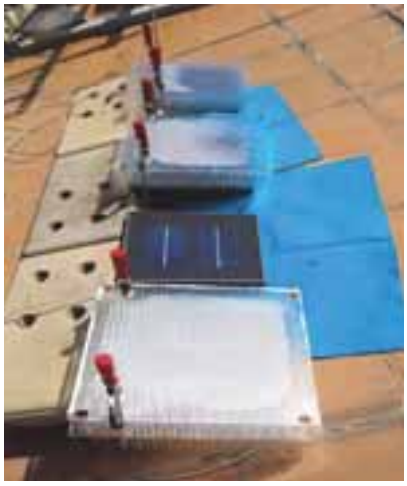

Fig. 4 Transmittance test set-up for different glass-TIM configurations under real climate conditions

As a result of previous analysis, and considering the numerical results, prototypes with four different TIM layer thicknesses (40mm, 50mm, 60mm, and 75mm) were manufactured to observe their influence on the overall performance. These prototypes were tested in the CTTC Solar Cell (see Figures 5 and 6), where tests up to 150 ºC and 8 bars can be performed using pressurized water. This experimental infrastructure allows for a comparative test employing two collectors in a parallel configuration.

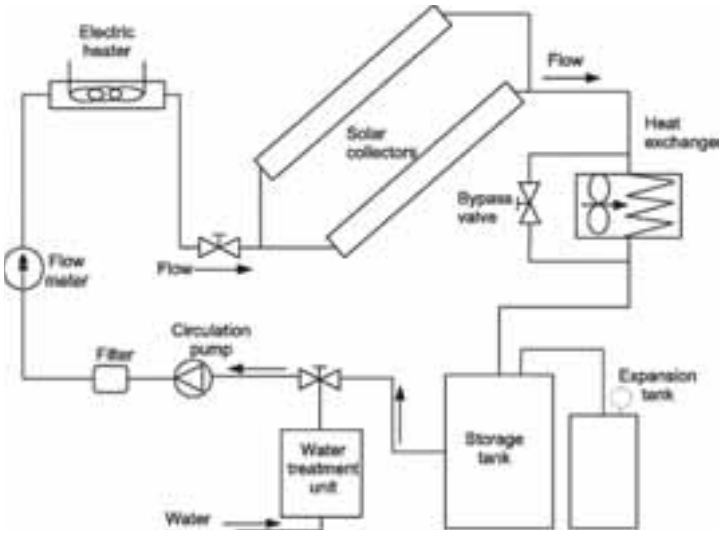

Fig. 5 Schematic view of the CTTC Solar Cell.

The main elements of the CTTC Solar Cell are the heater, water pump, filter, visor, expansion vessel, regulation and mixing valves, Coriolis flowmeter, storage tank, water treatment unit, heat exchanger, pyranometers for total and diffuse radiation in the plane of the tested collector, cup anemometer, 2D ultrasonic anemometer, temperature sensors, air vents. Some of these elements can be visualized in Figure 6. The experimental data is gathered using a data acquisition system, composed of a PC, an HP 3852A and two Agilent 34970A data acquisition units.

Fig. 6 Pictures of the key elements constituting the CTTC Solar Cell.

The manufactured prototypes are first subjected to the stagnation test, which is carried out to determine the maximum

temperature the collector can reach in the absence of mass flow. As no heat is transferred to fluid, the internal energy of the solar collector gradually increases, finally rising the temperature of the system up to an elevated temperature. It has been observed that the collector reached at the temperature of approximately 108 ºC when the thermally actuated door opened and started to cool down the collector. At that moment, TIM temperature was observed to be approximately 95ºC, which is well below the maximum temperature this element can resist. Visually inspecting the collector, TIM apparently was not damaged during the stagnation test, confirming that the effectiveness of the overheating protection system. In Figure 7, different temperatures registered during the stagnation test of a first generation prototype is depicted.

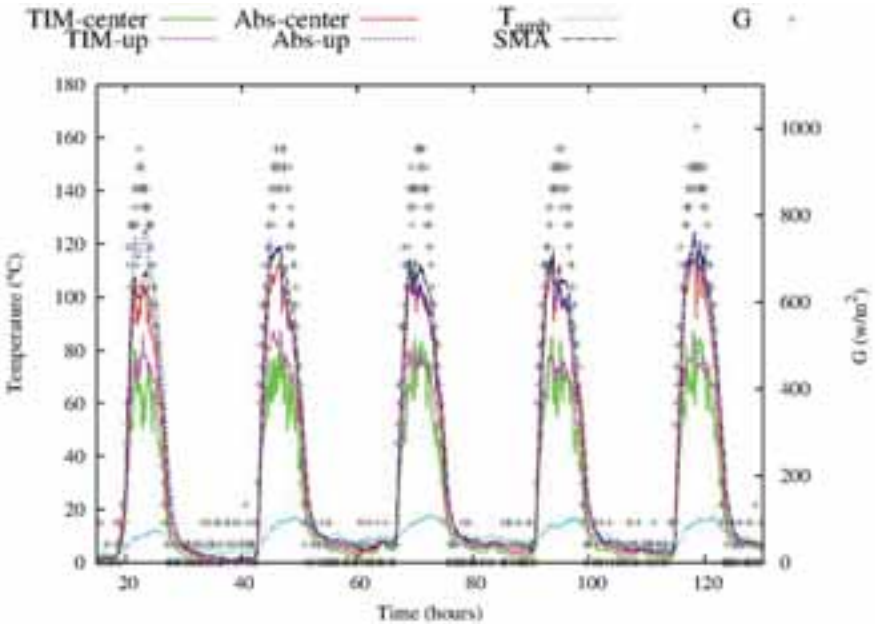

Fig. 7 Temperatures corresponding to different locations of TIM, absorber plate, sma spring, outdoor and total radiation on the tilted plane of collector registered during the stagnation test for an initial prototype.

After confirming that the prototypes are stagnation-proof, the outdoor steady-state efficiency test was performed following the recommendations of the international standard procedure described in ISO 9806-1. Accordingly, the prototypes were exposed to outdoor conditions for prolonged periods of time, assuring a constant temperature of the collector at the inlet. A mass flow rate of 0.042 kg/s was employed considering the collector absorber area. The collector is tested at 35, 50, 70, 90, and 110 ºC. The measurements obtained in periods close to solar midday are selected in order to fulfill criteria related with the angle of incidence. Other criteria regarding the amount of total solar radiation, the percentage of diffuse radiation, permitted variations in outdoor temperature and collector inlet temperatures throughout the test period are carefully attended. As the test were carried out under real climatic conditions in outdoors, it was not always possible to obtain favorable conditions for the collector testing. This caused requiring an important period of time to conduct the experiments and having to repeat the tests at different inlet temperatures.

The manufactured prototypes are tested in lab-scale where some of the shortcoming of the design were detected and improved, such as the condensation phenomenon observed due to the humidity absorbed by the plastic TIM material (see Figure 8). This problem was solved by means of introducing small ventilation holes, thus improving the ventilation and reducing the differences between the micro-climate of the collector and the outdoor ambient conditions. During the lab-scale tests, the emphasis is given to the influence of TIM material

Functioning of the thermally actuating door system is adjusted, with the objective of improving the phenomenon of premature opening of the channel. An experimental trial-error procedure was followed in order to determine the location and configuration of different elements constituting the overheating protection system, to make sure that thermally actuated spring is able to activate the ventilation channel under stagnation conditions while the channel can effectively be deactivated as the system is cooled down as a result of the heat evacuation by means of the ventilation channel.

Attachment of the TIM layer to the glass has been secured by more effective mechanisms, avoiding detachment of the cheap transparent insulation material under extreme conditions.

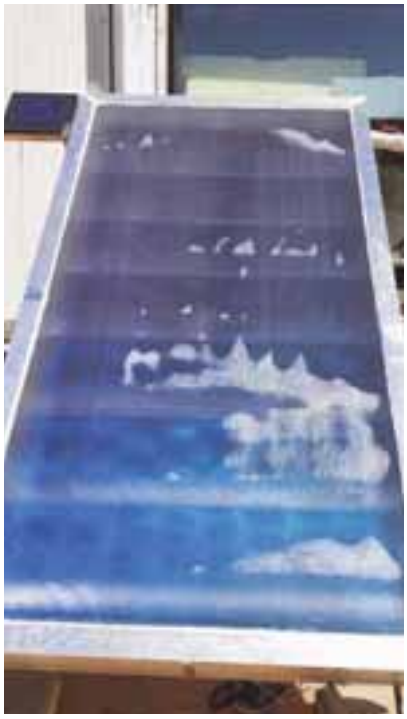

Fig. 8 Condensation phenomenon observed in a preliminary prototype

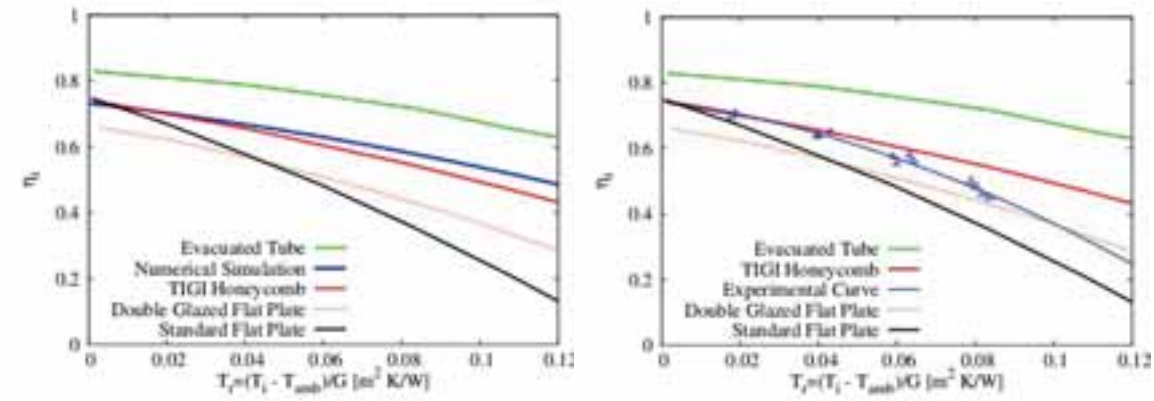

Fig. 9 Numerical (left) and experimental (right) steady-state efficiency curves of the prototype with 60mm TIM compared with solutions in the market.

In Figure 9, both numerical and experimental results during lab-scale tests are presented. The experimental curve corresponding to a first generation of prototypes is depicted in this graph. Note that these results anticipate an improvement with respect to the standard flat plate solar collector, at only slightly higher cost, since both TIM and overheating protection system use low-cost materials. The prototype achieves a somewhat lower performance with respect to the evacuated tube collector, though this type is expected to be approximately twice as costly as the manufactured prototype. In order to achieve the theoretical expected performance, improvements were implemented, especially affecting the insulation of the whole collector.

After the improvements with respect to the first generation of prototypes, a second generation was manufactured. In this second generation, a TIM layer of 75mm was used. This collector was also tested in laboratory conditions, obtaining finally the following steady-state efficiency curve given in eq.1:

$$\eta_i = 0.698 - 0.985\frac{(T_i - T_{amb})}{G} - 0.025\frac{(T_i - T_{amb})^2}{G} \qquad \text{(eq. 1)}$$

This curve is depicted comparatively in Figure 10, together with the curves of the previous generation of prototypes and commercial flat plate solar collector with TIM (TIGI LTD., 2011).

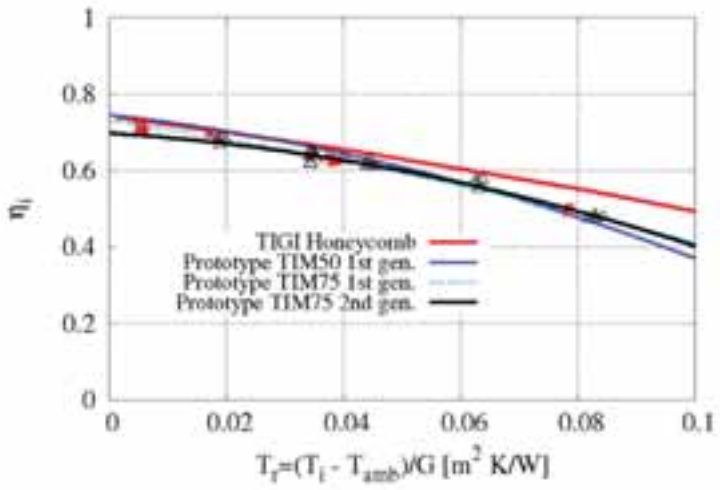

Fig. 10 Steady-state efficiency curves of different prototypes, compared with commercial flat plate solar collector with TIM.

Considering that the prototype involves a layer of TIM, it is of interest to the analyze the influence of the angle of incidence on the performance. Note that the steady-state efficiency curve is obtained for irradiation at or near normal incidence conditions. To that end, the prototype with TIM75mm is tested in outdoor conditions for a set of days in summer and autumn, always in clear sky conditions. In Figure 11, the results of the incidence angle modifier test are depicted. The experimental results reveal that the optical effects penalize the collector of the order of approximately 7 %, 10 %, and 32 % for the angles of incidence of 30º, 45º, and 60º, respectively. The methodology followed was to obtain the efficiencies for steady-state periods of 15 minutes, for symmetric intervals of time before and after solar midday, assuming an average angle of incidence of the given interval, and comparing it with the normal incidence efficiency for that particular conditions.

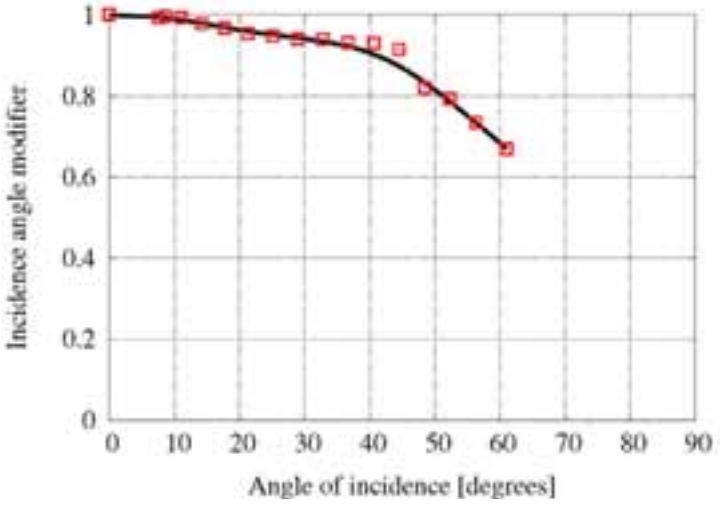

Fig. 11 Incidence angle modifier of the Prototype with TIM75mm, obtained by outdoor testing using a stationary test rack.

4. Long-term performance in demo site

Three prototypes, only differing in the TIM layer thickness (40mm, 50mm, and 60mm) are installed in the roof of a hospital building close to Barcelona (see Figure 12), where they are being tested comparatively with a commercial flat plate solar collector under real working and meteorological conditions during prolonged periods of time. The commercial collectors installed in the roof of the demo building do not have a layer of TIM. The steady-state efficiency curve provided by the manufacturer is given in eq. 2:

$$\eta_i = 0.739 - 3.706\frac{(T_i - T_{amb})}{G} - 0.017\frac{(T_i - T_{amb})^2}{G} \qquad \text{(eq. 2)}$$

The site is instrumentalized by means of mass flow, temperature, and radiation sensors. The long-term performance test in demo site provides realistic data for the functioning of the solar collectors, especially considering the solar heat delivered to the system and the reliability of the prototypes during prolonged periods of time. In the present work, demo site performance of the collectors are analyzed for winter and spring conditions.

Fig. 12 Solar energy capturing field of the Albada Building in Parc Tauli Hospital. The three prototypes are tested alongside the conventional flat plate solar collectors without TIM.

4.1 Winter Performance:

The prototypes, due to the employment of TIM are expected to have improved performance with respect to the standard flat-plate solar collectors, especially under the winter conditions where the losses to the ambient are pronounced as a result of important temperature gradient between intermediate collector working temperatures and outdoor conditions. In Figure 13, the ambient temperature and the total solar radiation on the plane of the collectors are depicted for a typical sunny day in the demo site location. Considering that the temperature in the inlet of the collectors was between 65-70ºC for this period, which is optimized considering the domestic hot water and space heating system installed in the hospital services building, important losses to the ambient can be anticipated.

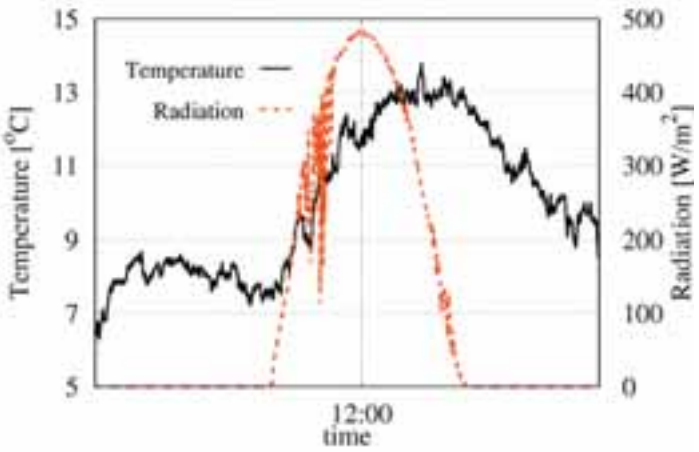

Fig. 13 Ambient temperature and solar radiation in the plane of the collectors for a sunny day in January 2017, mesured in Parc Tauli.

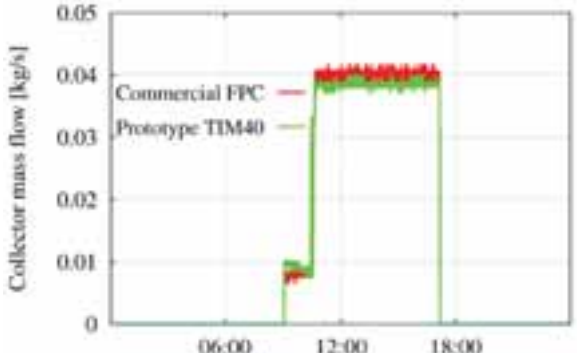

Fig. 14 Mass flow through the prototype and commercial flat plate collector without TIM for a representative sunny day in January 2017.

Note that the solar energy capturing circuit is activated only when a critical solar energy availability is reached. See Figure 14 for the registered mass flow through a prototype and a conventional flat plate solar collector without TIM.

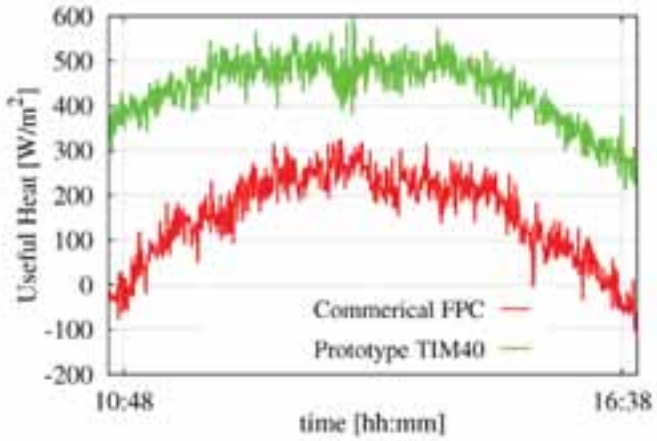

Fig. 15 Delivered useful heat for a representative day in January 2017 for the compared collectors.

In Figure 15, instantaneous useful heat delivered to the system is depicted both for the prototype and conventional flat plate collector without Tim for the day represented in Figure 14. This figure indicates a substantially better performance of the prototypes with TIM with respect to the conventional flat plate collectors, especially in winter conditions, when the losses from the collectors to the ambient are naturally enhanced, and the demand for space heating and domestic hot water is relatively higher.

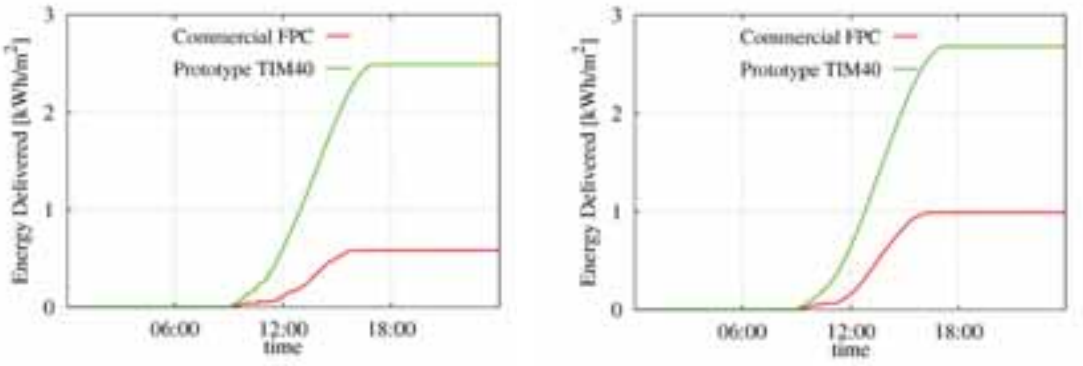

Fig. 16 Accumulative energy delivered to the system by the prototype and conventional flat plate collector without TIM for consecutive days in winter.

The trend captured in Figure 15 can be observed for other days during winter period of dissimilar solar availabilities, as shown in Figure 16, where the accumulative energy delivered to the system by the two compared collectors are depicted.

The steady-state efficiency curves of the collectors give valuable information on the thermal behavior of the collector under steady-state conditions with near-to-normal solar angle of incidence, together with some other additional conditions. However, a daily average collector efficiency can be defined, based on the energy delivered during the whole day by a collector and the solar energy available on the collector surface. Note that, this daily average efficiency will naturally have lower values with respect to the corresponding efficiencies indicated by the characteristic curve of the collector, as the curve is obtained by considering only the optimum conditions. Using the average data obtained in the vicinity of these days, which indeed are close approximation of the average day of the month considering the declination angles of the sun for this month, the daily average efficiencies for the prototype and conventional flat-plate collector are found as 41% and 16%, respectively.

In the absence of continuous readings due to technical problems in the demo site, these observed daily average efficiency values can be employed to obtain an approximation of the energy savings by both collectors for the winter meteorological conditions of the demo site. In Table 1, the total solar radiation in the vicinity of the demo site is provided, using the database of Meteonorm © software. The present estimation anticipates important savings as the high efficiency solar thermal collectors are employed for the given working conditions of the demo site.

Tab. 1: Total radiation on the inclined surface of the collectors and the estimated delivered heats during winter months.

Month	Total Radiation on Titled Plane (kWh/m^2)	Energy Delivered by Commercial Collector (kWh/m^2)	Energy Delivered by Prototype (kWh/m^2)
December	111	17.76	45.51
January	123	19.68	50.43
February	131	20.96	53.71
Winter Total	365	58.40	149.65

4.1 Spring Performance:

During the months of Spring, some experimental data could also be gathered in the demo site. Note that, due to relatively increased ambient temperatures, general losses of the collectors are reduced with respect to those in the winter season. Collectors are expected to work at higher efficiencies, which, especially in the case of the conventional collector, is expected to close the gap with the prototypes employing TIM.

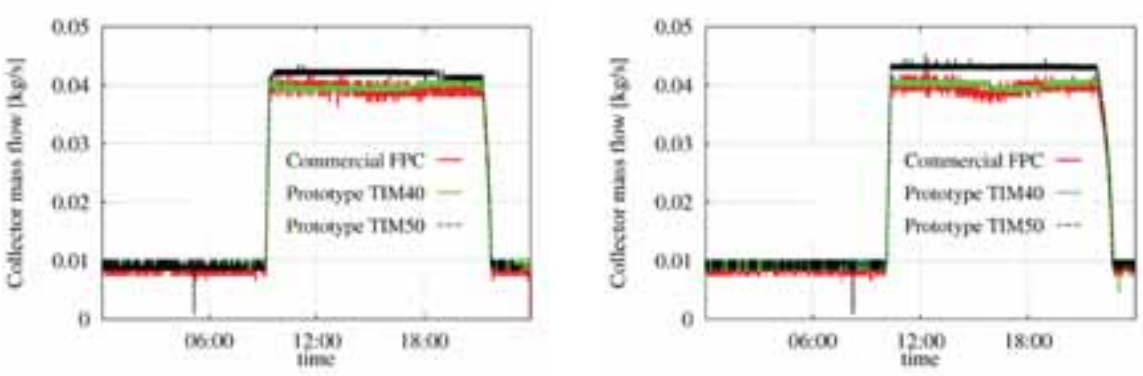

Fig. 17 Mass flow through two prototypes (TIM40 and TIM50) and commercial collector without TIM for two days with solar avaliability in March 2017.

In Figure 17, mass flows passing through the analyzed collectors are depicted for March 2017. Note that, due to requirements of the installer of the hydraulic circuit, the mass flow was not set to zero during periods of insufficient solar radiation. In the calculation and comparison of the accumulated energy delivered to the system by the analyzed collectors (see Figure 18), the effect of the nighttime flow was not taken into account, as it is considered as a temporary practice.

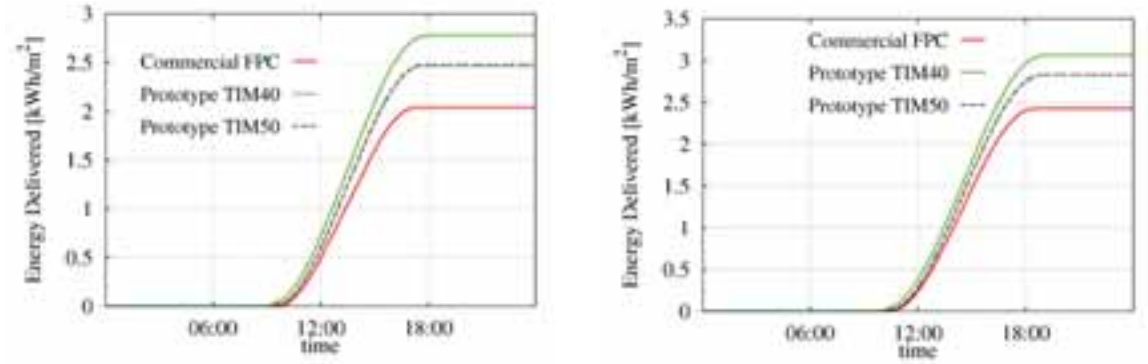

Fig. 18 Accumulative energy delivered to the system by the prototypes (TIM40 and TIM 50) and commercial flat plate collector without TIM for two representative days with solar availability in March..

Note that the commercial flat-plate collector improves its performance with respect to the winter period, even though it still delivers less amount of energy per area when compared with the prototypes. 40mm TIM layer prototype was observed to show better performance. Following the previous approach for defining an average efficiency for the

collectors based on these two test days, daily average efficiencies of 43% and 31% are obtained for 40mm layer TIM collector and commercial flat-plate collector, respectively. This information is used to estimate the delivered energies per area for both collectors during the tested spring period, as shown in Table 2.

Tab. 2: Total radiation on the inclined surface of the collectors and the estimated delivered heats during spring months.

Month	Total Radiation on Titled Plane (kWh/m^2)	Energy Delivered by Commercial Collector (kWh/m^2)	Energy Delivered by Prototype (kWh/m^2)
March	165	51.15	70.95
April	168	52.08	72.24
May	173	54.68	73.40
Spring Total	506	157.91	216.59

5. Conclusions

It has been demonstrated that different variants of the designed prototypes are capable of delivering higher amounts of heat to the domestic hot water and space heating system of a specific hospital building when compared with the conventional flat plate solar collector. The employment of the designed novel collector is especially interesting for the present application, as the practical working temperatures give rise to important losses during winter periods. The visual inspection of the prototypes does not present any issues related with ageing of TIM, problems with TIM adhesion, any damage of TIM due to stagnation conditions, which indicate a proper functioning of the overheating protection system. It is worth noting that due to the faults registered in different elements of the circuit, not necessarily related with the solar energy capturing field, the hydraulic circuit of the system did not function during prolonged periods of time in spring and summer. Thus, it can be stated that, this circumstance provided the necessary exposure of the designed prototypes to the stagnation conditions, building confidence in the reliability of the prototype collectors.

Thus, although the tested period does not yet cover a representatively long time span, the initial outcomes indicate promising results in terms of both energy efficiency and reliability of the present design.

EXPERIMENTAL AND CFD OPTIMIZATION ON FLOW AND HEAT TRANSFER TO A SOLAR FLAT-PLATE GLASS COLLECTOR

Pascal Leibbrandt, Thomas Schabbach, Michael Dölz, Martin Rhein
Institut für Regenerative Energietechnik, University of Applied Sciences Nordhausen (Germany)

Abstract

In the project solar flat-plate glass collector, a new type of solar collector will be developed which, simplified, consists of four glass plates. As part of the project, the full volumetric flow in the fluid layer and the convective heat transfer in the insulating gas layer were investigated by using experimentally and numerically methods. Regarding to the fluid layer, an optimal fluid layer structure has been found which distributes the fluid well and ensures an optimal collector efficiency factor of nearly 99%. With the numerical simulation of the convective flow in the isolation gas layer it was shown, that the most used equation by Hollands (1976) presumably needs to be extended by the aspect ratio of the gas volume and other boundary conditions. These results are currently being validated experimentally. In addition, the filling/drainback process was examined for a potential drainback application.

Keywords: glass collector, fluid distribution, convective losses, CFD, validation

1. Collector construction and operation

In context of the research project “Nurglas-Solarflachkollektor” a collector with lower production costs is developed which consists primarily of glass. Due to the simplified construction, cost intensive production steps such as the absorber welding are unnecessary and enable an automated production process with fewer production steps. Manufacturing costs can thus be reduced by approximately 20% compared to conventional standard flat-plate collectors. Another advantage is the reduced collector thickness of < 40 mm which allows an simplified installation and collector field connection, so that other application areas (especially in facade) can be opened up.

The glass collector consists of four planar glass plates, which are glued and sealed by a frame and a fluid layer structure. As shown in Fig. 1, the heat transfer medium (yellow) passes directly through the middle rectangular space. The coatings on the glasses ensure optimal radiation absorption in the fluid layer and minimize the radiation losses due to reflection and emission, see also Leibbrandt et al. (2014). The heat transfer fluid has to be distributed full volumetric through the flow channel to ensure an optimal heat transfer coefficient $\mathbf{h_{fl}}$ in the fluid to optimize the collector efficiency factor. The fluid layer structure should also be able to absorb inner/outer forces from/to the fluid layer. Insulating gas layers (green) minimize convective heat losses to the front ($\mathbf{h_{igf}}$) and back ($\mathbf{h_{igb}}$).

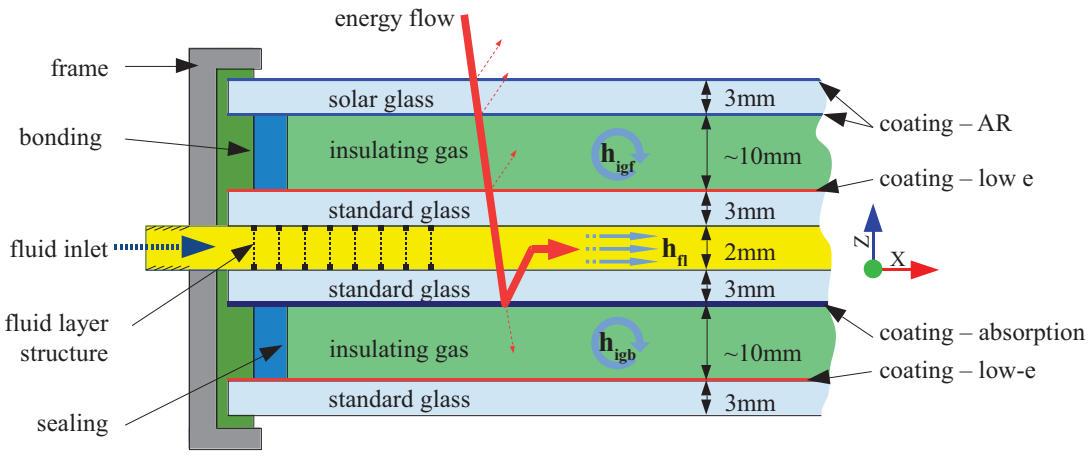

Fig. 1: Construction of the glass collector

doi:10.18086/swc.2017.31.08 Available at http://proceedings.ises.org

2. Fluid layer: full volumetric flow and heat transfer

With an optimal collector efficiency factor F′, the overall collector efficiency is ensured. F′ is the theoretical ratio of the useful energy gain to the useful gain that would result if the absorbing surface would be at the fluid temperature, Duffie Beckman (2013). The collector efficiency factor is at its maximum if the flow would be full volumetric. For flat-plate collectors with a fin width of 90-120 mm, the collector efficiency factor is about 88-94%, Wesselak et al. (2017). The internal heat transfer U_{int} is at its maximum when the flow is fully homogeneous (without flow areas with no/low flow velocity) and turbulent. It is

$$F' = \frac{U_{int}}{U_{int} + U_{loss}} \qquad \text{(eq. 1)}$$

Fluid layer full volumetric flow

The flow channel with size L x B s_f = 2000 x 1000 2 mm should be flowed through full volumetric in the ideal case. In flow channels without internals, a flow like in Fig. 2 - A results. The flow field $\overrightarrow{u_i}$ consist of local velocity components in each direction. The ideal homogeneous velocity field (Fig. 2 - B) consists only of velocity components in x-direction and is equal in any position of the flow channel. It is

$$\boldsymbol{A}\text{: } \overrightarrow{u_i} = \begin{pmatrix} u_i(x,y,z) \\ v_i(x,y,z) \\ w_i(x,y,z) \end{pmatrix} \qquad \boldsymbol{B}\text{: } \overrightarrow{u_i} = \begin{pmatrix} u_i(x) \\ 0 \\ 0 \end{pmatrix} \qquad \text{(eq. 2)}$$

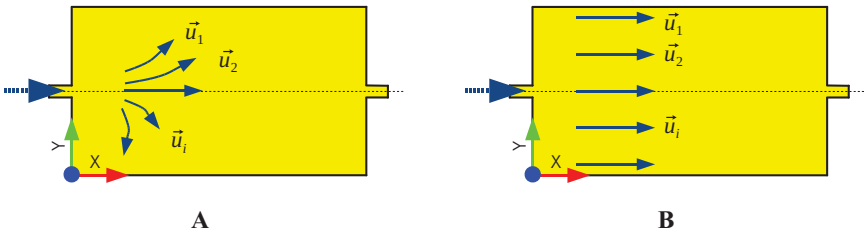

Fig. 2: Fluid Layer velocity fields

First 2D CFD simulations are able to model the flow in the fluid layer sufficiently precisely so that a further optimization of the fluid layer structure is carried out with CFD simulations. Results of the optimized version from a detailed 3D CFD model (flow channel 2000 x 1000 x 2 mm) with different fluid layer structure are illustrated in Tab. 1. The fluid layer structures with rectangular flow channels in meandering shape led to the best results in terms of flow distribution.

In addition to the local scalar velocities (row **1**) in the fluid layer (at z = 1 mm), the volume uniformity of the local velocities uni_u over the flow volume V was used to determine the homogeneity of the flow (row **2**). It is

$$uni_u = 1 - \frac{\sum_i |u_i - \bar{u}| \cdot V_i}{2|\bar{u}| \sum_i V_i} \qquad \text{(eq. 3)}$$

Tab. 1: Flow results for different fluid layer structures

	Structure 0 no inner web	**Structure 1** web with narrow bars (1 mm)	**Structure 2** web with wide bars (10 mm)	**Structure 3** web with wide bars (10 mm) and end gaps	**Structure 4** web with wide bars (10 mm) and end roundings
1					
2	uni_u = 0.723 m/s (reference)	uni_u = 0.812 m/s (+12,4%)	uni_u = 0.817 m/s (+13,0%)	uni_u = 0.799 m/s (+10,5%)	uni_u = 0.823 m/s (+13,9%)

An appropriate fluid layer structure, which distributes the heat transfer fluid almost full volumetric in the 2 mm fluid layer results of the detailed 3D CFD model. Experimental investigations of fluid layer prototypes confirm the simulation results and the flow behavior. In Fig. 3, an optical measurement of the flow field (left) is compared with 3D CFD results (right), see also Leibbrandt et al. (2017).

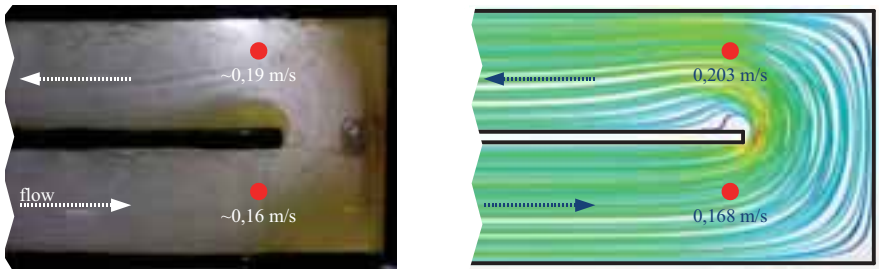

Fig. 3: Experimental and 3D CFD velocity field

At the same time the pressure drop and the filling/drainback performance is determined by experiments for a potentially drainback system application.

Fluid layer heat transfer

After the optimization of the fluid layer structure, the influence on heat transfer is investigated. The fluid layers' dimension is set to L x B x s_{fl} = 2000 x 1000 x 2 mm, the inclination of the layer is 45°.

For the simulations two fluid layer structures, similar to structure 0 and 2 are analyzed. The backside of the fluid channel is set up with a constant heat flow density $\dot{q}_{abs} = 700\ W/m^2$, which corresponds to the absorbed solar radiation power. At the front convective heat transfer with a constant heat transfer coefficient and fixed ambient temperature is assumed. In reality, the convective heat transfer coefficient depends on the front side temperature, too. The sides of the fluid channel have been supposed to be adiabatic. The fluid inlet temperature is 20 °C; the inlet velocity is varied between 0.25 – 1.00 m/s (35 – 140 l/(m² h)).

To rate the quality of the heat transfer coefficient h_{fl} through the fluid layer the useable enthalpy-flow $\dot{q}_{use}$ at the layer outlet is set into relation to mean fluid and absorber temperature difference. It is:

$$h_{fl} = \frac{\dot{q}_{use}}{\overline{T_{abs}} - \overline{T_{fl}}} \qquad \text{(eq. 4)}$$

To compare the collector efficiency factor of the fluid layer F_f' with standard flat-plate collectors it is assumed, that the overall loss heat transfer coefficient is $U_{loss} = 4\,W/(m^2K)$. U_{loss} describes the collector heat losses over the sides and the back of the collector which are not part of the presented CFD simulations. The efficiency factor of the fluid layer F_{fl}' is:

$$F_{fl}' = \frac{h_{fl}}{h_{fl} + U_{loss}} \qquad \text{(eq. 5)}$$

Tab. 1: Influence of fluid layer structures on heat transfer (3D CFD results)

		u_{in} in m/s		
		0.25	0.50	1.00
Structure 0	$\dot{q}_{use}$ in W/m²	565.95	630.53	657.35
	h_{fl} in W/m²/K	372.86	365.07	360.68
	$\boldsymbol{F_{fl}'}$	**98.9%**	**98.9%**	**98.9%**
Structure 2	$\dot{q}_{use}$ in W/m²	556.11	617.33	651.18
	h_{fl} in W/m²/K	343.25	421.14	625.53
	$\boldsymbol{F_{fl}'}$	**98.8%**	**99.1%**	**99.4%**

The useable enthalpy-flow $\dot{q}_{use}$ of structure 2 is less than in structure 0 because the heat loss to the front side is greater due to higher internal heat transfer and higher fluid temperatures.

Fig. 4 shows the temperature field inside the flow channels. A temperature inhomogeneity can be seen especially at the end of the individual fluid channels. They are formed due to the lower flow velocity and lead to local temperature maxima (hot spots). They should be minimized by a suitable flow guidance. At these hotspots the heat transfer reduces and high temperature gradients occur which also lead to stresses in the glasses.

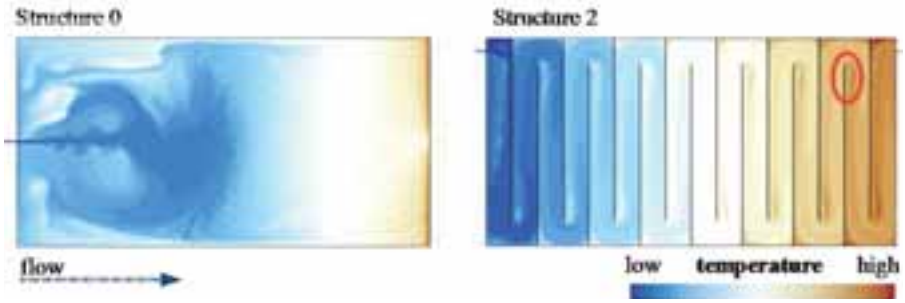

Fig. 4: Fluid Layer temperature fields (3D CFD results)

3. Insulating gas layer heat transfer

To ensure an optimal collector efficiency the convective front losses through the insulating gas layer is investigated. The gas volume, filled with insulating gas has a length L, a width B and a glass distance s, see Fig. 5. The resulting aspect ratio AR = L/s is about 80 at standard flat-plate collectors (distance between absorber and front glass) and about 200 at the presented glass collector. The most used approach to calculate the convective heat transfer was investigated by Hollands et al. (1976).

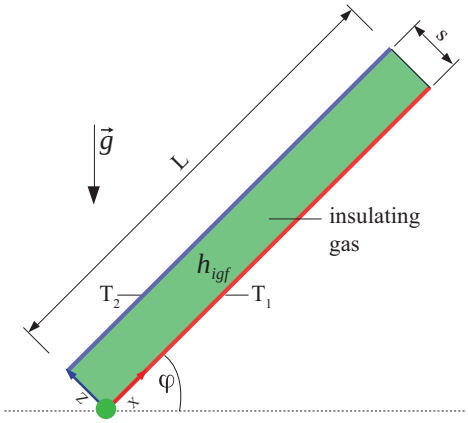

Fig. 5: Problem definition insulating gas layer

The internal heat transfer coefficient h_{igf} is at its minimum at the point where the gas flow velocity is low and the conductive isolating behavior of the gas is at its maximum.

The boundary conditions (e.g. temperature difference, homogeneity and level) and the geometric relationships (aspect ratio and vault of glasses) of the glass collector do not match those by Hollands et al. (1976). The deviations, when using the Hollands equation, for varying boundary condition were demonstrated, for example, by Föste (2013) by investigating an insulating glass flat-plate collector experimentally. Eismann (2014) showed the influence of the temperature inhomogeneity on the basis of collector simulations. The data in Tab. 2 show the wide range of geometry and boundary conditions. The error in calculating the heat transfer, as mentioned above, presumably results in these deviations.

Tab. 2: Geometry and boundary conditions

	Glass collector	Standard collector	Hollands et al. (1976)
Length L in mm	2,000	2,000	610
Glass distance s in mm	10	25	12.7
Aspect ratio AR	200	80	48
Insulating gas	argon	air	air
T_1 in C	70	120	26.67 (80 F)
T_2 in C	35	20	15.56 (60 F)
ΔT in K	35	100	11.1

The internal heat transfer is calculated with

$$\dot{Q} = A \cdot h_{igf} \cdot (T_1 - T_2). \qquad \text{(eq. 6)}$$

The heat transfer coefficient h_{igf} is calculated from the Nusselt number Nu, which depends on the Rayleigh number Ra. The Rayleigh number describes the internal free convection.

$$Nu = Nu(Ra) \qquad \text{(eq. 7)}$$

The Rayleigh number depends on the Grashof number Gr (ratio of lift forces and internal viscous friction forces) and the Prandtl number (material data).

$$Nu = \frac{h_{igf} \cdot s}{\lambda} \qquad \text{(eq. 8)}$$

$$Ra = Gr \cdot \mathrm{Pr} = \frac{g \cdot \beta \cdot \Delta T \cdot s^3}{\nu \cdot a} \qquad \text{(eq. 9)}$$

Hollands et al. (1976) developed the following Eq. from experimental measurement. The Eq. is split in three parts, depending on the Rayleigh number of the problem. The part $[\dots]^+$ activates the terms in brackets for different Rayleigh numbers.

$$Nu = 1 + 1.44\left[1 - \frac{1708\,(\sin(1.8 \cdot \varphi))^{\frac{1}{6}}}{Ra \cdot \cos(\varphi)}\right]\left[1 - \frac{1708}{Ra \cdot \cos(\varphi)}\right]^{+} + \left[\left(\frac{Ra \cdot \cos(\varphi)}{5830}\right)^{\frac{1}{3}} - 1\right]^{+}$$

Three different flow types, regarding to $Ra^* = Ra \cdot \cos(\varphi)$ are illustrated in Fig. 6. For $Ra^* < 1708$, the flow is quasi-conductive because the heat transfer media does move with very slow velocity. In the transition area $Ra^* = 1708 \dots \sim 5830$, the flow topology is characterized by a mono-cellular base flow. A multi-cellular flow regime arise for $Ra^* > 5830$. The optimal point of minimum heat transfer is at about $Ra^* \approx 1708$, where the isolating behavior of the gas is at its maximum.

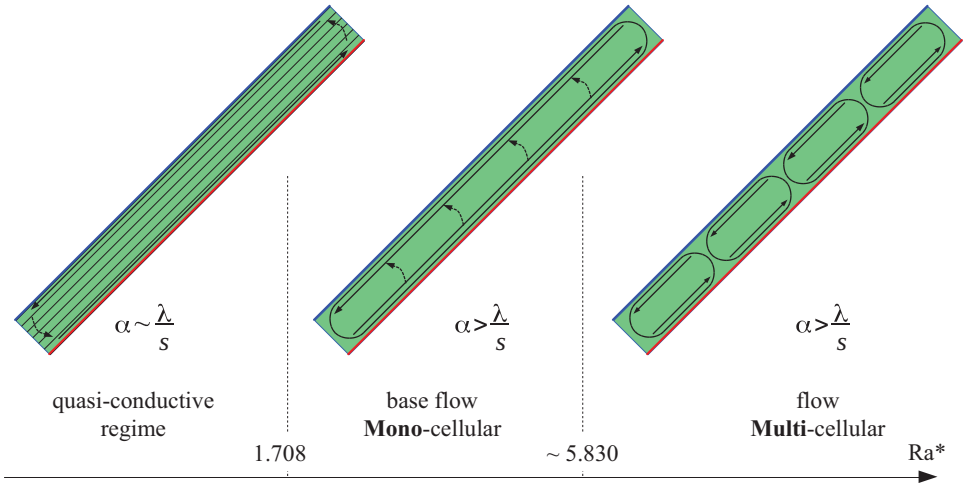

Fig. 6: Flow regimes

Based on intensive literature research, see Leibbrandt et al. (2016), the following conclusions for internal free convective flows in inclined cavities are known until now:

- Hollands et al. (1976) developed the correlation (see above) from experimental measurement and based on earlier theoretical research. The gas volume was captured between two nearly isothermal copper plates in a vacuum vessel. The change in Rayleigh number was set with varying pressure inside the vessel. So the aspect ratio AR was constant because of constant distance s. Also the humidity of the captured air was not documented, which led to an uncertainty in the heat transfer coefficient up to 6%. The correlation from Hollands et al. (1976) is based on an evaluation of the heat transfer in a central area (130 x 130 mm)of the copper plates. Later investigations show that the total heat transfer is significantly influenced by higher local heat transfer coefficients at the ends (top and bottom) of the gas volume, too.
- Bartelsen et al. (1993) and Föste (2013) showed that measured data from flat-plate collectors led to higher heat transfer coefficients about 10% regarding to Hollands et al. (1976). Measurements by Föste (2013) on isolating glass collector showed a deviation up to 32%. Yiqin et al. (1991) also investigated mean differences up to 10% in the heat transfer.

Insolating gas layer CFD simulation and validation

In this project, a CFD model is used to check the influence of varying boundary conditions and geometry. Numeric discretization and physics models are checked first in a simplified 2D CFD model and are validated with a 3D CFD model. Based on the experimental setup from Hollands et al. (1976) a detailed 3D CFD model calculates the internal flow and the heat transfer. The geometry, boundary conditions and report area (central) are the same as in Tab. 2 (Hollands). The Rayleih number is set with varying pressure from 70 Pa up to 700,000 Pa to capture the range of the setup from Hollands et al. (1976).

In Fig. 7 (left) the influence of varying discretization of the 3D CFD model is shown. For normal (cell size 1.0 mm) and coarse discretization (cell size 2.0 mm), the flow topologies and the heat transfer phenomena are captured unsatisfactory. Just the fine discretization (cell size 0.5 mm) is able to capture the behavior of the flow well. The discretization accuracy confirm the former 2D CFD results. An even finer discretization would lead to a disproportionate simulation time with no appreciable increase of the accuracy. Fig. 7 (right) shows the simulation results with two different flow models. The chosen one (LowRe: Reynolds-averaged Navier-Stokes model, coupled energy and flow with standard K-Epsilon Low-Re formulation) is able to model the flow well. The maximum deviation in h_{igf} is about 6.5% at 400,000 Pa.

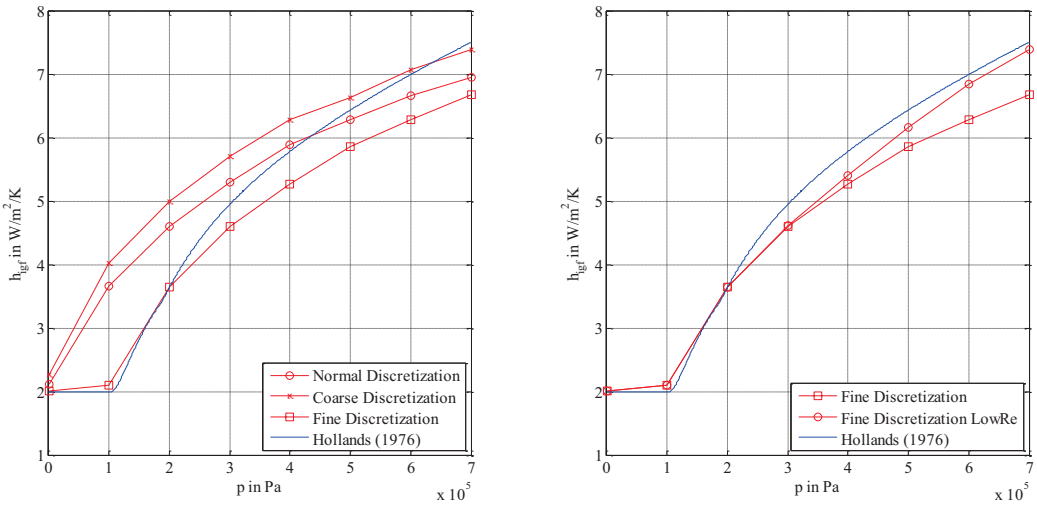

Fig. 7: Discretization influence (left) and flow model influence (right) of the 3D CFD model

Tab. 3 gives an overview of the different flow regimes. These results are scalar velocity- and temperature fields from a central section (bottom end) of the mentioned setup by Hollands et al. (1976) for fine discretization and LowRe flow model. The above-described flow regimes can clearly be seen in Tab. 3: for $p = 70\,Pa$ semiconductive behavior dominates, for $\mathrm{p} = 100{,}000$ Pa a mono-cellular flow topology is visible, for $\mathrm{Ra} > 200{,}000$ Pa turbulent multi-cellular flow cells are visible.

Tab. 3: Velocity- and temperature fields

p in Pa	Ra	Velocity field	Temperature field
70	0.001134		
100,000	2,313		
200,000	9,253		
300,000	20,820		
400,000	37,013		
500,000	57,832		
600,000	83,278		
700,000	113,351		

CFD simulation with varying boundary conditions

In the next step, the validated 3D CFD model is used to check the influence of heat transfer for varying geometry and boundary conditions. For this purpose all models and CFD setups are used, but for the first appraisal a 2D geometry is applied.

As mentioned above, the aspect ratio AR seems to have an influence on the flow regimes and so on the heat transfer phenomena. For this, simulations with varying $AR = 40 \dots 200$ are presented in Fig. 8. It is obvious that the variation of AR results in an a difference of h_{igf} and Nu. Nu differs up to 11.6% for high Rayleigh numbers.

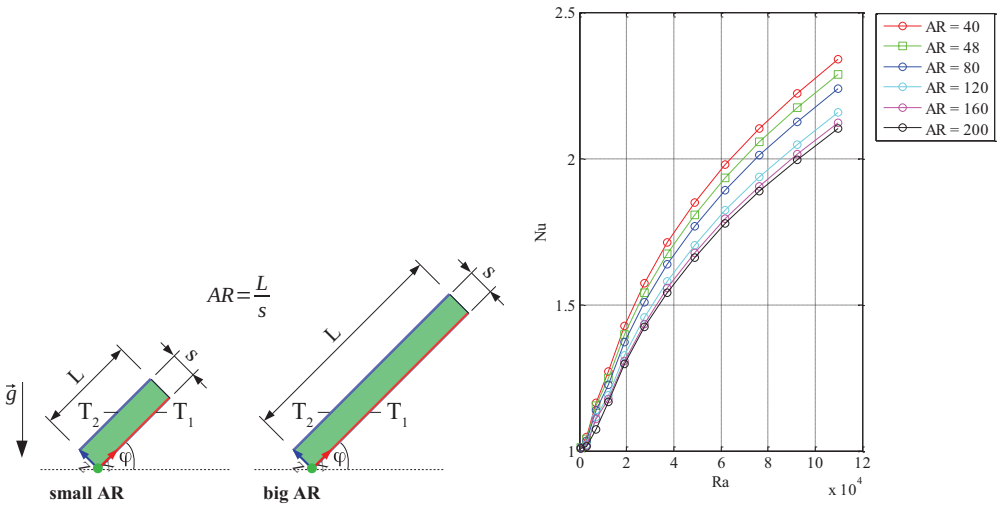

Fig. 8: Influence of varying AR (total area)

Another influence factor is the curvature of the glass plates. By default, the glass plates are considered as planar without any curvature. Due to varying temperatures while the collector operation, the resulting change in the density of the filling gas leads to a volume change of the gas and so to a curvature of the glasses. In the first step the glass planes are set to be parallel, so $s = const.$ and $ds = f(x)$, $ds(L/2)$ is varied with $ds_0 \dots ds_2 = 0 \dots 2 \dots 4\ mm$. Results are presented for $AR = 20 \dots 80$. For $AR = 20$, Nu differs up to 1.0% for $ds = 4\ mm$ and for $AR = 80$, Nu differs up to 0.7% for $ds = 4\ mm$, see Fig. 9.

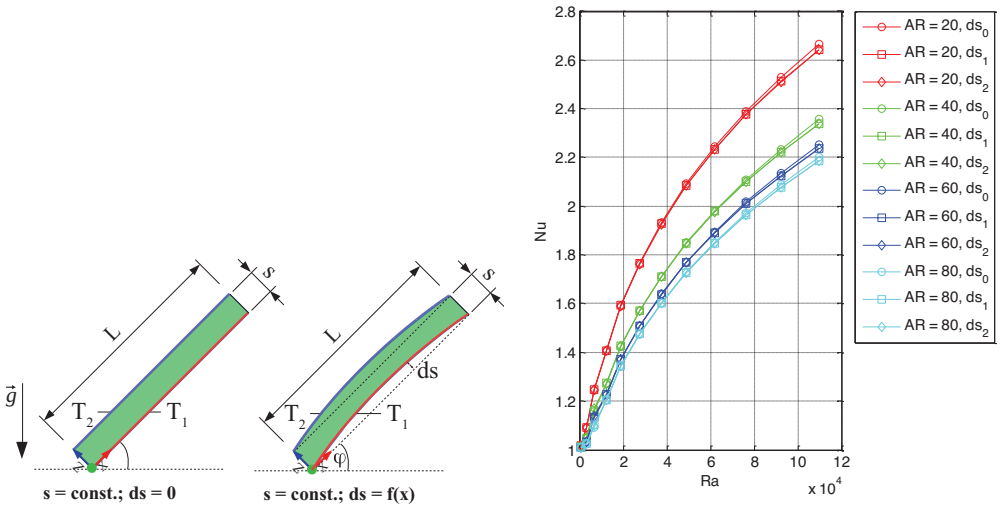

Fig. 9: Influence of varying ds (total area)

Last, the influence of a linear temperature profile $T_1 = f(x)$ is shown. In real collectors the fluid temperature increases over the collector length L due to the radiation absorption by a given flow direction. This effect is modeled by an linear temperature profile $T_1 = f(x)$, while the mean temperature $\overline{T_1}$ is constant. The influence of the linear temperature profile $dT/dL = 0 \dots 2 \dots 4\ K$ in Nu is maximum about 1.1% for $AR = 20$ and 0.5% for $AR = 80$.

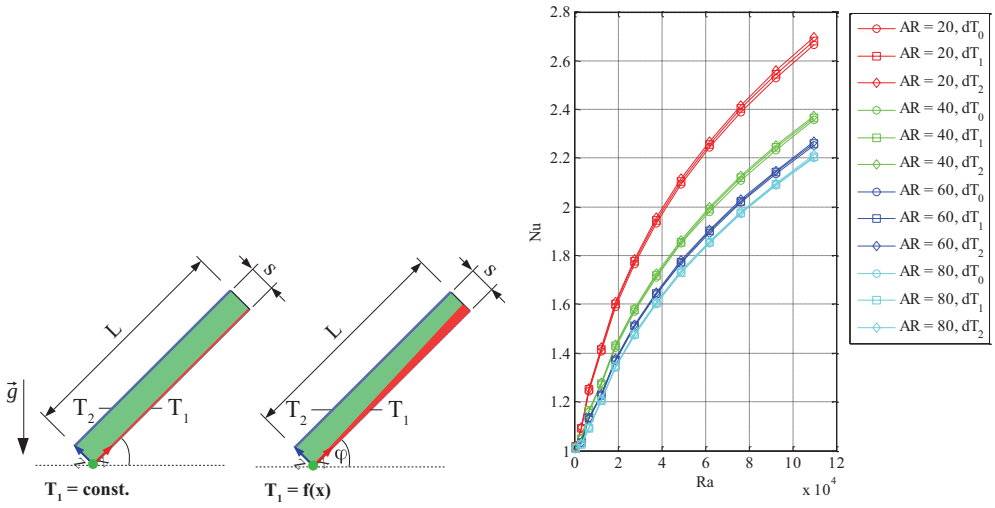

Fig. 10: Influence of varying T_1 (total area)

With CFD simulations, it is shown that the heat transfer coefficient h_{igf} depends on the boundary conditions mentioned above. This results for different AR in variation of h_{igf} up to 11.6%. The influence of AR is not component of the equation by Hollands et al. (1976), so that an extension of that equation should be carried out. For inhomogeneous temperatures and vaulted gas volumes, the influence is lower but not negligible.

Experimental investigations

To validate the simulation results, an experimental setup is under construction at the moment. A heating mat generates a one dimensional heat flux $\dot{q}(x,y)$ field, which is determined by a measurement layer and allows to measure the heat transfer trough the insulating gas layer. With temperature sensors, a spatially resolved heat flux field is used to calculate a spatially resolved heat transfer coefficient field $h_{igf}(x,y)$. The measurements are used to validate the simulation results and should allow to extend the present calculation approaches.

4. Outlook

In continuation to the project collector prototypes will be investigated experimentally. Target will be to increase the flow homogeneity, heat transfer and stability of the fluid layer. The pressure loss, manufacturability and long term stability must also be considered. The performance of the entire collector will be checked during QDT-testing. Mechanical load tests with internal and external forces will also take place.

5. Acknowledgement

The project “NUGLACOL – Development of a low cost solar flat-plate collector system based on glass”, FKZ 0325557, is carried out in cooperation with the companies Wagner Solar, Energyglas and Kömmerling and funded by the German Federal Ministry for Economic Affairs and Energy (BMWi) based on a decision of the German Federal Parliament. The authors are grateful for the financial support.

CFD analysis are carried out with the flow simulation software STAR-CCM+ by CD-adapco. Thanks for the support.

Solar Cooker Green Cooking

Md. Abdul Mozid

Orbit Solar Energy, Dhaka, Bangladesh

Abstract:

Food is one of the fundamental needs of mankind. Food preparation requires fuel which may be wood, coal, cow dung, liquid petroleum gas, and electricity consuming induction heaters or microwave oven. Availability of these non-renewable sources is a burning task. Moreover, it produces pollution which leads to the imbalance in nature. Solar cooker shall be a solution for cooking food. Solar Cooker is used for cooking food by sunlight only. No need fuel. Only sunlight is enough to cook a day's required food for an average family of Bangladesh. Bangladesh is situated underline of cancer as a result whole year has enough sun to cook the meal for a family by using Solar Cooker. There is a huge opportunity to use solar cooker in a village, suburban even some time in urban also.

Introduction:

Bangladesh is a highly populated country. We have around 170 million people in Bangladesh out of the 60 percent live in a village. The main food of our people is rice and curry. Village people are used to using wood, leaf, residual of crops and some time Bottled LPG for their cooking. There are very few Bio Gas plants are in village areas. Most people do not know about Co2 emission and environmental effect but they understand the cost. Now the above-discussed fuels are costly and emit CO2 gas which is hampering environment. They also lose their working hour and money to collect the fuel and the mothers lose their health to cook with the above fuels because that creates a lot of smoke which contaminate with air and hit their lungs directly.

We Orbit Solar Energy introduce a solar cooker considering food quantity of a family by using Solar Evacuated tube thermal cooking. We have two types of tube cooker with different quantity of food cooking at once.

Type OT-170:

The diameter of the tube is 170mm and the length is 900mm, there are three equal pots which capacity are 1.8 liters each. It can cook 5.4 liters foods at one time. This is portable and enough for a family contain 6-10 people

Type OT-125

The diameter of the tube is 125mm and length 800mm. there are three pots which capacity is 1x1.6 liter one and 2x0.8 liter. It can cook 3.2-liter foods at one time. This is portable and enough for a family of 4-5 people.

Technology& Design:

Solar cookers utilize the simple principles of reflection, concentration, absorption, glazing, insulation and the greenhouse effect to produce heat. **Solar Oven Evacuated Tube works as the same principle of solar cooking.** The evacuated tube style solar cookers are somewhat new on the market and in the solar cooking world, though they have been used for solar cooking by tinkerers and inventors for a few short

doi:10.18086/swc.2017.31.09 Available at http://proceedings.ises.org

years they have not been largely available to the commercial market until now. The older style box (ovens) cookers panel cookers and parabolic cookers have been around for much longer, some as long as fifty years, but now there is a new and very effective method of solar cooking in the form of the compact and very fast evacuated tube solar cookers.

We know that in a sunny day the sunlight energy per square meter is around 1KW, here we use the technology that direct light and reflected light is trapped (Greenhouse technology) in an evacuated tube which has very high thermal insulation, the trapped light turned into heat and this heat can cook food. The temperature rises up to 300 Degree centigrade.

Tube Glass

The tubes are made from a type of glass called Borosilicate. Borosilicate glass has the characteristic of being very strong and also has excellent light transparency (>92% @ 2mm thick).

Efficiency

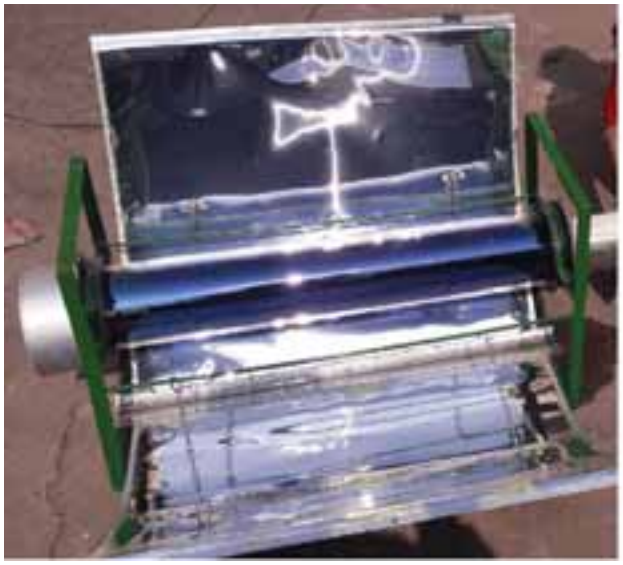
The combination of the highly efficient absorber coating and the vacuum insulation means that the coating can be well over 200oC / 392oF and the outer glass is cool to touch. In strong sunlight, each evacuated tube can provide over 60 Watts / 204 Btu of water heating output.

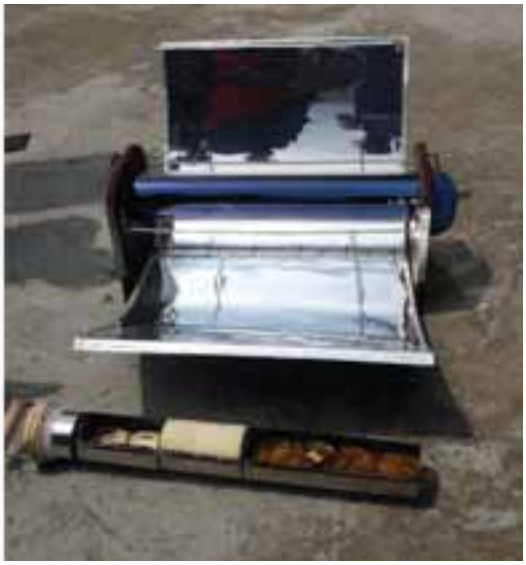
Vacuum Insulation

The name "evacuated" is used to describe the process that expels the air from within the space between the glass tubes, forming a vacuum. A vacuum is an excellent insulator against heat loss, and so evacuated tubes are able to operate very efficiently

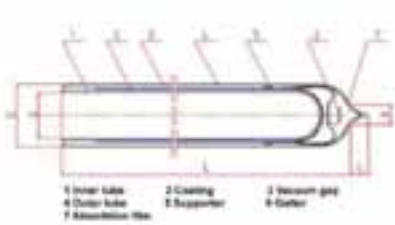
Evacuated Tube Oven Design:

The **Stove showed here**





Tube:



The evacuated tube design has an advantage in that it holds and retains its heat better than any other style of solar cooker, and it will heat up quite well even in less than optimum conditions.

Tube Dia: 125mm & 170mm

Length: 785mm & 900mm

SS Drum:

Inside the vacuum tube, there is a protection barrel inserted as the cooking chamber, which is made of stainless steel. Cooking Chamber, protect the tube from thermal shock.

Food Tray & Food Pots:

Made from SS and use for food holding and cooking, it's easy to load and unload these solar cookers using a sliding tray to place food inside.

Frame and Reflector:
