
One metal frame holds the tube over ground and support to parabolic anodized aluminum mirror reflector.

The material of the reflector panel is the aluminum reflector, hard-anodized.

The material of the backboard for the aluminum reflector is hot dip galvanized sheet.

The material of the support structures is colored MS Bar.

This solar oven tube allows you to cook anything that you can cook in a conventional oven. The inside and outside tube are nice clean Pyrex type glass with no coatings on it. This makes cleanup a breeze. It can be washed normally. If you are cooking a roast, you can use either an elongated tray or aluminum foil to hold the meat and allow you to slide it in and out. If you are boiling water, just fill pots with water and insert into the tube and put it in the Sun. The same goes for soups, stews, etc. Cooking temperatures regularly reach up to 120 degrees without reflectors, or if you add a reflector, temperatures can reach 200-300 degrees centigrade.

The Orbit Solar Oven Evacuated Tube:

Highly transportable

Compact

Mid-weight

Easy to set up

Easy to load

Cooks at high and fast temperatures

Retains heat well due to evacuated glass tubes

Cooking Option:

With the Orbit Solar Oven Evacuated Tube style cooker you can cook almost any kind of food that you desire, including:

Chicken, Fish, Meat, Breads-rolls and cakes, Soups, Vegetables, Pasta, rice and more.

Cooking Process:

Rice:

Clean rice, put rice in the pot with required water.

Fish and Meat or Chicken:

Clean, Mix with spices and vegetable.

No water or minimum water as per requirement and taste.

Vegetable:

Clean and mix with spices, no water required.

Boiling of Egg/Vegetable:

Clean and put into the pot and insert to a cooker, no water required.

Baking:

You can bake cake, biscuit and etc.

Cooking Time

Cooking Span: Whole day, best time from 8 am to 4 pm

Cooking Time: 1-2 hours depending on load (quantity of food)

Spending Time: 5-10 minutes for one cooking

Cooking days in a year considering Bangladesh weather is 280 days

Benefits:

No Fuel required, Energy from Sun is free

Direct saving Tk 1000-2000/month

Time-saving 2hours /day

No monitoring

Long Life 10-15 years

Maintenance free

No chance to burn food if there is a delay to take out the food.

Energy Savings:

As we discussed that the energy of sunlight per square meter is 1kw, our covered area is 0.8m square (appx,), considering 50% efficiency, total trapped power is 400w.

Total trapped Power in a day - 2.4 KWh

Total Trapped power in a year- 672 KWh

Environmental Benefit:

No fuel burn so no Smoke and no Co2 produce at cooking

Co2 emission saving = 0.82kg/KWh (Avg for KWh Electricity Generation)

Considering above calculation total Co2 emission saving is 672*0.82=551kg/ year

Social Effect

No monitoring required for cooking, Women can save their time to other works, it will be honored and empowered our mothers. Around 2 hours can be saved for cooking per day and 2*280=560 hours per year.

Around the globe, hundreds of millions of people have limited access to cooking fuels [source: SCI]. In most cases, electricity and gas are out of the question; only charcoal and firewood are within reach, and even charcoal can be too expensive. So we're left with wood. The problem is that in many poor, rural areas in places, trees are scarce. It takes a lot of wood to cook meals for an entire family every day, and what few wood sources there are continue to dwindle. Families have to walk for hours to collect cooking wood, and they end up spending what little money they have on their fuel, leaving less money to buy food.

Solar cookers are useful during times of disaster or power outages. A solar cooker can be used at any time of the year, any place in the world. They're great for family camping trips since they're lightweight and easy to transport. But solar cookers are also smart to have on hand during disasters.

Nutrition Benefit:

It can result in healthier cooking. Solar cooking doesn't use smoke that can contain carcinogens or microwaves that expose your food to potentially dangerous radio waves. When you cook over a campfire, the smoke can irritate your eyes and respiratory system, and open fires present dangers to children.

Plus, when you cook in a solar appliance, the nutrients stay in the food and don't leach out. That's because you don't use water in solar cooking. And, the temperatures in a solar oven are moderate – around 325 F – so nutrients aren't destroyed during cooking at a high temperature like on a grill or over an open flame.

Health Benefit:

Another problem that can be solved by solar cooking has to do with the simple act of burning wood. Fires release pollution into the air. This smoke, filled with particulates, is bad for the environment, but it's even worse for the people who are breathing that air. When people use open fires to cook indoors, they end up inhaling microparticles that can cause all sorts of health problems, including both lung and heart disease. One estimate puts the number of people who die from this type of air pollution at 1.5 million per year [source: Madrigal]. A solar cooker eliminates the need for an open flame, meaning cleaner air.

Geographic Benefit:

Bangladesh is situated under Line of Cancer (23.5 deg north) as a result whole year has enough sun to cook a meal for a family except disturbance of weather. There is a huge opportunity to use solar cooker in the village, suburban even some time in urban also.

Prospect:

Bangladesh is a small country by area but in population, it is very big, geographically and weather wise very much suitable for a solar cooker. There are few units we provide to people and they are happy with the performance of cooker.

The challenges are as follows:

This is a very new concept for people. It is required huge campaigning. People are used to traditional cooking habit. The initial price of Solar Cooker is high compared to traditional cookers. People cannot cook at night and windy day, we made a solution by using an Electric heater inside the tube for the night and windy days (Evacuated Tube Hybrid Solar Cooker).

Life of Cooker:

Since it is made of glass, it will last virtually forever if it isn’t chipped or otherwise broken.

Safety:

Use gloves or cloth at put on and off the tray from the tube.

Do not put a hand inside the tube because the temperature may rise 300 degree centigrade.

Our Mission:

Our mission is to aware people to use solar cooker all over the country.

Pilot Cooking:

In a village rice Cooking:

Roof Top at Dhaka City:

In a Fair at Dhaka:

Abstract

Thermochromic absorber coatings switch their emissivity for long wave radiation depending on the absorber temperature. Below the specific switching temperature of 68 °C the coating's emittance is quite similar to a commercial, highly selective absorber coating ($\varepsilon \approx 5$ %). At higher absorber temperatures the emittance reaches $\varepsilon \approx 35$ %, whereby the collector heat losses increase. As a result, the stagnation temperature is reduced by 30 K and an overheating or vaporization of the heat transfer fluid can be entirely prevented. We have carried out collector performance measurements according to ISO 9806. By means of dynamic system tests (ISO 9459-5) we predict the performance of a domestic hot water system with standard and thermochromic collectors. At typical daily tapping rates the marginally lower absorptance of the thermochromic coating raises the auxiliary energy demand up to 2.5 % and reduces the solar fraction by about 1 %-absolute. In additional system stagnation tests, we analyzed the stagnation behavior of thermochromic collectors, especially the vaporization of the heat transfer fluid, the steam expansion into the solar pipes and the thermal stagnation load on sensitive solar loop components. A reduction of the stagnation period by 60 % and a limitation of the stagnation temperature to 145 °C were investigated.

Keywords: thermochromic absorber coating, flat plate collector, dynamic system testing, stagnation load

1. Introduction

The steady performance enhancement of solar flat plate collectors leads to higher thermal solar system gains but increases the temperatures in the whole solar loop as well. The stagnation temperature of standard flat plate collectors can easily reach up to 200 °C. Thus, temperature resistant and also cost intensive system components have to be used, to withstand the thermal stagnation loads and temperature distribution in the solar loop. Additional measures need to be taken, especially for larger thermal collector arrays or systems with short solar piping, to protect the whole system against thermal damages (e.g. degradation of heat transfer fluid), as Scheuren (2006) investigated.

Hausner et al. (2003) investigated the stagnation behavior in detail and characterized different collector types on the basis of their steam production performance. To prevent overheating and handle the stagnation loads, Harrison et al. (2012) and Frank et al. (2015) summarized different protective arrangements and stagnation control strategies. Föste et al. (2016a) developed different heat pipe collectors with reduced stagnation temperature and protection against vaporization of the heat transfer fluid. To reduce the stagnation loads in flat plate collectors, Brunold et al. (2007) suggested thermochromic layers as a potential method and Föste et al. (2016b) investigated industrially manufactured thermochromic flat plate collector models first. Drainback solar thermal systems can prevent any vaporization in the solar loop, as Botpaev 2016 summarized.

2. Thermochromic absorber coating

Thermochromic absorber coatings have a highly temperature dependent emissivity for thermal radiation. This innovative smart selective coating increases its emittance ε above a predetermined "switching point" ($T_S \approx 68$ °C

doi:10.18086/swc.2017.31.10 Available at http://proceedings.ises.org

absorber temperature) from 5 % up to 35 %. The increase of the emittance above T_S can be explained as a first-order phase transition, which changes the internal crystalline structure in the thermochromic layer. The electronic band structure is altering from a semi-conductive to metallic character, whereby the electrical conductivity increases and influences the emittance. Pazidis et al. (2015) and Mercs et al. (2016) investigated, that this "switching" is a fully reversible process, as can be seen in Figure 1.a, as well as the long-term stability with accelerated aging tests. The layer stack on aluminum substrate consists of the active vanadium dioxide (VO_2) layer with an antireflective coating (SiO_2) on top (Figure 1.b).

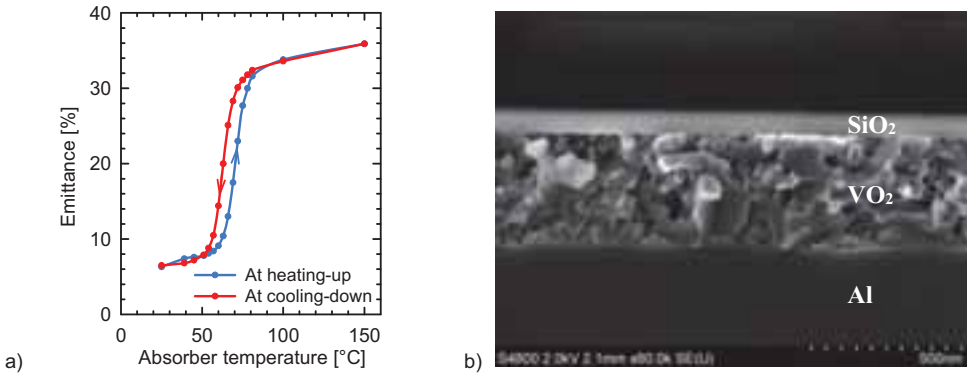

Fig. 1: Temperature dependent, fully reversible switching of emittance (a) and SEM cross section of absorber coating (b)

The thermochromic collector's behavior in the typical operating range is quite similar to a standard flat plate collector with a commercially available highly selective absorber coating ($\alpha > 94$ %, $\varepsilon \approx 5$ %). But in the switched state, the heat losses from the absorber to the glass cover increase significantly. Hence, the stagnation temperature is reduced by 30 K, the vaporization of the heat transfer fluid could be prevented more easily and the thermal stress for sensitive solar loop components (e.g. solar pump or membrane expansion vessel) could be lowered. Because of the reduction of thermal loads during stagnation, the components in typical solar thermal applications can be re-dimensioned or substituted to reduce the specific system costs and maintenance efforts.

3. Collector efficiency measurement

We have carried out collector performance measurements on an industrially manufactured thermochromic flat plate collector according to ISO 9806 (2013). Due to the fact, that our innovative coating changes its characteristic after the switching point with temperature T_S, the collector efficiency curve is splitted in two sections: the first describes the efficiency below the switching temperature and the second is valid for temperatures above T_S, both with their explicit collector efficiency parameters η_0, a_1 and a_2. For the evaluation we measured stationary collector efficiencies at three different absorber temperatures in each section as shown in Figure 2.

	$\eta_{0,Ap}$ -	a_1 W m^{-2} K^{-1}	a_2 W m^{-2} K^{-2}
Standard collector	0.786	4.19	0.0135
$T < T_S$	0.757	4.27	0.0065
$T > T_S$	0.830	6.17	0.0103

Fig. 2: Collector efficiency curves of a thermochromic and a standard flat plate collector related to their absorber temperature

Due to a marginally lower absorptance of the thermochromic absorber coating, the conversion factor η_0 is 3 %-absolute lower compared to an identically designed standard flat plate collector (η_0 = 0,786, related to

aperture area). The characteristic in the un-switched state is otherwise comparable to that of a standard collector. The higher emittance and heat losses at temperatures above T_S reduce the collector efficiency, which can be expressed in the gain of the linear heat loss coefficient a_1 from 4.27 to 6.17 W m^{-2} K^{-1}. Thus, the stagnation temperature was measured to 167 °C, 25 K lower compared to a standard flat plate collector (192 °C).

The splitted collector efficiency curve represents its characteristic sufficiently accurate. In system simulations with TRNSYS, the collector efficiency parameters switch instantaneously (without any hysteresis (cf. Fig. 1.a)), if the absorber temperature exceeds the temperature T_S. In the Solar Keymark certificate both curve sections are displayed as well as the "mixed" curve, which includes all measured stationary points. The annual collector outputs at mean fluid temperatures of 25 °C and 50 °C are calculated with the lower ($T < T_S$) efficiency parameters.

4. Experimental system yield prediction

4.1 Dynamic system testing

For an experimental performance assessment of the innovative selective absorber coating, we carried out dynamic system testing (DST) according to ISO 9459-5 (2007) on a solar domestic hot water (SDHW) system equipped with thermochromic collectors. The DST describes a dynamic short term measurement method for the evaluation of a SDHW system within 3…4 weeks, without testing each component by its own and no requirements of steady-state conditions. To acquire sufficient measurement data, the system operates in three different test sequences predefined by the standardization, to identify the thermal behavior of a SDHW system by pursuing it in all its relevant states. There is no need of measuring internal quantities, why this method is also compared with a "black box" approach. So only eight external quantities (e.g. irradiance, auxiliary energy demand, temperature of domestic hot water, wind velocity) have to be measured meanwhile as a function of time.

Mathematically, the whole system is described by seven system specific parameters, which have to be identified on the basis of measured data by dynamic fitting (DF) algorithm. The software minimizes the difference between measured and simulated system performance of the implemented physical SDHW system model. This physical model and the software DF are described by Visser and Pauschinger (1997) and Spirkl (1997), respectively. A long term performance (LTP) prediction of the annual solar system gain, auxiliary energy demand and solar fraction can be calculated with the mentioned short term test procedure from the identified parameters under arbitrary weather conditions.

The two SDHW systems were installed on an outdoor testing roof. The thermochromic system is compared to an identical solar thermal system equipped with standard collectors. Both systems have a gross area of 5 m² (2 collectors per array) each and a domestic hot water tank with a volume of 300 liters. An electrical immersed heater with a power of 6 kW is used for providing the auxiliary energy demand. The collector arrays are sloped by 38° and faced to south. The measurement and the investigations are carried out synchronously under the same environmental conditions, so that the systems can be compared directly with each other.

4.2 Evaluation and long term prediction

The identified system parameters (by DF) represent basically a combination of several physical phenomena, interactions between system components and even neglected effects. However, according to Spirkl (1992) it is possible to interpret some of them as real physical parameters, referring directly to a system component. Therefore U_S, C_S and f_{Aux} describe the total hot water tank heat loss rate, the thermal capacity and the share of store volume heated up with the immersed heater. The auxiliary parameters D_L and S_C characterize the mixing effects during hot water tapping and the SDHW tank stratification while storage charging, respectively. A_C* and u_C* are related to the collector area and its overall heat loss coefficient and describe mathematically the whole solar loop.

The parameters identified by the synchronous DST measurement are shown in Table 1. Due to the marginally worse optical properties of the thermochromic layer, as mentioned in chapter 3, the identified effective collector area A_C* of the thermochromic system is 3.4 % smaller than the standard collector one. The rising collector heat losses in the switched state are responsible for the higher u_C* of the thermochromic collector. Some other identified system parameters can be compared with measured data as well. For example the total heat loss rate

of the SDHW tank U_S amounts to 2.2 W K^{-1} and the thermal capacity C_S to 1.25 MJ K^{-1}. According to manufacturer's data sheet of the installed SDHW tank, the share of auxiliary heated volume f_{Aux} should be 0.44. The identified D_L value of almost 0 is equal to no mixing during draw-off, which can be expected for this kind of bivalent SDHW tank.

Tab. 1: System specific parameters identified by the DF alogrithm

Parameter	A_C* m²	u_C* W m^{-2} K^{-1}	U_S W K^{-1}	C_S MJ K^{-1}	f_{Aux} -	D_L [1] -	S_C [2] -
Standard collector system	2.96	10.16	2.44	1.27	0.54	0.018	0.042
Thermochromic collector system	2.86	10.55	2.33	1.28	0.55	0.017	0.034

[1] $D_L = 0$ is equal to no mixing during draw off
[2] $S_C = 0$ is equal to a solar heat exchanger, immersed at the bottom

For the LTP prediction of the system performance the predefined boundary conditions in ISO 9459-5 (2007) were used, with a draw-off temperature of 45 °C, an auxiliary set-point temperature of 60 °C and an ambient store temperature of 15 °C. The weather data for the four reference locations (Athens, Davos, Stockholm, Würzburg) given in the Standard were substituted by data from Meteonorm 7 (2012), due to comparability with system simulations done in TRNSYS.

The system performance is assessed by the auxiliary energy demand Q_{Aux}, which is provided by the immersed electrical heater into the SDHW tank in addition to the solar thermal gain to cover the domestic hot water energy demand Q_{DHW}. For this kind of investigation and system comparison it is the most meaningful parameter, because an increase of Q_{Aux} due to the installation of thermochromic instead of standard flat plate collectors leads to higher annual costs for the operator. At the reference location of Würzburg, the increase of auxiliary energy demand is less than 2.5 % over a wide range of daily tapping rates as shown in Figure 3. This is equal to 33 kWh a^{-1} at a daily tapping rate of 140 liters. At the other locations we predicted qualitatively the same increase of Q_{Aux} with maximum values of 5.6 % (Davos), 5.1 % (Athens) and 1.7 % (Stockholm).

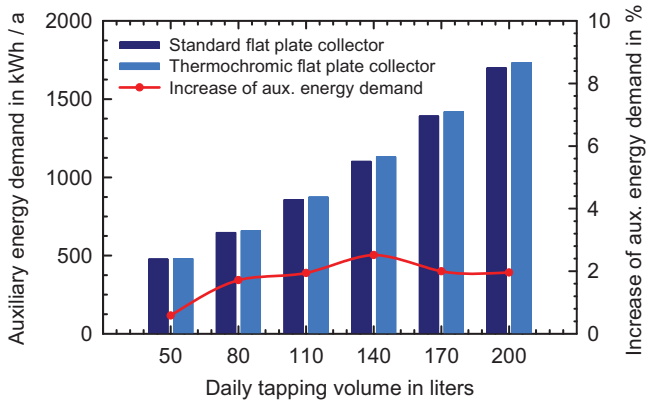

Fig. 3: Auxiliary energy demand for the thermochromic and standard SDHW system at the reference location of Würzburg

The solar fraction of a SDHW system characterizes the share of solar thermal gain into the SDHW tank, related to the domestic hot water energy demand Q_{DHW}. Furthermore and in reference to the Standard, the thermal gain can be expressed as the difference between the load energy Q_L and auxiliary energy demand Q_{Aux}.

$$f_{Sol} = \frac{Q_L - Q_{Aux}}{Q_{DHW}} \qquad (eq.1)$$

Figure 4 shows the solar fraction for all four reference locations over a wide range of daily tapping volumes (50…600 liters per day). At Würzburg, the f_{Sol} of the standard SDHW system reaches its maximum of 47.5 % at daily tapping rates of 110 liters and decreases for lower and higher tapping rates. These are typical values for this combination of collector gross area and SDHW tank volume. The SDHW system with thermochromic collectors exhibits qualitatively the same characteristic, but the solar fraction is 1 %-absolute lower than the standard system. The difference in solar fraction is nearly independent from the daily tapping rate. So it can be

assumed, that the difference in system performance depends primarily on the slightly worse optical properties of the thermochromic coating as on the increased thermal losses in the switched state.

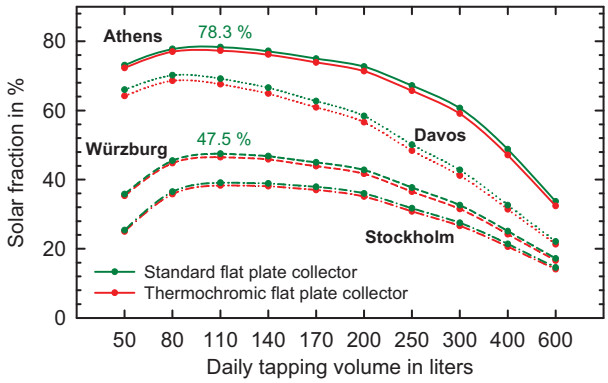

Fig. 4: Solar fraction for all four reference locations, variation of daily tapping volume and measured SDHW systems

Similar results are achieved considering the other reference locations. The mean difference in f_{Sol} over the whole range of tapping rates can be assessed to 1.2 (Athens), 1.6 (Davos) and 0.9 (Stockholm) %-absolute.

4.3 Cross-check with TRNSYS replica

To check the plausibility of the DST procedure and especially the LTP of the annual thermal system gain, we carried out system simulations with the software TRNSYS. Furthermore, a cross-check for the use of the implemented collector model with thermochromic collectors was investigated, as well. Thus, the installed SDHW system was modelled in TRNSYS in detail, considering all system parameters, e.g. length of solar piping, collector gross area, heat loss rate of SDHW tank, auxiliary power, etc. (cf. chapter 4.2). Even the matched flow operation mode was implemented into the system controller. The SDHW tapping was adjusted to the requirements of the Standard (one tapping per day; tapping rate 10 liters per minute; six hours after solar noon).

The comparison between the system simulations with the TRNSYS SDHW-replica and the DST long-term performance prediction was assessed by considering the solar fraction and the auxiliary energy demand again. The solar fraction of the thermochromic collector at the reference location of Würzburg can be modelled with an accuracy of less than 2 %-absolute within a wide range of daily tapping volumes (50…600 liters per day). As can be seen in Figure 5.a, within the range of 140…600 liters per day the difference decreases to less than 1 %-absolute. The auxiliary energy demand (see Figure 5.b) reports maximum differences of 3.1 %. For typical daily tapping rates (80…170 liters per day) the deviation does not exceed 1.5 %.

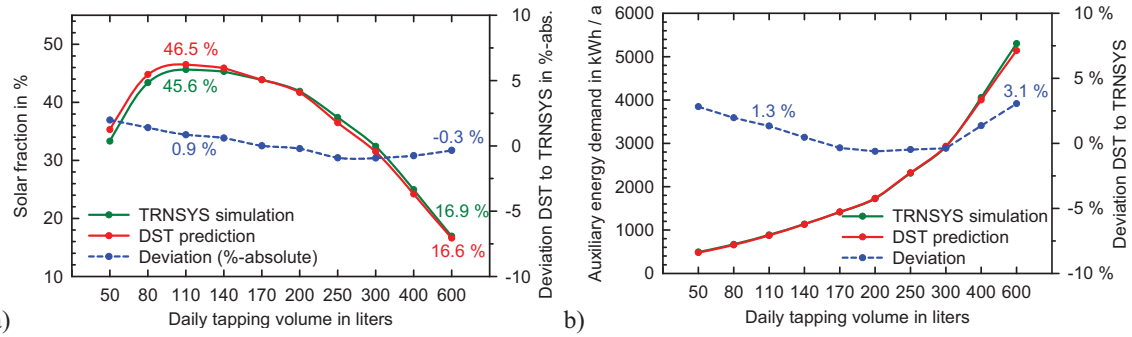

Fig. 5: Comparison of solar fraction (a) and auxiliary energy demand (b) for a system with thermochromic collectors between TRNSYS simulation and DST long-term performance prediction

For the standard collector array, we achieve similar results. Over the whole range of daily tapping rates, the auxiliary energy demand and the solar fraction are simulated with deviations of less than 5 % and 3.5 %-absolute, respectively compared to the DST long-term prediction.

The evaluation was carried out for the other three reference locations as well. The results for Athens are similar to those for Würzburg. At Stockholm, the deviations between simulation and DST prediction are marginally

lower, with maximum differences in auxiliary energy demand and solar fraction of 1.8 % and 1.4 %-absolute, respectively. The solar fraction at Davos can be modelled within 2.8 %-absolute and the auxiliary energy demand with deviations less than 6 %.

The results of our TRNSYS simulations with both SDHW systems confirm the DST long-term performance prediction as well as the applicability of the DST method to thermochromic flat plate collectors.

5. Stagnation tests

Pazidis et al. (2015) reported in a previous simulative study, that a thermochromic SDHW system could lower the stagnation time (here: timespan, in which the absorber temperature is above 120 °C) by more than 70 %. According to the simulation results, the maximum absorber temperature under normal operating and environmental conditions can be limited to 145 °C (Würzburg). To verify these investigations and experimentally evaluate the stagnation behavior of thermochromic collectors, we have carried out additional stagnation tests to analyze the steam expansion in the solar pipes due to the vaporization of the heat transfer fluid, the stagnation load on the collector itself and the temperature distribution in the whole solar loop. We focused especially on the thermal load on sensitive components, like the membrane expansion vessel or solar pump. An increase of the system pressure will be investigated in detail to raise the saturated steam temperature of the heat transfer fluid and prevent vaporization in the solar collector.

5.1 Experimental setting

We used both SDHW systems for our investigations, with the specifications mentioned in chapter 4.2 (see Figure 6.a). The overall solar loop length is 30 m per system to measure the steam expansion in detail, which is the most representative indicator for stagnation loads. Therefore, we installed temperature sensors (Pt1000) directly onto the solar piping, starting from the collector in- and outlet at intervals of 1.5 meters. The temperature distribution in the collector array is measured with four sensors at each absorber. Some more sensors were installed to quantify the thermal load on the solar pump and the membrane expansion vessel. One pressure sensor was added at the collector array outlet to investigate the stagnation dynamics and possible hydraulic shocks during stagnation. All sensors and their positions are displayed in the hydraulic schema in Figure 6.b.

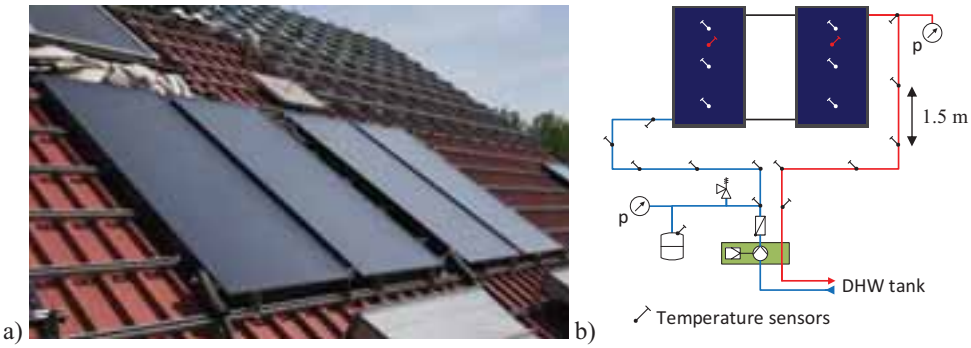

Fig. 6: Investigated SDHW collector arrays on the outdoor testing roof (a) and hydraulic schema with temperature and pressure sensor positions

The survey started in late 2016. During the tests the two systems were operated synchronously under well-defined stagnation conditions. We detected eight stagnation events, whereof four days under clear sky conditions. On these four representative days, the system operated at three different relative system pressures (2.0 bar, 2.2 bar, 3.2 bar). On one of these days, a so called “noon stagnation” was manually performed, by switching off the solar pump only at solar noon.

5.2 Evaluation of representative days

Maximum absorber temperatures occur usually at two-third of collector’s height. Figure 7.a compares these temperatures for the thermochromic and the standard flat plate collector at three different relative system pressures. The stagnation temperature of a collector is independent from its system pressure. Due to higher heat losses, the stagnation temperature of the thermochromic collector is limited to 145 °C under natural conditions

(including wind). Hence, we report a reduction of 30 K.

If the absorber temperature exceeds at any position in the collector array the saturated steam temperature of the used heat transfer fluid (TYFOCOR LS) at the specific relative system pressure, the fluid starts to vaporize. The saturated steam temperatures for the three investigated system pressures 2.0 bar, 2.2 bar and 3.2 bar are 139 °C, 141 °C and 150 °C, respectively. The steam expands into the solar pipe with increasing steam volume. We could detect the steam front, by comparing the pipe temperature recorded by the sensors to the current saturated steam temperature. The start of the fluid vaporization is attended by a soaring temperature at the collector outlet, as displayed in Figure 7.b. If the temperature at the collector outlet falls below the saturated steam temperature, the vapor condensates completely and no steam fills the solar piping anymore.

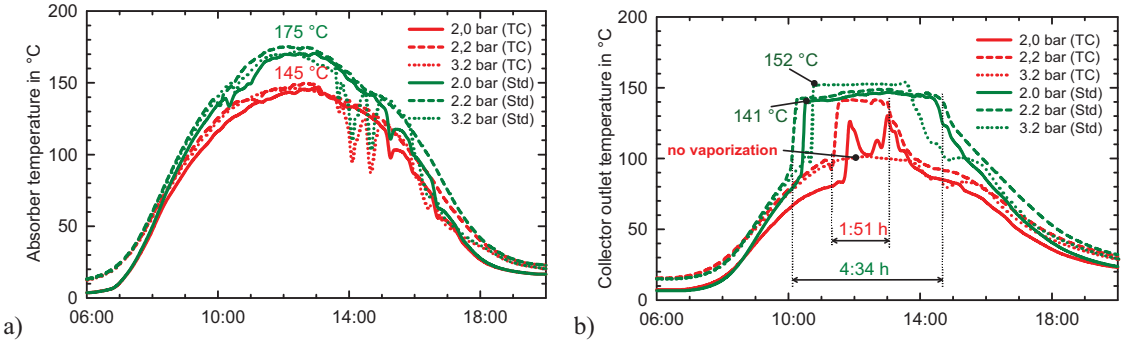

Fig. 7: Absorber temperature of thermochromic (TC) and Standard (Std) collector at two-third of the collector's height (a) and collector array outlet temperatures (b) for various relative system pressures

We define "stagnation period" as the timespan between the start of vaporization and the time, at which the entire system is free from steam again. For the evaluation with a system pressure of 2.2 bar, the stagnation period is reduced by 60 %, from 4:34 hours (standard collector array) to 1:51 hours. At 2.0 bar the stagnation period could be halved. The entire vaporization could be prevented at system pressures higher than 3.2 bar (see Figure 7.b). In this case, no steam expands into the pipes and the thermal load and the temperature distribution in the solar loop could be significantly lowered. The maximum outlet temperature is reduced from 154 °C in the standard collector array to 102 °C in the thermochromic collectors.

Insufficient data acquisition for the evaluated period in 2016, with a few stagnation events only, could not represent the stagnation behavior of both SDHW systems in detail. We will carry out the measurement and double the collector area in addition. To investigate the stagnation dynamic and the draining behavior more in detail, a high frequency pressure measurement at collector array outlet is planned. For further investigations, we calibrated both membrane expansion vessels to determine the whole steam volume in the collector loop only by measuring its fluid inlet temperature and the system pressure at the expansion vessel. This method was developed and introduced by Scheuren (2008). With the system steam volume and qualitative measured steam expansion, an evaluation of residual fluid and draining behavior is feasible.

6. Conclusions and outlook

By means of synchronous dynamic system tests according to ISO 9459-5 we predicted and compared the long-term performance of SDHW systems equipped with thermochromic and standard flat plate collectors. Our results confirm the high performance of a SDHW thermochromic system. The increase of auxiliary energy demand, by installing thermochromic instead of standard collectors, is less than 2.5 % for daily tapping rates between 50 and 600 liters at the reference location of Würzburg. Even for the warmer reference location Athens, the gain in auxiliary energy demand does not exceed 5.1 %. The low increase in auxiliary energy demand and the marginally low difference in solar fraction over a wide range of daily tapping volumes and locations reveal, that the slightly worse optical properties of the thermochromic collector influence the system performance more than the higher heat losses in the switched state.

On the basis of system simulations with TRNSYS, we could cross-check the DST long-term performance prediction and confirm the applicability of the implemented DST collector model on thermochromic flat plate collectors. We assume that the dynamic short-term measurement method can be extended to all kind of

collectors with unsteady efficiency behavior, e.g. collectors with thermally actuated ventilation door (cf. Frank 2015) or heat pipe collectors (cf. Föste 2016a). The results confirm the high performance of the thermochromic collectors in a SDHW system, which is comparable to that of a standard collector.

The stagnation behavior was analyzed by additional experimental stagnation tests. We report a limitation of the stagnation temperature at 145 °C and, thus, a reduction of 30 K compared to a standard flat plate collector. The stagnation period – the timespan, in which any steam is detected in solar thermal system – could be reduced during the measurement up to 60 % at normal system pressures. The vaporization can be entirely prevented by a slight pressure rise, which offers great potential for further reduction of system costs. We assume a significant reduction in installation and maintenance costs or the use of cost-effective (not high temperature-resistant) materials by avoiding vaporization and therefore less thermal loads for the whole system.

The thermochromic coating is currently under further development, with the aim to improve its optical properties and extend its temperature operating range. The main goals are the increase of the solar absorptance (α > 95 %), as well as the thermal emittance in switched state (up to 60 %) and a shift of the switching temperature T_S to 80 °C. We expect a gain in collector performance and a further reduction of the stagnation temperature at once.

Acknowledgement

The project “Process technology, quality assessment and system solutions for thermochromic absorbers in solar thermal collectors” presented in this paper is funded by the German Federal Ministry of Economic Affairs and Energy based on a decision of the German Federal Parliament (reference numbers 0325858 A and B). The project ProTASK is carried out in cooperation with Viessmann Werke GmbH & Co. KG.

The authors are grateful for the financial support and responsible for the paper’s content.

Prototype of Integrated Collector Storage (ICS) Using Phase Changes Material and Thermosyphon Heat Pipes

Mickaël Pailha[1], Gilles Fraisse[1], David Cloet[1]

[1] CNRS, LOCIE, Université de Savoie, Le Bourget du Lac (France)

Abstract

Conventional thermal solar systems consist of roof-mounted collectors, a storage tank inside the building and various elements that ensure the operation of the system (controller, pump, etc.). This ultimately leads to relatively complex systems, leading to major disadvantages such as a relatively high cost, storage volume footprint and maintenance. The development of "passive" solar systems is therefore a strategy to be favored. It is in this context that we have studied numerically and experimentally a new concept of integral collector storage with phase change materials and heat pipes.

A prototype was tested in outside conditions at INES. Thermosiphon heat pipes work very well by transferring the absorbed solar energy to the storage located at the back of the absorber, and by acting as a thermal diode. Concerning storage, a small difference in temperature is observed between the 2 faces of the cavity containing the phase change material, which shows the efficiency of the honeycomb to transfer the heat. In terms of performance, the prototype is very well placed for its productivity. However, storage is largely discharged at night. This implies a low annual solar fraction. The metallic fixation which maintains the cavity is largely responsible for these losses. It is therefore sufficient to limit the thermal bridges to greatly improve the solar fraction.

1. Introduction

1.1. Context and Issues

Market development of solar thermal systems in France is penalized by the cost of investment compared to other solutions that use fossil fuels or electricity. Moreover, today's solar solutions are more adapted to the new than the renovation (additional space required for storage) that is the major energy issues in the building sector. The research activities should encourage the development of innovative solutions integrating these two issues. The integrated collector storage (ICS) are very interesting because they allow financial savings compared to a conventional solar thermal system: fewer components, simplicity, passive operation, possibility of industrialization "all in one" and setting work faster (Sadhishkumar and Balusamy, 2014). The first ICS exist since the end of 19th century (Smyth and Al, 2006). Currently, about ten companies propose ICS of various geometries and using water as a storage medium (http://www.sunwindenergy.com/ 1+2/2013). The ICS are suitable both for new buildings and at an energy renovation (Timilsina and Al, 2012). They avoid putting storage in a room, which is generally disadvantageous for reasons of space available in existing system and of cost of square meters in the new. The ICS are thus promising systems for the development of the solar thermal market. However, the main drawback of such systems is related to high thermal losses knowing that the storage is generally poorly isolated to the outside. Consequently, the ICS are rather used in soft climates of Mediterranean type.

The work suggested in this article presents a new prototype of integrated collector storage using phase-change materials (PCM), and thermosyphon heat pipes to transfer solar energy from a plane collector to storage. The use of PCM allows to reduce the thickness of the storage cavity as compared to water. Architectural integration is thus greatly improved knowing that it is about major problems for most currently available ICS. Through the use of PCM, storage presents no problem with the gel. A coil type heat exchanger finally allows to draw the energy contained in the ICS. The prototype is fully instrumented with flow rate, temperature and weather condition measurements. Tests are realized under real outdoor conditions.

2. Experimental setup

2.1. Proposal for a new ICS concept

We have designed a new generation of ICS from very difficult specifications to satisfy: high energy performance in a cold climate, considering the risks of frost, simplicity of operation, quality architectural integration (low thickness), great reliability and cost comparable to conventional systems. This is the challenge of this project, which aims to demonstrate the feasibility of the new concept of ICS thanks to the experimental study carried out on a prototype. The originality of the concept is based on the use of heat pipes for the solar circuit and phase change materials (PCM) contained within an aluminum honeycomb structure for storage (figure 1).

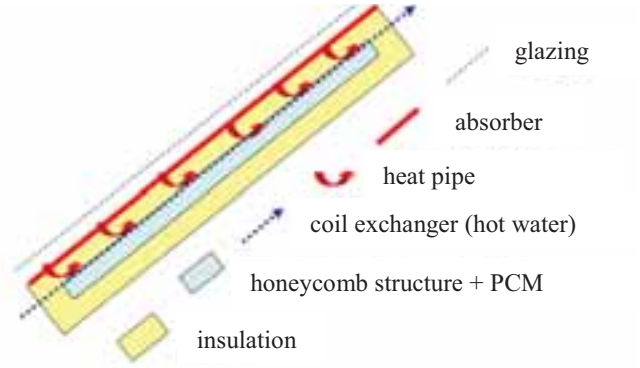

Fig. 1: Schematic of a new concept of ICS with PCM and heat pipes

We have thus developed the new concept of ICS around three points:

- Use of thermosiphon heat pipes: thermal diode operation possible, high thermal transfers and no risk of frost in the heat transfer between the sensor and the storage.

- Complete insulation of the storage volume to achieve energy performance comparable to conventional systems with hot water tank. This is very rarely the case for self-storage sensors.

- The PCM combined with an aluminum honeycomb structure seems well suited for storage in a self-storage sensor: low thickness (architectural integration), no problem with frost for the PCM (phase change), excellent characteristics of the honeycomb structure both in terms of heat transfer (compensation of the low thermal conductivity of the PCM by a large exchange surface) and mechanical strength (specific to the geometry of the honeycomb).

Concerning freezing, roof integration must be designed so that the cold-water supply to the rear is in an isolated volume. If this is not the case, an anti-freeze fluid and an exchanger must be used. This may be relevant in the case of a collective installation (limited cost). Finally, heat recovery is not provided within the self-storage sensor in the ADEME project. We considered it simply downstream of the auto-storing sensor.

We did not identify in the bibliography a ICS combining the use of heat pipes, the presence of a completely isolated storage and the use of a nida / PCM storage cavity. This is the originality of this ADEME project.

2.1. Principle of operation

The operating principle of the new ICS concept using heat pipes and PCM in a honeycomb structure (figure 2) is described in this section. Our solution is based on a conventional flat-plate collector. It has on the upper face a glazing beneath which is placed an absorber which converts the incident solar rays into heat. In our case, the solar loop is replaced by thermosiphon heat pipes which transfer the heat directly from the absorber to the storage (exchange n° 1 in figure 3). The heat pipes are in direct contact with the absorber on its rear face. This is called the "evaporator" part of the heat pipes. The heat pipes (six on the height of the prototype) are elements that conduct

heat by using the phenomenon of phase change as soon as a temperature difference is observed between the evaporator and the other end designated "condenser" which is in contact with the cavity. The heat pipes are in fact hermetic copper tubes containing a fluid (methanol in our case) filled to about 30%. Methanol vaporizes due to an energy input from the absorber. The steam goes up along the heat pipes to reach the level of the storage cavity. This is the condensation zone: the vapor of the fluid contained in the heat pipes condenses because the temperature in the storage is lower than that of the steam. The fluid releases the latent heat by condensing and then transmits it to the storage (exchange n ° 2). The designation "heat pipes" in this study corresponds in fact to thermosiphons since the flow of the liquid phase is by gravity. The heat pipes used have a very particular geometrical configuration since the slope is rather small: the inclination is not directly in the direction of the height of the sensor but over its length since the cavity is at the rear of the absorber, as in Fig. 4.

About phase change material, we used polyethylene glycol (PEG). The PEG6000 is placed in the cells of the honeycomb (figure 2). Each of the cells are filled with 75% in our case. A filling level of less than 100% is necessary because of the mechanical stresses associated with the volume change accompanying the phase change (during the fusion, the volume of PCM increases). The honeycomb is closed on both sides by aluminum plates. The assembly system by bonding makes it possible to hope for the sealing of each cell containing the PCM.

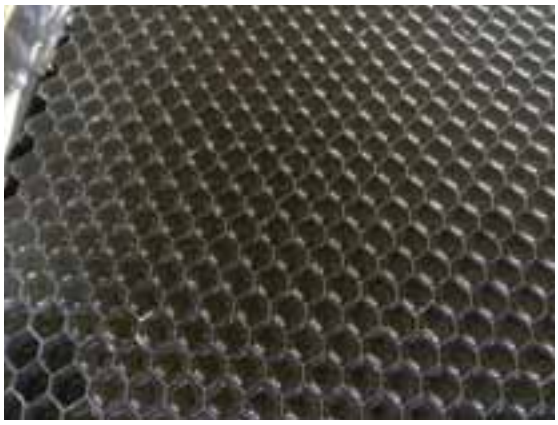

Fig. 2: Honeycomb filled with PCM

A water circuit (copper coil) is also present on the upper surface of the cavity where the condenser part of the heat pipe is located. Cold water from the water supply is injected during the withdrawals linked to the needs of the users. This water circulates in the coil exchanger which is pinned around the heat pipes on the upper aluminum plate of the cavity. PCM in a liquid state releases the latent heat and solidifies when there is a transfer between the PCM and the pulsed water (exchange No. 3). The melting / crystallization temperature of the PCM is chosen close to the set point (about 55 °C.). The water circuit placed on the front of the storage with the heat pipes is an advantage which allow a direct transfer of thermal energy from the heat pipe. This is exchange 4.

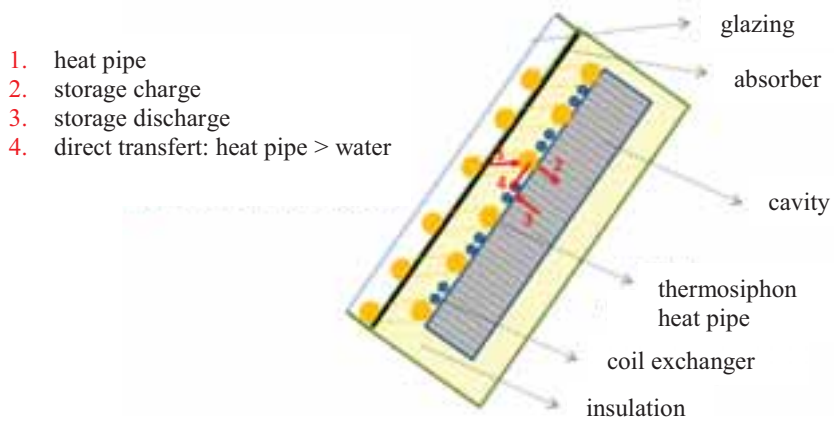

Fig. 3: Operating principle of the new concept of ICS

The table 1 shows all the characteristics of one module. For a complete installation, several modules will be required. The amount of module required will be sized according to the needs.

Tab. 1: Characteristics for each prototype module

Data for each prototype module
Surface d'ouverture : 1m x 0,5m
Storage cavity : aluminium, filled with 75% of PCM
Storage cavity size : 1m x 0,5m x 0,04m
Insulation of the cavity : 10 cm roch wool, λ: 0,04 W/(m.K)
Area of a honeycomb cell: 0,74 cm² (aluminium)
PCM : Polyethylen glycol (PEG 6000), latent heat of fusion: 192 kJ/kg ; Tfusion : 58,5°C ; 1 210 kg/m3 ; λ: 0,2 W/m.K ; volum in the cavity : 0,015 m3
Heat pipes : 6 made of copper, filled with 30% of methanol
Glazing : 4mm thick, Dim. 1006*605 mm, absorption coefficient 0,07, solar factor : 87%
Absorber : copper, λ : 380W/(m.K), 0,2mm thick
Water coil exchanger : cuivre, 12m long (diam int : 6mm, diam ext: 8mm)
ICS inclination : 30°

Photos of the prototype installed on the test platform are presented on figure 4.

Fig. 4: Front and back view of the prototype

2.3. Instrumentation of the prototype

The prototype is fully instrumented with flow rate measurements at the inlet and outlet of the coil exchanger. Weather conditions are recorded, included global solar irradiance within the ICS plane, and the temperature at back of the system. Temperatures are measured with 35 thermocouples on the absorber, on the cavity and on either side of the insulation. These thermocouples have previously been calibrated by performing cold junction compensation. The measurement accuracy of the thermocouples thus obtained is 0.1°C. All data is recorded with an Agilent 34972A acquisition unit. These measurements allow to characterize the system.

2.2. Withdrals

Water withdrawals are made to discharge the storage of the sensor. The withdrawal flow is regulated by a valve

placed upstream of the ICS and is measured by a flow meter. The programming of the withdrawal scenarios is made possible by a solenoid valve which opens at specific times and for fixed periods of time. The energy withdrawn by the water is determined by measuring the flow rate and the temperature at the inlet and the outlet of the water exchanger.

3. Experimental results

Experiments were carried out at the INES (National Institute for Solar Energy). Different withdrawals scenarios are carried out to allow the study of the charge of the discharge as well as stagnation temperature tests at the hottest of summer.

3.1. Study of the charge

The programmed withdrawal to study the charge is the following: a flow rate of 9.3L / min for 19min every morning at 6h, which represents approximately 177 liters of water per day evacuated in a single withdrawal. This choice was made to unload as much storage as possible at the beginning of each day to concentrate initially on the storage phase. This also made it possible to start each day with a maximum unloaded cavity. The first study week (May 24 to 19, 2017) revealed the following results (figure 5).

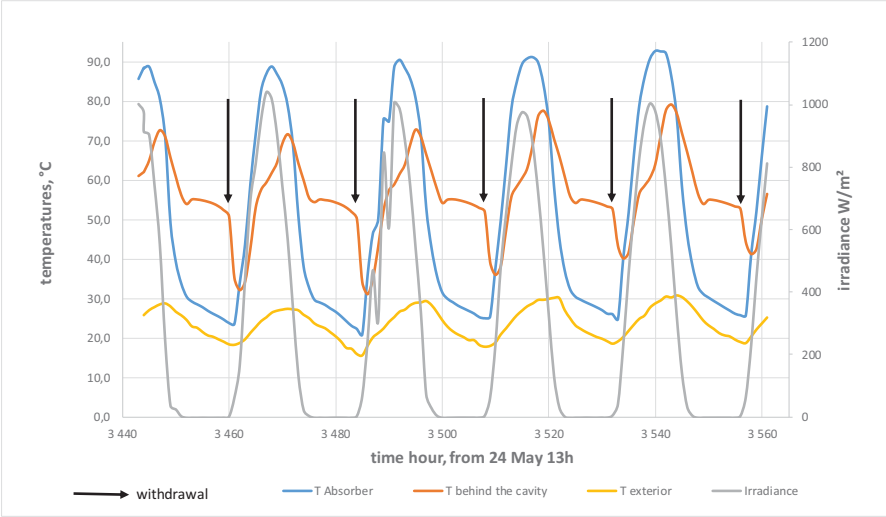

Fig. 5: Experimental results from 24 to 29 may 2017 (arrows indicate a withdrawal)

During these summer days, the irradiance reaches maximum values close to 1000 W/m² in the plane of the absorber (inclination 30°). The absorber temperatures reach 90 to 95°C in the middle of the day and follow the irradiance curve quite well. About storage (measured at the rear of the cavity), its temperature increases over the day, reaching a maximum of 70°C to 90°C in the middle of the afternoon. It is observed that the rise in temperature of the storage is rather fast in the solid phase (sensible heat). The phase change then limits this rise. The temperature change is again faster in the liquid phase (sensible heat) when the whole MCP is melted. The maximum temperature observed is approximately 90°C. Limiting the maximum temperature reduces the risk of degradation of the cavity. A plateau appears on the storage temperature every day around 9 pm for several hours because of the phase change (around 55°C) because of the crystallization of the PCM. The thermal losses of the cavity cause this phase change to be rather slow and create a long "plateau" on the temperature curve. The melting stage is much faster due to the higher solar contributions. We will again discuss the heat loss afterwards, knowing that they seem already quite important because the PCM goes down in temperature up to the level of crystallization during each night. It should be noted that this temperature profile is linked to our withdrawal profile: it would be radically different with a withdrawal in the day for example. A slight phenomenon of supercooling also appears at the end of each day. This phenomenon is related to the fact that the temperature of the PCM drops below its solidification temperature while remaining liquid. This is not inconvenient in our case given the large amplitudes of variation of the temperatures. We can also note that the daily withdrawal (indicated by the arrows) causes the temperature of the storage to drop to about 35°C before rising due to the solar contributions the following day.

This first week of study makes it possible to say that the rise in temperature of the PCM on its sensitive part is rather fast. In order to show this, the following comparison was made (from the experimental data collected):

Tab. 2: Temperature rise of PCM and water

	PCM (PEG 6000)	Water: traditional Solar water heater (TRNSYS simulation)
Initial temperature	30°C	30°C
Setpoint temperature	55°C	55°C
Temperature rise	8.3°C/h	6.2°C/h

This comparison shows the rapid rise in temperature with PCM compared to water. This phenomenon therefore implies, for an installation in operation, a reduced use of the make-up because the PCM reaches the desired setpoint more quickly. This is a particularly interesting point in terms of energy efficiency.

If the temperature of the absorber is analyzed with the outside temperatures, it is realized that for the night the absorber temperature drops very rapidly and reaches a difference of lower than 10 ° C between the absorber and the exterior (the absorber is protected from the outside by the glazing). The heat pipes thus appear to play their role as thermal diodes. Otherwise, the absorber would have a higher temperature.

A second withdrawal was scheduled for a few weeks. The flow rate was decreased from 9 to 3.3L / min for 1 hour at 3am. The total quantity of water discharged remains approximately the same, i.e. approximately 180 liters of water drawn off daily. A lower flow rate was chosen to analyze more finely the evolution of the water temperatures at the inlet and outlet of the sensor. The acquisition step has also been refined (from 1 minute to 3 seconds). The withdrawal was shifted from 6 to 3am in the morning because it coincids with the beginning of the next day's sunlight.

This second scenario allowed us to follow more precisely the evolution of the water temperatures at the inlet and the outlet of the sensor (figure 6).

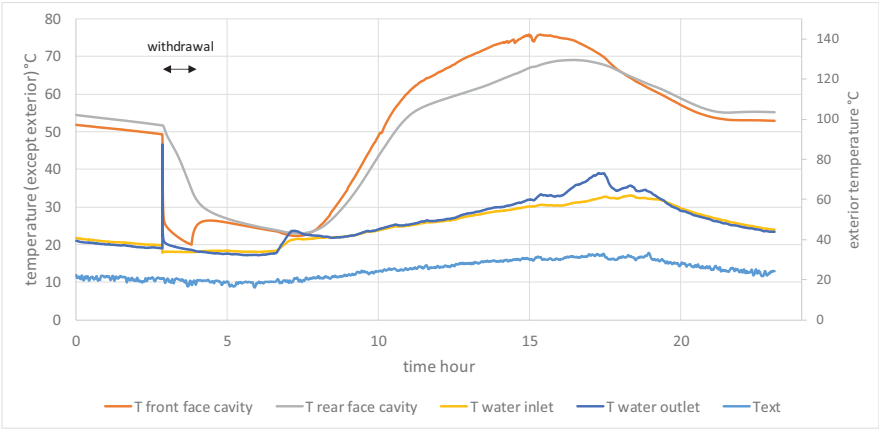

Fig. 6: Evolution of the temperature at the front and rear faces of the cavity, the exterior temperature and the water temperatures at the inlet and outlet, 5 July 2017

By considering a lower flow rate and a finer acquisition step, it is possible to observe more precisely the temperature changes during the withdrawal. Regarding the temperatures on either side of the cavity, their evolutions are similar to what was previously studied.

For water temperatures, it should first be stressed that only the withdrawal periods are meaningful because, without drawing off, the thermocouples measure stagnant water temperatures in the pipes. At the time of the withdrawal, the water in the pipes having been previously renewed, the inlet has a temperature close to 18°C. The outlet temperature rises rapidly to the temperature Tpe (front face of the cavity) which is close to 50°C (figure 6). This temperature decreases to about 25°C. very rapidly after the withdrawal. This hot water is actually stagnant water in the sensor that has been evacuated. The fact of not having water at 50°C for a sufficient time is mainly linked to the high value of the withdrawal flow rate compared to a conventional withdrawal. Moreover, the analysis of the losses during the night rises that the destocking is quite important. This is also due to the temperature of the front face of the cavity: before the withdrawal, it is at 48°C. The PCM has therefore resolidified (at least partly) because of the losses.

3.2. Case without withdrawal

The summer temperature made it possible to carry out a stagnation test on the prototype by not performing any withdrawal. The period concerned was from 13 July to 24 August. The interest is to subject the prototype to high heat and then check that it has not been damaged. During this summer period, outdoor temperatures reach up to 37°C for the hottest days and irradiance exceeds 1000W / m² in the middle of the day for almost all the study days (figure 7).

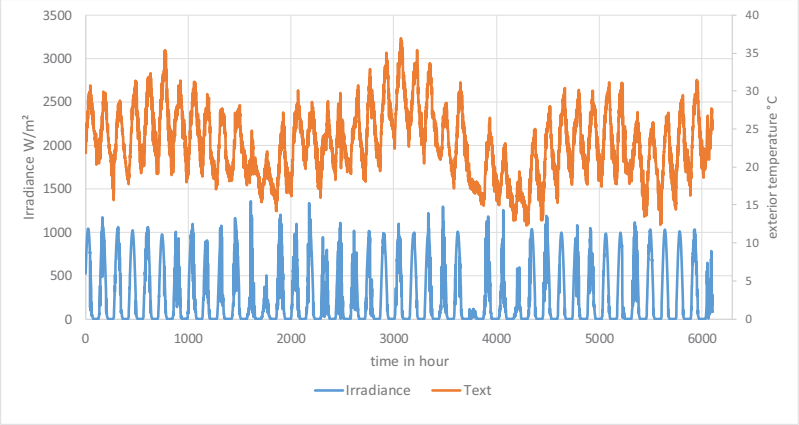

Fig. 7: Irradiance and exterior temperature from 13 July to 24 August

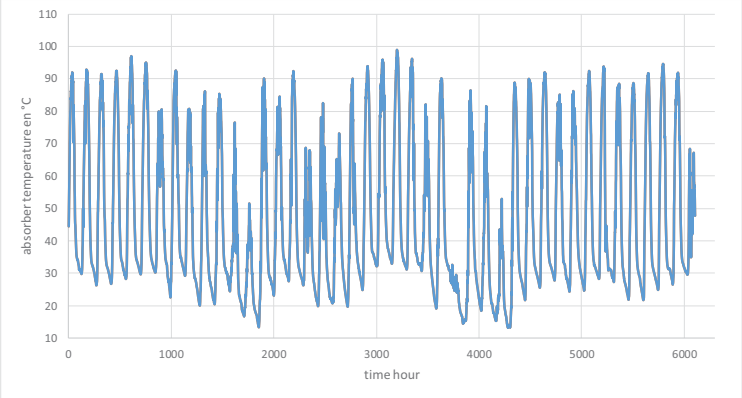

Fig. 8: Absorber temperature without withdrawal, from 13 July to 24 August

When the absorber temperatures are analyzed (figure 8), it can be seen that the absorber does not exceed 100°C. on any day and remains within the range of values observed with a withdrawal.

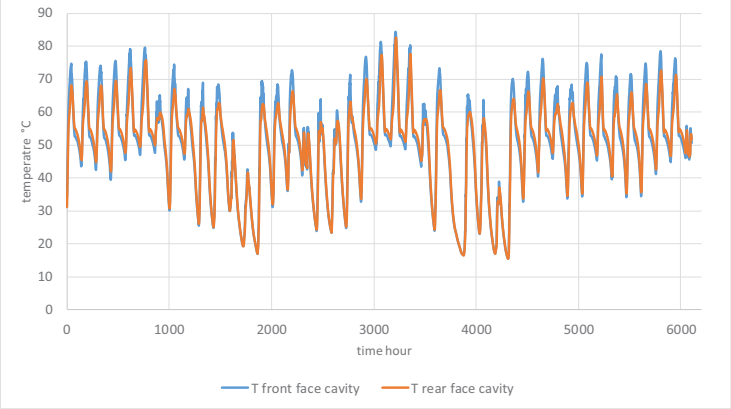

Fig. 9: Temperatures of the front and rear faces of the cavity, from 13 July to 24 August, period without withdrawal

The cavity temperature reaches a maximum of 80°C (figure 9), i.e. slightly higher levels than with a daily withdrawal. Moreover, temperatures generally do not fall as low as with a withdrawal: they are maintained between 30 and 40 ° C (or even more for warm nights) against an average of 20°C with a water withdrawal.

The results obtained in that stagnation test show that, on the one hand, the maximum temperatures reached by the absorber and the cavity remain within acceptable values: there is no rise in temperature which can damage the system. So from a reliability point of view, this is rather reassuring. On the other hand, the fact of not having higher temperature rises in this configuration shows that the sensor exhibits too high thermal losses. With an optimized prototype reducing the thermal losses of the storage, we evaluated, using a numerical model, a maximum temperature between 130°C and 140°C.

3.3. Study of the discharge

This last phase of the test was aimed at studying the phenomenon of discharge of the storage with a realistic flow. A lower withdrawal rate was selected: 0.87 L / min for 30 minutes at 17h. The withdrawal scenario was shifted at the end of the day to estimate the energy recovered by the withdrawal before the night losses partially discharge the cavity. The figure 11a represents the withdrawal at 17:00 for the day of 22 September. The same day, at 12h, flow adjustments were carried out on the experiment, resulting a short withdrawal, hence the first peak on the outlet temperature. The small temperature difference between the 2 faces of the cavity can be observed throughout the day (less than 10°C.). The thermal transfer by the honeycomb is therefore done correctly. The upper surface is logically warmer during the day (sunspot) and colder at night due to the larger losses on the front which is more exposed to the outside environment.

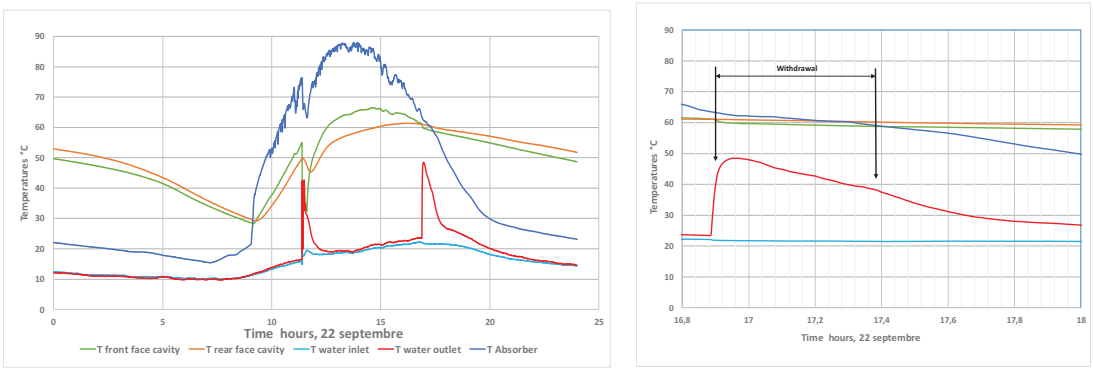

Fig. 10 : Evolution of the temperature on the front and rear faces of the cavity, on the absorber and the water temperatures at the inlet and outlet, 22 September 2017

The temperature of the absorber does not seem to be influence by the withdrawal at 17h, whereas the first at noon is accompanied by a decrease of its temperature and the cavity temperature. An explanation is that in the morning, the storage was not sufficiently charged (mainly sensitive part). Thus, when water has been drawn off, mainly the sensible heat has been removed, causing a drop in temperature. At 17h, the stored energy being mainly in latent form, the withdrawal allowed to partially discharge the cavity without causing a drop in temperature on the elements of the front face of the cavity.

If we look more specifically at the second withdrawal (figure 10b), the evolution of the temperatures allow to calculate the power extracted during the drawing (figure 11). It is about 1.6 kW for 0.5m² of sensor (ie 3.2 kW / m²), which is almost half of what was envisaged in the best case (6 kW / m²). Although the flow rate is slightly lower than expected (0.87 l / min instead of 1 l / min), it is likely that the contact between the coil and the top plate of the cavity should be improved. This explains why the outlet temperature does not reach the temperature of the cavity. Nevertheless, the outlet temperature is maintained at a level above 40°C during the withdrawal period (30 minutes), which is quite suitable.

The maximum outlet temperature is 48.7°C (61°C in the cavity at the same time), 43.5°C after 15 minutes and 40.0°C after 30 minutes. The discharge of the storage is therefore done correctly. The temperature in the cavity decrease only by 1°C.

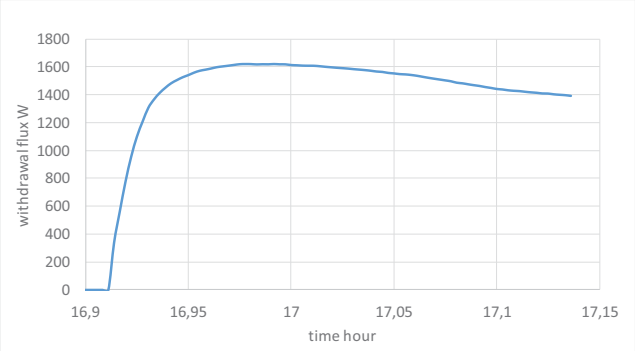

Fig. 11: Puissance récupérée grâce au soutirage d'eau le 22 septembre

4. Conclusion

This study focused on an innovative integrated collector storage concept which couples heat pipes to an MCP storage in a honeycomb. It appears that the rise in temperature of such a storage is much faster than with conventional water storage: 8.3°C/h (experimental) versus 6.2°C/h for a conventional CESI of 300L. In addition, the volume gain from this technology is important (counting at least a factor of 1.65). However, the implementation of the heat pipes proves to be quite complex. The phenomenon of thermosiphon requires to place the condenser above the evaporator.

A prototype was tested in real conditions at the INES. The concept has thus been validated experimentally. It appears that the prototype showed no signs of malfunction (leakage of MCP ...). It is charged correctly every day, the temperature levels reached by the cavity are satisfactory for the durability of the system (including without withdrawal). The solar energy is well transmitted to the storage: the heat pipes play their role well as expected. The thermal diode effect (of the thermosiphons) is also validated. A small temperature difference is observed between the 2 faces of the cavity, which shows the efficiency of the honeycomb structure to transfer the heat.

In terms of performance, it appears that the prototype is relatively well placed in terms of its productivity compared to a traditional individual solar water heater. However, storage is largely discharged at night, which explains why there is no rise in temperature during non-withdrawal periods (experimentally tested). The complete crystallization of the MCP shows that losses are almost equivalent to storage. The losses represent an average power of the order of 100W/m² permanently. This implies a fairly low solar coverage over the year. It is clear that the U-shaped profiles and the metallic fasteners which hold the cavity strongly accentuate the losses of the cavity. All this is not really worrying knowing that these problems of thermal bridges can easily be solved.

If one considers a more efficient version of the ICS, the maximum temperatures reached by the cavity could be between 130°C and 140°C. If it is desired to limit this maximum to a hundred degrees, the ICS must not have an excessive transmission coefficient of glazing and / or an absorber with low emissivity coating.

Numerical Model for Solar Thermal Collectors and Thermal Energy Storages Based on Phase Change Slurry

Gaia Prearo, Gianluca Serale and Marco Perino

Politecnico di Torino, DENERG Energy Department, Turin (Italy)

Abstract

The efficiency of conventional solar thermal collectors and related thermal energy storages is often reduced by the requirement for high irradiation levels and the heat losses due to the relatively high temperature of the heat transfer fluid. In order to overcome those limitations, a solar thermal system capable of working at low temperatures through the exploitation of latent heat storage is presented in this paper. The proposed system was based on a novel heat transfer fluid and storage media, composed by a mixture of water and micro-encapsulated phase change material (PCM), named Phase Change Slurry (PCS). This paper introduces a numerical model capable of accurately describe the physical process and the dynamics of the proposed technology (collector, thermal energy storage and control logics). Results were validated by means of experimental tests and a long-term monitoring on a real full-scale prototype. Furthermore, experimental tests were performed to carry out the actual PCS thermo-dynamical properties that are strongly dependent on the concentration of micro-capsules in the heat transfer fluid.

1. Introduction

The pursuit to obtain higher levels of comfort has led to a dramatic increase of the energy demand in buildings. In Europe the overall energy demand of the building sector accounts for about 40 % of the total energy consumption (Pérez-Lombard et al., 2008). Solar technologies are a leading solution to face the challenge of reducing the impact of the building sector (http://www.iea-shc.org/programme-description). However, the full profitability of RES is often limited to a great extent by their stochastic variation and the time mismatch between availability and demand (Heier et al., 2015). Thus, energy storage strategies are becoming a crucial requirement to partially mitigate this gap.

A field that is particularly promising is represented by active Thermal Energy Storage (TES) technologies, (SHC Annual Report, 2012). Indeed, in buildings the active TESs allow the surplus of energy production to be stored and then released whenever demanded by the occupant. In particular, the peak power consumption can be mitigated by means the adoption of the TES. In this way the RES are better exploited and the size of the auxiliary systems can be effectively reduced. For the implementation of storage technologies directly into the buildings, compact tank solutions are required.

A further improvement in TES performance has been represented by the introduction of solutions exploiting latent heat exchanges. These solutions are commonly referred as Latent Heat Thermal Energy Storages (LHTES) and can be based on different technologies and storage media (e.g.: ice cold storages, salt hydrates, Phase Change Materials). Advances in industrial technologies have led to the development of Phase Change Materials (PCM), whose phase transition process occurs in many temperature ranges. Thus it is possible to select the material whose features are the most suitable for each specific application. The exploitation of latent heat represents a possible benefit in terms of reducing the size of the component and improving the overall system performance (Rodriguez-Ubinas et al., 2012). Indeed, on one hand the great amount of energy due to the phase change increases the energy stored density. On the other hand, the phase change can be exploited to reduce the temperature differences affecting the system, thus improving the overall system performance by

doi:10.18086/swc.2017.31.12 Available at http://proceedings.ises.org

means of a reduction of both the dispersion and the internal entropy dissipations.

Nowadays, the scientific literature offers numerous works dealing with technologies and solutions concerning LHTES. Particularly encouraging are those in which LHTES is coupled with solar thermal systems. In general, the presence of a PCM leads to an overall annual increase in the solar fraction, a higher efficiency of the system and major storage heat capacity. In the last few years, the use of PCMs has been tested in several different types of solar thermal systems. Three different methods in particular have been proposed to incorporate PCMs into solar thermal systems: the integration of a PCM directly in a layer of the solar collector (Sharma and Chen, 2009 and Eames and Griffiths, 2006), the addition of PCM nodes to the primary HTF solar loop pipes (Haillot et al., 2013) and the addition of PCM elements to the inside of a storage tank (Cabeza et al., 2006).

In 2015, some of the authors of the present paper (Serale et al., 2015) proposed an innovative solar thermal system based on Phase Change Slurry (PCS). The PCS is a mixture of water with glycol and a dispersed micro-encapsulated Phase Change Material (PCM). Micro-capsules allow the PCS to be pumpable regardless the state of aggregation of the material contained in their core. For this reason, it was possible to use the PCS both as the storage media and the Heat Transfer Fluid (HTF) in the primary loop of the solar thermal system. In this way, the phase change transition occurred also in the collector reducing the operating temperatures of the system due to the exploitation of latent heat exchange instead of a traditional sensible HTF temperature increasing. On the one hand the system dispersions to the ambient were reduced and on the other hand the fraction of hours of exploitable solar radiation were also increased, due to a reduction of the threshold limit of the solar radiation necessary to produce energy.

In order to investigate the potentialities of this PCS-based technology, a numerical model for solar thermal collector based on latent heat exchanged was formulated extending the Hottler-Willier for traditional solar thermal collectors (Serale et al., 2016). The present paper is an extension of the numerical model formulated in (Serale et al., 2016). In particular, the extended model herewith presented considers not only the collector, but the entire solar thermal system, including also the system PID controller and the LHTES tank. The integration of these models with the one previously built of the solar thermal collector, allowed a simulation of the prototype as a whole. Eventually, the paper shows the validation process of the numerical model using data gathered during an experimental campaign and a field test on a real-scale prototype.

The work is organised as follow. Section 2 summarises the main features of the numerical model of the collector, the TES and the closed-loop controller for solar thermal system capable of exploiting both latent and sensible heat. Section 3 briefly introduces and describes the solar thermal system analysed as case study. Section 4 reports the results of the experimental tests necessary to characterise the PCS used as HTF. Section 5 outlines the results of an experimental campaign undertaken to validate the numerical model with real data gathered on field. Section 6 is the conclusion of the work.

2. Methods: a numerical model for solar thermal systems exchanging latent heat and sensible heat

In order to better investigate the opportunities offered by the adoption of PCS in solar thermal system, a numerical model was necessary to perform simulation and parametrical analysis. These allow the system performance to be tested under different boundary conditions and climatic parameters. The numerical model had to be capable to describe both the sensible and the latent heat exchanges occurring in the system. In this way both traditional water-based and innovative PCS-based HTF can be tested and the system performance compared. The following Figure 1 provides a comprehensive framework of the numerical model carried out in the present work.

The solar thermal system model was characterised by 3 key elements: the collector model, the TES model and the closed loop controller that regulates the pump speed, thus the flow rate flowing in the system. Both the collector model and the TES model were finite elements thermodynamic models capable to describe the system evolution in terms of internal energy and temperature of the nodes. The model was entirely developed by means of Matlab scripts and Simulink flows. The model can be used to simulate both traditional water-based and PCS-based solar thermal systems. The switch between the two options can be uptaken by different setting of the features of the heat transfer fluid and storage media. Since the numerical model has to work both with water and with a phase change material, an enthalpy approach, instead of a temperature one, was used to

evaluate the internal energy of the system. In this way it was exploited the property of the enthalpy itself of being a continuous and invertible function of the temperature ($h=h(T)$).

The external disturbances influencing the system were the external weather conditions and the energy demand by the occupants. The external weather conditions that mainly affect the system heat exchanges were the ambient temperature T_a, the beam solar radiation G_b, the diffuse solar radiation G_d, the angle of incidence of the solar radiation θ on the collector, the wind velocity w_a, and the radiative temperature of the sky T_{sky}. The TES model considered the ambient temperature as unique weather disturbance, while the solar thermal collector model was affected by all the previous parameters. The occupancy energy demand affected the model of the TES and in particular the inlet temperature of the heat exchanger $T_{hx,in}$ and the thermal energy required in the heat exchanger Q_{hx}. Some general assumptions and simplifications were made in the model to make the physical–mathematical description of the components easier:

- quasi steady-state of the collector components (cover, plate, back insulation casing);
- uniform weather boundary conditions over all the system components;
- heat loss toward the same heat sink, considered at the outdoor air temperature;
- the HTF has constant density and thermal conductivity;
- the temperature of the HTF in the outlet of the collector is, unless a negligible error, the temperature in the inlet of the TES.
- the temperature in the outlet of the TES is approximately equal to the inlet temperature of the solar collector.

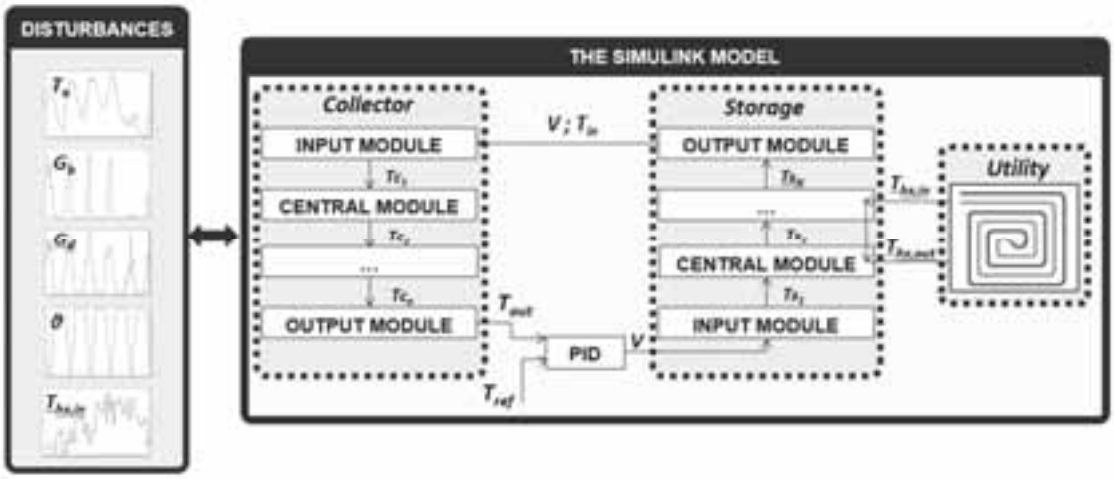

Fig. 1: General framework of the numerical model for solar thermal systems exchanging latent and sensible heat.

2.1 Numerical model for solar thermal collectors based on sensible or latent Heat Transfer Fluids

The solar thermal collector numerical model is the evolution of the previous version presented in (Serale et al., 2016). The numerical model was suitable to simulate different type of HTFs, thus with different thermo-physical properties. In this new version of the numerical model, the collector was a-priori discretised in 10 segments of the same length. Each segment was a lumped node having constant thermodynamic properties (e.g., temperature, specific enthalpy, conductivity, etc.). For each segment an energy balance based on the Hottel-Willier model for solar thermal collector was formulated and computed in order to carry out the temperatures of the components and the heat fluxes involved in the process (Duffie & Beckman, 2013). The solution of this energy balance depended on the HTF used, thus the thermal and rheological proprieties of the HTF had to be set in the model as a function of its temperature. In particular, the adoption of specific enthalpy vs. temperature curves defined by means of look-up tables allowed the model to be easily switchable from sensible to latent heat exchanges.

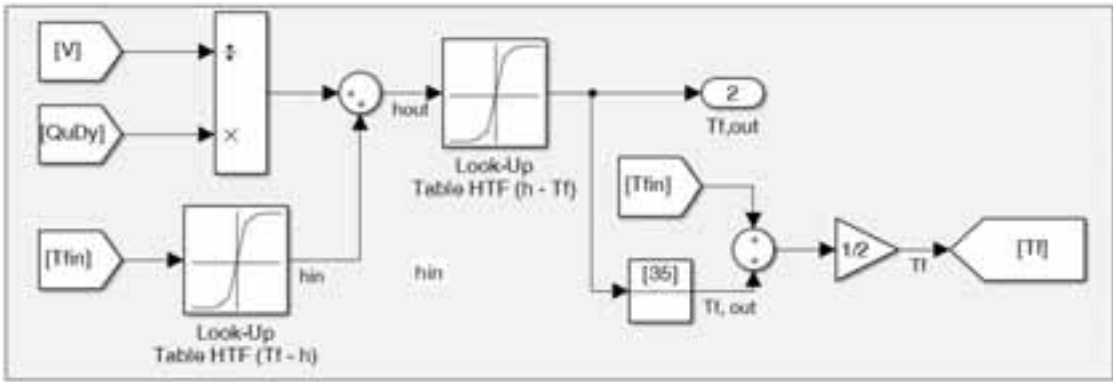

Fig. 2: The sub-section of the Simulink model exploiting the look-up tables used to define the HTF temperature as a function of the enthalpy.

2.2 The multi-node Thermal Energy Storage numerical model

A dynamic lumped energetic model was used to reproduce the thermal behaviour of the TES. In particular, a multi-node model (Streicher, 2008) was selected as the most suitable one to simulate with good accuracy the TES filled either with water or with PCS. Consequently, the TES tank has been virtually segmented into 7 lumped nodes representing finite horizontal volumes. Each node was considered filled with the internal storage media perfectly mixed, thus at one uniform temperature. Likewise the collector model, every node is influenced only by the flow rate entering from the previous one and it influences only the subsequent. The initial node receives the outlet flow rate of the collector, while the terminal node determines the inlet flow rate of the collector.

For each TES node the energy balance was defined by means of Eq.1.

$$\dot{Q}_{dp,j} + \dot{Q}_{hx,j} + \dot{Q}_{aux,j} + \dot{Q}_{cond,j} + \dot{Q}_{loss,j} = m_j \cdot \frac{h_j^{n+1} - h_j^n}{dt} \qquad \text{(eq.1)}$$

This balance considered negligible the pressure drop inside the tank and the heat losses to the ambient were taken into account using a global heat transfer coefficient. Referring to each *j*-th node of mass m, $\dot{Q}_{dp}$ is the heat flux due to the mass flow rate coming from the solar collector, $\dot{Q}_{hx}$ is the heat flux exchanged with the heat exchanger that delivers the space heating energy, $\dot{Q}_{aux}$ is the heat provided by an auxiliary heating source (e.g., a backup boiler or a backup electric heater), $\dot{Q}_{cond}$ is the heat flux exchanged by conduction between two adjacent nodes and $\dot{Q}_{loss}$ is the energy losses to the outdoor environment. The adoption of specific enthalpies h discretised over time on the right term of eq. 1 allowed the TES model to be easily adapted to the HTF used as storage media by means of the same temperature dependent look-up tables adopted for the model of the collector.

During an experimental campaign, every term of eq. 1 for each *j*-th node could be easily derived from the data gathered by thermocouples suitably placed into the TES. If the thermocouples in the TES were not enough to enable the direct solution of the balance in each node (e.g., temperatures monitored in the TES inlet and outlet only), the intermediate node temperatures would be linearly interpolated from these terminal data. Indeed, a quasi-linear trend could be justified by the very small temperature difference between the inlet and the outlet (e.g., at most 10 °C).

2.3 The control loop in the numerical model

Coping with a phase change fluid, the control logic was more complicated compared to traditional water based solar thermal systems. On one side, the controller had to avoid the overcoming of some technology limits of the system components (e.g., not exceed the 60°C maximum temperature thresholds that can damage the system). These control logics for the PCS-based solar thermal system could be based on Rule Based Controllers (RBC) extensively discussed in (Serale et al., 2015).

On the other side, an effective control logic was essential to fully exploit the available solar radiation and to optimise the coupling of the production with the users' demand. In order to maximise the overall energy

efficiency of the system the HTF latent heat should be exploited as much as possible. For this reason, the optimal working condition of the solar collector could be approximated to the one in which the PCS concludes its transition phase (around 40 °C) exactly at the collector outlet. In this way the heat for the isothermal phase change could be fully exploited and the thermal losses can be minimised by maintaining the lowest possible average working temperature of the solar panel. This control logic was addressed by means of a PID controller that managed the primary collector loop pump speed, thus the HTF flow rate flowing in the solar thermal collector. The target of the PID was to maintain the collector outlet temperature as much closer as possible to the set-point equal to the end of PCM transition phase.

The PID controller was implemented in the numerical model to control the flow rate flowing between the solar thermal collector and the TES tank. In the case of PCS the collector outlet temperature, which is the PID set-point, was set equal to 40 °C, a temperature slightly above the upper limit of the material phase change transition and always sufficient to guarantee the supply temperature for space heating. This allows the latent heat of the PCM to be fully exploited. The parameters of the PID controller were changed in the simulation model to evaluate the dynamic response of the system, and to tune the real controller of the prototype. Whereas the P value allows to reach the set-point faster, the I value deletes the error in regime permanent when the disturbances are constants and the D value allows to anticipate the future trend of the error. After preliminary tests, the controller was simplified to a Proportional-Integral controller and the Derivative term was neglected. Indeed, in this specific application, the disturbances - such as the solar radiation and the ambient temperature - are extremely variable, thus predicting the future error would also increase the instability of the system.

2.4 Auxiliary equations for considering the Phase Change Slurry features

A numerical model for a PCS-based solar thermal system required the proper setting of the PCS thermo-physical and rheological properties. These properties strongly depended on the concentration of the micro-encapsulated PCM in the PCS mixture. However, whereas the thermal properties could be easily calculated as the mass weighted average of the properties of the two components of the slurry, the rheological features showed a highly non-linear behaviour. Thus, the choice of the concentration of micro-encapsulated PCM dispersed in the mixture was not trivial. Indeed, it affected both the energy required in pumping and heat transfer, thus in the efficiency and in the energy savings of the system in real building applications. The selection of the most suitable concentration was a quite tricky trade-off, since enhancing a characteristic may cause the worsening of the other one. Indeed, boosting the concentration of micro-encapsulated PCM increased the available latent energy stored in the PCS mixture, but at the same time it determined higher pressure drops due to the increased fluid viscosity, which in turn means higher energy demand for pumping. However, higher thermal storage capacity also implied lower flow rate, and thus a reduction in electric energy demand from the pump (Serale et al., 2014). For these reasons, the authors decided to develop the model with PCS thermal and rheological characteristics that varies accordingly to the micro-encapsulated PCM concentration in the mixture, defined as φ. PCS viscosity and thermal conductivity were defined by means the following eq.2, eq.3 and eq.4, while the enthalpy or specific heat vs. temperature curves were determined with experimental tests for different concentrations.

On the one hand, the PCS dynamic viscosity has been calculated taking advantage from the Vand's model (eq 2):

$$\frac{\eta_b}{\eta_f} = (1 - \varphi - A\varphi^2)^{-2,5} \qquad \text{(eq.2)}$$

where η_b is the dynamic viscosity of the micro-encapsulated PCM, η_f is the dynamic viscosity of the dispersing phase, thus the water with concentration, φ is the volumetric concentration of the micro-encapsulated PCM in the mixture and A is a constant value that depends on the diameter and the geometry of the micro-capsule.

On the other hand, the PCS thermal conductivity was estimated by means of the (eq.3 and eq.4):

$$\frac{\lambda_{eff}}{\lambda_b} = 1 + B\ \varphi\ Pe_p^m \qquad \text{(eq.3)}$$

$$\frac{\lambda_b}{\lambda_f} = \frac{\left(2+\frac{\lambda_p}{\lambda_f}+2\varphi\left(\frac{\lambda_p}{\lambda_f}-1\right)\right)}{\left(2+\frac{\lambda_p}{\lambda_f}-\varphi\left(\frac{\lambda_p}{\lambda_f}-1\right)\right)} \qquad \text{(eq.4)}$$

where λ_{eff} is the thermal conductivity for the flowing PCS fluid, λ_b is the conductivity of the PCS in static conditions, λ_f is the conductivity of the fluid in which the micro-encapsulated PCM is dispersed, whereas Pe_p is the Péclet number of the particle. This last parameter depends on the dimension of the particle and of the pipe in which the fluid flows, on the radial position of the particle in the pipe and, moreover, on the mean velocity of the fluid. Finally, B and m can be considered as constants for defined ranges of the Péclet number.

3. Materials: a PCS-based solar thermal system

In order to validate the model, a real-scale prototype was necessary to undertake an experimental campaign and gather monitored data. In particular, the solar thermal collector and TES prototype described in (Serale et al., 2015) was used to this purpose. This prototype was designed to couple well with low temperature space heating terminals (e.g. radiant panels or Thermal Activated Building Elements). The prototype can use as HTF and storage media either water, eventually with glycol, or a PCS, which exploits the latent heat. The TES was powered by a flat plate solar thermal collector and heat was delivered to the building through a secondary heat exchanger placed inside the component. Furthermore, a complete monitoring system was installed in the prototype to gather data every second about the temperatures and the flow rates of the various components. In particular, energy meters monitored the electrical consumption of the auxiliaries, 20 thermocouples were placed in the collector, in the TES and in some crucial points of the pipes, 2 manometers (one for each loop) and a Corioli's flow meter were used in the secondary loop to measure the fluid flow rate inside the heat exchanger of the TES. On one side of the collector, a pyranometer measures the global solar radiation on the collector tilted plane.

Fig. 3: Left: schematic of the analysed PCS-based solar thermal system. Right: the full scale prototype at Politecnico di Torino.

Figure 3(left) reports a schematic of the prototype and its monitoring system, while Figure 3(right) is a picture of the real scale system installed on the roof of the energy laboratories of Politecnico di Torino. The main component was the solar thermal collector with a net area of 2.1 m^2. The panel was equipped with a motorised cover that worked both as a protection for adverse weather conditions and as a strategy to avoid an undesired overheating of the HTF. The TES tank volume was equal to 200 l. The TES connected the primary collector loop with the demand side heat exchanger that was an internal copper coil of 2.5 kW. A fiberglass insulation layer of 10 cm limited the TES thermal losses to the external ambient. Moreover 8 visors were installed in the TES to visually evaluate the fluid inside the tank. To move the PCS without damaging the PCM micro-capsules dispersed in the mixture, two peristaltic pumps were used, one for the primary collector loop and one in the TES to continuously recirculate the fluid and thus limit the creaming phenomenon (Fan et al., 2015). The peristaltic pump in the primary collector loop was the one controlled by means of the PID controller. Four

solenoid valves were used to control the RBC logics and the operating modes of the solar thermal system (Serale et al., 2015).

4. Experimental tests undertaken to derive the PCS features

The PCS used as HTF was a mixture of water with glycol and a dispersed micro-encapsulated PCM. The PCM contained in the micro-capsules core selected for this application was n-eicosane with a nominal melting temperature of about 36 °C and a specific enthalpy of fusion equal to 195 kJ/kg. Since the thermal properties of the whole PCS mixture strongly depended on the capsule concentrations experimental tests were necessary to define the enthalpy or specific heat vs. temperature curves. The T-History method was selected as the most suitable experimental test for this approach. T-History method defines the correlation between the fluid temperature and its enthalpy at the various micro-encapsulated PCM concentrations. In this case the concentration suitable for the adoption in the solar thermal system were investigated. An extensive description of the T-History tests for the analysed PCS can be find in (Buttitta et al., 2015).
Elaborating the monitored data of the T-history method experiments it was possible to find the enthalpy vs temperature curves at different concentrations using the correlations of Marvin et al. (Marin et al., 2003) (eq. 5-7).

$$H_m = \frac{m_w c_{p,w} + m_t c_{p,t}}{m_t} \frac{A_2}{A_1'} (T_0 - T_s) \qquad \text{(eq.5)}$$

$$\Delta H_p(T_i) = \left(\frac{m_w c_{p,w} + m_t c_{p,t}}{m_p}\right) \frac{A_i}{A_i'} \Delta T_i - \frac{m_t}{m_p} c_{p,t}(T_i) \Delta T_i \qquad \text{(eq.6)}$$

$$H_p(T) = \sum_{i=1}^{n} \Delta H_{p,i} + H_{p,r} \qquad \text{(eq.7)}$$

where H_m is the latent heat, H_p is the enthalpy of the micro-capsule of PCM, $H_{p,r}$ is the enthalpy of a reference fluid whose value is assumed known (in this case distilled water was used as reference fluid), T_0 is the fluid temperature at the experiment initial condition, T_s is the initial temperature of the phase change transition, A_1' is the integral of the temperature difference between the reference fluid and the ambient temperature, A_2 is the integral of the temperature difference between the PCS fluid and the ambient temperature. Both the integrals refer to a period of time ranging from the beginning till the end of the phase change transition. The subscript w indicates the water, whereas t is the tube of the sampler and i is the i-th time instant.
Afterwards, the calculation of the specific heat was possible. The specific heat is defined as the derivative of the enthalpy - temperature curve. The trend of the specific heat can be described as the combination of two Gaussian curves, one for the liquid part and the other one for the solid part (eq. 8).

$$c = \begin{cases} c_s + (c_m - c_s) e^{-\left(\frac{T_m - T}{\omega_s}\right)^2} & T \leq T_m \\ c_l + (c_m - c_l) e^{-\left(\frac{T_m - T}{\omega_l}\right)^2} & T > T_m \end{cases} \qquad \text{(eq.8)}$$

in which the subscribe s refers to the solid state, l to the liquid state and m is the peak value.
Thus, the final equation for the enthalpy curve results in eq. 9.

$$h = \begin{cases} c_s(T - T_{min}) - (c_m - c_s) \frac{\sqrt{\pi}}{2} \omega_s \left[\operatorname{erf}\left(\frac{T_p - T}{\omega_s}\right) - \operatorname{erf}\left(\frac{T_p - T_{min}}{\omega_s}\right)\right] & T \leq T_p \\ c_l T - (c_m - c_l) \frac{\sqrt{\pi}}{2} \omega_l \operatorname{erf}\left(\frac{T_p - T}{\omega_l}\right) + (c_m - c_s) \frac{\sqrt{\pi}}{2} \omega_s \operatorname{erf}\left(\frac{T_p - T_{min}}{\omega_s}\right) - c_s T_{min} + T_p(c_s - c_l) & T > T_p \end{cases}$$

(eq.9)

A possible drawback occurring in test regarding PCS was the so called creaming effect. Indeed, the PCM micro-capsules showed a density that was lower than the one of the water in which they were dispersed. Thus, there was a migration process of the PCM micro-capsules in the upper part of the tubes. To limit the phenomenon during the T-History method, the tubes were placed horizontally and this allowed the results accuracy to be improved up to 18 % compared to the vertical position.
The results of the T-History method are shown in Figure 4. These results were implemented in the Simulink numerical model using Look-up tables. Moreover, Table 1 highlights the available latent heat for each analysed concentration. The creaming effect somehow influenced the reliability of the results and the lower the micro-encapsulated PCM concentration the higher this effect. Indeed, for 5 % w.t. concentration of micro-encapsulated PCM the MAPE was 18 %, while for 15 % w.t. of micro-encapsulated PCM concentration the MAPE decreased to 5 %.

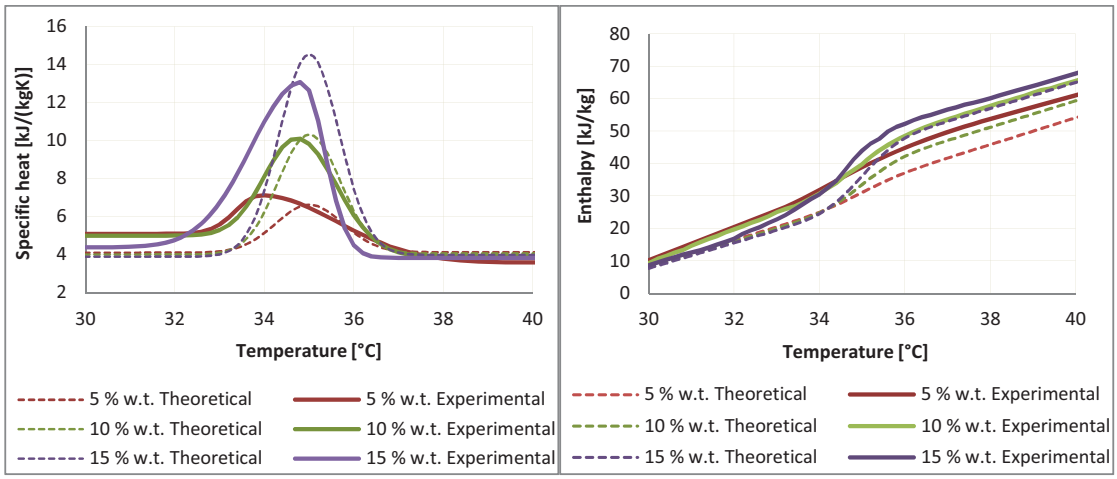

Fig. 4: Left: Enthalpy vs Temperature curves at different weight total concentrations of PCM. Right: Specific heat vs Temperature curve at different weight total concentrations of PCM.

Tab. 1: Comparison between theoretical end experimental PCS latent heat for different concentration of micro-encapsulated PCM in the mixture.

Concentration w.t. [-]	Theoretical latent heat [kJ/kg]	Experimental latent heat [kJ/kg]	MAPE [-]
5 %	4.73	5.74	18 %
10 %	10.97	11.14	2 %
15 %	17.81	18.77	5 %

5. Experimental tests to validate the model

The solar thermal collector and TES prototype were monitored in order to properly identify the parameters of the numerical model that best-fit the actual performance of the prototype. Firstly, the solar thermal collector and the TES were tested as stand-alone elements for 5 days each, afterwards the overall system was monitored for other 5 days. Thus, an uncertainly analysis between the data gathered from the plant and the results obtained from the numerical model has been done.

The implementation of the PID controller in the numerical model allowed not only to perform realistic simulations replicating the real control logics of the prototype, but also to investigate and improve the best Proportional, Integral and Derivative setting. Figure 5(left) shows the comparison of the temperature trend at the outlet of the real collector with the simulated data obtained introducing a P controller and a PI controller. The set-point tracked by the controller was a temperature of 40 °C at the outlet of the solar collector. The P value allowed the set-point temperature to be reached faster, while the I value deleted the error in permanent

regime where the disturbances were constants. The changes in the collector outlet temperature were due to the variation of the flow rate, influenced by controlling the peristaltic pump speed.

On the one hand adopting the P controller, when high level of solar radiation became available, the rotation speed of the pump decreased until the set-point temperature was reached (Figure 5(right)). However, if the solar radiation remained constant, it would not be possible to maintain the 40 °C set point with the P controller and the collector outlet temperature raised up to 44 °C. On the other hand, the combination of a P value with a I value solved this issue. Indeed, it is possible to infer from Figure 5(left) as the set-point was maintained also during all the central hours of sunny days when the solar radiation reached the highest levels. On the contrary, with either P or PI controller during cloudy days (e.g. the fourth and the fifth days of the monitored week), also maintaining the pump speed at the minimum value, the system was not able to reach the set-point could.

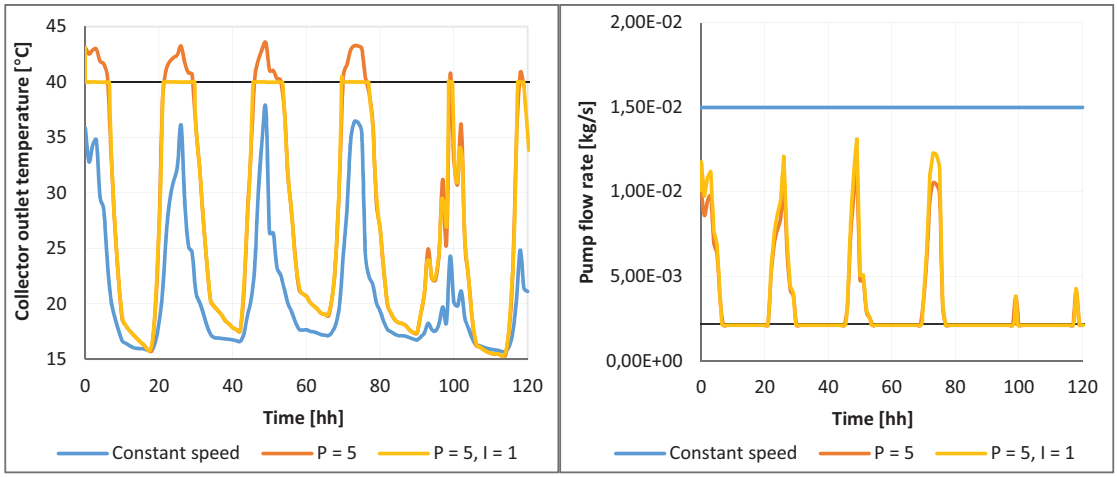

Fig. 5: Experimental results with different combinations of P and PI values. Left: Temperature at the outlet of the collector. Right: HTF pump flow-rates.

At the end of the calibration process for the solar thermal collector, the MAPE between measured and simulated outlet fluid temperatures with water was 1.8 % (i.e., a MAE of 0.5 °C). While the tests of the TES tank temperatures provided a MAPE equal to 1.6 % (i.e., a MAE of 0.3 °C). After those satisfactory results, the analyses of the entire closed loop system were performed. In this case, the difference between the simulated and the monitored data slightly increased. Nevertheless, the error indicators remained smaller than a MAPE of 8 % for the outlet temperature of the solar thermal collector and of 1.8 % for the TES nodes temperatures. The following Figure 6(left) shows the comparison between the simulation and monitored results obtained for the closed loop solar thermal system for 7 monitored temperature in the TES, whereas Figure 6(right) shows the collector outlet temperature.

The simulated trend of the collector outlet temperature followed the experimental results proving a good accuracy. Some small discrepancies were outlined only during peak loads of solar radiation and morning time. This was mainly due a difficult calibration of the solar radiation transmission coefficient of the solar collector glass cover as a function of the incidence angle. Indeed, this transmission coefficient strongly affected the panel performance, influencing the amount of the radiation effectively incident to the absorption plate of the collector. A delay affected the simulated results of the first hours of the day also concerning the TES temperature trends. This was influenced again by the uncertainties affecting the solar collector. Indeed, the outlet of the solar collector was the inlet of the TES.

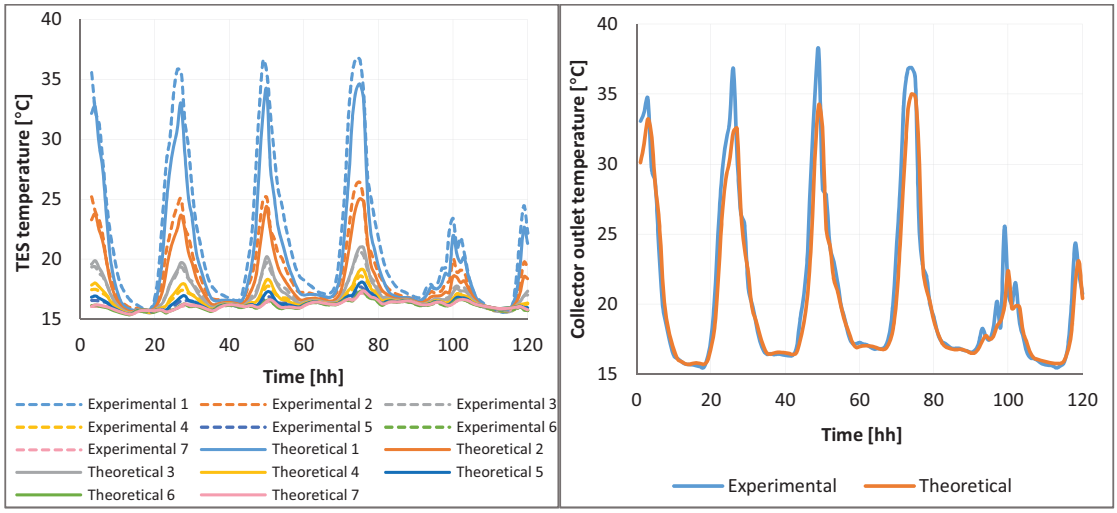

Fig. 6: Experimental vs simulation results. Left: Temperature at the outlet of the collector. Right: Temperatures of the 7 nodes of the TES tank.

The simulated trend of the collector outlet temperature followed the experimental results proving a good accuracy. Some small discrepancies were outlined only during peak loads of solar radiation and morning time. This was mainly due a difficult calibration of the solar radiation transmission coefficient of the solar collector glass cover as a function of the incidence angle. Indeed, this transmission coefficient strongly affected the panel performance, influencing the amount of the radiation effectively incident to the absorption plate of the collector. A delay affected the simulated results of the first hours of the day also concerning the TES temperature trends. This was influenced again by the uncertainties affecting the solar collector. Indeed, the outlet of the solar collector was the inlet of the TES. Eventually, a further discrepancy between real monitored data and simulation results was related to a temperature peak shift in the TES nodes farer from the TES inlet. Simulation results generally anticipated the real monitored data. This was due to some TES internal partitions that slowed down the HTF motion in the real tank and were not modelled in the lumped numerical model.

6. Conclusions

In the present paper a numerical model to describe the physical behaviour and the system dynamics of a complete PCS-based solar thermal system (collector, thermal energy storage and control logics) was presented. The HTF thermal properties were defined by means experimental laboratory tests whose results were herewith reported. Simulation performed by means of the numerical model resulted accurate enough to reproduce the real data gathered in-field during a monitoring campaign on a real scale prototype. Thus, the numerical model can be used in future works to perform comparative analyses to outline the possible benefits achievable by means of the proposed technology. Future works will also deal with additional experimental campaign aiming at adopting as HTF a PCS at different concentrations.

Abstract

SolCoSi (SOLar COllector Simulator) is a software program developed in order to determine the thermal performance of flat plate solar collectors used in solar water heating systems. SolCoSi can be used as a tool for design and optimize flat plate solar collectors, it enables an analysis of different materials and dimensions of the absorber, transparent covers, number of tubes, types and dimensions of insulation, selective surface, and different working conditions (mass flow rate, wind speed, solar radiation, etc.). The mathematic model consist in a two-dimensional arrange of nodes disposed in longitudinal and axial direction; in order to determine the temperature in each node, an energy balance was solved. As a result, SolCoSi predicts the thermal efficiency curves (lineal or quadratic), the incident angle modifier factor, the stagnation temperature (calculated for the particular case when the mass flow rate is near zero) and the temperature distribution in fluids and solids. The model developed is available as free online software in English and Spanish on the following website: http://solcosi.ier.unam.mx/

Keywords: Numerical model, flat plate solar collector, water heating, free software

1. Introduction

SolCoSi (SOLar COllector Simulator) is a software program developed by the Instituto de Energías Renovables – UNAM. This software can be used to predict the thermal efficiency curves (lineal or quadratic), the incident angle modifier factor, the stagnation temperature (considering as the outlet water temperature in the solar collector when the water mass flow rate is near zero) and the temperature distribution in fluids and solids of flat plate solar collectors used in water heating systems. In order to design new prototypes of solar collectors, it is necessary to modify the principal parameters of these equipment such as: materials and dimensions of the absorber, transparent cover, number of tubes, types and

doi:10.18086/swc.2017.31.13 Available at http://proceedings.ises.org

dimensions of insulation, selective surface, and its working conditions (mass flow rate, wind speed, solar radiation, etc.).

2. Mathematical model

2.1 Equation of energy balance

The model combines the multilayer method proposed by Cadafalch (2009) with a discretization also in the longitudinal axis proposed by García-Valladares and Velázquez (2009) in order to take into account the temperature profile along the risers. The discretization used for SolCoSi is shown in Fig. 1.

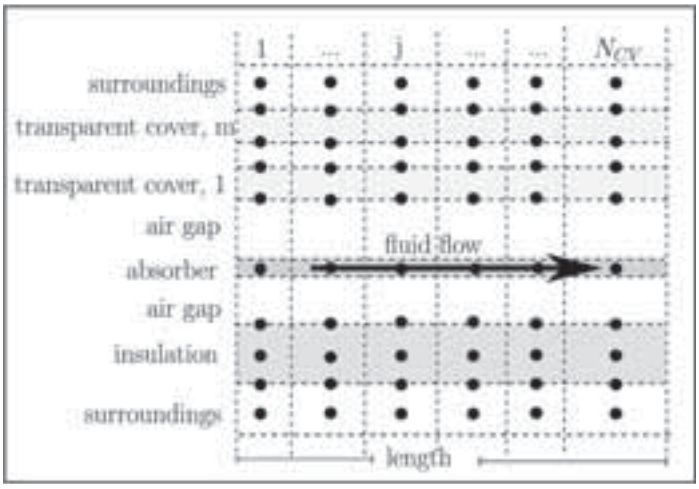

Fig. 1 Internal discretization of flat plate sola collector used for SolCoSi.

The eq. (1) shows the general form of the energy equation applied to each control volume. The model takes into account the following assumptions: steady state conditions, heat transfer in axial and longitudinal directions, the total water mass flow rate is divided into equals parts in each riser.

$$\left(Z_K + Z_{k-1} + Zs_j + Zs_{j-1}\right)T_{j,k} = Z_k T_{j,k+1} + Z_{k-1} T_{j,k-1} + \\ + Zs_j T_{j+1,k} + Zs_{j-1} T_{j-1,k} + q_{g,k} \qquad \text{(eq. 1)}$$

Where Z and Zs values correspond to heat transfer coefficients (conductive, radiative and convective) in each node in W/m^{2}K. The conductive and radiative coefficients are calculated with the Fourier and Boltzman's laws respectively using the thermophysical properties of the different materials. The convective coefficient are calculated using empirical correlations for each specific layer: (a) for the environmental heat transfer coefficient, the equations proposed by Duffie and Beckman (Duffie and Beckman, 2013); (b) for the fluid inside the tubes, the equation developed by Gnielinski (Gnielinski, 1979); and (c) for the air gaps between the back insulation and transparent cover the method suggested by Bejan (Bejan, 1993) are used respectively.

The $q_{g,k}$ term is the heat generation in W/m^2, $T_{j,k}$ is the temperature of the node analyzed and $T_{j,k-1}$, $T_{j,k+1}$, $T_{j+1,k}$ and $T_{j-1,k}$ are the temperatures of its neighbor nodes. The set of energy balance equation in each control volume is solved using the Tri-Diagonal Matrix Algorithm (TDMA) according to Patankar (Patankar, 1980). For more details see the following article (Pérez-Espinosa and García-Valladares, 2018).

3. Validation

In order to validate SolCoSi, a comparison with the experimental data of different commercial flat plate solar collectors (evaluated according to the international standard ISO-9806:2013 (2013) in different accredited solar laboratories around the world) has been carried out. A statistical analysis between the thermal efficiency curve predicted by SolCoSi (referred as the y−dependent variable) and the experimental thermal efficiency curve (defined as the x−independent variable) was used according to Verma and Santoyo (1997). In this statistical method, an ideal correlation is obtained when y=x; for this reason a ±3% error band was plotted in Fig. 2, this figure shows that 78.3% of the 23 numerical data points obtained were within and error band of ±3% and 95.7% were within and error band of ±5%. The mean deviation between experimental and numerical results was ±2.55%. With this analysis, a good agreement between numerical and experimental results has been observed. Appendix B shows the thermal efficiency data points of experimental and numerical results used in Fig. 2.

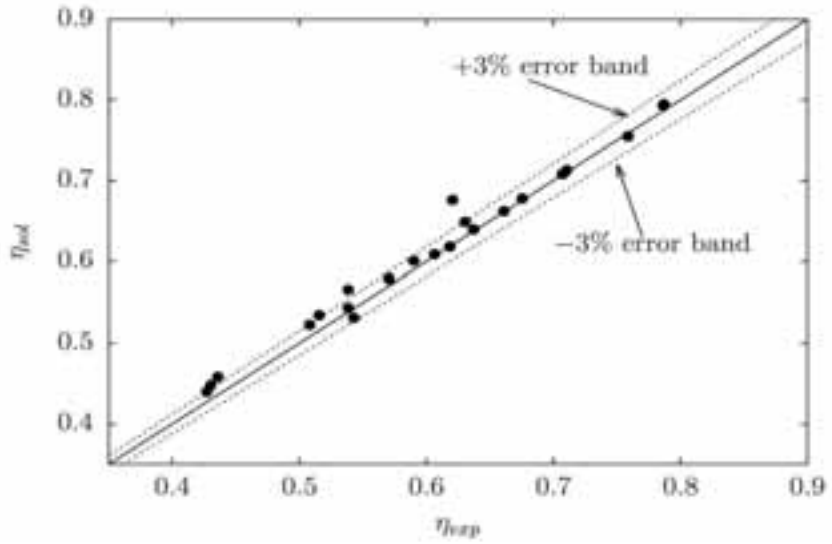

Fig. 2 Comparison of thermal efficiency between numerical and experimental data points.

4. Results

Once the SolCoSi was validated, the software was written in Java code and the program is now available in the website http://solcosi.ier.unam.mx with a visual interface and an English and Spanish versions. The result is a new software program named SolCoSi than can be used to evaluate the thermal performance of a flat plate solar collector: the thermal efficiency curve, the incident angle modifier and the stagnation temperature. These results can be download in a .pdf file as a report, the report includes: in the first section the principal values used in the simulation (values given by the user), after that it shows the linear and quadratic equations of the thermal efficiency (see Fig. 3); in the third section, it is shown the equation to determine the incidence angle modifier factor and the curve obtained with this equation (see Fig. 4); in the fourth section the stagnation temperature obtained by the simulation when the water mass flow rate is close to zero is shown. The main menu of the SolCoSi website is observed in Fig. 5.

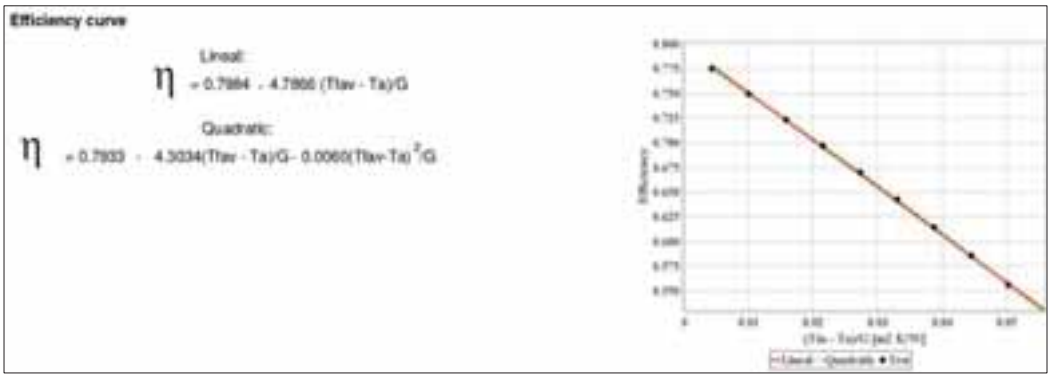

Fig. 3. Thermal efficiency equations and curves obtained by SolCoSi.

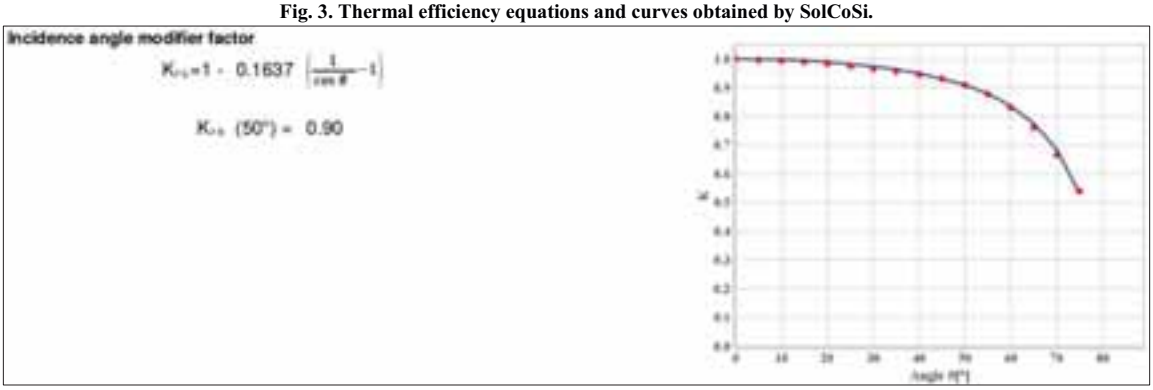

Fig. 4. Incidence angle modifier factor and its respective curve.

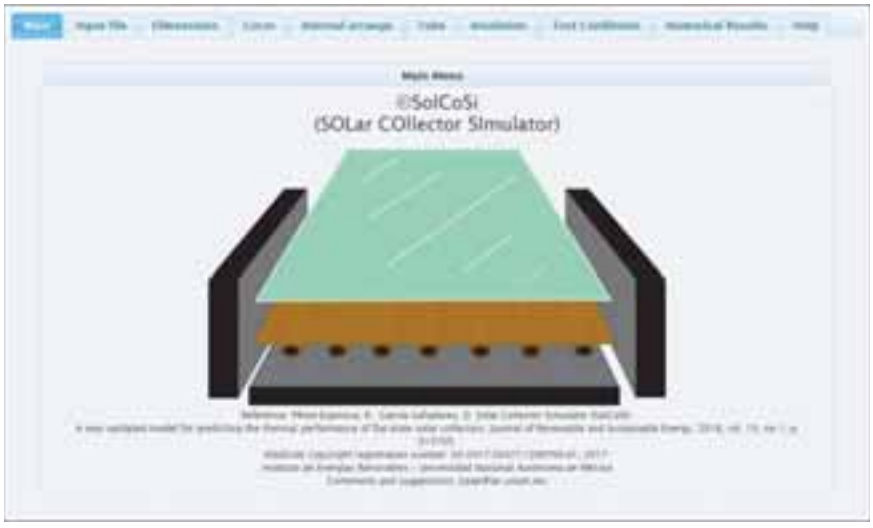

Fig. 5. Main menu of SolCoSi website.

5. Concluding remarks

A Solar Collector Simulator (SolCoSi) has been successfully developed. The model discretize the flat plate solar collector in the axial and longitudinal directions and it can be used to evaluate the thermal efficiency curve, the incident angle modifier factor, the stagnation temperature and the temperature distribution in fluid flow and solids.

SolCoSi was validated against a wide range of experimental data (70 experimental data points grouped in 23 groups) of different commercial flat plate solar collectors fabricated with different geometries, materials and working under different operating conditions; this

validation includes a comprehensive statistical analysis based on error bands. A good agreement between numerical and experimental results has been observed with a mean deviation of ±2.55%.

Abstract

In this article, a comprehensive optical analysis of a non-imaging elliptical hyperbolic concentrating collector has been carried out. This collector system has a wide acceptance angle so that it can be operated with no/minimum tracking based on the location of operation. Two types of receivers say flat and trapezoidal surface are considered and the flux distribution over these receivers are estimated and compared. It is found that maximum peak flux is intercepted by the trapezoidal surface receiver. The effect of concentrator geometrical parameters such as concentrator height (H_c) and concentration ratio (CR); receiver geometrical parameters such as aperture width (W_r) and receiver height (H_r) on optical performance of the collector has been studied. The optical efficiency varies between 5 – 15 % for the concentrators with height less than 1 m whose acceptance angle is about 60°, whereas for the concentrator height greater than 1m, the acceptance angle is ±45° and the optical efficiency varies between 20 – 30 % for incidence angles ±30°. The maximum flux incident on the trapezoidal surface is about 60585 W/m^2, however for flat surface, it is 40468 W/m^2. Based on the optical analysis, it can be seen that this system can be widely used for applications such as low and medium temperature applications and it requires less/no tracking with wider acceptance angle.

Keywords: Solar energy, non-imaging collector, hyperbolic concentrator, optical performance

1. Introduction

Non-imaging concentrators are widely used in low temperature solar process heating applications like water heating, air conditioning etc., For given concentration ratio, non-imaging systems provide wide acceptance angles for solar applications. Hence, these collectors require minimum or no tracking. A new type of non-imaging concentrator called elliptical hyperbolic concentrator has been developed which has wider acceptance angle and require less or no daily tracking and minor adjustment for seasonal tracking depending on the location of installation of collector. The use of hyperbolic concentrators were studied by Garcia-Botella et al. (2009). It has been concluded that the concentrators with hyperbolic profile have higher acceptance angle. Ali et al. (2009) compared the optical performance of 2-D and 3-D elliptical hyperbolic concentrator (EHC) and found that the optical efficiency of 2D and 3D system are 63% and 78% respectively. Ali et al.(2010) presented optical performance of 3D static circular and elliptical hyperboloids. Four different configurations of hyperboloids are studied based on the ray tracing techniques and flux distribution at the receiver aperture has been presented. A detailed parametric study on the elliptical hyperbolic concentrator has been performed by Ali et al.,(2013). Thermal analysis of concave cavity surface receiver of EHC was carried out by Reddy and Vikram (2015). In the present work, optical analysis of elliptical hyperbolic concentrator with two types of receivers are carried out and effect of various parameters such as concentrator height, concentration ratio, receiver height, receiver aperture on optical performance of the elliptical hyperbolic concentrator with trapezoidal/concave cavity surface receiver are studied.

2. Design of Elliptical Hyperbolic Concentrator

The elliptical hyperbolic concentrator is a non-imaging concentrator, which consists of a hyperbolic profile along the concentrator height with an elliptical aperture. This concentrator is the development of 3-D surface of revolution and falls under the category of family of surfaces called hyperboloid. The hyperboloidal surface considered in the present work is one-sheeted hyperboloid.

The equation of one-sheeted hyperboloid is given by (Gottwald, 2012):

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}-\frac{z^2}{c^2}=1 \qquad \text{(eq. 1)}$$

doi:10.18086/swc.2017.31.14 Available at http://proceedings.ises.org

The length of the major axis and minor axis at the top aperture of the concentrator is termed as 2A and 2B whereas at bottom aperture, it is termed as 2a and 2b respectively, and Hc being the height of the concentrator. The geometrical parameters of elliptical hyperbolic concentrator are shown in Fig. 1.

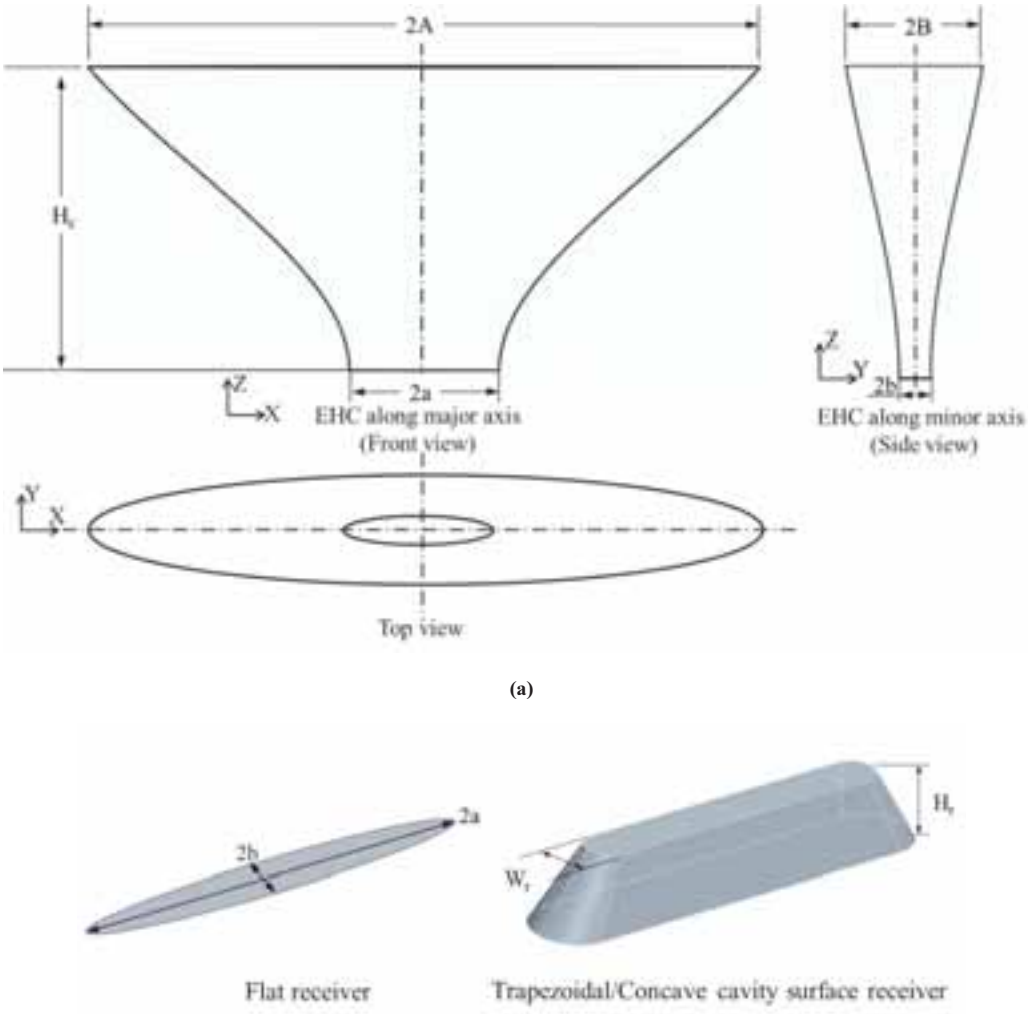

Fig. 1 (a) Elliptical hyperbolic concentrator and (b) receiver showing geometrical parameters

3. Modeling of Elliptical Hyperbolic Concentrator with receiver

The equation for hyperbolic profile is obtained by rewriting the Eq. (1) for two planes X-Z and Y-Z by substituting Y = 0 and X = 0.

For hyperbolic profile along X-Z plane (major axis side), substitute y = 0 and rewriting eq. (1) in terms of z, we get,

$$z_1 = c \times \sqrt{(x/a)^2 - 1} \qquad \text{(eq. 2)}$$

Similarly, for hyperbolic profile along Y-Z plane (minor axis side) is obtained by substituting x = 0 in Eq. (1), we get,

$$z_2 = c \times \sqrt{(y/b)^2 - 1} \qquad \text{(eq. 3)}$$

The equation for elliptical profile (at top and bottom aperture) is obtained by considering different values of z, ranging from 0 to H (height of the concentrator).

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 + \frac{z^2}{c^2} \qquad \text{(eq. 4)}$$

The ratio of semi major and semi minor axis (a/b) remains one of the important parameter in designing the elliptical hyperbolic concentrator. This ratio plays a role in deciding the shape of elliptic aperture. The value 1 corresponds to circular cross section of aperture, whereas 10 correspond to narrow elliptical cross section (i.e.,) lower major axis compared to minor axis. Hence a medium or average value of 5 is considered for the ratio of semi major and minor axis (a/b) in the present study. The ratio of height to aperture (H_c/a) plays a role in the amount of solar radiation entering the concentrator and reaching the receiver. An optimum ratio of H_c/a ratio is considered as 4 based on the previous studies by Ali et al., (2013). It can be seen that when the ratio of height to aperture is varied from 1 to 10, the effective concentration ratio increases or decreases depending on the incidence angle of the solar radiation. For incidence angles of 0 and 15°, the effective concentration ratio increases whereas, for 30° and 45°, the effective concentration ratio decreases beyond 4. It can be concluded that the optimum Hc/a ratio seems to be 4 and corresponding H_c/b ratio seems to be 20. The geometrical values of parameters considered for the design of elliptical hyperbolic concentrator are shown in Table 1. Based on the values provided in Table 1, the design of EHC is carried out by obtaining the equations for hyperbolic profiles along major and minor axis and elliptical apertures at bottom and top of the concentrator using Eq. (2) – (4).

Tab. 1: Geometrical specifications considered for design of EHC

Parameters	Values
Semi major axis at receiver aperture (a)	0.4 m
Ratio of semi-major to minor axis (a/b)	5
Height to aperture ratio (H_c/a)	4

The geometry of EHC is modelled using modeling software, AutoCAD 2012. The points for the profiles along the major and minor axis is calculated for different values of x and y. These coordinate points are generated and is used to model the geometry of the concentrator. The receiver converts the incident concentrated solar radiation into thermal energy with the help of fluid circulated through it. Hence the design of the receiver becomes necessary for its efficient conversion of solar radiation. The amount of solar radiation incident on the receiver depends on the concentrator and the receiver shape. In the present study, two different configurations of the receivers such as flat surface and trapezoidal surface are analyzed. The flat surface receiver has the dimensions same as the bottom aperture i.e., the shape of ellipse with major and minor axis dimensions equal to that of the bottom aperture of the concentrator. Fig. 2 shows the EHC system with receivers placed at bottom aperture of the concentrator.

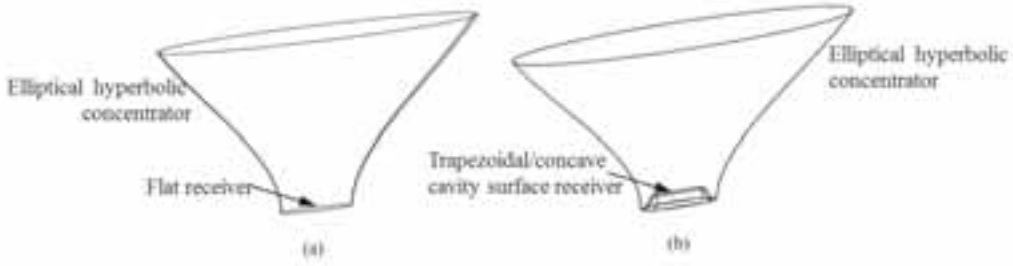

Fig. 2 EHC systems with receivers at bottom aperture (a) flat surface (b) trapezoidal surface

4. Optical ray tracing analysis

The optical ray tracing analysis is carried out to estimate the flux that is incident on the receiver and to calculate the optical efficiency of the system. ASAP (Advanced Systems Analysis Program) is an optical system-modelling software/tool based on Monte-Carlo ray tracing technique, which simulates the interaction of light with optical and mechanical structures (BRO, 2013). The geometrical model developed is imported to the ASAP software using suitable (iges or stp) format. After importing the model in ASAP, the system settings such as units, wavelengths are set. Then, the optical properties such as optical materials/coatings, refractive indices, reflectivity, and absorptivity are specified. Once the model is imported and the properties are defined, source is defined and appropriate number of rays for simulation is specified in the program. The source emitting the rays considered should have the properties of sun hence, subtended angle by the sun is specified while defining the source. After specifying the source, the ray tracing is carried out to concentrate the solar rays over the receiver through the concentrator. In the

present study, the reflectivity of the concentrator is considered as 0.94. This reflectivity corresponds to the reflectivity of Reflectech sheet (DiGarcia and Jorgenson, 2010) that is used over the concentrator. The ray tracing diagram for different incidence angles are shown in Fig. 3.

The optical efficiency is given by (Kalogirou, 2009):

$$\text{Optical efficiency},\eta_o = \frac{\text{Flux absorbed by the receiver}}{\text{Flux incident on the concentrator}} \quad \text{(eq. 5)}$$

$$= \frac{\sum_{i=1}^{N} I_i \rho_r^{\ m}}{I_o} \quad \text{(eq. 6)}$$

where, N and m corresponds to number of rays and number of reflections respectively.

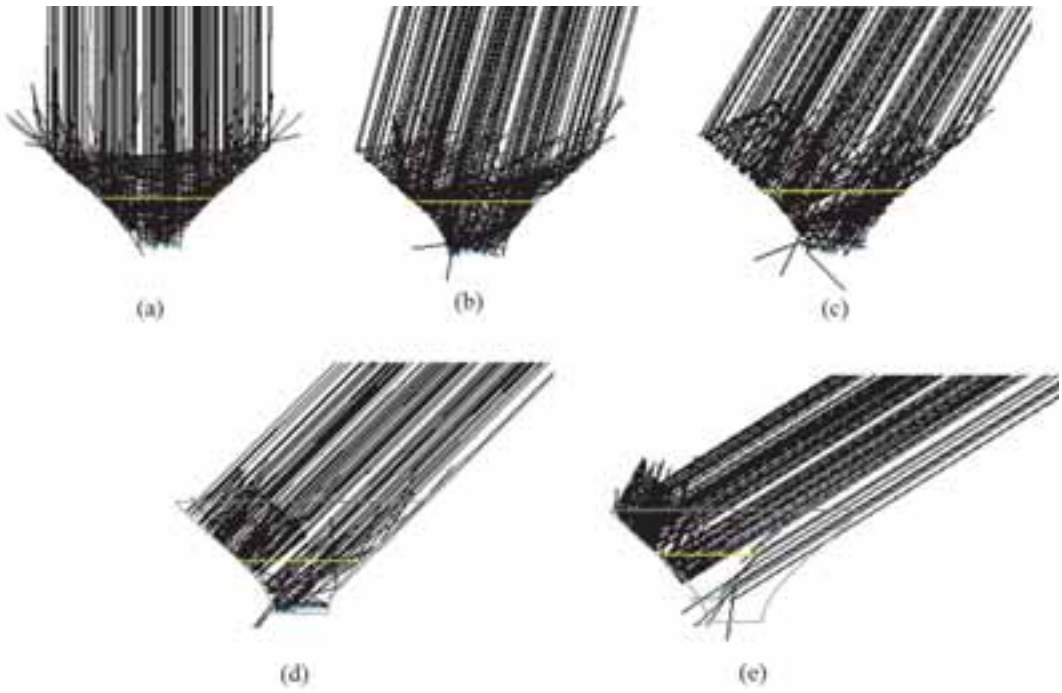

Fig.3 Ray tracing diagram for different incidence angles (a) 0º (b) 15º (c) 30º (d) 45º

The optical model/procedure needs to be validated to assure the correctness of the procedure that is followed. To validate the present optical model, the procedure is validated with optical analysis of two different geometries by Ali et al. (2010) and Abdullahi et al. (2013). Ali et al., (2013) carried out optical analysis of EHC system with flat receiver. The validation of present model with Ali et al. (2010) for Hc = 0.4 m, CR = 20, a/b = 5, a = 0.04 m was carried out. It can be seen that the variation of present model with the other model is minimum and found to have maximum deviation of 4.75%. Abdullahi et al. (2013) carried out optical ray tracing analysis of compound parabolic collector (CPC) with single and double receiver configurations. The geometry of CPC with single absorber of 11 mm radius is considered. It can be seen that the variation of optical efficiency with Abdullahi et al. (2013) is minimum.

5. Comparison of flat surface and trapezoidal surface receivers

The flux available at the bottom aperture of the elliptical hyperbolic concentrator is estimated and the receiver for EHC system has been designed based on the ray tracing analysis. The flux distribution on the receiver is important for conversion of incident solar radiation into useful heat. Hence, the receiver is designed as trapezoidal surface to intercept maximum amount of radiation that is entering the EHC system. The variation of optical efficiency for both flat and trapezoidal receiver surface is shown in Fig.4. The flux on a flat surface and trapezoidal surface for the solar incidence angle of 0° is shown in Fig.5. The optical efficiency of the flat and trapezoidal surface receiver is 27.3 % and 27.1% at normal incidence. The optical efficiency for the flat surface is slightly higher than the

trapezoidal surface at the maximum of 5 % at 30° incidence angle, however at other incidence angles, the variation of optical efficiency seems to be less than 5 %. This reduction of optical efficiency might be due to the geometry of the surface as the rays might miss the surface. Although the optical efficiency of the two receivers is close enough, the variation of flux incident on the receiver seems to be large.

The maximum flux incident on the trapezoidal surface is about 60585 W/m^2, however for flat surface, it is 40468 W/m^2. From Fig. 5, it can be seen that the maximum flux over the trapezoidal surface is 1.5 times higher than that of flat surface. An average flux of about 4236 W/m^2 and 4197 W/m^2 has been observed for trapezoidal surface and flat surface. The profile represented below and right side of the flux distribution corresponds to the flux along the centre line as indicated in the flux distribution diagram. Hence, using trapezoidal surface as receiver intercepts more flux than the flat surface. Hence, the trapezoidal surface receiver is considered for further analysis.

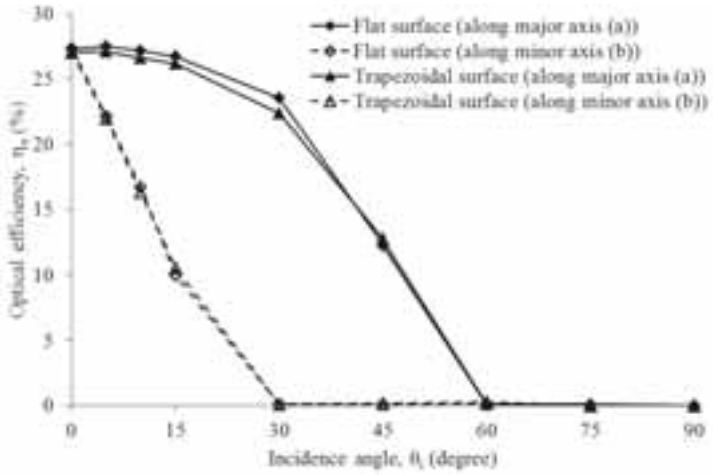

Fig. 4 Variation of optical efficiency for flat and trapezoidal surface receiver at normal incidence

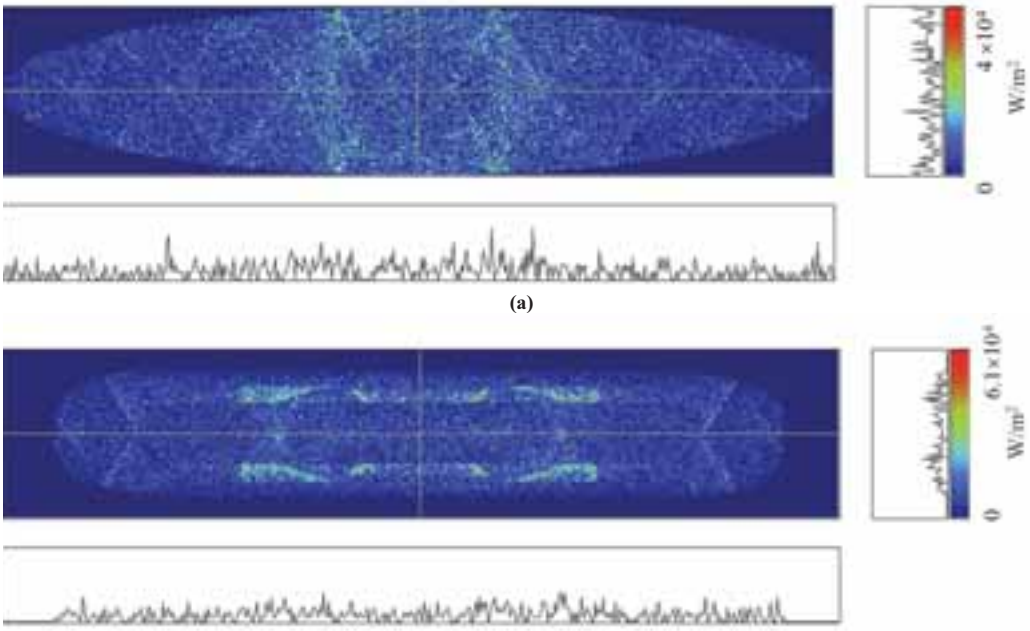

(a)

(b)

Fig. 5 Flux distribution over (a) flat surface and (b) trapezoidal surface receivers

6. Optical analysis of EHC

6.1 Effect of concentrator height

The variation of optical performance for different height of concentrator (H_c) ranging from 0.4 m to 2 m is studied. The effect of concentrator height for different incidence angles on optical efficiency is shown in Fig 6. The optical efficiency increases with increase in the height of the concentrator. The height of the concentrator decides the

acceptance angle of the concentrator. Higher the concentrator, lower will be acceptance angle depending on the aperture of EHC. When the concentrator height is less, for any ray to undergo multiple reflection is minimum. The optical efficiency is found to be maximum at normal incidence angle and varies for different incidence angles. The optical efficiency varies between 5 – 15 % for the concentrators with height less than 1 m whose acceptance angle is about 60°, whereas for the concentrator height greater than 1m, the acceptance angle is 45° and the optical efficiency varies between 20 – 30 % for incidence angles ± 30° and 5 – 20 % for another 15° variation in incidence angle.

The intensity of the flux incident on the receiver also depends on the concentrator height. As the concentrator height increases, the flux intensity increases. It can be observed that for the concentrator height of 0.4 m, the peak intensity of the flux incident on the receiver is 2.5×10^4 W/m^2, whereas for concentrator height of 2 m, peak intensity is 6.9×10^4 W/m^2 Fig. 7 shows the flux distribution over trapezoidal surface receiver at different incidence angles along major axis.

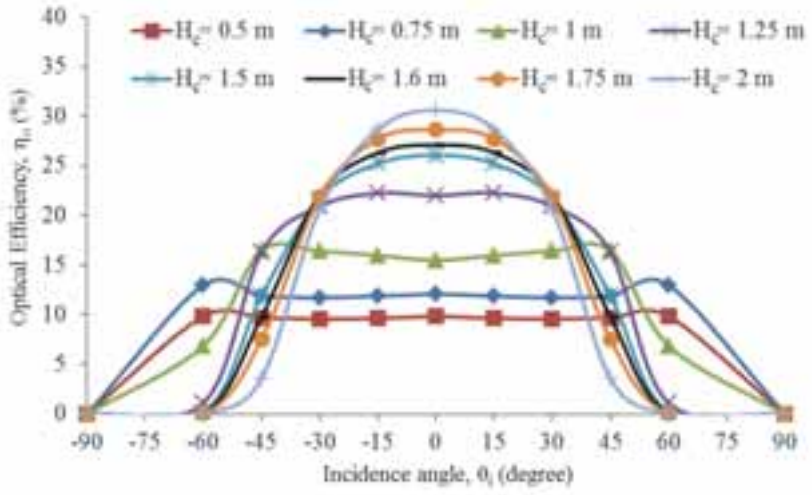

Fig. 6 Variation of optical efficiency for different concentrator heights

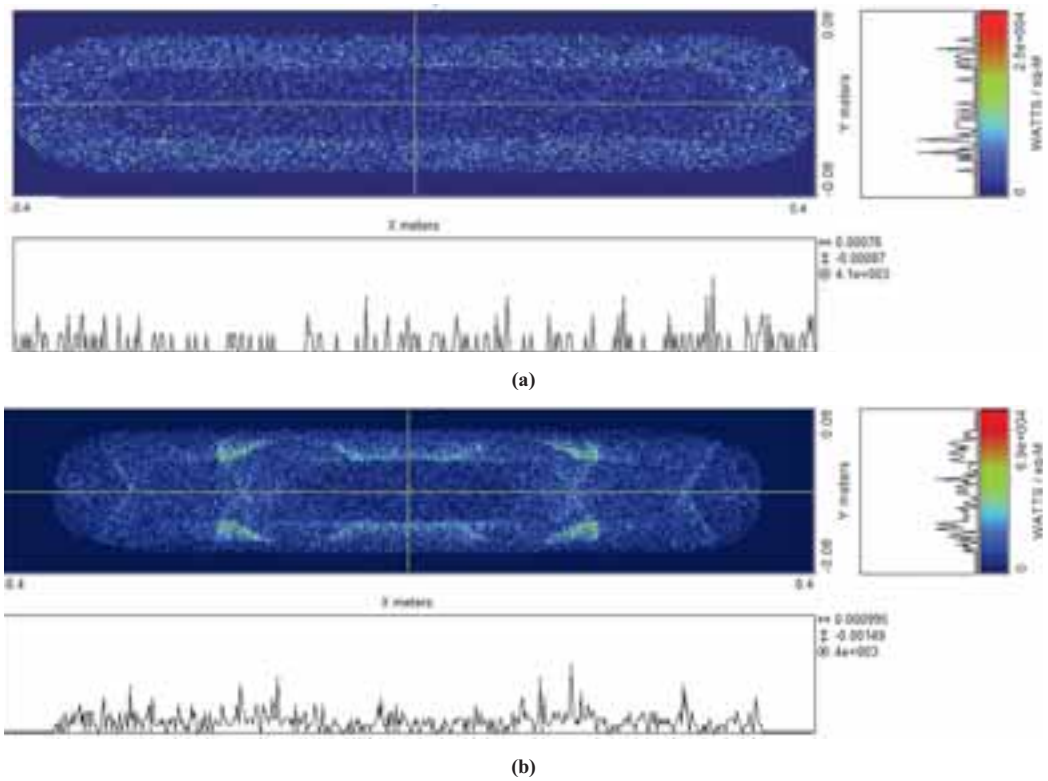

(a)

(b)

Fig. 7 Flux (2D) on receiver for two different heights of the concentrator (a) H_c = 0.4 m (b) H_c = 2 m

6.2 Effect of concentration ratio

The effect of concentration ratio (CR) of the EHC system is studied by varying from 5 to 30 in the steps of 5 by keeping H_c = 1.6 m. The aperture area at the bottom (receiver side) is kept constant and the aperture area at the top (entry of the concentrator) is varied to get different concentration ratio. The concentration ratio is defined as the ratio of aperture area of concentrator (A_{ap}) to that of aperture area of receiver (A_r). It is given by:

$$\mathrm{CR} = \frac{A_{ap}}{A_r} \qquad \text{(eq. 7)}$$

The effect of concentration ratio on optical efficiency is shown in Fig. 8. Lower the concentration ratio, higher the optical efficiency and it is peaked at normal incidence and drops drastically for other incidence angles. It can be seen that for CR of 5, the optical efficiency is 80% at normal incidence, however, at incidence angle of 15°, it reduces to 60%. Similarly for incidence angle of at 30° and 45° incidence angle, optical efficiency further reduces to 33% and 10% respectively. As the CR increases, optical efficiency reduces. It can be seen that for higher concentration ratios (CR = 20, 25 and 30), the variation of optical efficiency for incidence angles ranging between ± 45º do not vary much. This is due to fact that aperture area at top is wider and hence it accepts more amount of solar radiation for wide range of incidence angles. Variation in CR is the variation of the aperture area of the concentrator with respect to the aperture area at the bottom (receiver), which is kept constant. Higher concentration ratio ensures higher concentration of the solar radiation on the receiver but, the optical efficiency of the system decreases to very low say, about 10%, which is not a desirable factor for the design of the concentrator.

The variation of flux on the receiver for CR 5 and CR 30 is shown in Fig. 9. The maximum flux on the receiver for CR 5 is about 4.8×10^4 W/m^2, whereas, for CR 30, it is about 3.6×10^4 W/m^2. The maximum flux of CR 5 is higher than that of CR 30, because more number of rays are reflected towards the same location of the receiver from small surface area of concentrator in case of CR 5. But, in case of CR 30, the rays are reflected from wider surface area of concentrator. It can be seen that for CR of 5, more rays are incident on the left and right side surface of the receiver than on the top on the receiver.

But for CR 30, the flux is seen distributed over the entire surface of the receiver. Figure 10 shows the flux distribution over the concentrator surface for two different concentration ratios 5 and 30. The distribution of flux on the concentrator is more uniform for lower concentration ratio system than the higher concentration ratio system. It can be seen that the flux distribution over the concentrator for CR 30 is uneven and non-uniform showing peak flux at certain points on the concentrator. Hence, the aperture area of the concentrator plays a major role in deciding the flux incident on the receiver. The effect of the geometry of the concentrator on the optical performance of EHC have been discussed. It can be seen that the height of the concentrator plays a major role on the flux incident on the receiver and the acceptance angle of the solar rays. The aperture area of the concentrator (other words concentration ratio) is also important to which level the concentration of the solar rays on the receiver are desired.

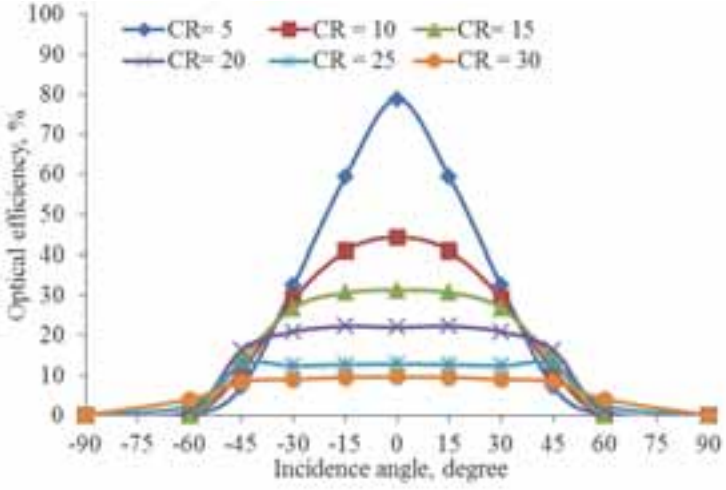

Fig. 8 Variation of optical efficiency with concentration ratio for different incidence angles

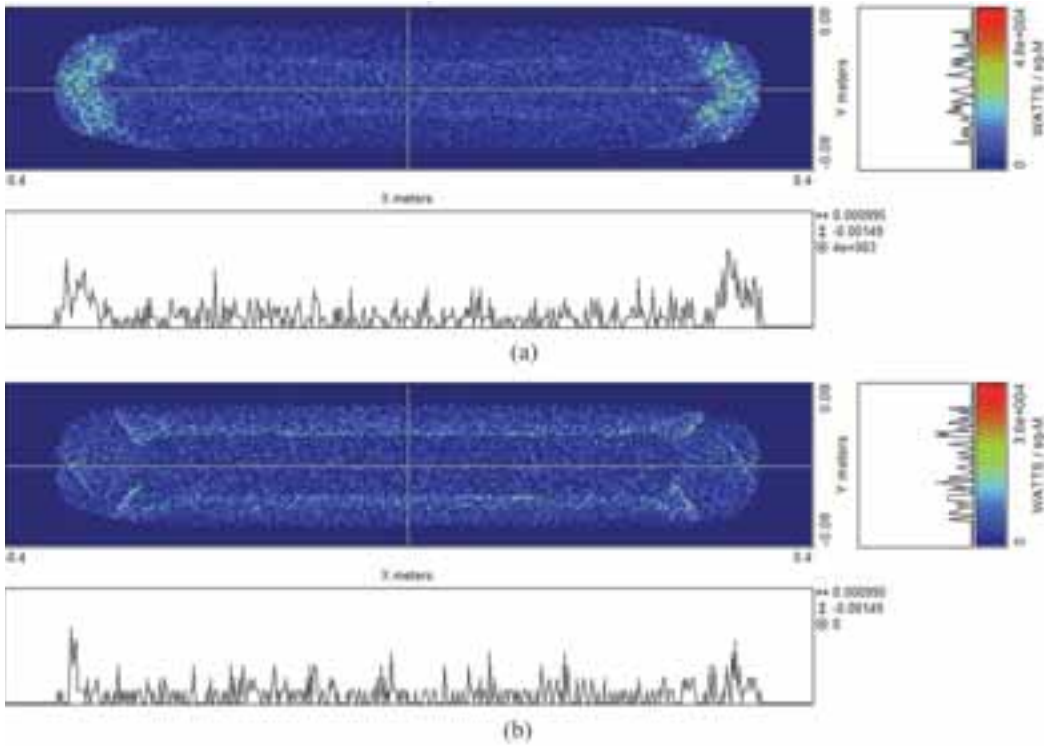

Fig. 9 Flux distribution (2-D) on the receiver for different concentration ratios (a) CR = 5 and (b) CR = 30

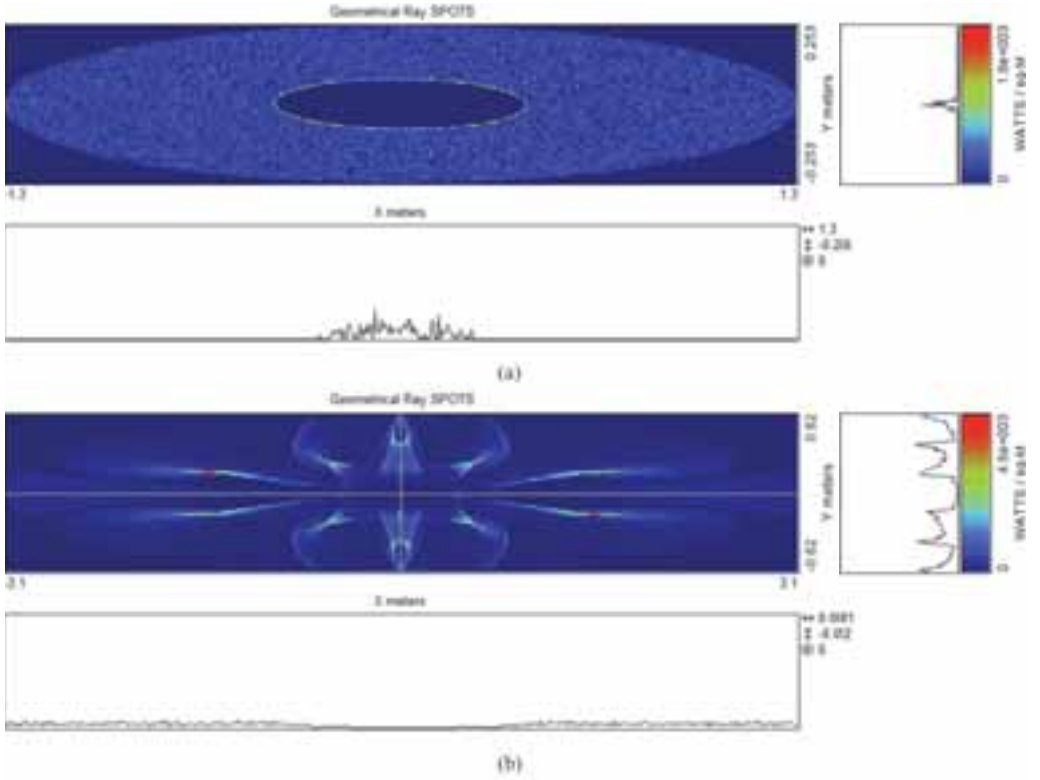

Fig. 10 Flux distribution (2-D) on the concentrator at different concentration ratios (a) CR = 5 and (b) CR = 30

6.3 Effect of receiver aperture

The effect of aperture width (W_r) of the top surface of the trapezoidal surface receiver of EHC on the optical performance is studied by keeping CR = 20 and H_r = 1.6 m. The different aperture width say, 30 mm, 45mm, 60mm, 90mm and 120 mm are studied. The variation of the optical efficiency of EHC for different aperture width is shown in Fig. 11. It can be seen that the variation of the optical efficiency for different aperture width is

negligible and it is found to vary around 22% for all aperture width considered. The flux distribution (2-D) on the receiver for different aperture width of 30 mm and 120 mm is shown in Fig. 12. When the receiver aperture width increases, the flux that is intercepted on the inclined surface is reduced, hence reducing the flux on the side surfaces of the receiver. Hence, it can be concluded that the effect of aperture width on the optical performance is negligible.

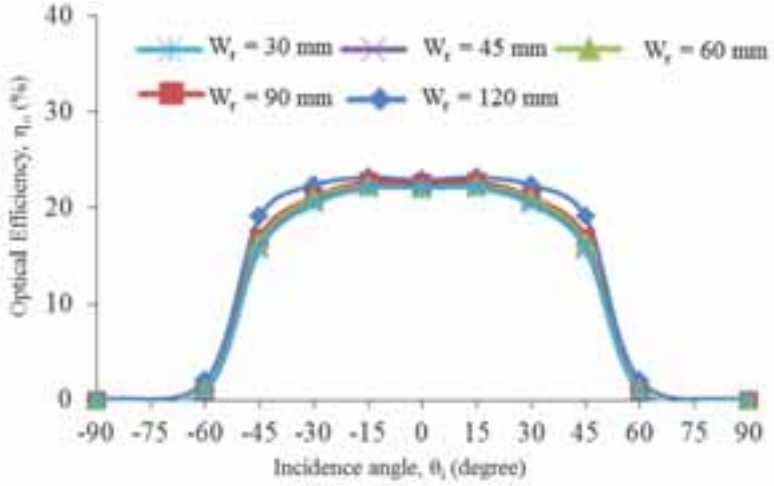

Fig. 11 Variation of optical efficiency for different aperture width

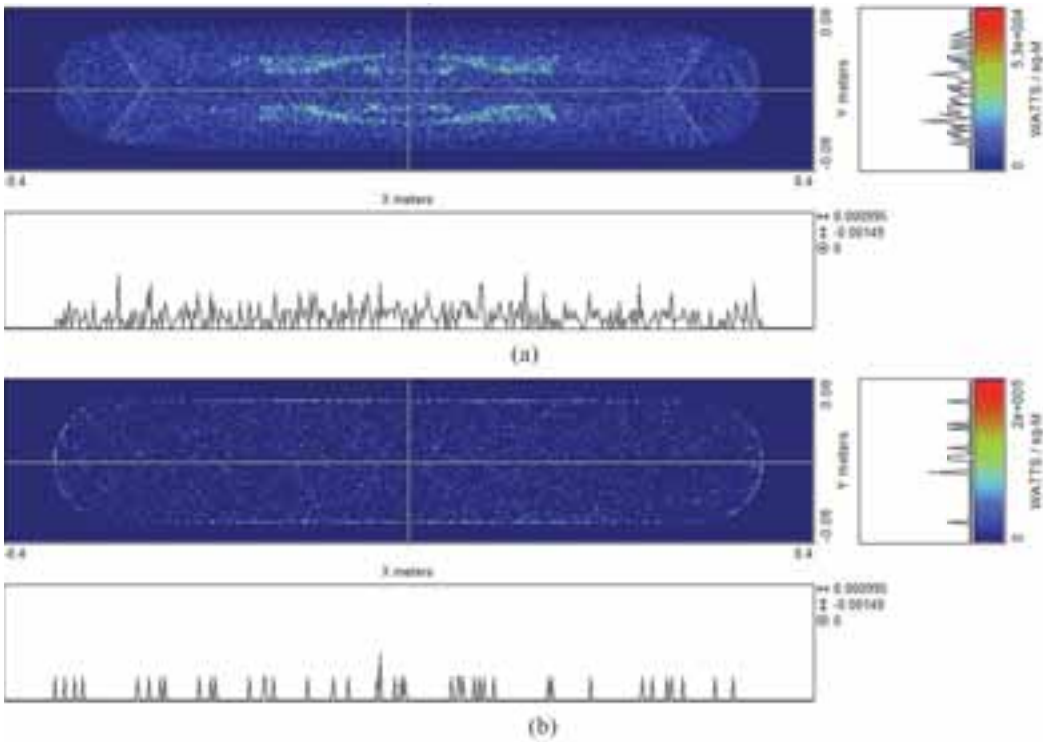

Fig. 12 Flux distribution on the receiver for different aperture width (a) 30 mm (b) 120 mm

6.4 *Effect of receiver height*

The effect of receiver height on the optical performance of EHC has been studied by varying the receiver height in four different values say 60, 90, 120 and 150 mm. Fig. 13 shows the variation of optical efficiency for different receiver height and it can be observed that the optical efficiency increases with receiver height. The flux variation on the receiver for different receiver height is shown in Fig. 14. It can be seen that, when the receiver height is varied, the amount of flux intercepted by the receiver is affected, consequently the optical efficiency of the system. It can be seen that the location of peak flux shifts from centre and moves outward when the height is increased. The variation of maximum flux on the receiver for different receiver height is found to be varying between 12kW/m^2 to 13 kW/m^2.

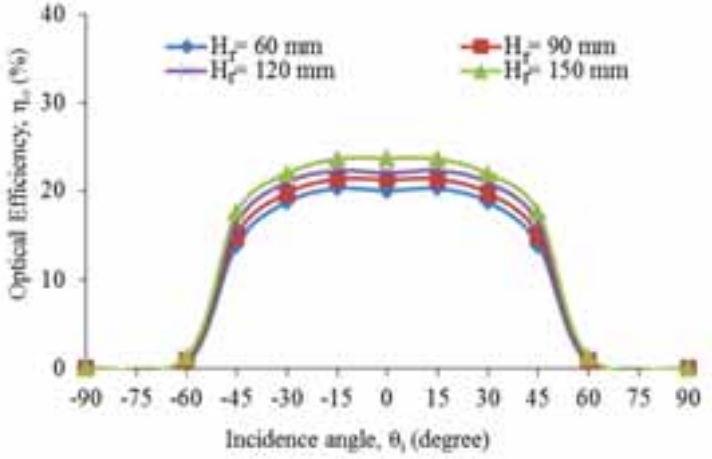

Fig. 13 Variation of optical efficiency for different receiver height

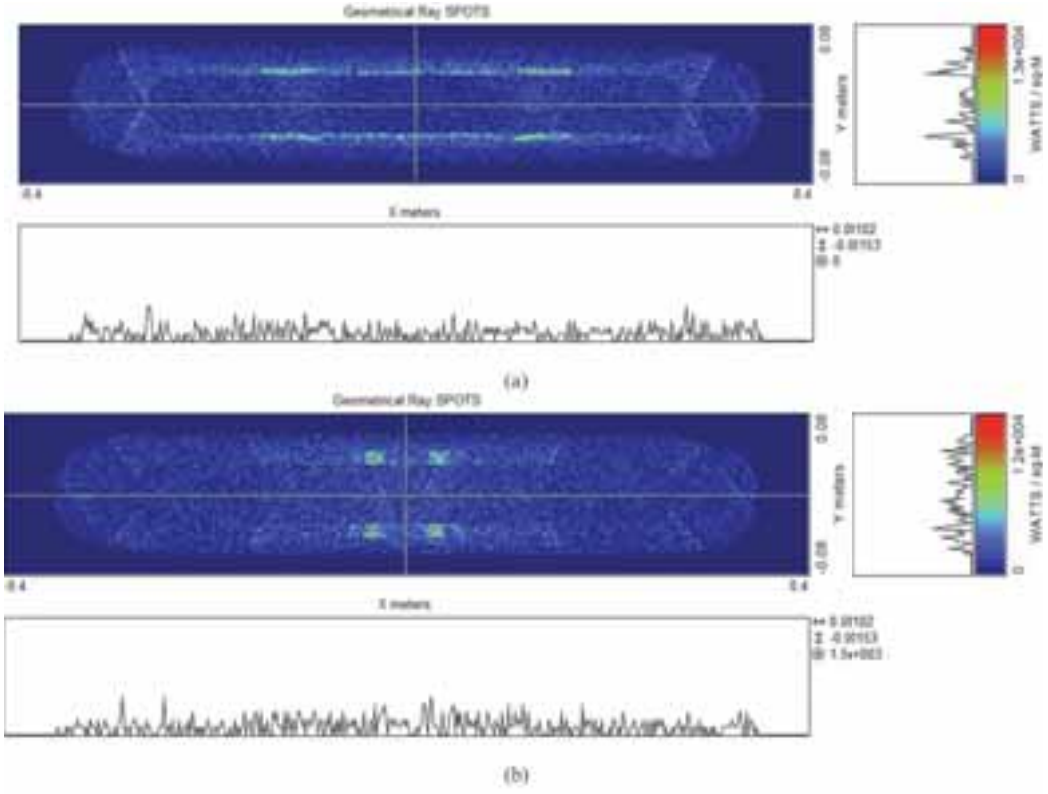

Fig. 14 Flux distribution on the receiver for different aperture width (a) 150 mm (b) 60 mm

7. Conclusion

The optical ray tracing analysis of a non-imaging concentrating collector with two types of receiver is studied. The effect of various parameters such as concentrator height, concentration ratio, receiver width and receiver height on optical performance of the system is studied. The flux distribution and optical performance of two types of receiver say flat receiver and trapezoidal surface receiver are compared and further based on the performance, trapezoidal receiver is considered for further analysis. The optical efficiency of the EHC system was found to be maximum at normal incidence and varies for different incidence angles. The optical efficiency varies between 5 – 15 % for the concentrators with height less than 1m whose acceptance angle is about ± 60º, whereas for concentrator height greater than 1m, acceptance angle is ± 45º and optical efficiency varies between 20 – 30 %. It can be observed that, for concentrator height of 0.4 m, peak flux intensity is 2.5×10^4 W/m^2 whereas for concentrator height of 2 m, it is 6.9×10^4 W/m^2. The effect of variation of CR is also studied. The effect of receiver aperture and height also play role in deciding the flux incident on the receiver. The effect of variation of receiver aperture width is negligible and it is found to vary around 22%. Similarly or variation of receiver height, flux incident varies between 12 –

13kW/m^2. This system can be effectively used for low and medium temperature applications based on the location with less/no tracking.

Abstract

A numerical study has been carried out to analyse the thermal performance of the receiver system of solar Linear Fresnel Reflector (LFR) module. Realistic flux conditions obtained by the optical analyses are applied as the boundary condition to the circumference of the absorber. Heat losses caused by convection as well as radiation from the parabolic secondary receiver are investigated under evacuated and non-evacuated annular region between the absorber and the glass tube. The investigation has been carried out to determine the heat loss by varying the annular gap between the absorber tube and the protective glass.

Keywords: Solar flux, variable flux distribution, evacuated, non-evacuated condition

1. Introduction

A progressive method observed is the Linear Fresnel reflector (LFR) technology to harness the solar energy for power and thermal needs of the society. An LFR system consists of the primary mirror strips in conjunction with the uniaxial tracking system, receiver system comprising a glass tube enclosing the absorber with a secondary reflector.The receiver system of solar Linear Fresnel Reflector (LFR) module plays a vital part in the conversion of the solar rays to thermal energy (Reddy and Kumar, 2014), (Singh et al., 2010)) and the schematic of the LFR is shown in Fig. 1(a).The present work has been carried out based on the study carried by peers on a wide range of collectors. Zou et al., 2017 comprehensively studied the optical performance of parabolic trough collector based on Monte Carlo Ray Tracing method (MCRT) and theoretical method. The angle span of each flux distribution region was derived theoretically, and the variations of those parameters with different geometrical configurations were displayed. Geometrical parameters such as aperture width, focal length and absorber diameter had a greater influence on the performance of the system. It was concluded that the absorber diameter had to be larger than the spot size of the reflected light cone on the absorber to avoid rays escaping which can cause great optical loss. Guadamud et al., 2015 modelled an LFR with a parallel modular object-oriented methodology which considered the elements of the receiver system namely the insulation material, glass cover, tube, pipe, etc. The global model is composed of 4 submodels -heat conduction, two/single-phase flow, thermal radiation and natural convection. It was found that the CFD&HT simulations using LES modelling allowed more realistic results. Chaitanya Prasad et al., 2017 used the variable aim lines for primary mirrors to defocus and spread the radiation flux in a more uniform manner over the absorber. Both the tilt angles and the radii of curvature of the individual Fresnel mirrors are modified to obtain a better flux uniformity. With the variable aim line concept high optical efficiency of 76.4% and a coefficient of flux variation value of 0.13 were obtained. On the other hand, 74.9% and 70.9% of optical efficiencies along with 0.17 and 0.33 values of coefficient of variation were obtained with compound parabolic concentrator and trapezoidal concentrator profiles respectively. Okafor et al., 2017, 2014 carried out a numerical study on the influence of circumferential uniform and non-uniform solar heat flux distributions on the internal and overall heat transfer coefficients of the absorber tubes of a linear Fresnel solar collector was investigated. A 3D steady-state numerical simulation was implemented based on ANSYS Fluent code version 14. The non-uniform solar heat flux distribution was modelled as a sinusoidal function of the concentrated solar heat flux incident on the circumference of the absorber tube. The k–e model was used to study the turbulent flow of the heat transfer fluid through the absorber tube. Hence it is clear that study of modelling and the heat loss analysis from the receiver system becomes crucial to determine the efficiency of the system. In the present heat loss analysis, circumferential non-uniform heat flux distribution on the outer wall of the absorber tube is considered. Investigation of non-

doi:10.18086/swc.2017.31.15 Available at http://proceedings.ises.org

uniform flux distribution around the absorber is the more practical way of analysis compared to the constant flux conditions carried out by the peers. In the present work the investigation is carried for two cases: First, the annular area between the absorber tube and the protective glass tube is considered to be in the non-evacuated state and secondly, in the evacuated state. Heat losses in the convection and radiation mode are analysed for different flux conditions.Investigation on the heat loss dependent on the annular gap between the absorber and the protective glass tube are studied. Initial work deals with the optical distribution of the flux and the distribution have been homogenised with the parabolic profiled secondary reflector (Balaji et al., 2016). The variable distribution around the absorber is shown in Fig. 1(b).

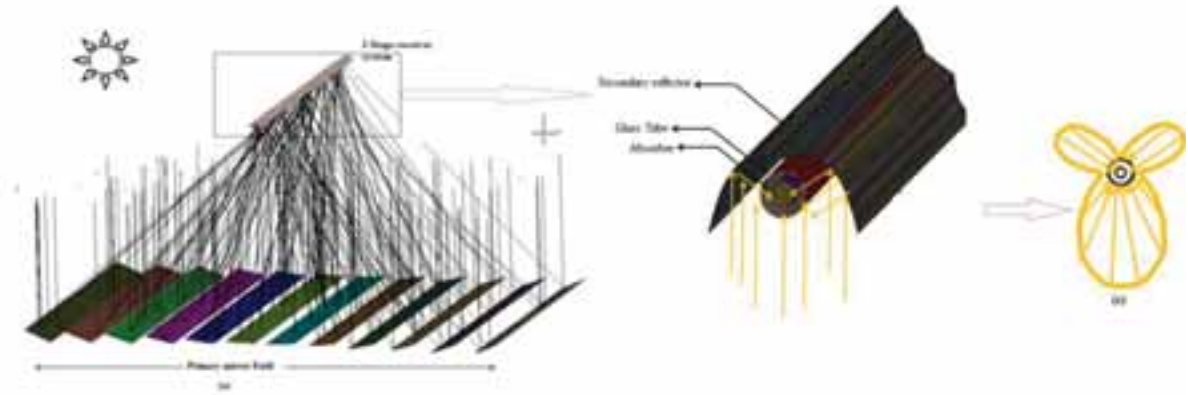

Fig. 1: (a) Schematic representation of Linear Fresnel Concentrator with secondary reflector (b) 2-Stage reflector system with solar ray (c) variable flux distribution around absorber

2. Description of LFR system

The Linear Fresnel Reflector/Concentrator(LFR) consists of an array of twelve long, parallel mirrors. The primary mirrors are tilted suitably and are equipped with one-dimensional tracking such that the solar rays from each mirror can be focused on one or more number of absorbers.An evacuated glass cover surrounds the absorber to prevent convective heat losses to the atmosphere. In the absence of the evacuated glass cover, the aperture opening of the secondary reflector covered by a glass pane. The absorber with the glass cover is mounted inside the secondary reflector module. Parameters of the pilot plant developed in Vallipuram (12.65N, 79.74E), Tamil Nadu, India is considered for the comprehensive study. The LFR system consists of a storage-integrated solar collector field of approximately 125 kWth capacity with the variable steam output (50 bar pressure and 350–400 °C temperature). Twelve primary reflectors with mild parabolic curvature are managed by a single axis tracking system. An absorber tube placed inside an evacuated glass cover for the reduction of convective heat losses is placed at the focal point of the primary reflectors. A selectively coated absorber tube for higher optical emissivity is used. A secondary reflector parabolic in profile surrounds both the absorber with the glass tube. In order to improvise the flux distribution along the circumference of the absorber thereby increase the concentration ratio, secondary reflectors are used. The second stage reflector maximizes the flux coverage area by re-reflecting the rays to the surface of the absorber. The 2 –stage reflector also ensures to enlarge the focused rays on the absorber thereby preventing the hot spots. Progressive analysis has been carried out to estimate the heat losses from the receiver system. Initially, the optical analysis is done to obtain an optimized flux along the circumference of the absorber and then the thermal study is performed.

3. Thermal Analysis

The thermal investigation is carried out for the receiver system comprising of the parabolic secondary reflector with an absorber tube placed in a glass tube. Optically optimised parameters from the earlier study namely the acceptance angle of the 2-stage reflector, truncation point on the reflector, the focal position of the absorber tube, the ratio of the gap between the reflector and the absorber to the height of the reflector are considered for the numerical study. The flux thus obtained from the optical analysis is applied as a user-defined function (UDF) in the form of a polynomial curve. The curve is a function of the angular position of the flux along the circumference of the absorber. The investigation is carried out with the different flux conditions and a parametric analysis is carried out to determine the heat loss for the different annular gap between the absorber and the glass tube. Laminar, steady state, 2D governing equations are solved in Fluent 14.5.The flow and thermal behaviours of the receiver system are considered under non-Boussinesq conditions.

3.1 Governing Equations

Flow and the heat transfer in the 2-stage reflectors are solved simultaneously by the mass, momentum and energy equations with Cartesian coordinates by Fluent Inc (2005). By the law of conservation of mass, the continuity equation is given by:

$$\frac{\partial(\rho_f u)}{\partial x} + \frac{\partial(\rho_f v)}{\partial y} = 0 \quad \text{(eq. 1)}$$

x- y Momentum equations:

$$\rho_f\left(u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y}\right) = -\frac{\partial P}{\partial x} + \frac{\partial}{\partial y}\left(\mu\frac{\partial u}{\partial y}\right) + \frac{\partial}{\partial x}\left(\mu\frac{\partial u}{\partial x}\right) \quad \text{(eq.2)}$$

$$\rho_f\left(u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y}\right) = -\frac{\partial P}{\partial x} + \frac{\partial}{\partial x}\left(\mu\frac{\partial v}{\partial y}\right) + \frac{\partial}{\partial y}\left(\mu\frac{\partial v}{\partial y}\right) + \rho g\beta(T-T_{ref}) \quad \text{(eq.3)}$$

Energy equation is solved by:

$$\rho_f C_p\left(u\frac{\partial T}{\partial x} + v\frac{\partial T}{\partial y}\right) = \frac{\partial}{\partial y}\left(k_f\frac{\partial T}{\partial y}\right) + \frac{\partial}{\partial x}\left(k_f\frac{\partial T}{\partial x}\right) \quad \text{(eq.4)}$$

where u,v represents the velocity components in x and y-direction respectively,ρ is the density of the air inside the cavity in kg/m^3, P is the pressure in N/m^2,k_f represents the thermal conductivity of the fluid in W/mK.

Surface-to-Surface (S2S) radiation model is used to model the radiation heat transfer of the secondary reflector system. This model helps to assume the receiver system in an air enclosed domain to be a non-participating medium by ignoring the emission and the scattering effects. The incident flux from the surface comprises of two components, the emitted flux and the reflected flux. Both the components of flux together constitute the radiosity (J_i) of the surface. The radiated flux depends on the flux falling on the surface from the surrounding and it is given by (Siegel, R., Howell, 2002) as

$$q_{out,i} = \varepsilon_i \sigma T_i^4 + (1-\varepsilon_i) q_{in,i} \quad \text{(eq.5)}$$

Interception by the two surfaces by radiation is defined as view factor F_{ij} that is independent on the surface properties and temperature. Hence the incident flux is given by.

$$A_i q_{in,i} = \sum_{j=1}^{N} A_j q_{out,j} F_{ji} \quad \text{(eq.6)}$$

Based on the reciprocity theorem

$$A_j F_{ji} = A_i F_{ij} \quad \text{(eq.7)}$$

Replacing (7) in (6),

$$q_{in,i} = \sum_{j=1}^{N} q_{out,j} F_{ji} \quad \text{(eq.8)}$$

$$q_{out,i} = \varepsilon_i \sigma T_i^4 + (1-\varepsilon_i) \sum_{j=1}^{N} F_{ij} q_{out,j} \quad \text{(eq.9)}$$

The sum of the reflected and the emitted fluxes, radiosity J_i is defined as the total radiation energy leaving a surface per unit time and per unit area. Hence

$$E_i = J_i - (1-\varepsilon_i) \sum_{j=1}^{N} F_{ij} J_j \quad \text{where } E_i = \varepsilon_i \sigma T_i^4 \quad \text{(eq.10)}$$

$E_i = \sum_{j=1}^{N} (\delta_{ij} - (1-\varepsilon_i) F_{ij}) J_i$ where δ_{ij} is the kronector delta given by $\delta_{ij} = \begin{cases} 1 \; when \; i = j \\ 0 \; when \; i \neq j \end{cases}$

Hence the radiosity expression is given by $E = KJ$ where K is a $N \times N$ matrix of the form

$$K = (\delta_{ij} - (1-\varepsilon_i) F_{ij)} \quad \text{(eq.11)}$$

In the above equations, J is the radiosity vector and E is the emissive power vector.

3.2. Boundary conditions

The 2-stage receiver system under study is an open aperture system and all the modes of heat transfer conduction, convection and radiation re influenced by the atmospheric condition. Hence the simulation is carried out by enclosing the receiver system in a domain property is simulated with the ambient conditions of temperature and pressure. The inlet of the domain is provided with pressure inlet boundary condition and the outlet of the domain is pressure outlet conditions, while the sides of the domain are pressure inlet conditions. The absorber tube is exposed to the flux reflected by the primary mirrors and the flux re-reflected by the secondary reflectors. Hence the non-uniform flux obtained from the optical study is imbibed as the boundary condition. The non-uniform flux is applied as the user-defined function. The absorber is coated with sputtered cermet of emissivity 0.075.The coupled condition is provided as a boundary value for the glass tube with the transmissivity of 0.95.Figure 2 shows the boundary condition of the 2-stage secondary reflector.

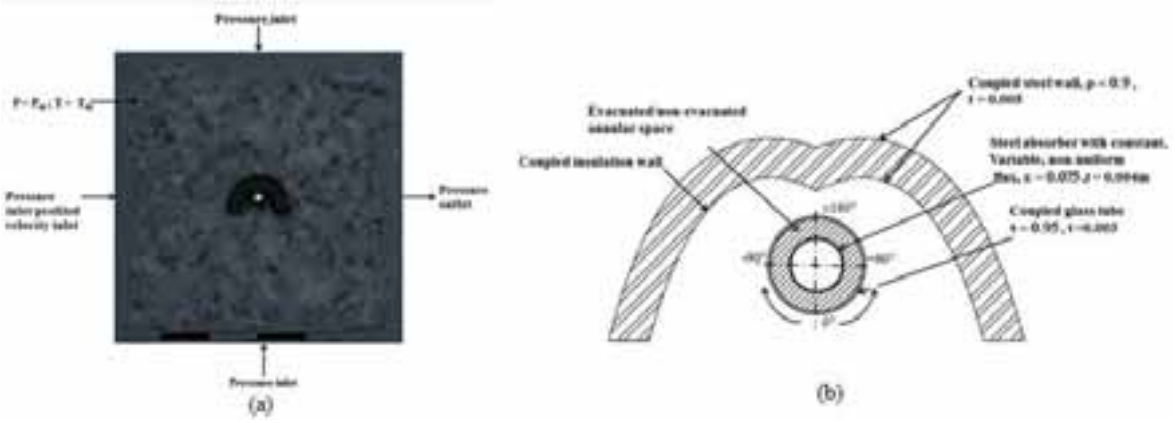

Fig. 2: Boundary condition of domain with 2-stage reflector of Linear Fresnel Concentrator (b) Boundary condition of 2-Stage reflector system

3.3. Boundary conditions

The size of the simulated domain is crucial since the heat loss output is dependent on it. Hence simulation is optimised by varying the inlet, side wall and the output length of the domain. Optimised domain size is assessed to be about 20D from the absorber on all the four sides. Skewness–Neighbor coupling of PSO algorithm is adopted with the convergence criterion of 10^{-6} on the residuals of the continuity equation and momentum equation. Deviation observed for the grid size with elements 8, 56,178 is appreciable to proceed the simulation. Validation of the present work was done with the work carried on by Reddy and Kumar, 2014; Sahoo et al., 2012 and the deviation in the results were found to be less than 10% which is acceptable.

4. Results and Discussion

A parametric study has been carried out based on the direct normal irradiance (DNI) and the annular gap between the absorber and the protective glass. The annular gap is non-dimensionalized by considering the ratio of the diameter of the absorber and the diameter of the protective glass. The study has been carried out for two different conditions of the annular gap: one, when the annular gap is filled with air as the residual gas and second, considering vacuum in the annular region.

4.1 Effect of DNI on the heat loss from the 2-stage receiver system

Temperature contours of the parabolic secondary reflector for DNI for 750W/m^2 and 1000W/m^2 for non-evacuated and evacuated annular region are shown in Fig.3.It is observed that because of the presence of air in the annular space between the absorber tube and the protective glass tube, buoyancy effect exist in the annular space. The hot wave in the annular space move upwards and the heat transfer occurs to the entire cavity region. Plume formation apparently illustrates the heat loss to the atmosphere. Whereas when the annular region is evacuated, the heat transfer from the upper portion of the absorber spread out symmetrically on both sides of the absorber within the cavity region. As the DNI increases the temperature increases and the hot wave distributes throughout the cavity and heat losses from the aperture opening.

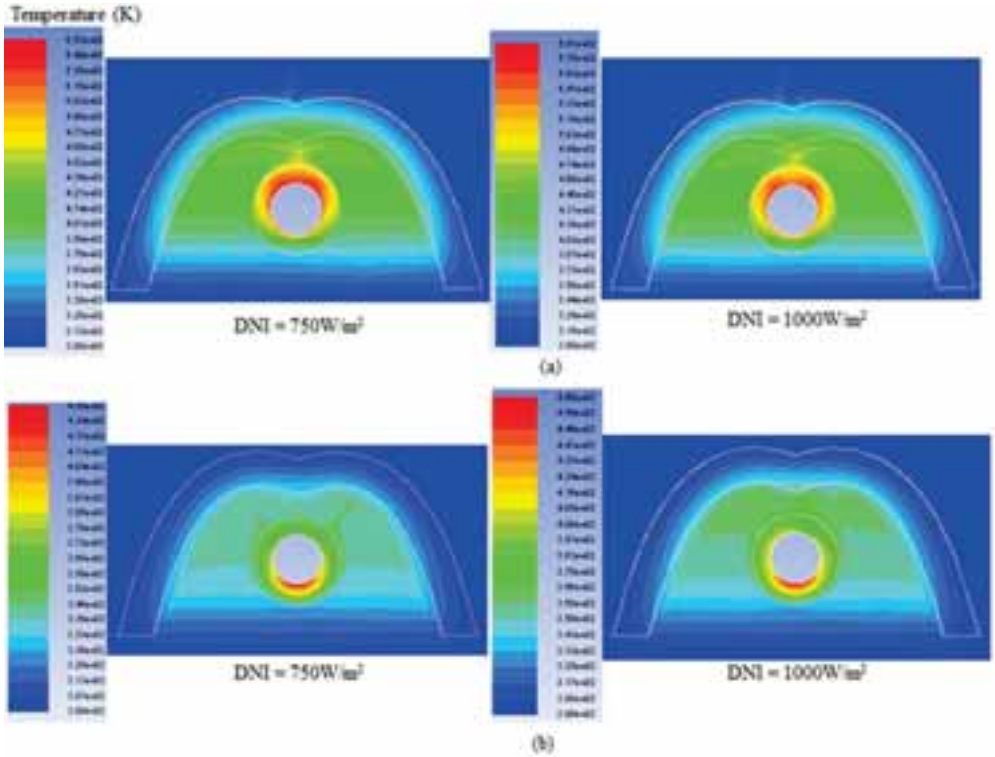

Fig. 3: Temperature contours of PB secondary reflector for different non-uniform flux distribution around the absorber tube with (a) non-evacuated annular (b) evacuated annular region

Figure 4 shows the total heat loss from the receiver system for the DNI ranging from 250W/m^2 to 1000W/m^2.under the non- evacuated condition i.e., when the annular gap is filled with air, the heat loss varies from 47.14W/m to 172 W/m for 250W/m^2 to 1000W/m^2 respectively .When the annular region is evacuated, the percentage of heat loss is reduced from 16% to 70%.It is observed that at lower DNI, the percentage of deviation is less compared to that at higher DNI.As expected, as the DNI increases, the percentage of heat loss also increases.

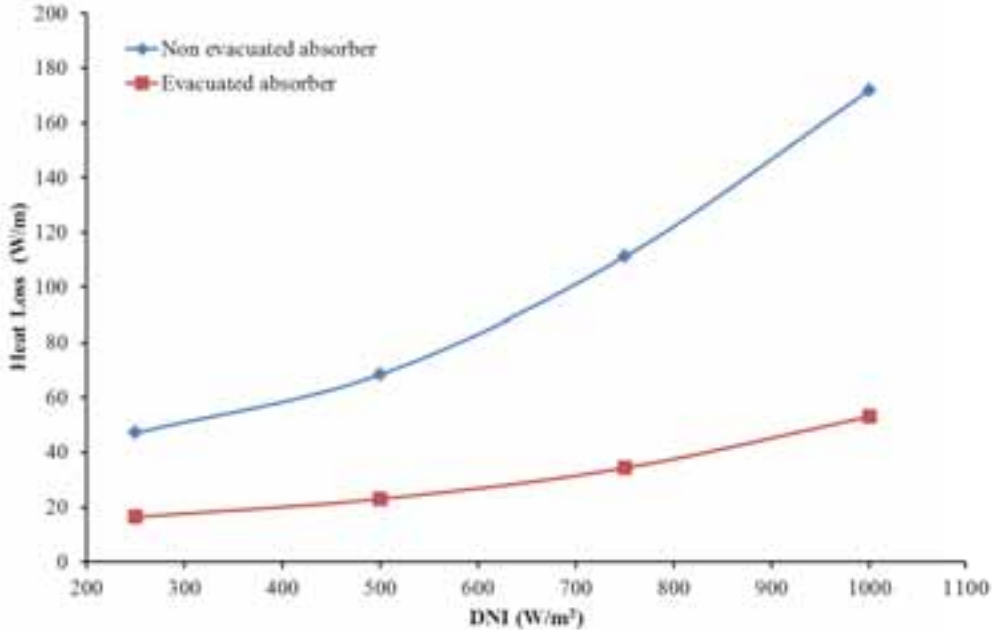

Fig. 4: Total heat loss for different DNI from the 2-stage receiver system

Figure 5 shows the convective and radiative heat losses for DNI ranging from 250W/m^2 to 1000W/m^2 for evacuated and non-evacuated annular region between the absorber and the glass tube. It is observed that the convection heat loss gets reduced by 40% under evacuated condition. Percentage of radiation heat loss varies between 28% and 57.5% from lower to higher flux conditions

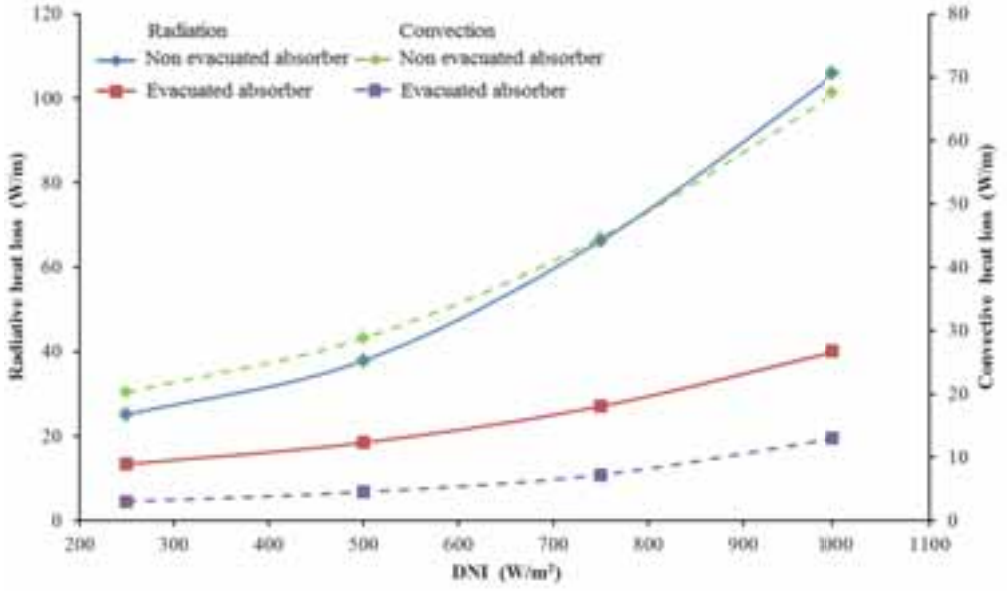

Fig. 5: Radiative and convective heat losses for different DNI

The individual components of heat loss, the radiative and the convective heat losses are studied. It is perceived that as the annular region is evacuated, the convective mode of heat transfer is minimized to a negligible amount and is shown in Fig. 5.When the residual gas in the gap is filled with air, the convective heat loss lies in the range of 30W/m to 100W/m for 250W/m^2 to 1000W/m^2. When the tube is evacuated, the convective heat loss reduces from 3W/m to 15W/m while the radiative loss is about 13W/m to 40W/m. It is obvious that as the tube is evacuated, the convective component of the heat loss is completely negligible.

4.2. Effect of gap between the absorber and the glass tube on the heat loss

Non-dimensionalization of the annular distance between the absorber and the glass tube is carried out by considering the ratio of the diameter of the absorber to the diameter of the protective glass.Total and the individual

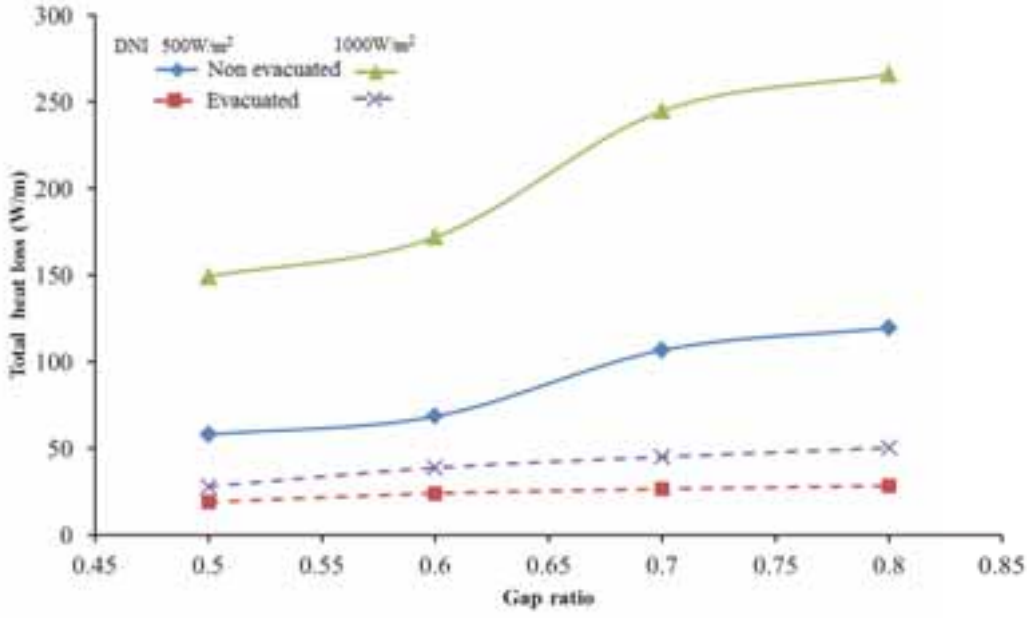

Fig. 6: Total heat losses for gap ratio between the absorber and the glass tube

components of heat transfer are studied.Variation in the heat loss for DNI of 500W/m^2 and 1000W/m^2 are investigated for both the evacuated and the non-evacuated conditions.Based on the commercial availability of SS absorber tube, the diameter of the absorber tube and the protective glass tube for the present study is chosen.Without compromising the diameter with the performance of the receiver system, it is observed from Fig. 6 that, the ratio of 0.6 has better performance and optimized annular region for less heat loss. When the tube is evacuated, the heat loss is observed to be constant for the range of gap ratio.The convective and the radiative heat loss components for the gap ratio between 0.5 and 0.8 for DNI of 500W/m^2 and 1000W/m^2 are shown in fig.7 and fig. 8 respectively. When the tube is non-evacuated both the

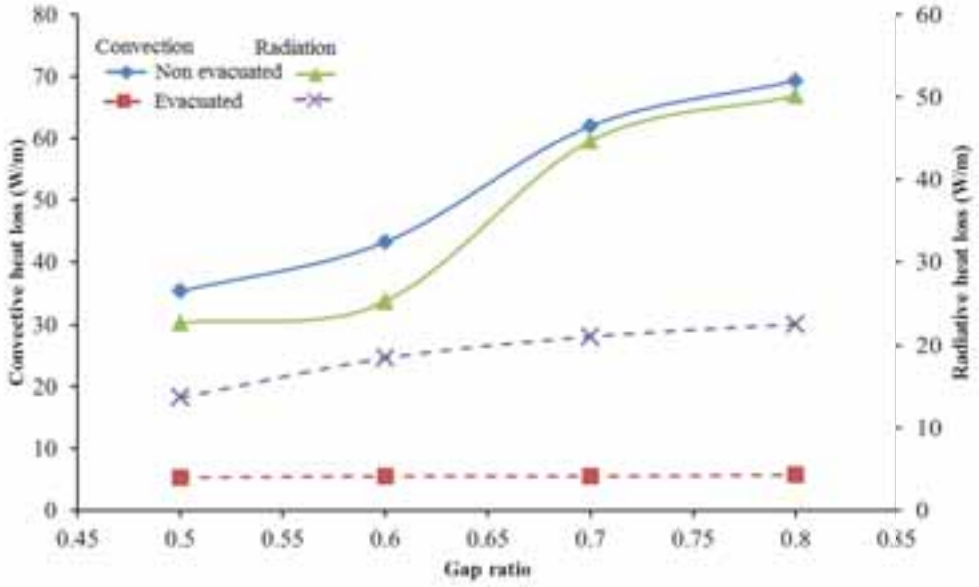

Fig. 7: Convective and radiative heat losses for different ratio of gap between the absorber and the glass tube for DNI of 500W/m^2

convective and the radiative components equally play a role in the heat loss. From Fig. 7, gap ratio of 0.5 to 0.6, heat loss of 35W/m and 22W/m on convective and radiative mode were observed. While at a higher ratio, convection and radiation heat loss exceed till 69W/m and 50W/m respectively. When the tube has vacuum, radiation component increases from 13.67W/m to 22.6W/m for the gap ratio from 0.5 to 0.8.

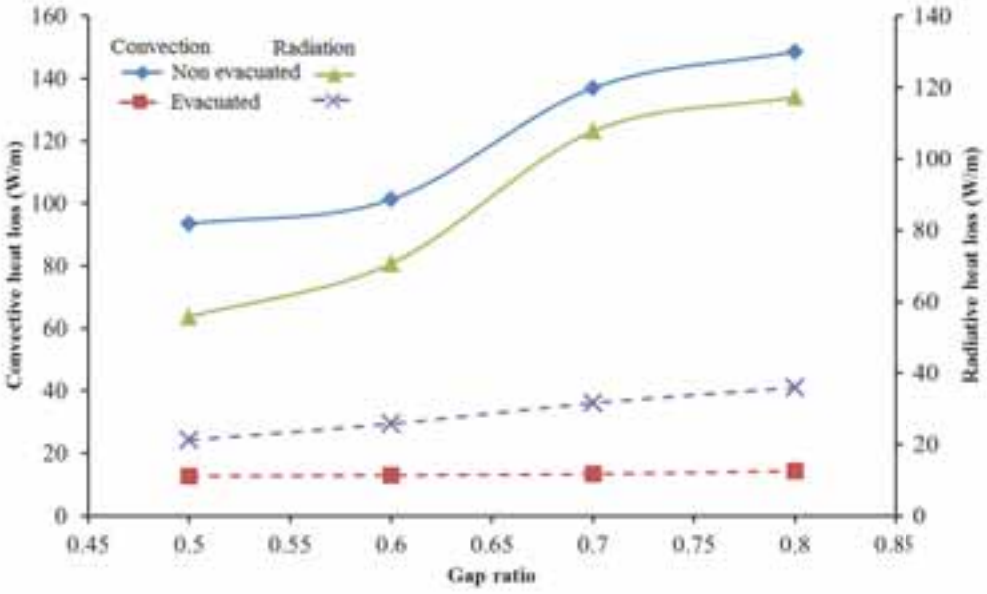

Fig. 8: Convective and radiative heat losses for different ratio of gap between the absorber and the glass tube for DNI of 1000W/m^2

The convective heat loss is at a constant level for different gap ratio.In Fig. 8, similar trend as of Fig. 7 is perceived.The convection and the radiation heat losses from the non-evacuated receiver increases by 57.5% and 58.5% and for evacuated conditions 36% and 59% respectively as the DNI increases from 500W/m^2 to 1000W/m^2 for the range of gap ratio.

5. Conclusion

A numerical study has been carried out to determine the heat loss from the 2-stage receiver system of the pilot plant in Vallipuram (12.65N, 79.74E), Tamil Nadu, India. Comprehensive analyses have been carried out to optimize the profile of the receiver system and then the thermal performance has been carried out. In the present work, the 2-stage receiver system is investigated when the absorber is under evacuated and non-evacuated conditions. A parametric study has been carried out by varying the DNI and the annular gap between the absorber and the protective glass. When the gap is filled with air, the heat loss varies from 47.14W/m to 172 W/m for 250W/m^2 to 1000W/m^2 respectively and when the region is evacuated, the percentage of heat loss is reduced from 16% to 70%. The convection and the radiation heat losses from the non-evacuated receiver increases by 57.5% and 58.5% and for evacuated conditions 36% and 59% respectively as the DNI increases from 500W/m^2 to 1000W/m^2 for the range of gap ratio.

Experimental evaluation of evacuated tube collectors with heat pipes to avoid stagnation loads in a domestic hot water system

Bert Schiebler, Finn Weiland, Federico Giovannetti

Institut für Solarenergieforschung Hameln (ISFH), Am Ohrberg 1, 31860 Emmerthal (Germany)

Abstract

Heat pipes in solar thermal collectors can reduce thermal loads in the solar circuit by using the physical effect of dry out limitation. By avoiding high temperatures and vapor formation, simplified, more reliable and cost effective solar thermal systems can be designed. The paper investigates a newly developed evacuated tube collector based on optimized heat pipes able to limit the temperature loads at the manifold up to a desired value. On the basis of efficiency measurements on a prototype heat pipe collector, we determine the annual yield of a collector field in a domestic hot water system compared to an identical system with direct flow collector according to ISO 9459-5. The results are validated by simulations with TRNSYS and show no significant difference between the performances of the two systems. By means of extensive outdoor stagnation tests on the same fields, we report a maximum temperature of 125 °C in the solar circuit of the heat pipe system, which is 95 K lower compared to temperature measured in the reference system.

Keywords: heat pipe, stagnation temperature, overheating protection, evacuated tube collector, dynamic system testing

1. Introduction

Heat pipes in solar thermal collectors are state-of-the-art devices for the heat transfer from the absorber plate to the solar circuit. In comparison to direct flow collectors the heat pipe represents an additional thermal resistance in the heat flow path. Therefore, a high thermal performance of the heat pipes is essential to achieve a high collector efficiency. Beside the simplified collector hydraulic the use of heat pipes provides the advantage of decoupling the absorber plate from the fluid circuit. If the two-phase flow inside the heat pipe is suppressed beginning from a certain temperature, no more heat is transferred from the absorber plate to the manifold. By taking advantage of this physical effect, which is called the dry-out limit of heat pipes, the maximum temperature in the solar fluid can be limited to reduce thermal loads. The shut-off behavior and the maximum temperature are mainly determined by the type and the mass of working fluid in the heat pipe. Above this temperature, the fluid exists only in the vapor phase, so that the heat pipe heat transport ability is disabled. The maximum temperature in the connected solar circuit can be limited to such an extent that the evaporation of the solar circuit fluid can be completely avoided. In contrast to other technologies, the temperature limitation by heat pipes is inherently safe and independent from thermomechanical devices. The suppression of vapor formation in the solar circuit leads to simplified and more reliable system configurations and to a reduction of the overall system costs.

2. Evacuated tube collector prototype with novel heat pipes

We developed and investigated an evacuated tube collector prototype with novel heat pipes by means of indoor performance measurements with a sun simulator according to EN ISO 9806. The evacuated tubes with pentane-filled heat pipes were manufactured in cooperation with the German company NARVA Lichtquellen GmbH & Co. KG. The prototype collector consists of ten single tubes, which are connected with the solar circuit by a typical manifold. The collector power curve was measured at an average wind speed of 3 m/s and an ambient temperature of about 26°C. Figure 1 shows the measurement results and compares the efficiency curve of the heat pipe collector to that of a similar direct flow collector (standard collector). The conversion factor of the new prototype amounts to 75.4 % and is about 2 %-absolute lower than the standard collector, which is a typical difference caused by the additional thermal resistance of the heat pipe in the heat transfer path. Up to an operating temperature of about 75 °C both collectors have nearly the same heat loss coefficients. Above this

doi:10.18086/swc.2017.31.16 Available at http://proceedings.ises.org

temperature the heat loss coefficient of the heat pipe collector changes significantly as a result of the starting dry-out process, as represented by the characteristic kink point of the efficiency curve. As consequence of this, the stagnation temperature in the solar circuit takes place at 125 °C (measured without wind), which is significantly lower compared to the standard collector.

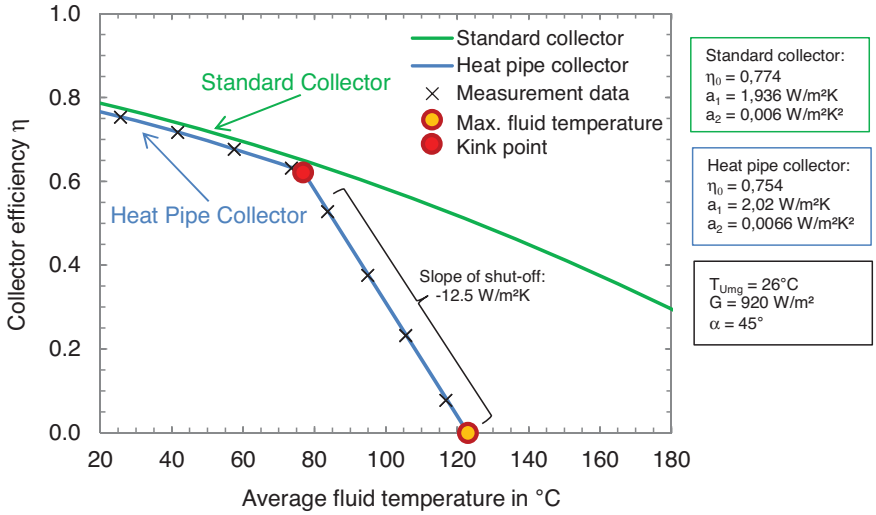

Fig. 1: Efficiency curve and coefficients of the prototype (measurement) and of a similar standard collector (TÜV-Rheinland 2014)

3. Experimental investigation of the system behavior

3.1. Experimental setup

For a comprehensive evaluation of the system behavior of heat pipe collectors with temperature limitation two identical experimental setups were installed on our test roof, which differ only in the collector hydraulic. We compared a prototype collector with deactivating heat pipes with an evacuated tube collector with direct flow as reference (Figure 2). Both systems consist of a field with an aperture area of 6 m² and a hot water tank with a volume of 400 l, which represent a common design for domestic hot water systems. The expansion vessel and all other solar circuit components are dimensioned in conformity with common guide lines. The specific system parameters of both systems are listed in Table 2 in the Appendix. Both solar plants are equipped with the necessary measurement and system technology according to ISO 9459-5 (see Figure 3, left). Additional temperature sensors and pressure measurement devices are installed in both solar circuits for investigating the stagnation loads (see Figure 3, right).

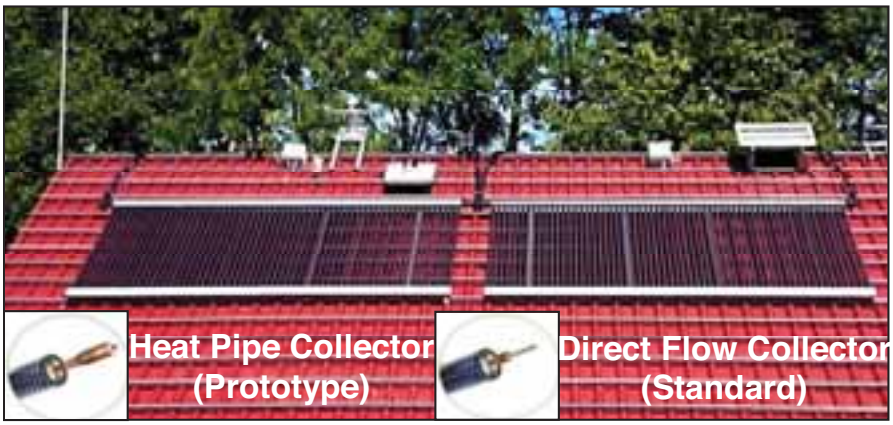

Fig. 2: Test roof with both prototype and reference evacuated tube collector fields

T_{ev}	Temperature of expansion vessel
p	System overpressure

Fig. 3: System scheme according to ISO EN 9459-5 (left) and additional sensors in the solar circuit (right)

The aim of the DST procedure is to determine the performance of complete solar systems under real conditions. The system is investigated under characteristic operating conditions by setting defined test sequences. Each sequence represents a separate period of measurement and needs several days. A complete data set consists of four measurement files, each with one sequence. These data can be used in a system simulation to determine the annual yield. The identified model parameters of both systems are shown in Table 1. The effective collector area *Ac** describe not only the collector geometry but also its optical properties. The slight difference can be explained by the lower conversion factor of the heat pipe collector (see Figure 1). The other parameters are almost in the same range.

Tab. 1: Identified model parameters of the dynamic system testing procedure for both the heat pipe and the standard system

Parameters	Symbol	Unit	Heat pipe system	Standard system
Effective collector loop area	A_C*	m^2	4.44	4.61
Heat-loss coefficient of the collector loop	u_C	$Wm^{-2}K^{-1}$	4.47	4.39
Heat-loss rate of the store	U_S	WK^{-1}	2.60	2.62
Heat capacity of the store	C_S	MJK^{-1}	1.54	1.48
Fraction of the store heated by the auxiliary heater	f_{aux}	-	0.573	0.595[1]
Draw-off mixing parameter	D_L	-	0.017	0.019
Collector loop stratification parameter	S_C	-	0.009	0.005

3.2. System performance in operation mode

The system performance is expressed by the annual yield and was determined by operating the two systems in parallel operation under identical conditions according to the DST procedure described in ISO 9459-5 (2007). The results depend on the tapping rates and on the climatic conditions of the considered locations. In general, the differences between the prototype and the reference system are almost negligible, as shown in Figure 4 (left) at a tapping rate of 200 l/d. For Würzburg, representing middle European climate, the deviation in annual yield amounts to 20 kWh/a (0.8 %). Thus, the auxiliary energy demand is increased by 20 kWh/a (2 %). For locations

[1] The annual yield is simulated with the same fraction values f_{aux} = 0.57 for both systems, because identical storages and auxiliary heaters are used.

with higher solar irradiation such as Athens or Davos the annual yield reduction of the heat pipe system further decreases down to 0.4 %. For locations with lower solar irradiation such as Stockholm, on the contrary, it increases up to 1.2 %.

The quotient of the annual yield Q_{sol} and the whole energy demand for domestic hot water Q_{DHW} is defined as the fractional system gain f_{sol} and is expressed by Equation 1. In general, the fractional system gain for both systems decreases with higher daily tapping rates (see Figure 4, right for Würzburg). For small tapping rates (< 100 l/d), the required temperature level, which has to be reached by the solar collector for contributing to the energy supply, has a negative impact on the performance, due to the prolonged standstill time and the increased heat losses. For common tapping rates of 100 to 300 l/d, the fractional system gain of both solar systems ranges between 77 and 60 %.

$$f_{sol} = \frac{Q_{Sol}}{Q_{DHW}} \qquad \text{(eq. 1)}$$

The deviations of the fractional system gain of the heat pipe system compared to the standard system are almost constant, between -0.5 and -0.8 %-absolute over the whole range of the considered tapping rates. That can be explained by the slightly lower annual yield of the heat pipe system. The losses in annual yield amount to about 1 % compared to the standard system (see Figure 4 right). That leads to higher auxiliary energy demands, which range between 1.5 and 3.5 % (about 2 % for typical tapping rates).

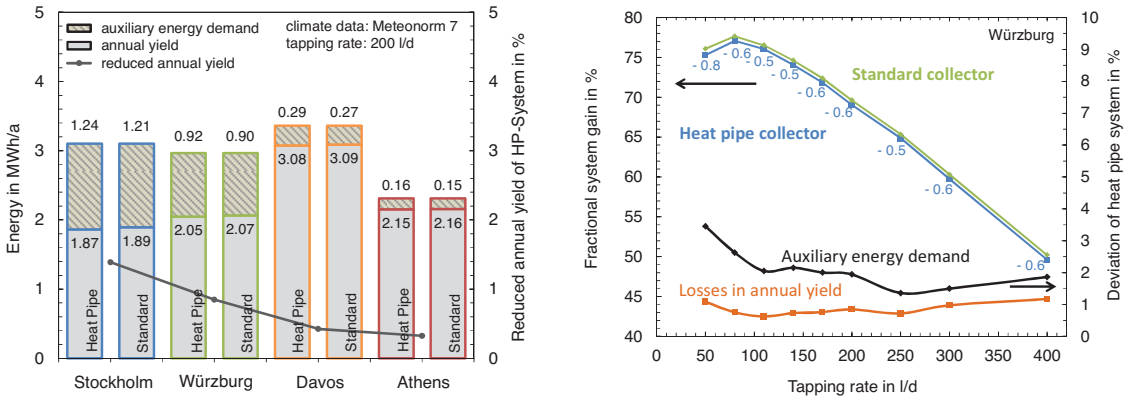

Fig. 4: Annual energy balances for all considered locations at a tapping rate of 200 l/d (left) and fractional system gain, deviations in annual yield and auxiliary energy demand for Würzburg against the tapping rate (right)

3.3. Validation with TRNSYS simulations

To validate the results of the DST procedure, the performances of both systems were simulated in TRNSYS. The characteristics of heat pipe collectors with inherently temperature limitation were implemented in a newly developed collector type model. Conditions such as the tapping and meteorological data were set equal to the DST procedure. The fractional system gain is determined as f_{save} according to IEA TASK 26, as the quotient of the auxiliary energy demand for domestic hot water with solar thermal system and the auxiliary energy demand of the same system without a solar thermal system (Streicher et al. 2003). Thus, storage losses generated by the solar system can be estimated and separated from conventionally generated losses. In the DST model the detailed procedure for calculating the heat storage losses is unfortunately unknown. For validation purpose, the electrical energy demand for the controller and pumping is not considered in both models, since their influence is negligibly small.

In the case of the heat pipe system the fractional system gain calculated according to both approaches have a maximum deviation of 5 %-absolute for all four locations and over a wide range of tapping rates (see Figure 5, left). Small tapping rates show the greatest differences. The reason could depend on the different consideration of the heat losses of the storage tank. In Würzburg and at a typical tapping rate of 200 l/d the fractional system gain differs by 1.0 %-absolute and the auxiliary energy demand by about 6.0 % (55 kWh), as shown in Figure 5, right.

According to the TRNSYS simulations the annual performance of the heat pipe system is, unlike the results of the DST model, slightly better ($\Delta f_{sol} \approx 0.5$ %-absolute) than that of the standard system. This difference can be

explained by the extremely simplified system modelling of the DST procedure. For example, the heat capacity of the collector, which is significantly lower for the heat pipe prototype, is not considered in the DST performance prediction. Only the simulation in TRNSYS can realistically represent the comparison in that point. Apart from these explainable small differences, both approaches confirm with sufficient accuracy, that the considered heat pipe collector prototype exhibits the same annual system performance as the standard collector.

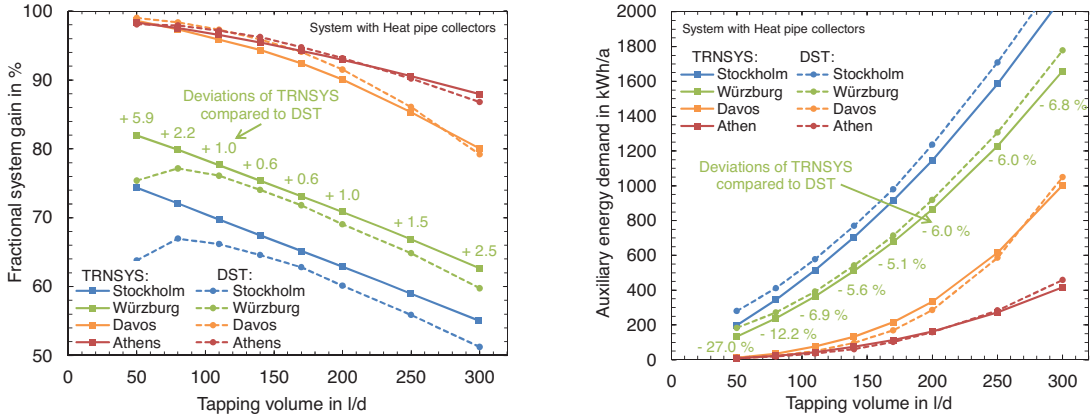

Fig. 5: Fractional system gain (left) and auxiliary energy demand (right) calculated with TRNSYS compared to the DST results against the daily tapping rate

3.4. Stagnation mode

In addition to the annual performance prediction, we investigated the stagnation behavior of both systems over several experimental test periods. During the tests the standstill of the solar circuit was realized by simultaneous switching-off the solar pump at solar noon and at an irradiance of about 1000 W/m². To evaluate the stagnation behavior we considered 30 stagnation days. The vapor formation has been investigated at different system pressure levels in the range between 1.0 / 1.8 and 2.0 / 2.8 bar system overpressure / absolute pressure at the collector.

In the case of the heat pipe collector we measured a maximum collector outlet temperature of 125 °C, which is up to 95 K lower than the maximum temperature recorded with the standard system. Figure 6 shows a typical stagnation sequence for both systems and the respective response of representative temperatures after deactivating the solar pumps at an overpressure level of 2 bars. For the standard system (red), a rapid increase takes place, so that the collector temperature significantly steps over the boiling temperature. The temperature at the inlet of the expansion vessel rises quickly to 115 °C. As a result of the vaporization, the system pressure increases in this case until the safety valve is triggered (> 6 bar). On the contrary, the temperature of the system with heat pipe collector (blue) achieves a maximum value of approx. 116 °C and the boiling temperature is not reached. The temperature at the expansion vessel is not affected by the stagnation sequence at all.

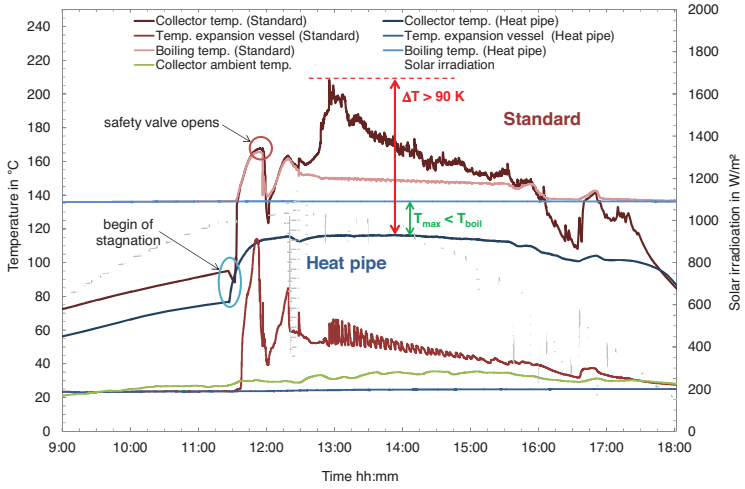

Fig. 6: Representative system temperatures over a stagnation sequence at an overpressure level of 2 bars

The boiling temperature of the solar fluid depends on the occurring system overpressure. For low system overpressures of only 1 bar, vapor formation takes place in the heat pipe collector, too. Figure 7 shows the maximum temperatures and pressures in both systems, as well as the resulting vapor formation in the solar circuit on the selected stagnation day. In the case of the standard system, the vapor at a temperature of about 155 °C is transported up to the solar station and the expansion vessel. In contrast to that, the maximum temperature at the heat pipe collector reaches 123 °C instead of 210 °C. The vapor transport is limited to few meters. The major part of the solar circuit shows a maximum temperature below 100 °C, which is significantly lower compared to the reference system.

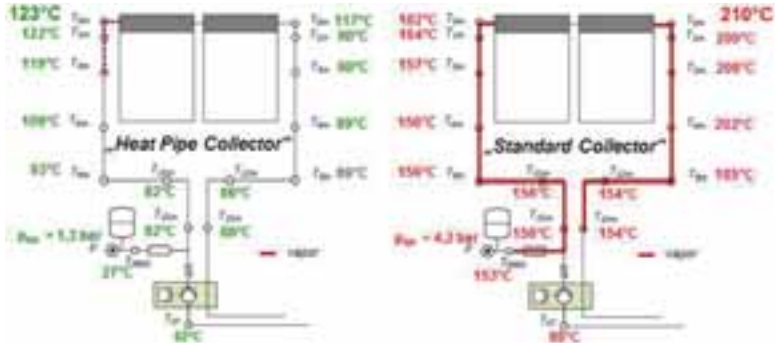

Fig. 7: Maximum temperature and pressure load in the solar circuit of heat pipe and reference system at a low system overpressure level of 1 bar

4. Parameter study with TRNSYS

4.1 System dimensioning

In addition to the annual performance both systems, as described in chapter 3, we investigate by means of TRNSYS simulations the influences of other boundary conditions, such as smaller designed collector fields. It was expected, that the differences of the annual performance between the systems could increase significantly with smaller collectors. Therefore the aperture area in the simulation was reduced whereby the storage tank volume was kept constant at 400 l. In general, the annual yield as well as the fractional system gain decreases and the auxiliary energy demand increases for both systems (see Figure 8 for Würzburg and for a tapping rate of 200 l/d). By reducing the aperture area to 4 m² (-33 %) the annual yields are correspondently reduced by about 20 % and the auxiliary energy demands rise by 40 %. If we focus on the differences between the collector types, the influence of the system performance is almost negligible. With refer to the annual yield, the relative deviation of the heat pipe system ranges from +0.6 % to -0.9 % by reducing the aperture area from 6 m² to 4 m². In consequence of this, the deviation in auxiliary energy demand varies from -1.2 % to +1.1 %. Contrary to our expectations the simulation results show that the annual performance of the heat pipe system is not significantly affected by smaller designed collectors compared to the standard system.

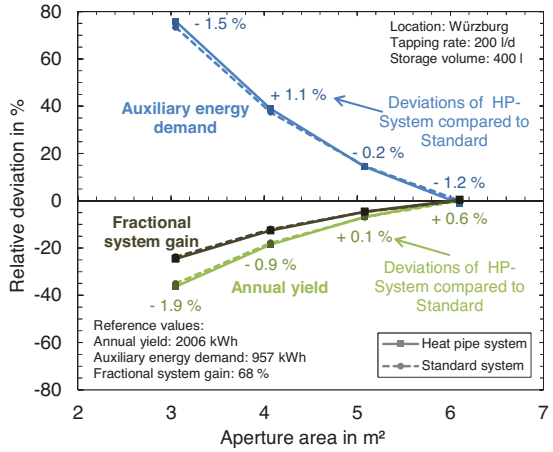

Fig. 8: Deviation of annual yield, fractional system gain and auxiliary energy demand for the heat pipe and standard system in dependency of the aperture area of the collector field

4.2 Shut-off behaviour and maximum temperature

The maximum fluid temperature of the heat pipe collector depends on several conditions. In particular, the type and amount of working fluid, which is inside the heat pipe, are the most important parameters. As a general rule, less fluid leads to lower maximum temperatures. A temperature shift by about ± 20 K can be simply managed by properly dosing the mass of a selected fluid in the heat pipe. Another important parameter is the slope of the collector power shut-off, which affects the kink point[1] (see Figure 9, left) and therefore the collector efficiency in the operating range. The slope of shut-off can be influenced i.e. by the type of working fluid, the heat losses and the internal thermal conductivity of the collector. Low heat transfer coefficients lead to flatter curves. By designing solar heat pipes for temperature limitation, both aspects have to be taken into consideration in order to achieve a significant reduction of the maximum temperature without compromising the annual system performance.

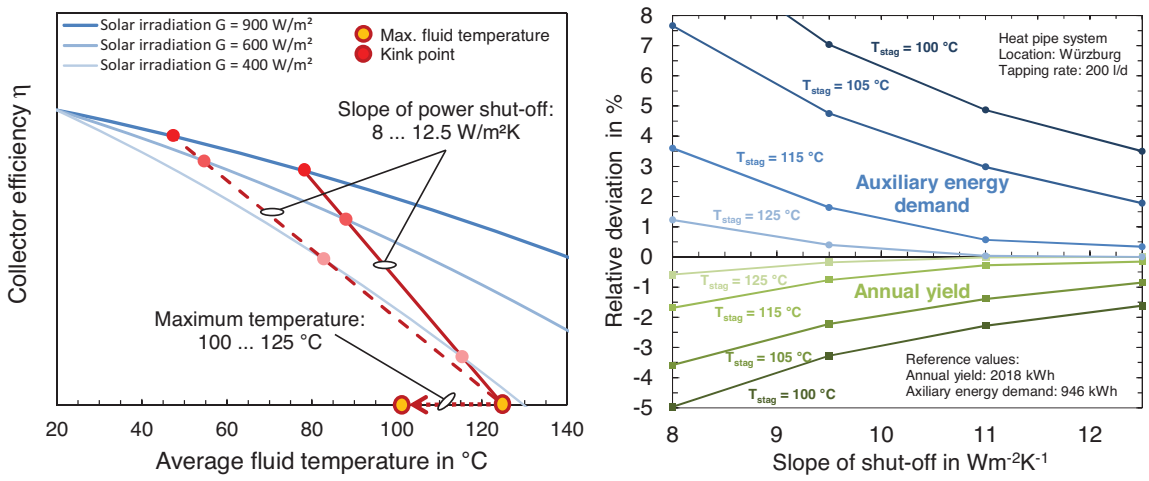

Fig. 9: Illustration of the varied parameters maximum temperature and slope of heat pipe power shut-off (left) and the annual yield and auxiliary energy demand as result of the parameter study (right)

The presented heat pipe prototype collector featured a maximum stagnation temperature of 125 °C and power limitation slope of 12.5 W/m²K. For a comprehensive evaluation, we further investigated the system performance for lower maximum temperatures and different slopes of power shut-off (see Figure 9, right). On the basis of our previous experience with different heat pipe prototypes, the maximum temperature was varied between 100 and 125 °C and the slope between 8 and 12.5 W/m²K. The parameter study was carried out with the system dimensions described in chapter 3 (collector area: 6 m², storage tank: 400 l). At a maximum temperature of 100 °C and a slope of 12.5 W/m²K the solar yield is reduced by 1.6 %, which leads to an increase in auxiliary energy demand by 3.5 %. If the stagnation temperature is limited to 105 °C, the solar yield is reduced by only 0.8 % and the auxiliary energy demand is increased by 1.8%. If lower values of the power limitation slope are considered, the effect is approximately negligible at T_{max} = 125 °C. In the case of T_{max} = 100 °C, significant losses are expected. A slope of 9.5 W/m²K, for example, leads to a lower annual yield by 3.5 % and a higher auxiliary energy demand by 7 %.

The parameter study shows, that a further reduction of the maximum temperature has a negative impact on the system performance. If a higher auxiliary energy demand by about 2 % is tolerated, the maximum temperature can be reduced to 115 °C with a minimum slope of 9.5 W/m²K or to 105 °C with a minimum slope of 12.5 W/m²K. If a temperature limitation to 115 °C is reached with a slope of 12.5 W/m²K, the demand of auxiliary energy increases by only 0.3 %. In consequence of this, vapor formation and the transportation of high temperatures in the solar circuit can be further reduced, in particular at a low system overpressure level, as shown in Figure 7.

[1] The kink point is not fixed at a certain temperature, but is affected by the slope of the shut-off and the occurring solar irradiation

5. Conclusion

We investigated a newly developed evacuated tube collector based on optimized heat pipes able to limit the temperature loads at the manifold to a maximum temperature of 125 °C. Additionally to collector efficiency measurements, we compared the annual yield of a heat pipe collector field in a domestic hot water system with an identical system with direct flow collector according to ISO 9459-5. The results show, that the heat pipe collector reaches almost the annual system performance of the reference collector. The system simulations in TRNSYS have confirmed the results of the DST procedure with a sufficient accuracy.

By means of extensive stagnation tests, we report a maximum temperature at the solar circuit of 125°C, which is 95 K lower compared to the reference system. As a main result, the vaporization can be completely avoided for a typical pressurized system and significantly reduced for low system overpressures. The use of these heat pipes can thus prevent the propagation of high temperatures in the system. The major part of the solar circuit shows a maximum temperature level below100 °C. Due to the significant reduction of thermal and pressure loads in the whole solar system the system design can be adapted and simplified. According to our parameter study with TRNSYS, a further reduction of the maximum temperature to 115 °C is possible without significantly affecting the annual performance.

As a result of the already achieved limitation of the maximum temperature to 125 °C and of the successful suppression of vapor formation, solar circuit components, such as the expansion vessel, the ballast vessel and the solar piping, can be resized or made by less expensive materials, i.e. by polymerics. According to our current estimation, the investment costs for the considered domestic hot water system can be reduced by about 8 – 10 %. Further simplifications in the installation procedure, i.e. by simpler filling and degasification of the solar circuit are possible. Finally, the lower system load can significant reduce the maintenance effort, in particular thanks to the prolonged life-time of the solar fluid. Taking into account the overall costs during the life-time of the system, the use of heat pipe collectors with temperature limitation can achieve a cost saving of 20 – 30 % compared to a state-of-the-art solution.

8. Appendix

8.1 Specific system parameters

The specific system parameters of both systems are listed in Table 2. The collector coefficients as well as the stagnation temperature of the heat pipe collector were determined at the ISFH (see Figure 1). For the direct-flow collector, the parameters were taken from a referenced Solar Keymark certificate (TÜV-Rheinland 2014). The effective heat capacities of both collectors have been determined according to DIN EN 12975-2 by weighting the physical capacities of the single components. The significant difference is due to the substantially lower mass of solar fluid in the heat pipe collector.

Tab. 2: Specific system parameters used for performance simulation with both the heat pipe and the standard system

Parameters	Symbol	Unit	ETC with heat pipe	ETC Standard
Collector:				
Aperture area	A^*	m²	6.1	6.1
Conversion factor	η_0	-	0.754	0.774
Linear heat loss coefficient	a_1	$Wm^{-2}K^{-1}$	2.02/12.50[1]	1.94

Investigation on Dustfall and Rainfall to Cover Transmittance of Flat-plate Solar Collectors in Beijing

Min Wang, Bojia Li, Tao He, Xinyu Zhang, and Boyuan Wang

China Academy of Building Research, Beijing (China)

Abstract

Nature dustfall influences on transmittance of flat-plate solar collectors cover and will furtherly influences on its working efficiency. A 12-month experiment of dustfall and cover transmittance has been conducted in Beijing. A dust deposition model describing the effect of rain on dust deposition has been studied. And the correlation of environmental factors, such as dustfall and rainfall, on cover transmittance has also been established. The maximum relative deviation between calculated and experiment transmittance is 6.42%. Therefore, the correlation is accurate enough and can be used for further analysis such as maintenance strategy of solar thermal system operating in Beijing or other areas with similar climate.

Keywords: dustfall, rainfall, flat-plate solar collector, cover transmittance, rainfall facto, extinction coefficient

1. Introduction

Flat-plate solar collector (FPC) is getting higher installed capacity in China due to its better safety performance and advantage of integrating with buildings. Normally, effect of environmental factors, such as dust deposition, rainfall and wind, would not be considered when calculating the thermal performance of FPC. That results in a significant difference between designing output and actual operation, especially in the special area with severe dust or wind. El-Nashar (2009) pointed out that in arid regions such as the United Arab Emirates, collector's thermal performance will drop by 40% in a year without cleaning. Elminir et al. (2006) proposed that the transmittance of glass fell 52.5%~12.4% according different slope and azimuth in Egypt. Research in China showed that thermal performance of flat-plate collector would drop 9.69% after 3 months in Lanzhou, the transmittance would fall 12.3% after 12 days in Xi'an (Liu, 2014; Hou, 2015).

Based on the analysis of effect mechanism of dustfall and rainfall on cover transmittance, A 12-month experiment of dustfall and cover transmittance has been conducted in Beijing. A dust deposition model describing the effect of rain on dust deposition has been studied. And the correlation of environmental factors, such as dustfall and rainfall, on cover transmittance has also been established. With the correlation, further analysis, such as maintenance strategy of solar thermal system operating in Beijing or other areas with similar climate, could be analyzed.

2. Effect mechanism

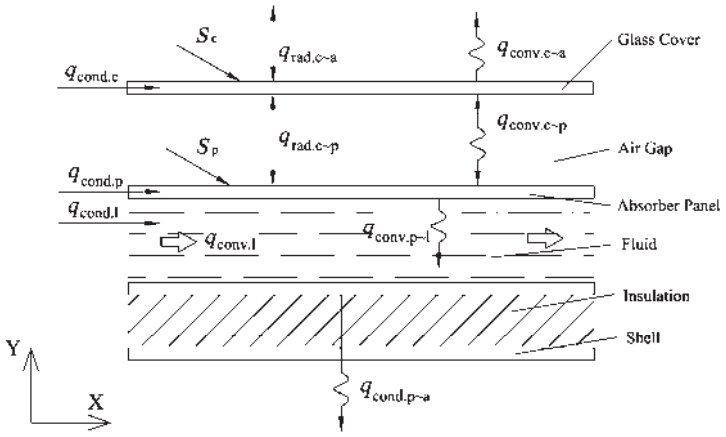
2.1. Working principle

The working principle of flat-plate solar collectors can be described as following:

- Solar radiation through the glass cover is absorbed by the absorber panel with selective coating;
- The temperature of the absorber panel increases, and the heat transfer to fluid in tubes;
- Fluid is heated and deliver heat to outside.

Heat transfer process between components is showed in Fig. 1.

doi:10.18086/swc.2017.31.17 Available at http://proceedings.ises.org



cond	Conductive heat transfer	c	Glass cover	a	Ambient
conv	Convective heat transfer	p	Absorb panel	*S*	Solar radiation
rad	Radiation heat transfer	l	Fluid	*q*	Heat transfer

Fig. 1: Schema of heat transfer in flat-plate solar collector

According to the working principle, transmittance of the glass cover has significant effect on collector's thermal performance. Decrease of the transmittance would reduce heat received by the absorber panel, which eventually leading to decline of heat gain and thermal efficiency.

For a flat-plate solar collector in operation, the cover transmittance is affected by the dustfall and rainfall. The effect mechanism could be described as following:

- Dust falls and deposited on the collector cover.
- Then it is washed by the rainfall.
- If the transmittance of clean glass cover is τ_c , transmittance of dust layer is τ_d, Then the transmittance of glass cover with dust is down to $\tau_m=\tau_c \cdot \tau_d$.

To describe the effect of dustfall and rainfall on cover transmittance, a dust deposition model has been studied as following.

2.2. Dust deposition

By deposition mechanism, the dustfall on the tilted collector cover could be divided into 2 parts: the gravity settling dust and particulate matter. The dust deposition on the tilted collector cover can be calculated from the following equation:

$$D_{d,\theta} = d_{1,\theta} + d_{2,\theta} = d_d \cos\theta + v_{d,\theta} C_{dp} T \times 10^{-3} \quad \text{(eq. 1)}$$

Where，θ is the titled angle of inclination surface; $D_{d,\theta}$ is the total dust mass on titled surface, g/m^2; $d_{1,\theta}$ is gravity settling dust mass on titled surface, g/m^2; $d_{2,\theta}$ is particulate matter mass on titled surface, g/m^2; d_d is daily gravity settling dust mass, g/m^2; v_d is particulate matter settling velocity，m/s; C_{dp} is particulate matter concentration, mg/m^3; T is calculation period of particulate matter，86400s.

2.3. Effect of rainfall on dust deposition

The rain will wash away part of the dust on the collector cover, but part of the sticky dust will still remain on the collector cover. Therefore, when describing the effect of rainfall on dust deposition, four different scenarios are proposed:

1) No rain, dust on the cover is not affected;

2) Little rain, but the rain is not strong enough to wash away the dust on the cover;

3) Small rain, the rain can only wash away part of the dust on the cover;

4) Heavy rain, the rainfall exceeds a certain threshold. Almost all the dust is washed away, but there will be a small part of sticky dust still stay on the cover.

Rainfall factor R is introduced as eq. 2 to describe the effect of rainfall on dust deposition. And the dust deposition model including rainfall effect has been established as eq. 3 ~ eq. 5.

$$R=\begin{cases}1 & r_{24}\le b_1\\ r' & r_{24}=b_2\\ r'' & r_{24}\ge b_3\\ 1+(r'-1)\dfrac{r_{24}-b_1}{b_2-b_1} & b_1<r_{24}<b_2\\ r'+(r''-r')\dfrac{r_{24}-b_2}{b_3-b_2} & b_2<r_{24}<b_3\end{cases} \quad \text{(eq. 2)}$$

Where, b_1, b_2, b_3 are different rainfall threshold, mm; r', r'' are the left dustfall proportion after rainfall flush, %.

$$D_r(i)=D_{r,1}(i)+D_{r,2}(i) \quad \text{(eq. 3)}$$

$$D_{r,1}(i)=R(i)\left[D_{r,1}(i-1)+d_d(i)\cos\theta\right] \quad \text{(eq. 4)}$$

$$D_{r,2}(i)=R(i)\left[D_{r,2}(i-1)+v_d C_{dp}(i)T\times10^{-3}\right] \quad \text{(eq. 5)}$$

Where $D_r(i)$ is the total dust mass after rainfall flush on i day, g/m^2; $D_{r,1}(i)$ is the total gravity settling dust mass after rainfall flush on i day, g/m^2; $D_{r,2}(i)$ is the total particulate matter after rainfall flush on i day, g/m^2.

2.4. Transmittance of collector cover with dust

According to Zhao (2006) and Katzan's (1991) research, the correlation between cover transmittance and dust deposition could be described as eq. 6 by defining the extinction coefficient of dust deposition K_d :

$$\tau=\tau_c\cdot\exp\left[K_d\left(\frac{D_{r,1}}{\phi_1}+\sum_{j=1}^{n}\frac{D_{r,2,j}}{\phi_{2,j}}\right)\right] \quad \text{(eq. 6)}$$

Where τ is the transmittance of dirty cover; τ_c is the transmittance of clean cover; φ_1 is equivalent diameter of gravity settling dust mass, m; $\varphi_{2,j}$ is equivalent diameter of particulate matter j, m.

To determine the rainfall factor R and extinction coefficient K_d in the correlation of dustfall and rainfall on cover transmittance of flat-plate solar collector, a 12-month experiment of dustfall and cover transmittance has been conducted in Beijing.

3. Experiment methods

3.1. Location

The dustfall and cover transmittance experiment has been carried out on the roof of a 3-floor building in Shunyi District, Beijing. There is no high-rise building around, and there is no obvious source of pollutants. The latitude of experimental site is 40°, longitude is 116°, average elevation of 35 m. Experimental site is 50 km away from city center.

The climatic character in Beijing is rainy and hot in summer, cold and dry in winter. 75% of the annual rainfall is in summer. Average annual rainfall is 571.3 mm. In January the average temperature is -4°C, and monthly rainfall is 2.8 mm. In July the average temperature is 26.3°C, and monthly rainfall is 177 mm.

3.2. Method

Experiment included 2 parts: dustfall measurement and cover transmittance measurement. Experiments period was 12 months, from April 2015 to March 2016. The dustfall measurement and cover transmittance measurement were carried out at the same time in each month. The rainfall data and daily PM_{10} concentration

from China Meteorology Data Center is recorded at the same time.

3.2.1. Dustfall measurement

The experiment was carried out according to the national standard GB/T 15265-94 "Ambient air -Determination of dustfall - Gravimetric method". The glycol water (Mixture of 100 mL $C_2H_6O_2$ and 100 mL water) was placed in a glass collection tank to collect the dustfall. The inner diameter of glass collection tank was 15 cm, and the height was 30 cm, the mass of dustfall was measured by gravimetric method. The glycol water was collected every 30±2 d. After evaporation, drying at 105°C, cooling at room temperature, the dust was weighted by analytical balance. The experimental site and equipment for dustfall measurement is showed in Fig. 2.

a. experimental site b. glass collection tank c. crucible d. Drying oven f. analytical balance

Fig.2: Experimental site and equipment of dustfall experiment

3.2.2. Cover transmittance measurement

Glass pieces were used as the sample of collector cover during the experiment. The glass pieces' size is 50 mm × 50 mm × 3 mm. The glass pieces were placed at three tilted angles of 0°, 40° and 90°. Monthly transmittance changes of glass pieces were measured every month, and the cumulative transmittance changes from the 1st month were also measured. As shown in Fig. 3, the transmittance was measured by a spectrophotometer, the transmittance of each glass pieces was tested twice to reduce the test error.

a. spectrophotometer b. glass pieces

Fig.3: Spectrophotometer and glass pieces

3.3. Uncertainty analysis

Measuring instruments used in the experiment included analytical balance, Vernier caliper, spectrophotometer. Main parameters of these instruments are showed in Tab. 1.

Tab. 1: Test instrument list

Item	Instrument	Model	Range	Resolution	Accuracy
Dust weight	analytical balance	JJ224BC	0~220g	0.1mg	±0.2mg
Inner diameter of glass collection tank	Vernier caliper		0~150mm	0.02mm	-
Transmittance	spectrophotometer	Cary-5000	300~2500nm	0.0001	0.0008

3.3.1. Uncertainty of dustfall

The relative synthetic uncertainty of dustfall was calculated by eq.7:

$$U(\mathrm{d}) = \sqrt{U(\mathrm{S})^2 + U(\mathrm{w})^2} \quad \text{(eq. 7)}$$

Where, U(d) was the synthetic uncertainty of dustfall; U(S) was the uncertainty of opening area of glass collection tank; U(w) was the uncertainty of dust weight.

The resolution of the Vernier caliper used to measure the inner diameter was 0.02 mm. Considering the average distribution, the confidence probability p= 95% was taken, and the corresponding inclusion factor k = 1.65. For the inner diameter of glass collection tank, the standard uncertainty u(L) of measurement results was 0.006 mm. Inner diameter of glass collection tank was 139 mm. After calculation, the uncertainty of opening area of glass collection tank was 0.0062%.

The accuracy of the analytical balance used to measure the dust weight was 0.2 mg. Considering the normal distribution, the probability of confidence is 95.45% and the corresponding inclusion factor k = 2. The standard uncertainty of the measurement results u(w) was 0.1 mg. The relative uncertainty U(w) was 0.25% when the measured dust was about 40 mg.

Therefore, the relative synthetic uncertainty of dustfall U(d) = 0.25%.

3.3.2. Uncertainty of transmittance

According the uncertainty analysis method, the relative uncertainty of transmittance $U(\tau)$ = 0.0667 %.

4. Experiment results

According to the experimental results shown in Fig. 4, total amount of dustfall at the experimental site was 58.653 t/km^2. And the maximum monthly dustfall was 9.718 t/(km^2·30d) in April, the minimum monthly dustfall was 2.254 t/(km^2·30d) in September. Seasonal changes of rainfall was obvious. There was rare rainfall in winter (December ~ March), while there was rich rainfall in summer (July ~ September). The maximum monthly rainfall is in July.

The transmittance of glass piece was affected by dustfall and rainfall. Monthly transmittance changes were different in different season. During December to March, there was rich dustfall and rare rainfall. The transmittance decreased obviously according to the increase in dustfall (Except February). From July to September, there was little dustfall and rich rainfall. The transmittance decreased a little and the glass kept clean. Relative change of transmittance was only 1.9%. In the first transition season (from October to November), there was little dustfall and rainfall. The transmittance decreased slowly. In the second transition season (from April to June), there was lot dustfall and rainfall. The transmittance fluctuated greatly.

Based on the annual experimental data, the cumulative transmittance in June and February increased significantly comparing with previous month, but the rainfall did not change significantly. Therefore the effect of rainfall needed further analysis.

Fig. 5 shows the maximum 24h rainfall in each month. It could be seen that the maximum 24h rainfall in June

and February was 12.1 mm and 7.3 mm respectively. During February, the maximum 12h rainfall was 7.3 mm. And the maximum 24h rainfall in May and January was 3 mm and 0 mm, respectively. In meteorology, if 12 hours rainfall ($r12$) was more than 5mm and less than 15 mm, 24 hours rainfall ($r24$) was more than 10mm and less than 25 mm, the rain was called moderate rain. If 12 hours rainfall ($r12$) was more than 15 mm and less than 30 mm, 24 hours rainfall ($r24$) was more than 25 mm and less than 50 mm, the rain was called heavy rain. According the analysis above, the increase of transmitters in June and February could be attributed to the occurrence of moderate rain or heavy rain in that month. As the monthly rainfall didn't reflect the rainfall intensity, it was more reasonable to use 24h maximum rainfall ($r24$) in eq. 2 when analyzing the impact of dustfall and rainfall on the cover transmittance.

During the experiment, the monthly and cumulative transmittance changes of the 0°, 40° and 90° glass pieces are shown in Fig. 6 and Fig. 7. The transmittance of clean glass piece (τ_m) was 0.8497. The decrease in the transmittance of the glass piece decreased with the increase of the tilted angle θ, and the change trend was non-linear. Transmittance of 40° glass piece was more like that of 0° glass piece.

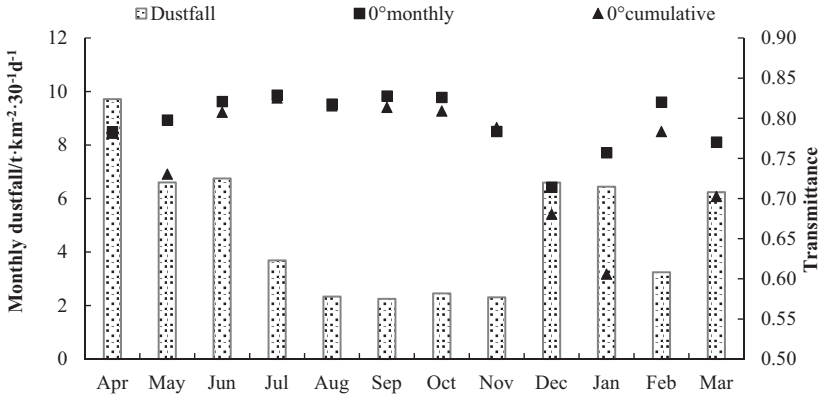


Fig.4: Results of monthly dustfall and transmittance on horizontal surface

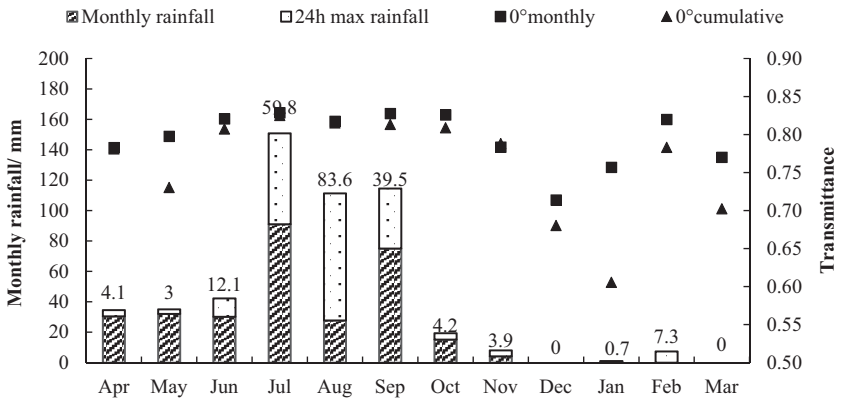

Fig.5 Results of monthly rainfall and transmittance on horizontal surface

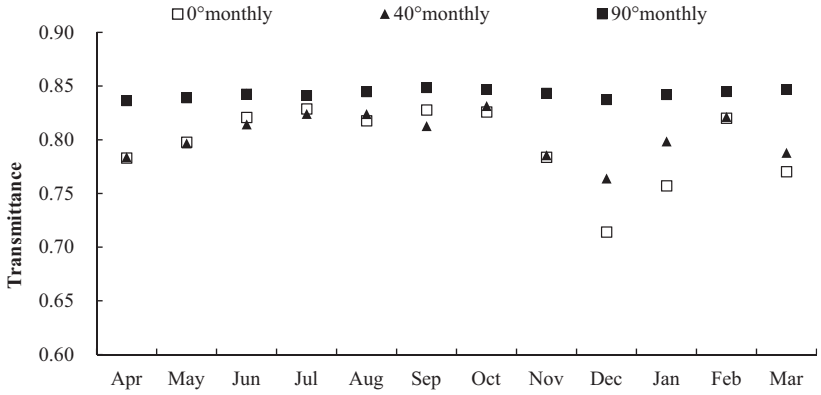

Fig.6: Results of monthly transmittance on different tilted surface

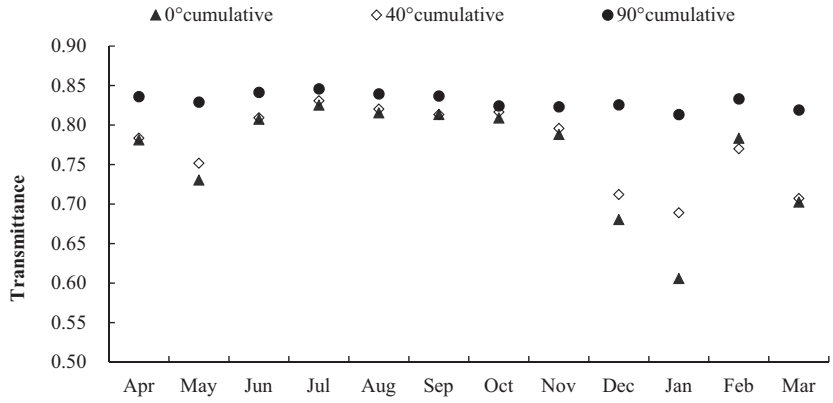

Fig.7: Results of cumulative transmittance on different tilted surface

5. Discussion

5.1. Dust deposition

The dust deposition could be calculated by eq. 1. In the equation, daily gravity settling dust mass could be achieved from experiment results.

Assuming that PM_{10} is composed of 4 kinds of particulate matter with diameter of 10μm, 5μm, 2.5μm and 1μm, the volume ratio of the 4 kinds of particulate matter are 72.2%, 15.3%, 8.3% and 4.2%, according to the results of Wu G. et al. (2005) and Wu C. et al. (2006). As a result, the amount of daily dust deposition can be calculated by eq. 8.

$$\tau_j = \tau_c \cdot \exp\left[K_d \sum_{j=1}^{n} R_j \left(D_{r,j-1} + \frac{d_d \cos\theta}{d_{p40}} + v_{dR,\theta,\mathrm{pm10}} C_{PM10,j} T \times 10^{-3}\right)\right] \quad \text{(eq. 8)}$$

$$v_{dR,\theta,pm10} = \frac{0.722 v_{d,\theta,\mathrm{dp10}}}{d_{p10}} + \frac{0.153 v_{d,\theta,\mathrm{dp5}}}{d_{p5}} + \frac{0.083 v_{d,\theta,\mathrm{dp2.5}}}{d_{p2.5}} + \frac{0.042 v_{d,\theta,\mathrm{dp1}}}{d_{p1}} \quad \text{(eq. 9)}$$

Where, j is days in a month;C_{PM10} is outdoor daily PM_{10} concentration, mg/m^3; $v_{dR,\theta,\mathrm{pm10}}$ is ratio of settling velocity to diameter of particulate matter; $v_{dR,\theta,\mathrm{dp}}$ is settling velocity of particulate matter with diameter of 10μm, could be calculated by equation proposed by Zhao (2006), You (2012) and Chen (2011); d_p is the diameter of particulate matter, m.

5.2. Regress of R and K_d

With the data of dustfall, rainfall, daily PM_{10} concentration and measured transmittance by above experiment in Beijing, the Rainfall Factor R and extinction coefficient K_d could be regressed, and the following equations are

obtained:

$$\tau_j = \tau_c \cdot \exp\left[-5.146\times10^{-7} \sum_{j=1}^{n} R_j \left(D_{r,j-1} + \frac{d_{d,\mathrm{d}} \cos\theta}{d_{p40}} + v_{dR,\theta,\mathrm{pm10}} C_{PM10,j} T \times 10^{-3} \right) \right] \quad \text{(eq. 10)}$$

$$\text{Where, } R = \begin{cases} 1 & r_{24} \le 2 \\ 0.13 & r_{24} \ge 6 \\ 1 - 0.218\times(r_{24} - 2) & 2 < r_{24} < 6 \end{cases} \quad \text{(eq. 11)}$$

It can be seen from eq. 11 that the rainfall factor R is divided into three stages. And b_1= 2, b_2= b_3= 6, $r'$and r is 1 and 0.13, respectively in eq. 2. The function is graphically shown in Fig. 8.

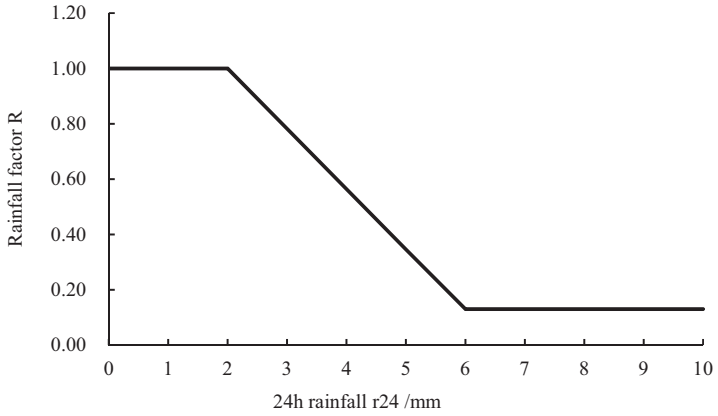

Fig. 8: Regressed rainfall factor *R*

With eq. 9, eq. 10 and eq. 11, the cover transmittance on titled surface can be calculated. The calculated and measured transmittance are compared in Fig. 9. It can be seen that the maximum relative deviation between calculated and experiment transmittance is 6.42%. Therefore, the correlation can fit the influence of environmental factors such as dustfall and rainfall on the transmittance of the collector cover. The fitting result is accurate enough and can be used for further analysis such as maintenance strategy of solar thermal system operating in Beijing or other areas with similar climate.

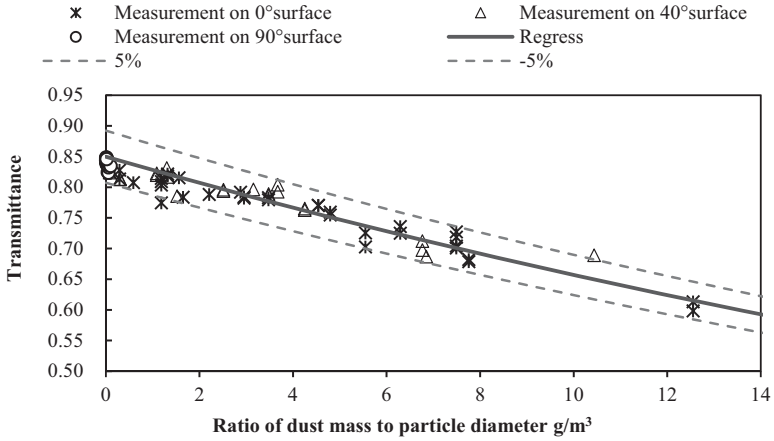

Fig. 9: Comparison of regress data and experimental data

6. Conclusion

A dust deposition model, as well as the correlation of environmental factors, such as dustfall and rainfall, on cover transmittance have been proposed in this paper. With a 12-month experiment of atmospheric dust and cover transmittance in Beijing, an empirical formula has been established to evaluate the effect of dustfall and

rainfall on the cover transmittance of solar flat-plate under natural environment. The detailed results are summarized as follows:

1) The dust deposition on the surface of collector cover is affected by the dustfall and rainfall. The correlation of dustfall and rainfall on cover transmittance has also been established as the following equation:

$$\tau_j = \tau_c \cdot \exp\left[K_d \sum_{j=1}^{n} R_j \left(D_{r,j-1} + \frac{d_d \cos\theta}{d_{p40}} + v_{dR,\theta,\mathrm{pm10}} C_{PM10,j} T \times 10^{-3} \right) \right]$$

2) A 12-month experiment in Beijing has been conducted. During December to March, there was rich dustfall and rare rainfall. The transmittance decreased obviously according to the increase in dustfall. From July to September, there was little dustfall and rich rainfall. The transmittance decreased a little and the glass kept clean.

3) The K_d and R were got by regress of experimental result as: $K_d = -5.146\times10^{-7}$ and

$$R = \begin{cases} 1 & r_{24} \le 2 \\ 0.13 & r_{24} \ge 6 \\ 1 - 0.218 \times (r_{24} - 2) & 2 < r_{24} < 6 \end{cases}$$

4) The maximum relative deviation between calculated and experiment transmittance is 6.42%.Therefore, the correlation is accurate enough and can be used for further analysis such as maintenance strategy of solar thermal system operating in Beijing or other areas with similar climate.

Abstract

The design and development of new medium-temperature solar thermal external compound parabolic concentrator (XCPC) is presented. A nonimaging reflector is paired with an evacuated tube absorber for efficient heat collection between 100-300 °C. Several absorber geometries are simulated, with the final selection of a modified pentagon absorber shape chosen for manufacturability. The modified absorber shape, gap loss, and truncated reflector result in a geometric efficiency of 93% compared to an ideal CPC. Several selective coatings are compared for down-selection, and a Mylar reflective film with ~89% reflectance is chosen for its low cost and durability. The final prototype has a 4.56 m^2 aperture. Simulations predict an optical efficiency of 71% and thermal efficiency of 50% at 200 °C and experimental test results have confirmed an optical efficiency of 62% and a thermal efficiency near 50% at 200 °C. The stagnation temperature was measured at 333 °C. World-wide installations are presented.

Keywords: External compound parabolic concentrator, XCPC, medium temperature, nonimaging, solar thermal

1. Introduction

Low temperature collectors (<100 °C) for residential and commercial hot water typically take the form of flat plate or evacuated tube collectors, the latter of which dominates the market space due to its widespread adoption in China. Parabolic trough collectors (PTC) have historically been the most commonly used high temperature collectors (>300 °C) for industrial process heating (IPH) and concentrating solar power (CSP), but have shared the space with compact linear Fresnel (cLFR), dish, and recently with centralized solar tower installations. The space in between these two classes of collectors (100 °C < medium temperature < 300 °C) has historically been served by high temperature collectors at lower-than-design operating temperatures. Today there exist several newer options including stationary evacuated flat plates (Buonomano et al. 2016), compound parabolic concentrators (Duff et al. 2004, Kim et al. 2013), semi-tracking micro linear fresnel reflector systems (Sultana et al. 2015), semi-passive tracking combined systems (Li et al. 2017), and tracking miniature trough (Fernandez et al. 2010) and dish (Cohen and Grossman 2016) systems. The best performance of these systems typically approaches 50% conversion efficiency at 200 °C under global irradiance.

In this paper we report on the most recent round of developments to the XCPC collector, a non-tracking solar thermal collector, and the experimental performance results of the prototype tested at the University of California, Merced (UCM).

2. Collector Design

The external compound parabolic concentrator (XCPC) consists of an evacuated tube receiver paired with a nonimaging reflector and is depicted in Figure 1. Inside the evacuated tube is a selectively coated metal fin which acts as the absorbing surface of the collector. The nonimaging reflector concentrates incoming radiation over a wide range of angles onto the absorber surface. This eliminates the need for any mechanical tracking mechanism as the optics provide passive sun-tracking. The combination of concentration and an evacuated receiver allows the XCPC to reach temperatures between 100 - 300 °C.

doi:10.18086/swc.2017.31.18 Available at http://proceedings.ises.org

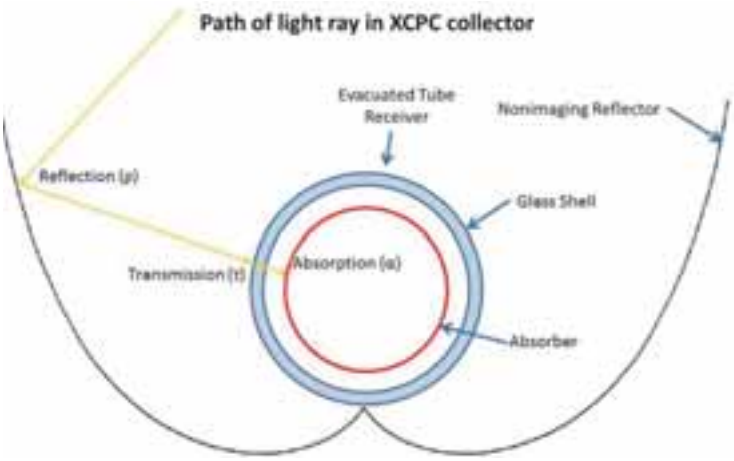

Figure 1 – Path of light ray in an XCPC collector.

The CPC profile was designed for a cylindrical absorber, but due to manufacturing limitations (specifically the geometric requirements of the ultrasonic welding machine at the prototyping facility) a new absorber geometry needed to be found. Optical simulations were performed in LightTools for the reflector profile with different absorber shapes shown in Figure 2 to determine the geometric efficiency of each case. The results of these simulations are summarized in Table 1.

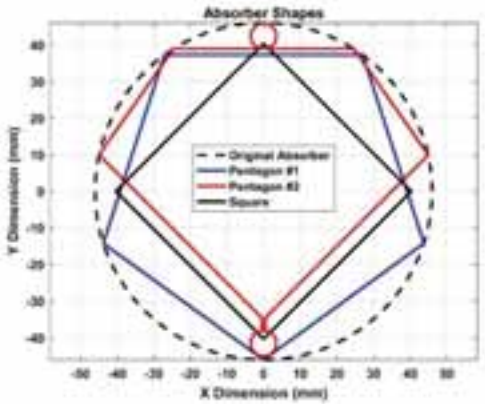

Figure 2 – Simulated absorber geometries: original circular absorber (dashed black), pentagon #1 (blue), pentagon #2 (red), and rotated square (black).

Table 1 – Geometric efficiency of CPC with different absorber shapes

Shape	Geometric Efficiency
Original Circle	1.00
Pentagon #1	0.97
Pentagon #2	0.94
Upper Tube Exposed	0.90
Lower Tube Exposed	0.84
Square	0.89

Pentagon #2 was selected after the geometry of Pentagon #1 prevented it from being welded shut by the ultrasonic welding machine. As is customary for practical reasons, the reflector was truncated to 95% of the original aperture width yielding a final design concentration ratio of 1.4X. Encasing the absorber in a glass tube results in a gap between the bottom of the absorber and the tip of the reflector. This should be minimized to reduce associated optical losses. For this design the gap was reduced to 3 mm to allow a 0.8 mm space between the absorber and the glass.

The incidence angle modifier (IAM) profile shown in Figure 4 was generated for the collector (truncated, with gap loss, and new absorber shape) by sweeping the incoming incidence angle from 0-60°.

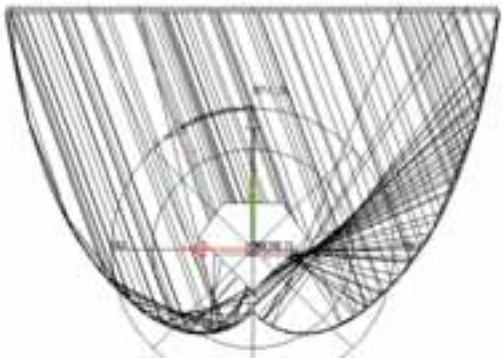

Figure 3 – Ray Trace Analysis of 40° E/W Collector with pentagon shaped absorber

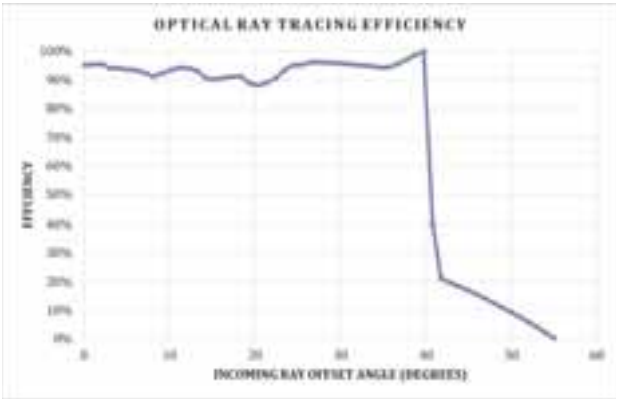

Figure 4 – Incidence Angle Modifier for 40° E/W Collector

The energy-weighted geometric efficiency η_g is calculated from Equation 1, where $\eta_{g,\theta}$ is the geometric efficiency as a function of incidence angle reported in Figure 5.

$$\eta_g = \frac{\int_0^\theta \eta_{g,\theta} \cos\theta d\theta}{\int_0^\theta \cos\theta d\theta} \qquad \text{(Eq. 1)}$$

As a result of the modified absorber shape and the 3 mm gap between the absorber and the bottom of the CPC, the total geometric efficiency is reduced to 93% compared to an ideal CPC. The optical design parameters of the final down-selected CPC design are listed in Table 2.

Table 2 – E/W XCPC Optical Design Parameters

Parameter	Value
Configuration	East-West
Acceptance Angle θ	±40°
Truncation Ratio (% of width)	0.95
Final Aperture Width	406 mm
Absorber Shape	Pentagon
Absorber Perimeter	285 mm
Concentration Ratio	1.4X

3. Materials Selection and Prototype Development

A selective coating is designed to absorb as much of the solar spectrum as possible while emitting as little as possible during operation. Several commercial flat-absorber vacuum tubes with different coatings were placed side by side outdoors, with thermocouples inserted to measure temperature. They were all uncovered at the same time and the temperature rise was recorded. The results showed a difference in performance between suppliers. Most coatings exhibited performance differences between batches, however, the Sunselect and TiNoX coatings showed stable quality and performance and were down-selected for a second round of testing. The second round of testing was performed again with the two commercially available flat absorber vacuum tubes, and for two coating manufacturers who were able to supply material for the prototype XCPC absorber. An image of the test setup is shown in Figure 5 and the results of the second test are presented in Figure 6.

As a result of these tests, SunSelect applied over a copper substrate was down-selected as the selective coating for the E/W XCPC prototype. The coating has a solar-weighted absorptance of 95% and an emissivity of 5% at 100 °C.

Borosilicate glass is typically used in solar applications because of its high solar transmittance. A borosilicate glass sample from the glass tube supplier was tested at NREL in 2007 and the transmission profile is presented in Figure 7. A total solar-weighted transmission of 91.7% is obtained which is consistent with the two Fresnel losses

going in and out of the glass.

Figure 5 – Side-By-Side Stagnation Test Setup

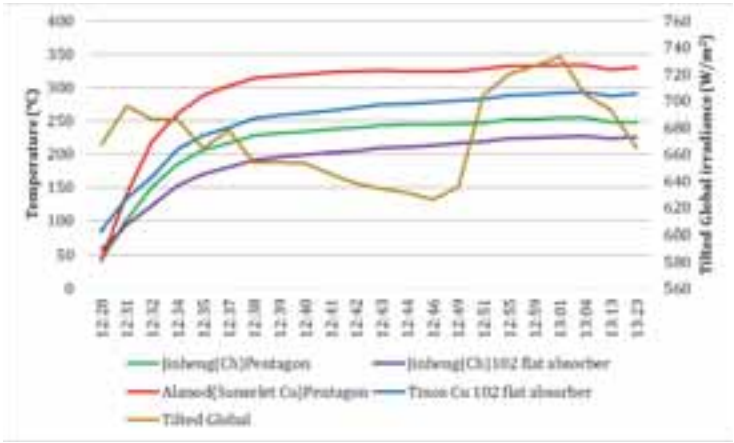

Figure 6 - Stagnation test results.

Several commercial reflector materials exist with high reflectance (>90%) and good outdoor stability. At the time of prototyping a reflective Mylar film was found for roughly $1/m^2. The hemispherical reflectance of the film was measured at 89%, which was maintained after 2 years of outdoor exposure (see Figure 8). As a result the film was selected for the E/W XCPC prototype reflector.

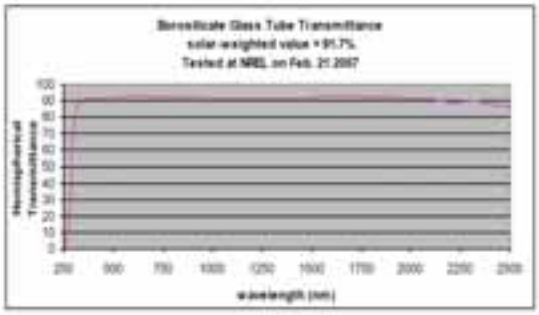

Figure 7 – Borosilicate glass transmission profile tested at NREL in 2007. The solar-weighted transmission is 91.7%.

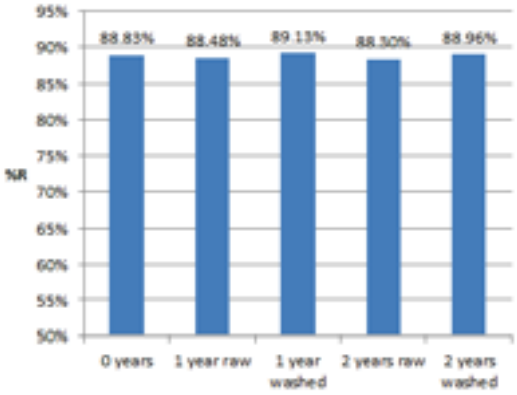

Figure 8 – Aluminized polymer film reflectance over time

A rendering of the final prototype design is shown in Figure 9 with a close up of the plumbing connections in Figure 10. Final specifications for the prototype are listed in Table 3.

Figure 9 – Final E/W XCPC collector prototype. 6 CPCs are plumbed off a centralized manifold box.

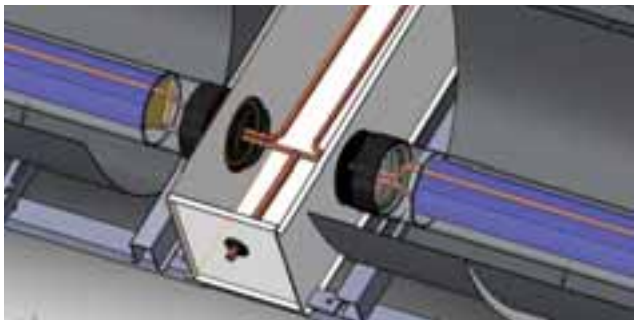

Figure 10 – Manifold Connections – Each side of the collector has 3 CPCs plumbed in series and both sides are plumbed in parallel.

Inside the evacuated glass tube is the selectively coated copper fin formed into the shape of a pentagon. A copper pipe is ultrasonically welded to the top and bottom of the pentagon with a 180° U-bend at the end. The copper pipe transitions into the glass tube via a glass to metal seal and the entire tube is evacuated and sealed below 10^{-4} mbar. A gas getter maintains the vacuum integrity and provides visual indication of vacuum quality.

The reflectors are formed of aluminum and overlaid with a reflective Mylar film. Their shape is supported by 4 ribs along the length of each reflector. The entire collector is formed by combining three XCPCs on either side of a central manifold box. Inside the manifold box, the tubes are piped together using copper flare connections and surrounded with fiberglass insulation. The two sides of the manifold box are piped in parallel, each with three CPCs piped in series.

Table 3 – E/W XCPC Collector Prototype Specifications

Parameter	Value
Selective Coating	SunSelect
Solar Weighted Absorptance (α)	0.95
Emissivity ($\varepsilon_{100\,°C}$)	0.05
Copper Pipe OD	8 mm
Copper Pipe Thickness	0.75 mm
Absorber Tube Length	1.9 m
Glass Material	Borosilicate
Solar Weighted Transmission (τ)	0.92
Glass Tube OD	102 mm
Glass Tube Thickness	2.2 mm
Reflector Material	Mylar
Total Hemispherical Reflectance (ρ)	0.89
CPCs per Collector	6
Aperture Area	4.5 m^2
Gross Area	5.4 m^2

4. Optical and Thermal Performance Models

Simulation of the completed design was performed in LightTools for 1 million rays using optical parameters of the materials used in the XCPC prototype. Ray trace diagrams are presented in Figure 11. At normal irradiance, an optical efficiency η_0 of 71% is obtained.

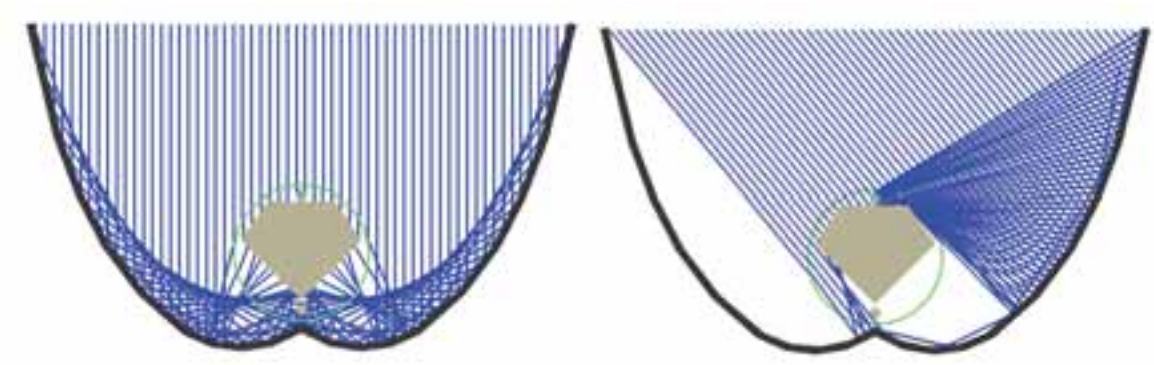

Figure 11 – Ray tracing of E/W XCPC collector for normal incidence and off-angle incidence.

A two-dimensional finite element model was created for the absorber where the polygonal fin shape was approximated by a generic 20-sided polygon (shown for n = 6 in Figure 12) and the tube length was divided into 40 nodes.

Uniform solar irradiance is assumed to be incident on all fins, which also radiate outward and conduct with their radial and axial neighbors. The fins at the top and bottom of the absorber are assumed to be at thermal equilibrium with the copper pipe, providing a conduction pathway to the interior surface of the pipe where heat is transferred to the fluid via convection. Since the absorber tubes are evacuated, no other convection is modelled. The heat

transfer coefficient between the inner pipe wall and the fluid is calculated based on the Nusselt number for laminar flow and using the Gnielinski and Dittus-Boelter correlations for turbulent flow.

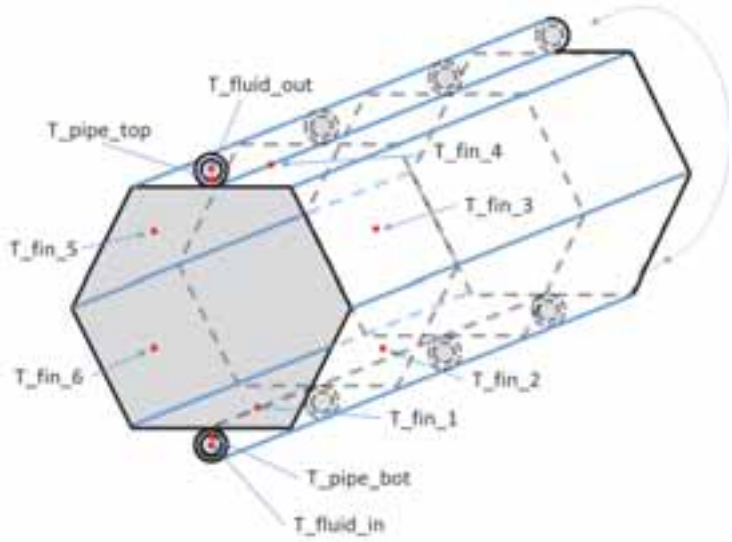

Figure 12 – Finite Element Analysis Mesh. The pentagon absorber is approximated by an n-sided polygon (shown for 6 sides here). The actual model used a 20-sided polygon and the length of the absorber was divided into 40 nodes.

Table 4 – Heat transfer model parameters

Parameter	Value
L_abs	1.8 m
n	40 nodes
L_fin	272 mm
n_fins	20 nodes
Fin_thickness	0.125 mm
Fin and Pipe material	Copper (Cu)
Piper inner diameter	6.5 mm
Pipe outer diameter	8 mm
G	1000 W/m^2
$\dot{m}$	75 g/s
k_{Cu}	400 W/m-K
ε	0.05 @ 100 °C, 0.08 assumed @ 200 °C

The parameters used in the model are listed in Table 4, assuming fluid properties for the mineral oil Duratherm 600. The emissivity of the selective coating is known to be 0.05 at 100 °C and was interpolated linearly to an emissivity of 0.08 at 200 °C. Matrix inversion was used to solve for the temperature at each node and the process was repeated until the temperature change between iterations was less than 0.01 °C.

The input solar irradiance to the model is calculated according to equation 2 and the solar irradiance absorbed by each fin from equation 3.

$$Q_{in} = A_{absorber} C_x G \quad \text{(Eq. 2)}$$

$$Q_{fin,absorbed} = \frac{Q_{in}\eta_0}{n_{fins} n} \quad \text{(Eq. 3)}$$

The net thermal generation of the collector ($Q_{thermal}$) is calculated based on the inlet and outlet temperatures from the model. This simulation was performed for temperatures between 25 °C to 400 °C and the efficiency calculated according to equation 5 is plotted versus temperature in Figure 13.

$$Q_{thermal} = \dot{m} c_p \Delta T_{col} \quad \text{(Eq. 4)}$$

$$\eta = \frac{Q_{thermal}}{Q_{in}} \quad \text{(Eq. 5)}$$

The efficiency jump between 125/150 °C is due to the transition from laminar to turbulent flow at which point the calculation of the heat transfer coefficient between the pipe wall and the fluid changes. Average temperatures along the length of the tube are presented in Figure 14 for an inlet temperature of 200 °C, showing a maximum temperature rise along the fin length of 40 °C.

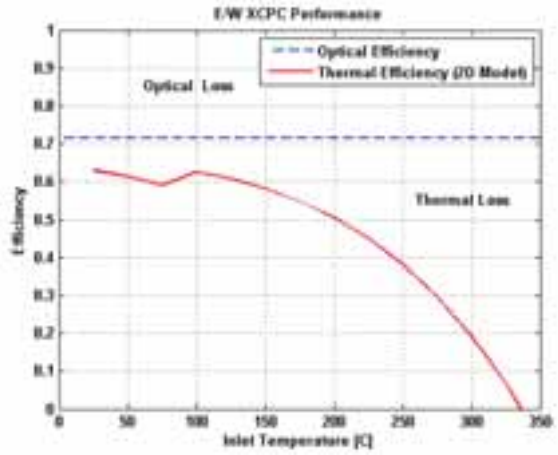

Figure 13 – Simulated performance results for an input irradiance of 1000 W/m².

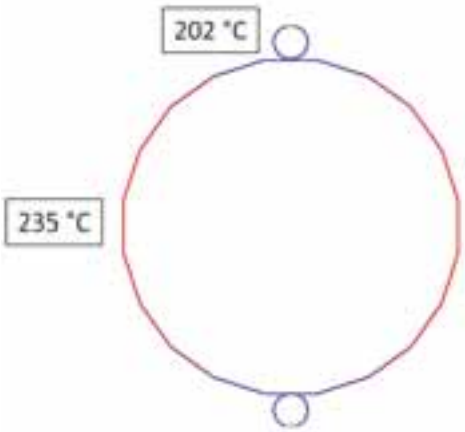

Figure 14 – Temperature profile of fins for an inlet temperature of 200 °C.

5. Experimental Test Results

Performance of the prototype XCPC collector was tested at the University of California Merced Castle Research Facility. In this section is a description of the test platform, testing methods, and experimental performance results.

The half-collector prototype (3 tubes) was mounted on a dual axis tracker to measure on and off-axis performance for characterization. A precision spectral pyranometer (PSP) and normal incidence pyrheliometer (NIP) mounted on the tracker measure the solar resource. The main test platform is a medium temperature oil loop (Figure 15) which contains a circulation pump, primary heating element, coriolis flow meter, thermocouple clusters, and an in-line calorimeter. A total of 33 sensors are installed in the system, including: 1 Coriolis flow meter (± 0.1 %); 25 K-type thermocouples, 4 pressure gauges, 1 current clamp sensor, 1 Precision Spectral Pyranometer (PSP), and 1 Normal Incidence Pyrheliometer (NIP). Data is collected using an Agilent 34970A data acquisition unit, which scans and records all sensor readings every 5 seconds. The instrument and measurement error are listed in Table 5.

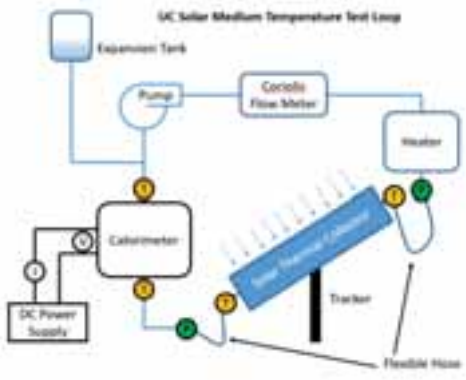

Figure 15 – UC Solar Medium Temperature Test Loop Schematic

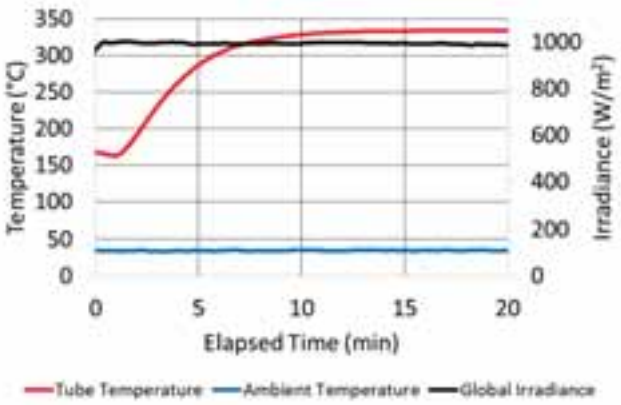

Figure 16 – Stagnation test results

Table 5 – Instrument and measurement error

Device	Instrument Error	Keysight Measurement Error	Temperature Coeff. [/°C ambient above 28°C]
k-Type thermocouple	±1.1°C or 0.4% (whichever is greater)	±1.0°C	+0.03%
Coriolis Mass Flow Meter	±0.1% of reading	±0.01% of reading	+0.001% of reading
UNI-T UT210 current clamp meter	±2.0% of reading	NA	NA
DC Voltage Measurement	NA	±0.0045% of reading + 0.003% of range	±0.0005% of reading + 0.0003% of range
Precision Spectral Pyranometer (PSP)	±2.5% of reading	±0.0050% of reading + 0.0040 of range	±0.0005% of reading + 0.0005% of range
Normal Incidence Pyrheliometer (NIP)	±2.5% of reading	±0.0050% of reading + 0.0040 of range	±0.0005% of reading + 0.0005% of range

A stagnation test was performed on August 11, 2017. Three thermocouples inserted at various lengths inside the upper fluid channel of a single evacuated tube on the XCPC collector measure the temperature over time. The results of this test are shown in Figure 16. The inside of the evacuated tube reached a final stagnation temperature of 333 °C.

Optical testing was performed between August 20th and September 6th using the setup shown in Figure 17. The efficiency is calculated according to equation 6, where $\dot{m}$ is the mass flow rate of the HTF in kg/s, c_p is the heat capacity of the fluid in kJ/kg-K, ΔT_{col} is the temperature difference across the collector in °C, A_{col} is the aperture area of the collector in m^2, and G is the global solar irradiance in kW/m^2.

$$\eta_{thermal,flow} = \frac{Q_{thermal,flowrate}}{Q_{solar}} = \frac{\dot{m}c_p\Delta T_{col}}{A_{col}G} \qquad \text{(Eqn. 6)}$$

These tests were performed using city water as the heat transfer fluid. Thermocouple clusters measured the average inlet and outlet temperature and the flow rate was measured manually by recording the time it took to fill up a 5 gallon bucket (which actually contains 5.6 gallons). The heat capacity of water was assumed to be a constant 4.18 kJ/kg-K. Results are presented in Figure 18 from which an average optical efficiency of 62% was obtained.

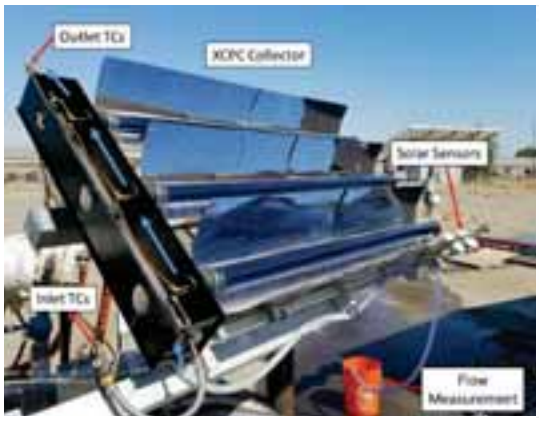

Figure 17 – Optical Testing

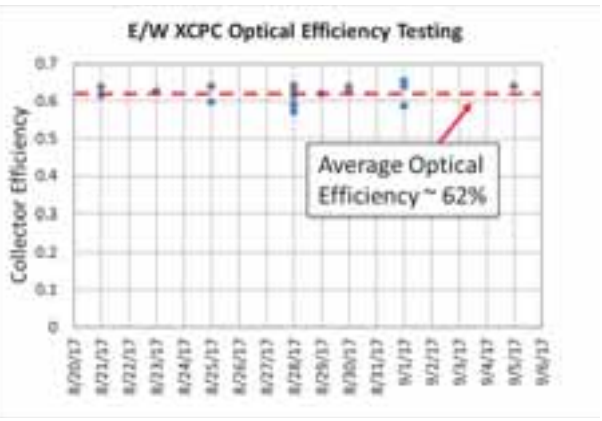

Figure 18 – Optical Test Results

The XCPC collector (Figure 19) was tested at elevated temperatures using the oil test loop. The instantaneous thermal efficiency of the collector was calculated using the standard flow rate method (equation 7) and also using

a calorimetric technique discussed below.

A calorimeter installed in-line with the solar collector generates heat using two 1 kW resistive heating elements placed inside two counter-flow tubes. The heat transfer oil enters the outer annulus of the counter-flow tube and exits through the inner annulus where it is in direct contact with the heating element (Figure 20). The two heating elements and oil flow path are constructed in parallel and the entire calorimeter is wrapped in aerogel insulation with the heated portions encased in all glass vacuum tubes to limit heat loss to the environment. Two k-type thermocouple clusters containing six thermocouples each measure the inlet and outlet temperatures of the calorimeter.

Figure 19 – Oil Testing

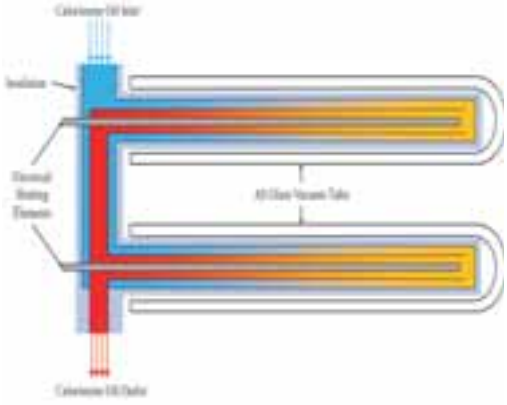

Figure 20 – Calorimeter Schematic

Since the calorimeter is plumbed in-line with the collector it sees the same heat transfer fluid (C_p) and flow rate as the collector. A known amount of power input generates a repeatable temperature rise across the calorimeter. By comparing the temperature rise across the calorimeter to the temperature rise across the collector, the power output of the collector can be determined. For example if the collector raises the temperature 10 °C and the calorimeter also raises the temperature 10 °C from 2 kW of power, we know the collector is generating 2 kW of thermal power.

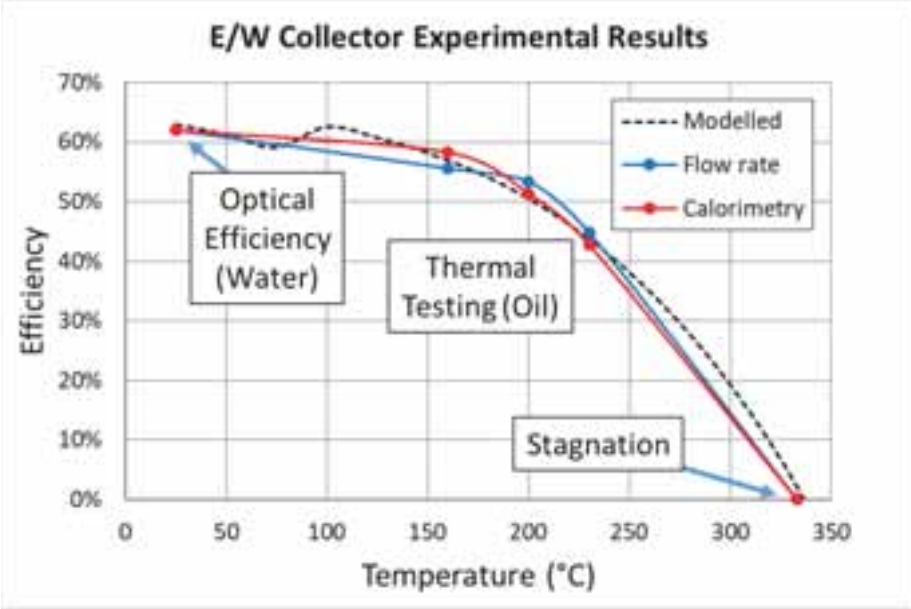

Figure 21 – Experimental Results

The use of a calorimeter provides a redundant measurement which eliminates the flow rate measurement and dependence on heat capacity which is prone to change from the manufacturers specifications over time. Instead they are replaced by more reliable temperature, current, and voltage measurements. The thermal efficiency

determined by the calorimeter is calculated according to equation 7, where ΔT_{cal} is the temperature rise across the calorimeter, V_{cal} is the DC supply voltage, and I_{cal} is the DC current. Results are presented in Figure 21.

$$\eta_{thermal,cal} = \frac{\mathrm{Q_{thermal,cal}}}{\mathrm{Q_{solar}}} = \frac{\frac{\Delta T_{col}}{\Delta T_{cal}} \cdot V_{cal} \cdot I_{cal}}{A_{col} G} \qquad \text{(Eq. 7)}$$

6. Installations

Figure 22 – Merced, CA Installation

The Merced installation shown in Figure 22 is a 20 kW array of the E/W collectors described in this paper installed alongside an earlier generation 20 kW N/S array. These arrays are used to provide thermal power for various projects including solar cooling (Widyolar et al. 2014), solar drum drying (Ferry et al. 2016), and is currently being commissioned for solar wastewater evaporation.

Some representative data is presented below in Figures A, and B for September 8th, 2016. The total solar energy incident on plane of the collector array between 11:45 pm and 5:00 pm was 175.5 kWh, resulting in a thermal generation of 76.9 kWh and 70.6 kWh of cooling from the chiller.

Experimental testing on a single E/W collector showed an efficiency of 55% at an operating temperature of 160 °C while the efficiency of the array tested in this experiment at the same temperature was around 44%. The decrease is attributed to heat losses through the insulated pipes which interconnect the collectors in the array. A rough calculation shows this is on the order of 2-3 kW from the 150 m of ¾" pipe insulated with 2" of fiberglass. Accounting for this heat loss makes the data from this experiment consistent with the previously reported test results. The E/W array took approximately 2 hours to warm up to an outlet temperature of 180 °C and provided 15-20 kW of direct solar powered cooling for an additional 6 hours. A solar COP of 0.44 demonstrated by the E/W array is comparable with other documented double effect solar thermal cooling systems.

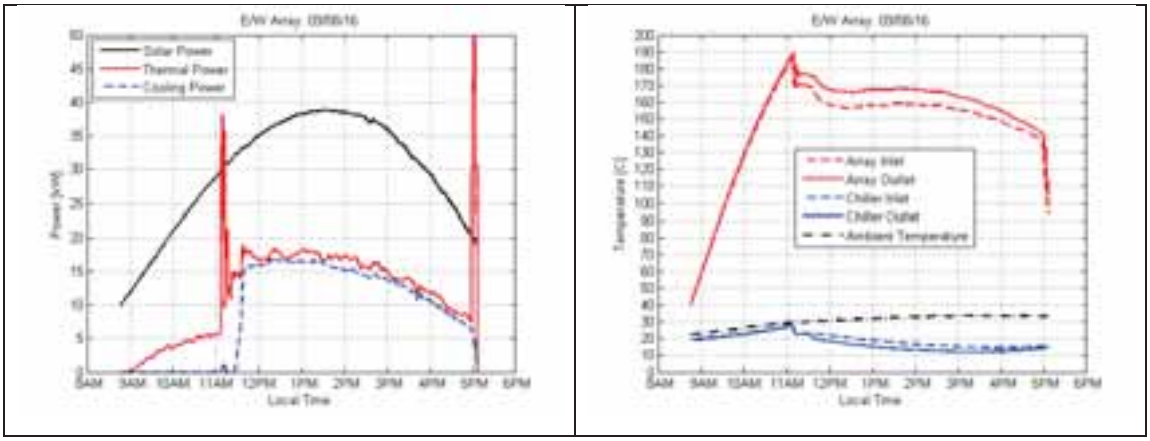

Figure 23 – Sept 8th, 2016 – E/W Array Performance	Figure 24 – Sept 8th, 2016 – E/W Array Temperatures

Table 7 – East-West Array – September 8th, 2016

		Range (instantaneous)	Operational Average*
Collector efficiency	Thermal power captured at 160 °C per available solar power.	0.350 – 0.565	0.438
Thermal COP	Cooling power per captured thermal power	0.721 – 1.101	0.919
Solar COP	Cooling power per available solar power	0.288 – 0.488	0.402

*Operational average taken between 11:45 am and 5:00 pm.

Figure 25 – UlaanBaatar, Mongolia Installation

The Mongolia installation shown in Figure 25 is a 5 kW E/W array installed to provide space heating (Winston et al. 2014). The collector system is installed completely off-grid, using a small PV panel to power a 24 VDC circulation pump which circulates antifreeze through the collector array. The heat is transferred into the ger by a heat exchanger, which is stored in 55 gallon insulated drums of hot water.

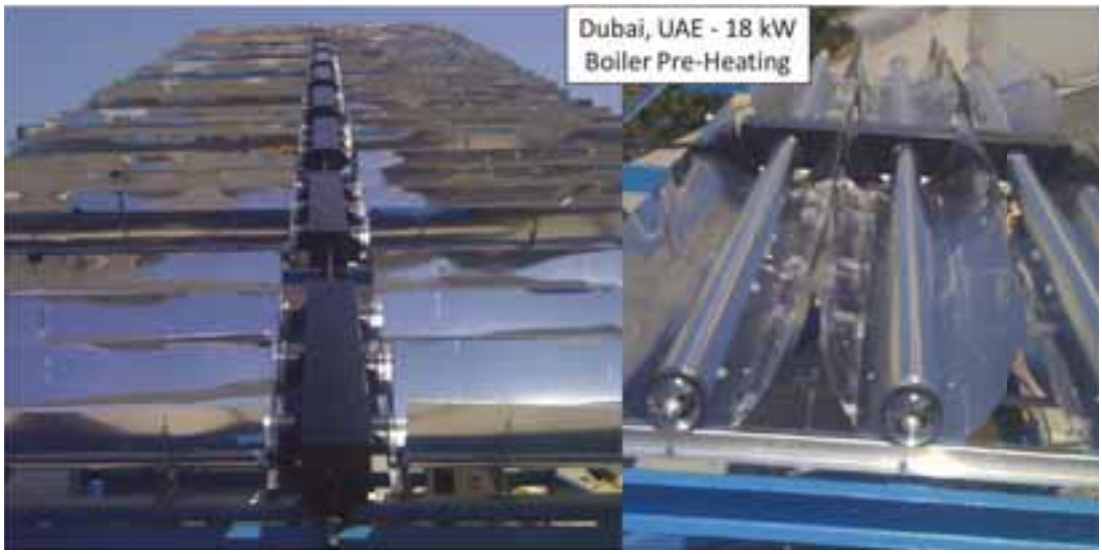

Figure 26 – Dubai, UA Installation

The Dubai installation shown in Figure 26 is the most recent installation and is currently being used to provide boiler pre-heating for sugar refining.

7. Conclusion

In this paper we present the most recent round of developments on the external compound parabolic concentrator (XCPC). The XCPC is a wide-angle concentrator which allows it to (1) collect sunlight year-round from a stationary position, (2) accommodate installation misalignment, and (3) collect a significant fraction of the diffuse solar resource while still providing 1.4X concentration on the absorber. The evacuated tube absorber allows efficient operation regardless of external climate conditions (hot or cold). Optical and thermal simulations have match the experimental data very closely. The collector has an optical efficiency of 62% and a thermal efficiency of 59% at 100 °C and 50% at 200 °C. Current installations are located in California, Mongolia, and the United Arab Emirates and the technology is being commercialized in the USA and India.

Abstract

In this paper it is introduced the development of solar thermal including solar hot water, solar heating combisystem, solar cooling, solar drying, solar cooker, solar desalination and solar thermal power etc during 2011 to 2015 and looking forward to these technologies developing including anticipation for technique progress and projects spreading during 2016 to 2020 in China.

Keywords: solar hot water, solar heating combisystem, solar cooling, solar drying, solar cooker, solar desalination, solar thermal power

1. Introduction

There are two influence factors for development of solar thermal during 2011 to 2015 in China. The favorable factor is policy supporting from governments, such as "the Demonstration Items for Renewable Energy Application in Buildings" supported by the Ministry of Finance and Ministry of Housing and Urban-Rural Development of PRC and demonstration projects of "Green Small Towns" and "New Energy Cities" supported by National Energy Administration, the Ministry of Finance and Ministry of Agriculture of PRC etc. The unfavorable factor is market environment. As national economy developing speed changing slowly especially gliding of real estate which has a close relation with solar thermal, developing of solar thermal also meet some difficulties. So it is necessary taking positive and useful measures to overcome them on the base to sum up the past experience for China's whole profession of solar thermal.

China's fast developing of solar thermal mainly depended on application of solar hot water in the past and now this market becomes saturated. Therefore an important countermeasure is extending application fields, such as from solar water heating system extending to solar heating combisystem, from solar heat for buildings extending to solar heat for industrial and agricultural processes and we will have a rather favorable circumstances in the next years. For decreasing serious air pollution, in the 13th Five-year plan (from 2016 to 2020) China government has decided a higher goal for renewable energy application and especially has made a guiding principle on cleaning space heating in countrysides of northern China. So under this background we can anticipate hopefully that solar thermal in China will have a better development in the future, and we should pay more attention to technical progress which includes raising product quality and improving system optimum design etc. At the same time we should also promote the international cooperation with developed countries having advanced technology of solar thermal and raise our ensemble capacity.

2. Development of Solar Thermal During 2011 to 2015

2.1. Industry of solar thermal

China has the largest solar thermal industry and market in the world. But it is different with many developed countries where the flat-plate solar collectors are the main products; manufactures for evacuated tube solar collector are still the most, although some manufactures have started to produce flat-plate solar collectors during these years in China. Figure 1 is shown year-quality of sale for collectors and the figure 2 is capacity in operation of solar thermal systems from 2005 to 2015 in China. We can know from these two figures that 2013

doi:10.18086/swc.2017.31.19 Available at http://proceedings.ises.org

is a changing year, the year-quantity of sale for collectors decreased after this year, but the capacity in operation of solar thermal systems has still a little increasing.

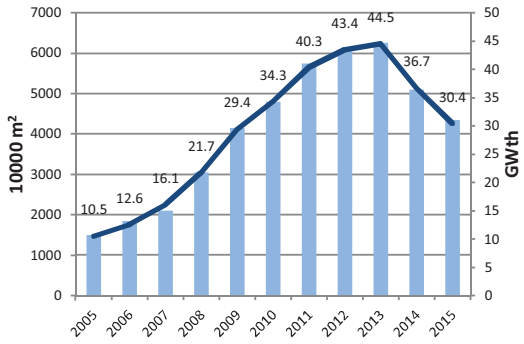

Fig. 1: Year-quantity of sale for collectors

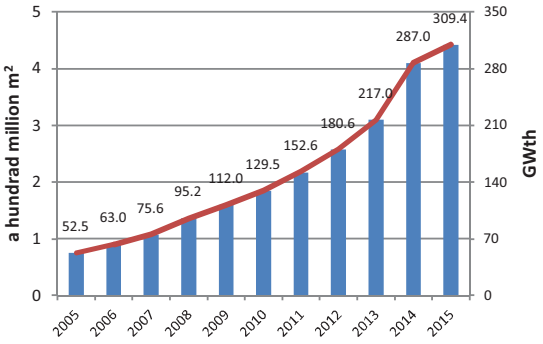

Fig. 2: Capacity in operation of solar thermal systems

2.2. Developing for new products

During 2011 to 2015 China enterprises of solar thermal developed following two key new products:

- Evacuated tube solar collector reaching 150 ℃ working temperature, when reduced temperature difference T_m* is 0.13 (m^2℃) / W, the collector instantaneous efficiency is 53%, its efficiency curve is shown in fig.3. The scale of year output can get three hundred thousand evacuated tubes and one hundred thousand collectors.
- Selective coating for flat-plate solar collector, absorptance is 0.94～0.95, emissivity is 0.05～0.07 and having better anti-aging performance. Automatic production lines for absorber plate with selective coating have been built in Sichuan, Shandong and Fujian provinces etc. The whole production capacity is 11 million m^2 and having own intellectual property.

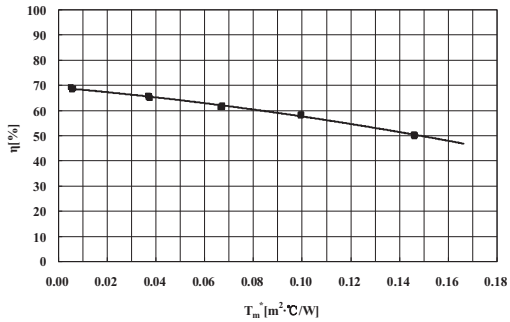

Fig. 3: Efficiency curve of collector

Fig. 4: Collector instead of balcony railing for a solar hot water system

The other important new product is solar air collectors having different structure types and some solar air collectors have realized industrialization.

2.3 Solar water heating system

During 2011 to 2015 application for solar water heating systems had some bigger progress and mainly reflected following three aspects:

- National standard 《Minimum allowable values of energy efficiency and energy efficiency grades for domestic solar water heating systems》 GB 26969-2011 was published and practiced in 2011. The standard gives the energy efficiency grades according to the coefficient of thermal performance for domestic solar water heating systems. There are three levels of energy efficiency grades, the highest is first level and the threshold enter to market is to reach the third level. So some worse quality domestic solar water heating systems are limited to sell in the market.

- As high-rise residential buildings in the cities are main users of solar hot water in China, so some suitable system types are developed to meet this special situation, such as collective-individual system (collective installation of solar collectors, individual installation of water tanks in each apartments) for easy hot water metering. At the same time to develop some new models for solar collectors integrated in buildings, such as collector instead of balcony railing (shown in Fig.4) etc and suitable installation measures to raise the safety and reliability for meeting the requirement of compulsory installation polices.

- Some new system auto-control measures are developed and got practical application, such as household heat exchange control to reach well-distributed heat supply for a collective-individual system. Heat metering was widely used; performance testing for a solar water system on site has became usual business of national or local testing agencies in China. Some projects have realized long term performance monitor and testing data can be delivered by internet.

2.4 Solar heating combisystem

Developing of solar heating combisystem is since 2000 in China and it is an important transition from demonstration projects changing to scale application duration 2011 to 2015. National standard 《Technical code for solar heating system》 and complement《Technical Handbook for Solar Heating》published and in practice in 2009 and in 2012 respectively, so give a stronger technical support to application of solar heating combisystem in China. Most projects of solar heating combisystem used short-term heat storage and application for solar heating combisystems with seasonal heat storage is still at the staring stage in China, but following two projects established a better foundation to developing of solar heating combisystem in the future.

- More than 0.4 million m^2 building area of peasant residences using solar heating combisystems with short-term heat storage have been built in suburbs of Beijing (Fig.5). From monitoring to the solar heating effects in a typical residence during whole winter, solar fraction is 100% in the case of room average temperature 12℃ and the highest room temperature 16℃. The solar cost of the system is 0.44 RMB / kWh, when the working life of the system is 15 years.

- For solar heating combisystems with seasonal heat storage, the technical level and application scale of China have a bigger difference compare with developed countries such as Denmark, Germany and Canada etc. Therefore the international cooperation project “Sino-Danish Renewable Energy Development Programme: Testing, Research & Demonstration for Large Scale Solar District Heating Systems” which was finished in 2015 gave a lot of best experience to China’s technicians and will promote its better application in China in the future.

Fig. 5: Peasant residence of solar heating in suburb of Beijing

Fig.6: Parabolic-trough collectors for solar cooling

2.5 Solar cooling

Technology of solar cooling is developed since 1970’s in China but its application is still at the demonstration stage. Following is some achievements in this field during 2011 to 2015.

- To develop heat-operated refrigerating machine be suitable to solar application, such as 50 kW adsorption refrigerating machine and 1.N-effect absorption refrigerating machine etc.

- National standard 《Technical code for solar air conditioning system of civil buildings 》 GB 50787-2012 was published and practiced in 2012.

- A solar adsorption air conditioning system (the total area of the solar collectors is 49.4m^2) was successfully used to a national grain depot and got better effects. At the condition of daily solar irradiation 16-21 MJ / (m^2 day), the average daily refrigerating power is 3.3-4.4 kW and operation time of the refrigerating machine in the system is 6.5-8.5h during each day.
- A solar lithium bromide absorption air conditioning system (323m^2 solar collectors and 35kW refrigeration unit) was completed in 2013 and has being stably worked till now. Average solar fraction during whole summer can reach 83% in the case of average environment temperature 32℃ and room average temperature 26℃ and average efficiency of the solar collector system is 50%.
- To develop a lower cost parabolic-trough collector for solar cooling and build some demonstration projects of solar air conditioning (Fig.6). According to the on-site testing for a demonstration project in 4 days having different solar radiation, average efficiency of the solar collector system is 55% and the average solar fraction is 68% in the case of 30℃ average environment temperature and 25.6℃ average room temperature.

2.6 Solar drying

Before 1980's there are only 4 solar drying devices of 183 m^2 total collector areas, but it developed faster after 2000 in China. At the present more than 200 solar drying systems were built and total solar collector areas are more than 4 million m^2, but the most is small system with collector areas lower than 200 m^2. There are two main types of solar drying device, using greenhouse or solar collector. The main drying materials are agricultural products including grain fruit and tobacco etc, and industry products including wood (Fig.7) and building materials etc.

Fig. 7: Solar wood drying

Fig.8 Concentrating solar cooker of sheet steel

Professional standard 《General specification for solar drying system》 NB / T 34022-2015 was published and practiced in 2015. It is a first standard for solar drying in China and gives a very important guidance to optimum design and normal installation of the solar drying devices. As solar air collector is a key component of the solar drying device, national standards 《Specification for solar air collectors》 GB / T 26977-2011and 《Test methods for the thermal performance of solar air collectors》 GB / T 26976-2011 which were practiced in 2011 promoted the quality improving of solar air collector greatly.

2.7 Solar cooker

Solar cooker was developed since 1950's in China. As solar cooker has important action for the peasants in the areas where lack of fuel but having better solar radiation, its developing is always stable and the capacity in operation for solar cookers is more than 4 million nowadays in China. In normal using condition one solar cooker can save about 1000kg firewood every year and is about 2 years of paying back time for cost.

There are main two types of solar cookers, box solar cooker and concentrating solar cooker. As Chinese cooking habit, the most of type is concentrating solar cooker in China (Fig.8), box solar cookers are fewer. China's agriculture professional standard 《Focusing solar cooker》 NY / T 219-2003 is the first concentrating solar cooker product standard of this field in the world.

2.8 Solar desalination

China is one of the 13 poor water countries listed by UN and water resource per person is only 1/4 of the world average level. So solar desalination is a continual interest technology for long time in China, but it is still at the research and experiment stage, although to get some better results such as patent of invention "solar air injection desalination device" etc in recent years, there is not demonstration project of practical application up to now.

2.9 Solar thermal power

During 2011 to 2015 solar thermal power including four types of tower, parabolic-trough, dish and Fresnel was all developed at different level in China. Some enterprises have already the capacity to produce heliostat, Stryn generator and evacuated collector tube be used at parabolic-trough collectors etc. There are more than 14 enterprises who can produce evacuated collector tube be used at parabolic-trough collectors and more than 7 enterprises of producing heliostat in China. Part of products passed the testing of foreign professional agency and performance can reach international level. Several solar thermal power systems have been built in China, such as China's first 1MW tower solar thermal power station (Fig.9) located in Badaling of Beijing, generated in August, 2012 and 1MW dish Stryn solar thermal power system (Fig.10) located in Tongchuan of Shanxi Province, completed in 2016 and Stryn generators are developed and produced by Xian Aero-Engine Plc.

Fig. 9: Tower solar thermal power station in Badaling of Beijing

Fig. 10: Dish Stryn solar thermal power system in Tongchuan

3. Technique prospect for solar thermal during 2016-2020

In 2020 the renewable energy will be 15% of total final energy use in China and among them contribution of solar thermal is 13.7% share. Therefore solar thermal is a key technique for completing this object and we should make more efforts during 2016-2020.

3.1 Industry of solar thermal

The industry of solar thermal in China will enter a key transitional stage, only those enterprises which have technical innovative capacity can be developed faster and change stronger. Therefore some enterprises have started cooperation with concerned department in advanced countries for improving own technical capacity. The industry developing will focus to new products and technologies suitable to middle and high temperature application of solar thermal, such as evacuated collector tube with working temperature higher than 250 ℃.

3.2 Solar water heating system

As solar water heating systems integrated in buildings are main types of solar hot water application nowadays in China, the most important tasks are further raising the system's energy saving effects and quality improving of hot water supply. It is necessary focus to system optimum design, automatic-control, heat metering and to step up efforts recommending different types of fine solar water heating systems integrated in buildings by publishing atlas of excellent projects and holding various training etc. At the same time supervision to compulsory installation for solar water heating systems will be strengthened, so that the market can get further normalization.

3.3 Solar heating combisystem

Solar heating combisystem will realize scale application gradually as two favorable policy decisions from government in the future. One is winter space heating by clean energy in northern part of areas; another is to

supply space heating for buildings in Tibet.

Coal is the main energy for space heating in northern part of China and it is an important influence factor to cause air pollution in winter. Therefore the government makes a policy decision to change this situation by using clean energy for space heating instead of coal for decreasing air pollution. In this year a demonstration item for space heating using clean energy in northern part of areas has been initiated by 4 ministries together, the Ministry of Finance, the Ministry of Housing and Urban-Rural Development, the Ministry of Environmental Protection and National Energy Administration. The item can get different level's financial support from the Ministry of Finance according to city's size. As one of clean energies, solar heating combisystem can be practiced in the item and get a chance to develop faster in the future.

Although the weather is very cold in Tibet, but there is no space heating measures in buildings in the past. Therefore to supply space heating is a very important decision for improving living condition of Tibet people. Tibet has the best solar energy sources but lacks of common energies, so to build scale demonstration projects of solar heating combisystems in Tibet can solve space heating problem and avoiding environment pollution at once. Several projects of solar heating combisystems have been carried out in practical implement items for space heating of Tibet, at the same time in the national research plan of the 13th Five-year Development Plan, some research and application items of solar heating combisystem for space heating in Tibet have been also listed. It can be expected that China's technique level of solar heating combisystem will be raised substantially after these items completing.

3.4 Solar cooling

As PV cost decreased continuously in recent years, solar PV electric refrigerating comes into a fine developing chance and a discussion of comparison for solar PV electric refrigerating and solar thermal power refrigerating is resulted. But to China's condition most of areas need space heating in winter and air conditioning in summer, so solar thermal power refrigerating can get better effects and cost performance compare with PV electric refrigerating. Therefore solar cooling using thermal power refrigerating should still have more application and we should pay more attention to two aspects. One is to expand the application scale of solar cooling in suitable areas such as in Turpan of Xinjiang Uygur Autonomous Region where it is dry, hot daytime but cool at night in summer and solar radiation is very nice. Another is to raise technical level for new product research such as to develop small unit of refrigerating capacity lower than 50kW etc. Fortunately, a large demonstration project of solar cooling has been practiced in Turpan, and it will promote the technology progress of solar cooling in China through experience summarization of this project's design, construction and operation etc.

3.5 Engineering construction national standards

In the past there are two types of engineering construction national standard in China. One is mandatory standard which includes some (at least having one) compulsory provisions. The compulsory provisions are only concerning safety, personal healthy etc requirements and must be executed strictly. Another is voluntary standard which has not compulsory provisions. But this system will be reformed in the future, only mandatory standard is still national standard, whole texts are compulsory provisions in it and the provisions will include the requirements to capacity, performance and technical measures, except safety etc. Voluntary standard will be changed to professional or association standard and not be controlled by government. For getting better reforming results some items have been started to research the compiling principle and text contents included in each mandatory standard etc. As the importance of energy efficiency and renewable energy to economy developing, one of the items is "compiling research to code for energy efficiency and renewable energy application in buildings" which includes the contents of solar thermal application in buildings. After the item completing the next task is to compile "Code for energy efficiency and renewable energy application in buildings" according to the item's research results and this code will produce an advantage to standardize application of solar thermal in buildings as well as to improve its energy saving effects in China.

3.6 Solar drying

Most of solar thermal application including solar hot water, heating combisystem and cooling is in buildings in the past, but in the future more will be changed to the fields of industry and agriculture in China. Solar drying is a main technique type used in the fields of industry and agriculture, so it can be expected that solar drying will meet an excellent developing chance and have larger scale of application. In the aspect of technology progress,

we should focus attention on to develop solar air collectors which have high efficiency and can be suitable to solar drying systems for different materials, low cost heat storage devices and build more demonstration projects.

3.7 Solar cooker

Tourism industry developed very faster in recent years in China. So an important developing direction of solar cooker is to research and produce new box solar cookers which are easy carry, having low cost and used to field cooking such as barbecue etc for tour. Some enterprises have produced several model machines, the next step is to improving performance further and to form a certain manufacture scale.

3.8 Solar desalination

During 2016-2020 solar desalination should be changed from theory and experiment research to demonstration application in China. The main focuses are integrating technique for solar thermal system with common sea water desalinization, system optimum design, to raise economical efficiency and to build demonstration projects for solar desalination in the islands where lack of fresh water etc.

3.9 Solar thermal power

During 13th Five-year plan more demonstration projects for solar thermal power will be started in China and several projects of solar thermal power have been approved by the National Energy Administration. After these projects finishing and generating, they can get financial subsidies by 1.15 CNY/kWh of sales price to power network. Compared with PV solar thermal power can be combined heat and power production, so research for technology of heat and power cogeneration suitable to solar thermal power is one of the important tasks in the field of solar thermal power, especially against the background of space heating using clean energy.

Solar Thermal Desalination Technology

Investigation of optimal design of direct contact humidification-dehumidification desalination cycle

Saeed Dehghani, Farzaneh Mahmoudi, Abhijit Date and Aliakbar Akbarzadeh

Energy Conversion and Renewable Energy Group, School of Aerospace, Manufacturing and Mechanical Engineering, RMIT University, Melbourne 3083, VIC, Australia

Abstract

Ongoing water scarcity around the world caused researchers to investigate renewable based desalination systems for providing fresh water. Direct contact humidification-dehumidification desalination is one of the recently introduced technologies for decentralized small-scale water supply. Major energy source of the cycle is heat that can be provided from any available low-grade heat sources such as waste heat or solar thermal collectors. In this paper, a thermodynamic based analysis implemented to the cycle. And through a theoretically investigation, effect of various operational variables such as bottom and top temperature, flow rates and components effectiveness on the cycle performance parameters has been studied in order to evaluate the cycle performance and address optimal working condition. Understanding optimum working condition of the system can provide outstanding technical information for fabrication and sizing of experimental test rig as well as actual module in advance.

Keywords: humidification dehumidification, HDH, Desalination, Solar energy, GOR

1. Introduction

Providing fresh water is a vital need of human being for living all around the world. Desalination methods are the main technological solution for producing fresh water from saline or impure water. Therefore, various type of desalination methods were proposed and developed that can be categorized in membrane and thermal type.

The first and widely commercialized desalination processes based on evaporation technique are multi-stage flash distillation, multiple effect distillation and vapor compression. The second category of desalination processes uses membrane technologies including reverse osmosis, electro-dialysis and membrane distillation.[1] Humidification-dehumidification (HDH) desalination distillation is a one of recently well-studied technologies among the researchers.

The main features of the HDH cycle including remote area water supply, small scale application makes it a competitive alternative application among other desalination technologies. Availability of solar irradiation and any type of impure water such as seawater or brine can make it a sustainable solution for producing pure water. Therefore, all regions of the world like small islands close to the equator with availability of daily solar irradiance as well as saline water the HDH technology is a considerable option. Moreover, the components of the HDH technology is using available and affordable materials that can be find in market as well as maintenance of the system in not demanding in the terms of skilled labor [2, 3].

Basically, the direct contact (DC) HDH desalination system utilizes two main components for producing distilled water. These are humidifier and dehumidifier. As it shown in Fig. 1 in humidifier saline water after heating up through heat source sprayed over air in order to moisturizing it by increasing the air temperature. Then, the hot moisturized air transferred to dehumidifier in which cold fresh water spraying over it and condensed the vapor content of the humid air by decreasing the temperature of it. The distilled water with fresh cooling water will be collected together at the bottom of the dehumidifier and fresh water will be cooled down through a heat exchanger and sprayed again. It should be note that; humidifier and dehumidifier are heat and mass exchange (HME) devices in which there is simultaneous heat and mass transfer occurrence for these devices. Heated fresh water after dehumidifying process can be cooled down with saline water before it enters to heater. Therefore, the fresh water can be cool down as well as the saline water can be preheated in practical approaches for system designing. However, as matter of simplicity this possibility is not incorporated in this study.

There are different configurations of HDH cycles based on which stream is heated up as well as which stream is open or close. In close air/water cycles, air/water is circulated in a closed loop between humidifier and

doi:10.18086/swc.2017.32.01 Available at http://proceedings.ises.org

dehumidifier while water/air is open loop. The air in these systems can be circulated by either natural convection or fan forced by adding a blower. For instance, closed-air open-water (CAOW) water-heated cycle is demonstrated in Fig. 1. Therefore, different types of the HDH cycle can be considered such as close-air open-water(CAOW) air-heated cycle, close-water open-air (CWOA) water-heated and close-water open-air cycle (CWOA) air-heated. [2, 4, 5]

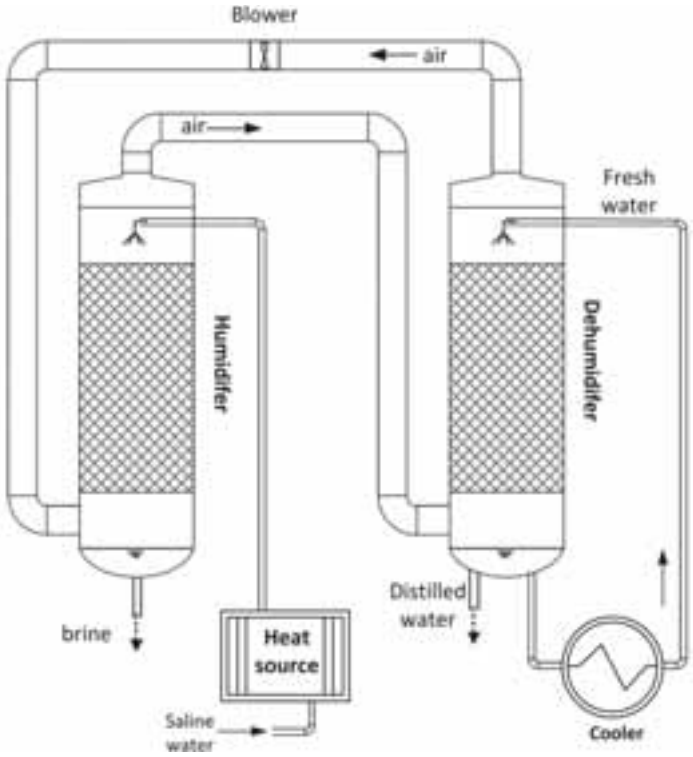

Fig. 1: Overview of the humidification-dehumidification with direct contact dehumidifier

There have been numerous works on non-direct condensers for dehumidification in the HDH cycle.[5-10] Moreover, in this area, several studies have been performed to replace the thermal energy sources of the process from fossil fuel with renewable ones and especially solar energy.[11-13] Also, in other studies, an alternative low-grade heat source such as industrial waste heat or geothermal [14-17]were considered for supplying thermal energy demand of the cycle. These sources of heat can be applied to the HDH cycle with direct contact as well. To make the dehumidifying process in non-direct HDH cycle cost effective, an efficient low cost dehumidification method can be alternated to condense water vapor out of the air stream. With a large fraction of the air/vapor mixture being non-condensable, direct contact condensation is considerably more effective than film condensation. In addition, direct contact condensation within a packed bed is more effective than droplet direct contact condensation.

Bharathan et al. [18] initially introduced a direct contact condenser approach to enhance the heat transfer rate in presence of non-condensable gas. James et al. [19] fabricated a laboratory scale direct contact condenser to study the variation of temperature, humidity, and condensation rate through the condenser system. They evaluated their result by considering a finite volume method for analyzing the packing condenser.

Eslamimanesh and Hatamipour[20, 21] conduct a theoretical analysis for the open-air open-water HDH cycle to study effect of working parameters on water production rate as well as an economic study of the system. Mehrgoo and Amidpour investigated the optimum water production rate utilizing constructal design theory for a fixed-size HDH system.[22] Ettouney [19] introduced different types of the dehumidifier including vapor compression, desiccant air drying, and membrane air drying.

A lack of study for the CAOW water-heated cycle can be observed from the literature review. Therefore, in this study a comprehensive theoretical analysis of a HDH cycle with direct contact dehumidifier performed in order to understand the optimum working condition of the system.

2. Mathematical modeling

In order to study cycle's behavior with variation of operational variables a theoretical study of the HDH cycle from thermodynamic standpoint a theoretical modeling is implemented. As it shown in Fig. 2 the cycle components are considered "black-box" that do not consider transport properties inside the components.

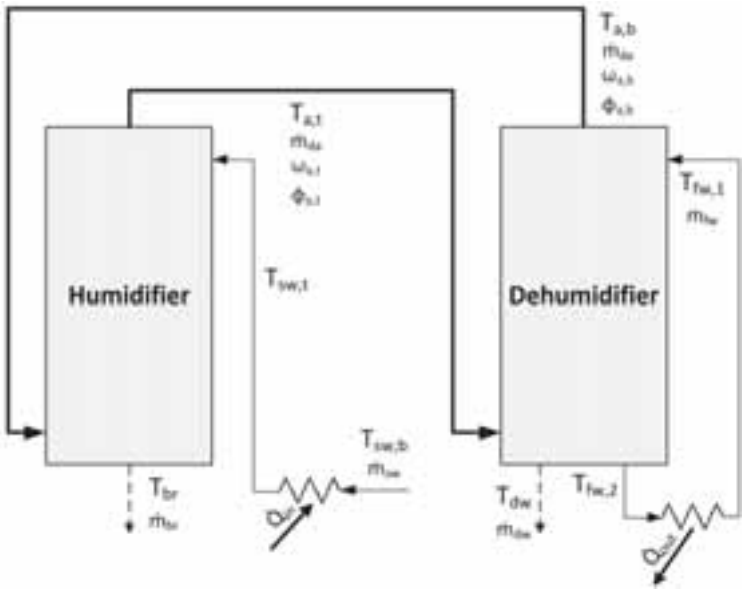

Fig. 2: Schematic diagram of the humidification-dehumidification with direct contact dehumidifier

Following assumptions are considered in theoretical modeling of the direct contact HDH cycle.

- Cycles operate at steady state and steady flow conditions.
- Humidifier and dehumidifier are adiabatic and there is no heat loss from any of the cycle pipelines to their surroundings.
- Pumping and fan powers are negligible in comparison to total thermal energy input of the system.[5, 23]
- Kinetic and potential energy terms are excluded in the energy balance.
- The water condensed in the dehumidifier is assumed to leave at a temperature which is the average of the humid air temperatures at inlet and outlet of the dehumidifier.[5]

The presented model in this study is based on the energy and mass balance implementation on each system components including humidifier, dehumidifier, heater and cooler, so they can be find in thermodynamic text books.[24] However, to solve the governing equation some cycle variables should be known. These parameters are saline water temperature of humidifier inlet, fresh water temperature of the dehumidifier inlet, effectiveness of humidifier and dehumidifier as well as relative humidity of air entering humidifier and dehumidifier. Therefore, for a range of variation of these variables the analysis is performed.

The governing equations can be summarized as following:

Humidifier energy and mass balance:

$$\dot{m}_{sw} + \dot{m}_{da}\omega_{a,b} = \dot{m}_{br} + \dot{m}_{da}\omega_{a,\mathrm{t}} \tag{1}$$

$$\dot{m}_{sw}h_{sw,t} + \dot{m}_{da}h_{a,b} = \dot{m}_{br}h_{br} + \dot{m}_{da}h_{a,\mathrm{t}} \tag{2}$$

Dehumidifier energy and mass balance:

$$\dot{m}_{da}\omega_{a,t} = \dot{m}_{dw} + \dot{m}_{da}\omega_{a,b} \tag{3}$$

$$\dot{m}_{fw}h_{fw,1} + \dot{m}_{da}h_{a,t} = \dot{m}_{fw}h_{fw,2} + \dot{m}_{da}h_{a,b} + \dot{m}_{dw}h_{dw} \tag{4}$$

It should be noted that, the dry mass flow of air is constant through the humidifier. Also, enthalpy of humid air is considered as a binary mixture of dry air and water vapour, in other words: $h_a = h_{da} + \omega h_v$

Heater and cooler:

$$\dot{Q}_{in} = \dot{m}_{sw}\left(h_{sw,t} - h_{sw,b}\right) \tag{5}$$

$$\dot{Q}_{out} = \dot{m}_{fw}\left(h_{\mathrm{fw},2} - h_{fw,1}\right) \tag{6}$$

In order to discover outlet streams conditions in the humidifier and dehumidifier, effectiveness equation needs to be defined and considered for mathematical solution. Principally, effectiveness compares the actual thermal energy versus ideal thermal energy transferred from each stream and is defined as actual enthalpy rate variation to the maximum possible enthalpy rate variation, in other words $\varepsilon = \Delta\dot{H}/\Delta\dot{H}_{\max}$ [25]. Therefore, effectiveness of humidifier and dehumidifier would be extracted as following:

$$\varepsilon_h = \max\left(\frac{\dot{H}_{a,t} - \dot{H}_{a,b}}{\dot{H}_{a,t}^{ideal} - \dot{H}_{a,b}}, \frac{\dot{H}_{sw,t} - \dot{H}_{br}}{\dot{H}_{sw,t} - \dot{H}_{br}^{ideal}}\right) \tag{7}$$

$$\varepsilon_d = \max\left(\frac{\dot{H}_{a,t} - \dot{H}_{a,b} + \dot{H}_{dw}}{\dot{H}_{a,t} - \dot{H}_{a,b}^{ideal} + \dot{H}_{dw}}, \frac{\dot{H}_{fw,2} - \dot{H}_{fw,1}}{\dot{H}_{fw,2}^{ideal} - \dot{H}_{fw,1}}\right) \tag{8}$$

In both humidifier and dehumidifier, the ideal outlet air enthalpy happens when the outlet air is fully saturated at the water inlet temperature, and the ideal outlet seawater enthalpy is when its temperature is equivalent to the inlet air temperature.

In addition to considering effectiveness equations, relative humidity of air at bottom and top air streams should be known. Nawayseh et al. [11] assumed that exit air from humidification column was saturated according to the experimental. Moreover, distilled water temperature is assumed as average of the humid air temperatures at inlet and outlet of the dehumidifier, in other words $T_{dw} = (\mathrm{T}_{a,t} + \mathrm{T}_{a,b})/2$ as is required that the number of equations and unknowns should be same. [5] Therefore, by solving the system of nonlinear equations, unknown variables can be obtained.

For incorporating accurate and reliable thermodynamic properties of the moist air and water and seawater, ASHRAE handbook[26] as well as Engineering Equation Solver (EES) software[27] are applied. EES software has completer library of thermophysical properties for a wide range of substances including moist air properties with the formulation presented by Hyland and Wexler[28] as well as water properties using the formulation of IAPWS (International Association for Properties of Water and Steam) [29].

The obtained system of nonlinear equations was solved utilizing the EES software, which calculates moist air and water properties using built-in functions. These functions have been previously defined in software and evaluate the thermophysical properties of various substances based on a set database in the software. EES is a numerical solver, using an iterative procedure for solving the system of equations. The EES automatically identifies and groups equations that are solved simultaneously. The convergence of the numerical solution is verified by using two methods: (i) 'Relative equation residual' which is the difference between left-hand and right-hand sides of an equation divided by the magnitude of the left-hand side of the equation; and (ii) 'Change in variables changing in each iteration. The calculations are converged if the relative equation residuals are less than certain value for example 10^{-6} or if variable change is less than 10^{-9}. Both relative equation residuals and change in variables are adjustable for desirable precision. Besides, there are two stopping criteria consisting of (i) 'number of iteration' and (ii) 'elapsed time' that can be set for obtaining variables with higher accuracy. EES software is widely used by the scientific community for thermodynamic system evaluations for thermodynamic analysis.[30, 31]

3. Cycle metrics

In order to evaluate the HDH cycle performance in the terms of thermal energy recovery, energy efficiency and water production rate, performance parameters of the cycle are defined.[2] they are basically non-dimensional parameters.

Gain output ratio (GOR): GOR is the ratio of the latent heat of evaporation of the distillate water produced to the total heat input to the cycle from the heat source. It represents the amount of heat recovered in the cycle.

$$GOR = \frac{\dot{m}_{dw} h_{fg}}{\dot{Q}_{in}} \tag{9}$$

Recovery ratio (RR): recovery ratio is the amount of distilled water over inlet saline water to the cycle, which is a criterion for water production efficiency of the cycle. It should be noticed that for low recovery ratios, brine disposal treatment is not necessary.

$$RR = \frac{\dot{m}_{dw}}{\dot{m}_{sw}} \times 100 \tag{10}$$

4. Result and discussion

In order to study the effect of cycle's variables on the performance a range of variation is considered. The fresh water temperature in the cycle at the entrance to dehumidifier may range between 15–30 °C due to the seasonal temperature changes. The top brine temperature in the cycle at the humidifier inlet is assumed to be in the range of 65–80 °C which is basically a low-grade heat source temperature. The effectiveness of both the humidifier and dehumidifier are assumed to be within the range of 65–95%. As there is direct contact humidification and dehumidification process, it is expected that air is fully saturated. However, to study the effect of air humidity a relative humidity range of 70–100% is considered. Therefore, under the basic working condition including, fresh water temperature of 20 ºC and top brine temperature of 70 ºC as well as humidifier and dehumidifier effectiveness of 85% and top and bottom relative humidity of 90% simulation are performed.

In order to find effect of mass flow rate of saline water, fresh water and air on the system efficiency, mass flow rate ratio of humidifier is defined. ($mr_h = \dot{m}_{sw} / \dot{m}_{da}$). In Fig. 3 effect of these mass flow rates on GOR is illustrated. As it shown, by increasing both the flow rate of fresh water and flow rate of dry air at a constant saline water flow rate, the GOR of the cycle would be enhanced. In practical approaches the minimum values of mass flow rate ratio of saline water to fresh water based on available heat source and heat sink capacity can be determined. Therefore, here in a case of flow rate of saline water to fresh water equal to 0.5, higher value of GOR can be obtained.

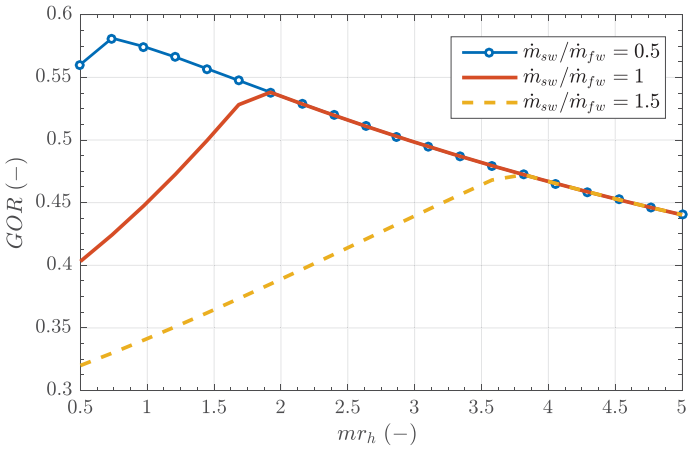

Fig. 3: Effect of mass flow rates saline water, fresh water and air on the cycle GOR

By determining the ratio of the saline water to fresh water, the effect of operational parameters on cycle performance can be studied in detail. Therefore, for flow rate ratio of saline water to fresh water equal to 0.5, impact of operational parameter on cycle performance are investigated in following section.

Fig. 4a demonstrates the GOR against mass rate ratio at fresh water inlet temperatures. As it shown by increasing the humidifier inlet fresh water temperature, both gain output ratio and recovery ratio are decreasing. The maximum value of GOR and RR happening at the same mass flow rate ratio of saline water to dry air. However, for lower temperature of fresh water the optimum happening at smaller mass flow rate ratios. A maximum of 0.62 for GOR can be obtained.

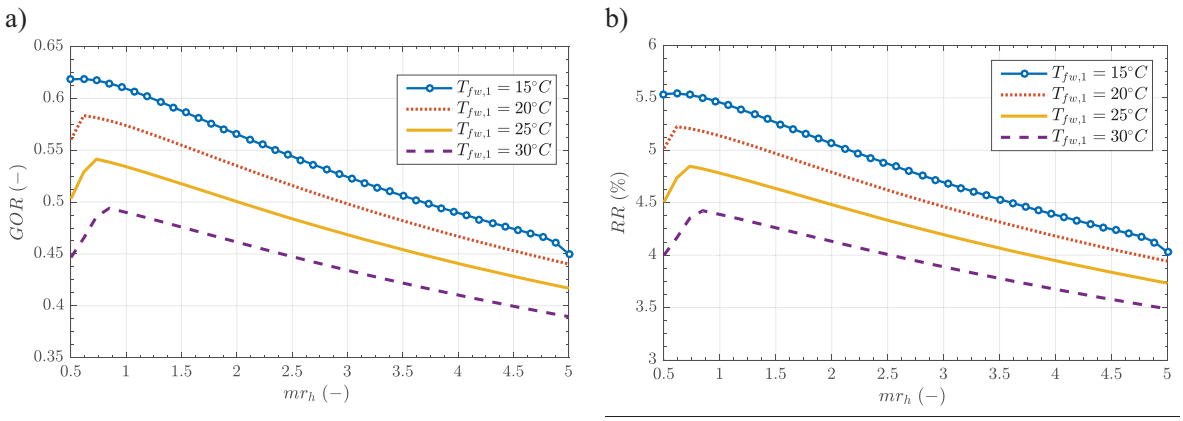

Fig. 4: Effect of inlet fresh water temperatures on gain-output-ratio (a), recovery ratio (b) at different mass flow rate ratios of humidifier

In Fig. 5 the effect of top brine temperature on GOR and RR in depicted. Generally, higher temperature of top brine temperature results is higher GOR and recovery ratio, however; the recovery ratio shows higher values of improvement for higher temperature in comparison to lower temperatures of top brine temperature. Moreover, the optimum value of mass flow rate ratio is slightly rising for higher temperatures of top brine temperature.

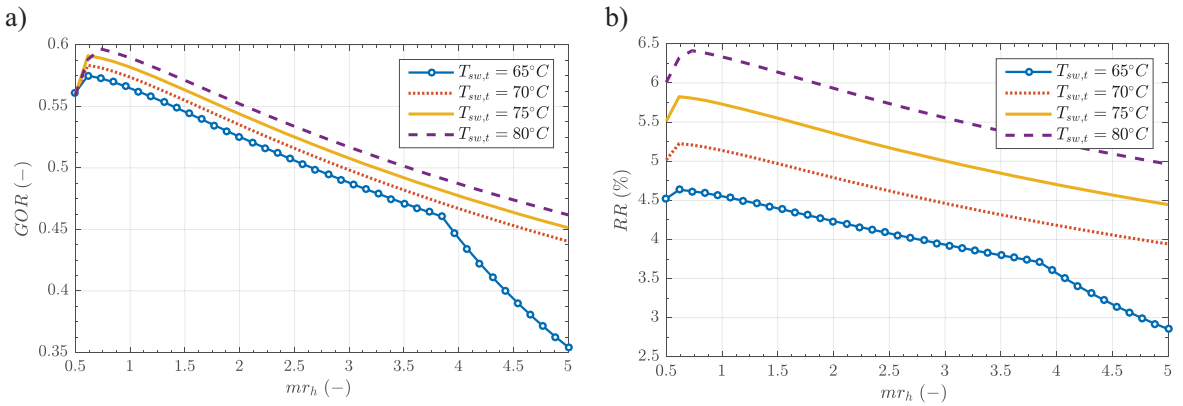

Fig. 5: Effect of top brine temperature on gain-output-ratio (a), recovery ratio (b) at different mass flow rate ratios of humidifier

Relation between the humidifier effectiveness with GOR as well as recovery ratio is shown in Fig. 6. As it displayed, improving the humidifier effectiveness affects the enhancement of both recovery ratio and GOR. Also, optimum point of mass flow rate ratio is almost same for all of the humidifier effectiveness values.

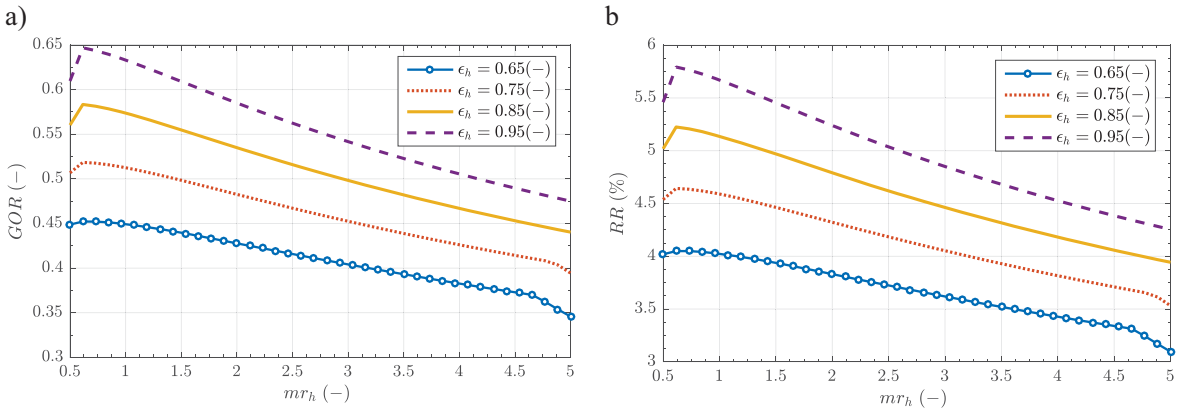

Fig. 6: Relation between the gain-output-ratio (a), recovery ratio (b) and humidifier effectiveness against mass flow rate ratios of saline water to dry air (mr_h)

In Fig. 7, relation of dehumidifier effectiveness with GOR and RR are presented. In general, by increasing the dehumidifier effectiveness both gain-output-ratio and recovery ratio would be enhanced. However, a high effectiveness dehumidifier value would keep wider spectrum of the mass flow rate ratios rather than a low effectiveness values.

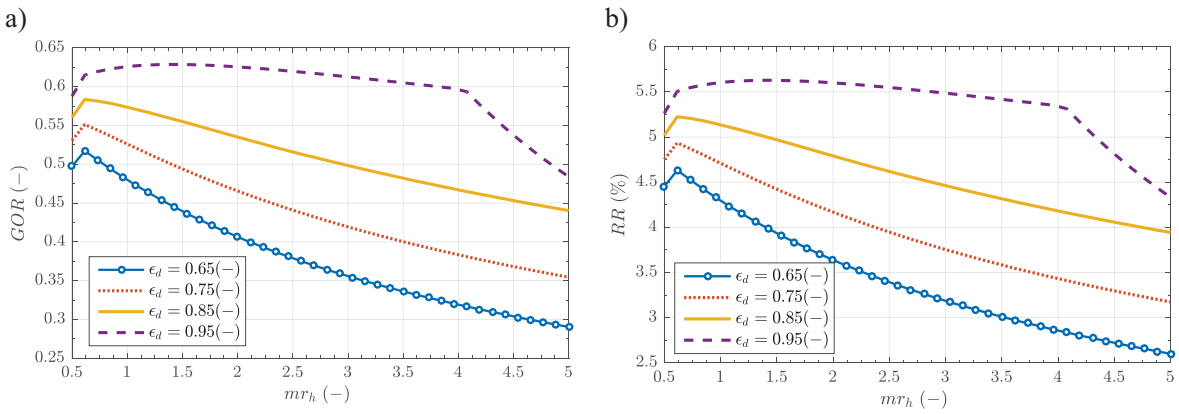

Fig. 7: Relation between the gain-output-ratio (a), recovery ratio (b) and dehumidifier effectiveness against mass flow rate ratios of saline water to dry air (mr_h)

Variation of the GOR and recovery ratio at different mass flow rate ratios is displayed in Fig. 8. As it shown, by intensifying the relative humidity of the air after humidifier outlet, both GOR and RR slightly would be grown. Further, the optimum mass flow rate ratio value shows a slight raise for higher mass flow rate ratios. It should ne mentions that in the experimental study [11] outlet air from humidification column indicated as fully saturated. However, to investigate the effect of air humidity on cycle performance this variable is studied as well.

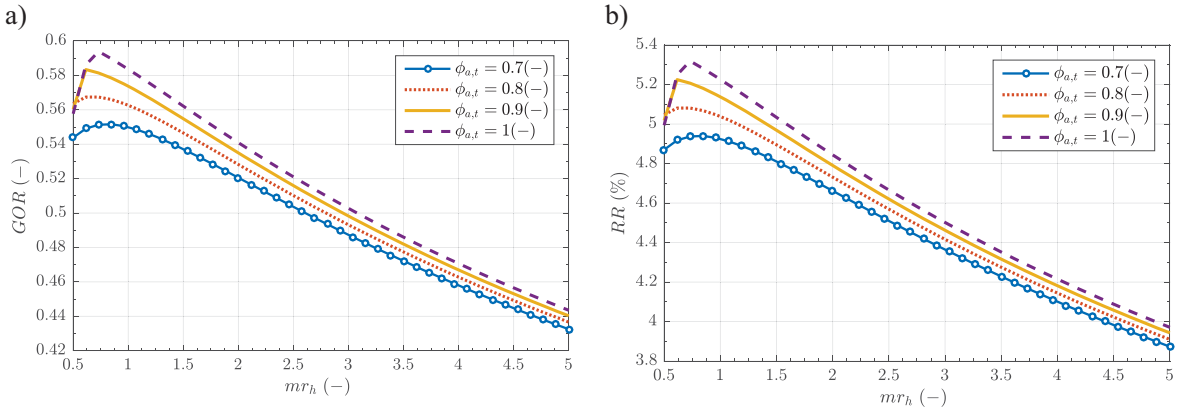

Fig. 8: variation of gain-output-ratio (a), recovery ratio (b) and air humidity after humidifying process against mass flow rate ratios of humidifier

In Fig. 9, variation of gain output ratio and recovery ratio for different values of air humidity are presented. Both GOR and recovery ratio are enhancing by growing the relative humidity. The effect relative humidity after dehumidifying process is pretty similar to the effect of relative humidity after humidification. The reason is that both processes are naturally similar to each other except the working temperature is different.

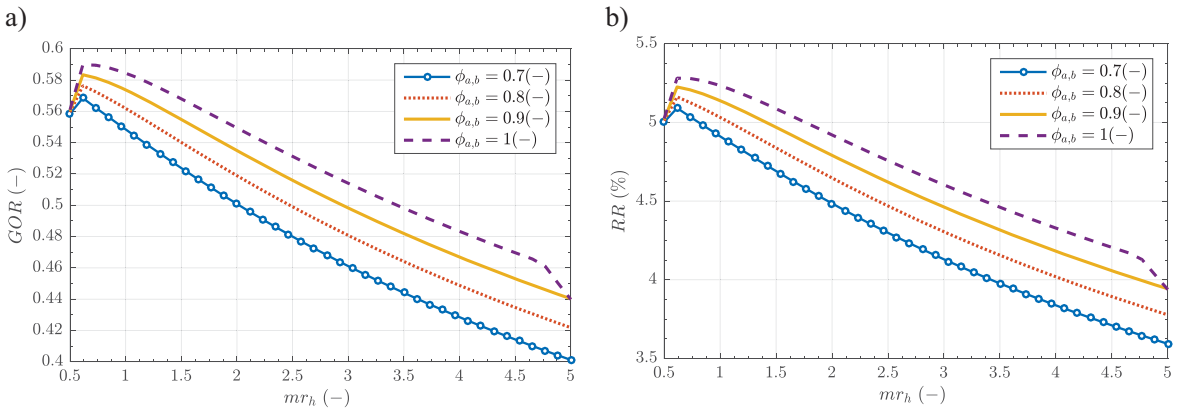

Fig. 9: variation of gain-output-ratio (a), recovery ratio (b), and air humidity after dehumidifying process against mass flow rate ratios of humidifier

5. Conclusion

A parametric study of close-air open-water water-heated HDH cycle with direct contact dehumidifier are performed in order to investigate the optimum working condition of system. To investigate the optimal working condition firstly the mass flow rate of fresh water to saline water is determined. It shown that, by increasing both the flow rate of fresh water and flow rate of dry air at a constant saline water flow rate, the GOR of the cycle would be enhanced. Notice that, in practical design approaches the values of mass flow rate ratio of saline water to fresh water can be determined based on available heating and cooling capacities. Then, at different working condition the optimum mass flow rate ratio of saline water to dry air are discovered. Air flow rate can be adjusted at constant saline water flow rate to reach desirable mass flow rate ratio.

Effect of the top brine temperature on recovery ratio in comparison to its effect on GOR is more considerable as it shows higher values of enhancement. Also, higher top brine temperature is the main variable than can help to improve the recovery ratio of the cycle.

Dehumidifier effectiveness is more important that humidifier effectiveness at high values of effectiveness. Also, the cycle can work on a wider spectrum of mass flow rate ratios with highly effective dehumidifier. As the effect of relative humidity on cycle metrics are small, therefore considering a fully saturated air can be assumed too.

Sustainable Seawater Desalination by Permeate Gap Membrane Distillation Technology

Farzaneh Mahmoudi[1], Mohammad E. Pishbin, Saeed Dehghani[1], Abhijit Date[1], Aliakbar Akbarzadeh[1]

[1]Energy CARE Group, School of Aerospace, Manufacturing and Mechanical Engineering, RMIT University, Melbourne (Australia)

Abstract

Membrane distillation (MD) as a thermally driven process with moderate operating temperatures is a known effective technology for salt-water desalination. In this research, the permeate gap membrane distillation configuration (PGMD), as a novel sustainable MD design having internal heat recovery characteristics, is introduced, designed and the system performance investigated in terms of permeate water flux rate and specific thermal energy consumption (STEC). The experimental results show that, increasing the feed flow rate from 0.1 to 1.1 L/min for the feed salinity in a range of (0−30) ppt, led to increasing the fresh water flux from 2 to 12 kg/m^{2}h, however STEC of the system also showed an increase and varied in a range of 1000 and 2500 kWh/m^3.

Furthermore, a single node theoretical model is developed and the modeling results validated with experimental values. It is concluded, optimization of the MD module performance to improve internal heat recovery and produce higher fresh water rate would be achievable by adjusting the effective membrane surface area and feed flow rate.

Keywords: Sustainable desalination, permeate gap membrane distillation, specific thermal energy consumption, permeate flux rate

1. Introduction

According to the World Water Council, 17% of the world population will be living in short of the fresh water supply by 2020 (Charcosset, 2009). Therefore, the demand for alternative sustainable water sources including ground water, desalinated water and recycled water increased in recent years and thus, the implementation of desalination plants is growing on a large scale. Fresh water can be derived from sea water by evaporation processes e.g., multi-stage flash (MSF), multi- effect distillation (MED) or by membrane based processes, including reverse osmosis (RO), electro dialysis (ED) and membrane distillation (MD).

Membrane distillation is a separation process which involves phase change (liquid-vapour equilibrium) across a hydrophobic, highly porous membrane. In contrast to most membrane separation processes, which are isothermal and have driving forces as trans membrane hydrostatic pressures, concentrations, electrical or chemical potentials, MD is a non-isothermal process.

The commercially developed RO technology consumes high electrical energy normally ranging from 6 to 12 kwh/m^3 that is presently being generated from non-renewable and polluting fossil fuels (Bai et al.). In contrast, MD is a thermal desalination process using lower top temperature (80 °C or less) with respect to the traditional thermal desalination processes.

However, the MD process is still under study and the lack of experimental data has indicated that there is a need for more comprehensive research in this field. The central issues are the external energy source for MD units, lack of MD membranes and fabrication of modules for each MD configuration. Overall, optimization of MD plants is required in order to reach higher MD performance and to decrease energy consumption (Meindersma et al., 2006), an appropriate redesign of the MD module is demanded in order to achieve mass transfer improvement and to increase the membrane surface area per module volume. Moreover, the energy source of the MD process is an

doi:10.18086/swc.2017.32.02 Available at http://proceedings.ises.org

important issue for commercialization of this technology as a sustainable process. Membrane distillation associated with renewable energy is considered to be a highly promising process, especially for situations where low-temperature solar, waste or other heat is available. The STEC of MD systems varies based on the module configuration, setup scale and operating condition. A wide dispersion of reported values is observed in literatures for STEC, which the ranges from 1 to 9000 kWh/m^3 (Khayet, 2013).

Generally direct contact membrane distillation (DCMD) as depicted in Fig. 1-left is the most studied MD configuration (Alkhudhiri et al., 2012). In DCMD the membrane is in direct contact with the feed solution on one side and the permeate on the other side with the temperature difference across the two sides of the membrane as the process driving force. A novel introduced configuration of MD, is called PGMD which by creating a third channel for produced fresh water via an impermeable film on the permeate side, the cold fluid in the condenser side separates from the permeate and therefore it could be any other liquid like saline feed water. The permeate is extracted from the highest module position, so that the gap between the membrane and the impermeable film fills with permeate during the operation (Fig. 1- right).

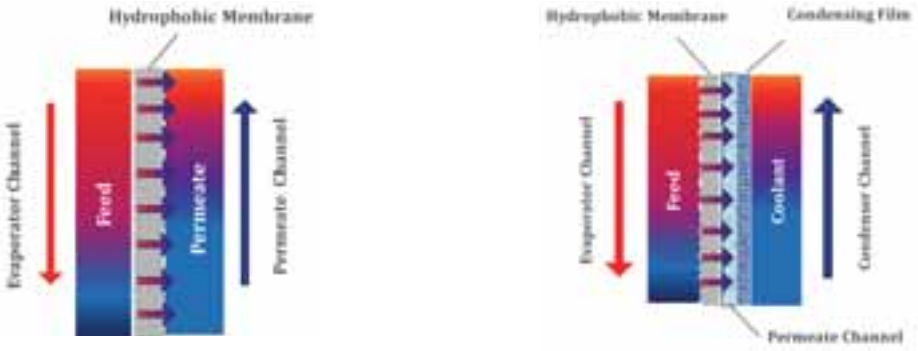

Fig. 1. Left: DCMD configuration; Right: PGMD module arrangement with internal heat recovery

In recent years, some commercial MD modules in different configurations have been developed. (Zaragoza et al., 2014) made a comparison among the most advanced commercial MD prototype technologies with different configurations (air gap, permeate gap and vacuum) and different structures including plate-and-frame and spiral wound. Concerning comparing different MD configuration, Cipollina et al.(Cipollina et al., 2012) also developed a lab scale plate-and-frame membrane distillation module for solar energy seawater desalination and investigated three different channel configurations during this research, including free air gap, permeate-gap and partial vacuum air gap. Winter et al. also developed and optimized MD setup with lowest STEC to reduce the external energy demand of the system, with a 10 m^2 spiral wound PGMD configuration (Winter et al., 2012).

In this paper, by considering the result of comprehensive literature review regarding recent projects in MD field, an experimental approach by designing and developing a lab scale PGMD system configuration is followed to provide a good estimation of the most important characteristic value of a MD setup, including permeate flux, STEC, GOR and its dependency to the modular design and particularly operating conditions. Furthermore the numerical modeling of the heat and mass transfer phenomena in this configuration is studied and a single node theoretical model is developed using some simplifying assumption and the modeling results validated with comparing to the experimental data

2. Laboratory scale PGMD system experimental rig

A novel optimized experimental approach was based on a lab scale plate-and-frame PGMD module with 0.12 m^2 effective membrane area. The hydrophobic PTFE membrane, with 0.22 µm nominal pore size and (140 - 200) µm thickness, with an effective surface area (760 * 160) mm^2, was applied. This plastic PP film had a thermal conductivity similar to that of the PTFE membrane. The permeate channel was separated from the condenser

channel by an impermeable 100 µm clear polypropylene film, which filled with plastic net spacers both as mechanical support between membrane and condensing polymeric films and also as turbulence promoters. The gap width in condenser and evaporator channels was adjusted to 1.5 mm and the gap width in the permeate channel was 3 mm and rubber gasket frames were used for sealing purpose.

A schematic diagram of the lab scale experimental setup is shown in Fig. 2-left. The feed water was pumped from a 100 L storage tank using a small 12 V DC water pump, the feed flow rate to the module controlled either by adjusting the DC pump voltage or by an in-line control valve. A 100 µm pore size mechanical filter was installed before the pump to protect the module and pump from unwanted solids. To adjust the inlet feed temperature to the condenser channel, the lab cooling circuit was used.

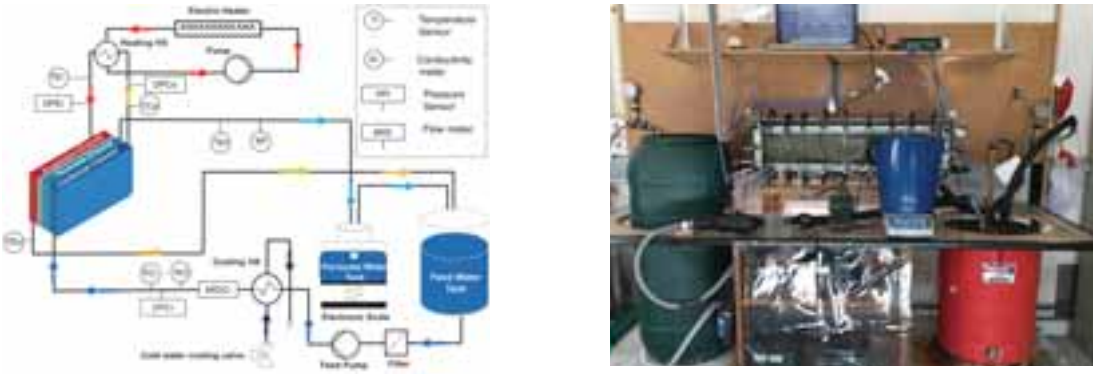

Fig. 2. Left: Schematic diagram of the MD experimental setup; Right: Actual indoor lab scale PGMD experimental setup

The feed water gradually preheats whilst flowing through the condenser channel and using the latent heat of condensation and conduction via the PP condensing film. The condenser outlet temperature was increased by using an external electrical heat source immersed in an insulated electric water tank (2.4 KW), to provide the required evaporator channel inlet temperature for the PGMD module. In the evaporator channel the hot water vaporizes at the membrane surface, diffuses through the hydrophobic PTFE membrane pores and condenses on the permeate channel film. The evaporator channel outlet feed, with higher salinity than the inlet feed to the condenser channel, returns to the feed tank. In order to maintain the feed tank salinity at a constant level, the fresh water pumped from permeate tank by applying a floating ball valve and electronic scale. The produced fresh water exited from the top manifold of the permeate gap. Each experiment ran for at least 90 min to reach a steady state condition and the average values of the recorded data in the steady state condition were used for analysis. Fig. 2-right, shows the indoor lab scale MD setup.

3. Mathematical Model Development in PGMD

To predict the PGMD module performance, a single node theoretical model is developed using some simplifying assumption. The following assumptions are considered:

Steady state condition; stagnant air inside the membrane pores; permeate channels fully filled with pure water; no total pressure difference across the membrane, so no mass transfer by viscous flow; no heat loss by conduction to the environment; stagnant permeate in the permeate channel and so no heat transfer by convection in the permeate gap.

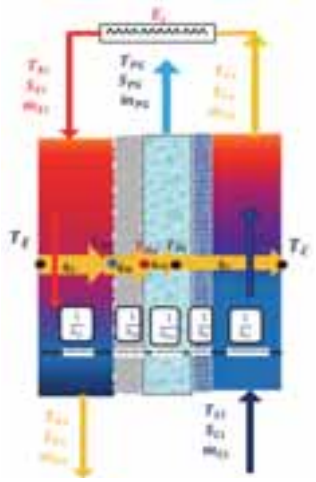

Fig. 3. Single node approach for mathematical modeling of PGMD module

To model the PGMD system, the above assumptions, heat and mass conservation laws in all channels and the five main thermal resistances between evaporator and condenser channels, as shown in Fig. 3 are considered. In addition, by defining the known variables including: T_{Ci}, T_{Ei}, $\dot{m}_{Ci}$, $\dot{m}_{Ei}$, S_{Ci} and S_{Ei} which are respectively temperature (°C), mass flow rate (kg/s) and salinity (g/kg) at the condenser and evaporator channels inlets, governing equations are developed. It is also required to specify the membrane properties, bulk conditions and module geometry in order to carry out numerical modeling.

The convective heat flux from the evaporator channel to the membrane surface is expressed in Eq. 1:

$$\dot{q}_E = h_E\left(\frac{T_{Ei}+T_{Eo}}{2} - T_{Me}\right) \tag{1}$$

Where, $\dot{q}_E$ is the evaporator channel heat flux (W/m^2), h_E is the heat transfer coefficient at the evaporator channel (W/m^2K). T_{Ei} and T_{Eo} are respectively the temperatures at the evaporator channel inlet and outlet and T_{Me} is the temperature at the evaporator side of the membrane surface.

The heat transfer rate from the membrane surface $\dot{q}_M$ arises from the latent heat of the produced vapour flux and the heat transferred by conduction across both the membrane matrix and the gas-filled membrane pores (Khayet, 2011).

Also

$$\dot{q}_M = \frac{K_m}{\delta_m}\left(T_{Me} - T_{Mp}\right) + J_p h_{fg} \tag{2}$$

In this equation T_{MP} is the membrane surface temperature at the permeate gap side, h_{fg} is the water vaporization enthalpy (kJ/kg), K_m and δ_m are the membrane thermal conductivity (W/mK) and thickness (m) respectively. J_p (Kg /m^2s) (based on Eq. 3) is defined as a function of partial vapour pressure on the two sides of the membrane and of the membrane mass transfer coefficient (C_m).

$$J_p = C_m \left(P_{v,swe} - P_{v,swp} \right) \tag{3}$$

For the applied membrane samples with specified structure and under the system operating condition, the dominant mass transfer mechanism is defined as a combination of Knudsen and molecular diffusion (0.01 < Kn <1) (Schofield et al., 1987, Alklaibi and Lior, 2006, Alkhudhiri et al., 2012, Nakoa et al., 2014) . Figures for membrane mass transfer coefficient (C_m) also was in a range of $3\times10^{-7} < C_m < 5\times10^{-7}$ kg/Pa m^{2}s for (30 - 80) °C temperature range and assuming atmospheric pressure in the membrane pores, which was in close agreement with some reported values(Winter, 2014, Swaminathan et al., 2016, Dow et al., 2016, Kullab, 2011).

Based on the assumptions made, the produced permeate is considered stagnant in the permeate channel, so that the heat transfer from the gap takes place only in the form of conduction calculable by Eq. 5.

$$\dot{q}_{PG} = \frac{1}{\frac{\delta_{PG}}{2K_{PG}}} (T_{Mp} - T_{PG}) \tag{4}$$

In this equation, T_{PG} is the permeate temperature at the permeate gap, K_{PG} (W/mK) and δ_{PG} (m) are the permeate gap thermal conductivity and thickness, respectively.

Moreover, the heat is transferred from the permeate gap to condenser channel by a series combination of thermal resistances including permeate channel and impermeable polymeric film and condenser side thermal resistances. Therefore, the condenser channel heat flux ($\dot{q}_C$) is defined as below:

$$\dot{q}_C = \frac{1}{\frac{\delta_{PG}}{2K_{PG}} + \frac{\delta_F}{K_F} + \frac{1}{h_C}} (T_{PG} - \frac{T_{Ci} + T_{Co}}{2}) \tag{5}$$

Similarly, in this equation h_C (W/m^{2}K) is the heat transfer coefficients at the impermeable polymeric film and condenser channel, K_F (W/mK) and δ_F (m) are the impermeable polymeric film thermal conductivity and thickness, respectively, T_{Ci} and T_{Co} are the temperatures at the condenser channel inlet and outlet, respectively.

Considering the energy balance correlations for both evaporator and condenser channels and the total membrane surface area (A_m), Eq. 6 and 7 could be assumed respectively for the evaporator channel and condenser channel heat fluxes ($\dot{q}_{hot}$ and $\dot{q}_{cold}$).

$$\dot{q}_{cold} = \frac{\dot{m}_{Ci}\ C_{pC} \left(T_{Co} - T_{Ci} \right)}{A_m} \tag{6}$$

$$\dot{q}_{hot} = \frac{\dot{m}_{Ei} C_{pE} \left(T_{Eo} - T_{Ei} \right)}{A_m} \tag{7}$$

Given the assumption of a steady state condition, it may be concluded that:

$$\dot{q}_E = \dot{q}_M = \dot{q}_{PG} = \dot{q}_C = \dot{q}_{cold} = \dot{q}_{hot} \tag{8}$$

Solving the 7 main equations (1 to 7) using the Matlab Equation solver, the 7 unknown variables (T_{Me}, T_{MP}, T_{PG}, T_{Co}, T_{Eo}, J_P, $\dot{q}$), as depicted in the mathematical modelling schematic, may be calculated. Furthermore, to be able describe the performance of a MD system, permeate flux (J_P), STEC and GOR parameters are investigated as the most important characteristic values which are defined as:

The permeate flux J_P could be defined by dividing the permeate output rate $\dot{m}_{PG}$ (kg/s) to the total membrane area (Am):

$$J_p = \frac{\dot{m}_{PG}}{A_m} \tag{9}$$

The quantity q_{STEC} is the amount of total energy input (E_i) to produce 1 m^3 of fresh water (Sanmartino et al., 2016). In this equation $\dot{V}_P$ is the produced distillate rate (m^3/s).

$$q_{STEC} = \frac{E_i}{\dot{V}_p} = \frac{\dot{m}_{Ei} C_p (T_{Ei} - T_{Co})}{\dot{V}_p} \tag{10}$$

The GOR is an indication of how well the total energy input to the system is utilized to produce fresh water:

$$GOR = \frac{\dot{m}_{PG} h_{fg}}{E_i} \tag{11}$$

4. Results and discussion

In this section, the effect of different feed water flow rates and salinities on internal heat recovery through the system, besides the most important characteristic values including permeate flux, STEC, and GOR are presented.

The effect of feed water salinity on internal heat recovery is depicted in Fig. 4-left. As seen in this figure, the amount of internal heat recovery inside the cold flow channel, decreased by increasing the feed flow rate within the system operating condition. Increasing of feed flow rate, lead to the lower feed residence time in the flow channels, so there was less time for heat transfer between hot and cold channels, so the temperature rises in condenser channel was less significant (Xu et al., 2016, Khayet, 2011, Guillén-Burrieza et al., 2015). In addition, as seen in this figure, by increasing the feed water salinity from fresh water feed (nearly 0% salinity) to seawater salinity (around 30 ppt) and then up to a higher value to 130 ppt, the temperature rise in the condenser channel (internal heat recovery rate) decreased. This pattern could be explained by the negative effect of salinity on permeate flux rate, which leads to a lower amount of released latent heat of condensation at the higher salinity.

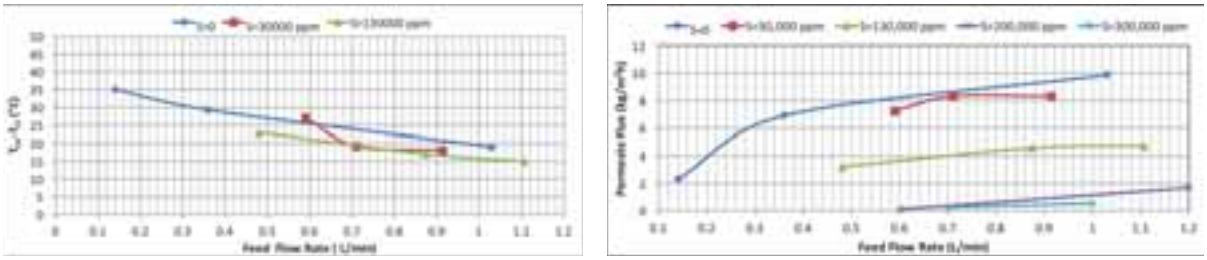

Fig.4. Left: Fresh water temperature rise (T_{Co}-T_{Ci}) by internal heat recovery through the membrane, Right; Permeate flux at different feed flow rates and salinities, test condition: TCi=15ºC, TEi=82ºC

The effect of the feed flow rate on permeate flux is also shown in Fig. 4-right. As it is seen in this graph by increasing the feed flow rate, the permeate flux increases. For fresh water feed (assuming zero percent salinity), increasing feed flow rate from 0.14 to 1.03 L/min, led to approximately 400 per cent increase in the permeate flux. For a feed sample with 130 ppt (nearly four times seawater salinity), doubling the feed flow rate led to a similar upward trend on produced distillate rate. That is the, J_p increases from approximately 3 to 5 kg/m^{2}h (nearly 70 per cent increase). This effects may be explained by the higher turbulence in the flow channel at the higher feed flow rate, associated with higher value for the Reynolds number, which improved the heat transfer rate in flow channels and reduced the temperature polarization effect on the two sides of the membrane surface. As a result, the temperature difference across the membrane surface increased, leading to higher permeate flux.

Fig. 4-left also presents the effect of salinity on permeate flux, which shows a decrease in permeate water flux for saline water compared to the fresh water feed case. The produced distillate rate decreased significantly for high salt concentration (200-300) ppt, which is near the saturated state of saline feed water. As seen in this graph, for a feed sample with 20 ppt salinity and at nearly 1 L/min flow rate, the distillate flux decreased to less than 2 kg/m^{2}h.

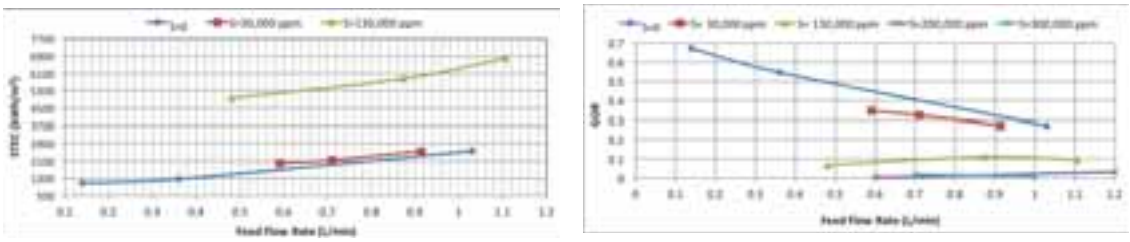

Fig.5. Left: STEC Right; GOR at different feed flow rates and salinities, test condition: TCi=15ºC, TEi=82ºC

The effect of feed flow rates on STEC of the system is shown in Fig. 5-left. The results show that by increasing the feed flow rate, the required amount of thermal energy will increase. High feed flow rate leads to shorter feed residence time in the flow channel, therefore a less efficient sensible heat recovery in condenser channel is possible. As a result, for a similar operating condition, T_{Co} decreases and the amount of external heat demand (STEC) to reach the designed value for T_{Ei}, increases. On the other hand, as seen in Fig. 4, right by increasing the feed flow rate, the permeate flux rate increases (higher value of $\dot{V}_P$ in Eq. 10). However, the overall the effect of higher energy demand is not completely compensated by higher permeate flux, so the STEC values increase at the higher feed flow rate. As is seen from this figure, at higher feed salinities, the STEC is also increases because of the lower permeate output at higher salinities which is also confirmed by previous studies (Winter et al., 2011, Cipollina et al., 2012).

Gained output ratio is an alternative representation of the STEC and for analyzing the thermal efficiency of the desalination systems may be used to quantify the module's capability for internal heat recovery. As is explained by Winter et al. (Winter et al., 2012), in MD desalination systems because of heat loss by conduction through the MD module, all the thermal energy input can not be applied to the evaporation process and the GOR must be less than 1. However, in ideal MD systems with optimum internal heat recovery with high surface area for heat transfer

between hot and cold fluids, a higher value of GOR would be possible.

As investigated in this study and illustrated in Fig. 5-right, by increasing feed flow rate and feed water salinity, GOR values show a downward trend. The maximum value achieved for GOR was approximately one, which confirmed the high heat loss rate through the lab scale module and insufficient internal heat recovery by the developed PGMD module with the geometry described. A longer module flow channel with higher membrane surface area will provide more efficient sensible heat recovery leading to a higher GOR value and so develop a more thermally efficient MD system (Winter et al., 2012).

Based on the developed theoretical model described in section 3, the influences of feed flow rate and salinity on two important desalination system characteristic of permeate flux (J_p) and internal heat recovery rate (T_{Co}-T_{Ci}) are plotted and the results are compared with the measured values. Figs. 6 shows a good comparison between experimental results and theoretical values for produced fresh water rate and for internal heat parameters. Comparison is made for feed flow rate in the range 0.1 to 1.1 L/min and with three inlet feed salinities of approximately (0, 30 and 130) ppt. As is evident from these graphs, values obtained from numerical modeling using heat and mass balance equations and using the Matlab Equation solver for a single node model, as explained in the mathematical model development section, are in good agreement with experimental measured values. The developed theoretical model could be applied as a reliable tool, to design the geometrical configuration of an optimized PGMD system based on simulation of the system performance.

The theoretical study also provides a basis for developing a more efficient PGMD module by estimating the effect of system parameters including module length, feed flow rate and temperature on the main output parameters including permeate flux rate and STEC .

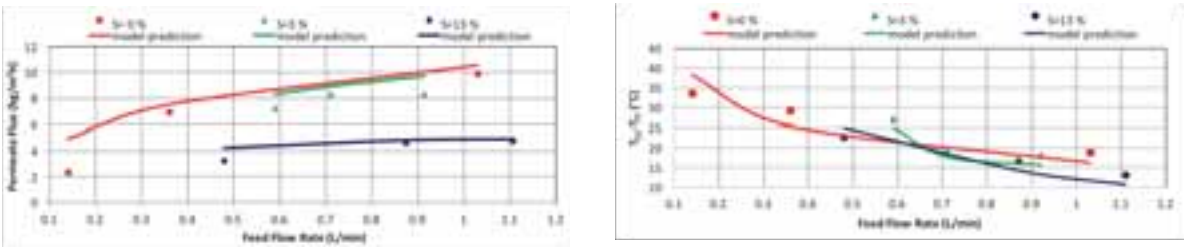

Fig. 6 Theoretical and experimental value comparison for influence of feed flow rate and salinity on: Left: permeate flux; Right: internal heat recovery at condenser channel(Bai et al.)

5. Conclusion

A lab scale plate-and- frame PGMD module with 0.12 m^2 effective membrane area has been developed and tested. A set of experimental test has been performed to investigate the designed MD module's main characteristics in different operating condition including feed flow rate and salinity. Under the designed system conditions, T_{Ci}=15 ºC, T_{Ei}=82 ºC, feed flow rate in range of 0.1 to 1.1 L/min and feed salinity in a range of (0 - 30) ppt the permeate flux varied from (2-12) kg/m^2h, specific thermal energy consumption was between 1000 and 2500 kWh/m^3 and GOR was below 1.

The experimental results show that lower feed flow rate provides higher residence time and lower STEC (higher GOR). Operation at lower STEC is also achievable by increasing flow channel length and providing more contact time between feed stream and membrane surface leading to higher heat recovery and lower external energy demand of the system. However, working at low feed flow rate and high membrane surface area results in lower permeate flux and higher investment cost respectively. Therefore, to develop a sustainable PGMD configuration design, from the design point of view, the module length and effective membrane surface area need to be optimized in order to improve internal heat recovery rate in the system and so reduce the external energy demand, especially in the situation where the external energy source derives from non-renewable fossil fuels. In conclusion, the research results provides an reliable technical data for a scaled up PGMD module characterization to design a more

efficient and sustainable desalination system via minimizing the thermal energy demand of the system and also producing higher distillate rate.

Solar and Heat Pump Systems

Field tests of a novel solar-assisted dual source multifunctional heat pump

Abstract

In this paper, we present the results of field study concerning a novel solar-assisted dual-source multifunctional heat pump, installed in a detached house in Milan. The system couples hybrid photovoltaic/thermal (*PVT*) panels with multifunctional and reversible heat pump. The proposed system is equipped with an "*air source*" evaporator and a "*water source"* evaporator, connected in series and operated alternatively, based on the ambient conditions and system parameters. The "*air source*" evaporator is an external unit; conversely, the "*water source"* evaporator is connected with a storage tank, fed by the *PVT* system. The *PVT* system is connected with the heat pump by two storage tanks to be used to produce domestic hot water and to be used in "*water source"* evaporator. Based on the operating conditions, the hot water is sent to one of the storage tank. The proposed system has been tested experimentally; the results show that the system was able to maintain high efficiency in the different seasons and was able to produce domestic hot water. It was found that the use of the "*water source"* evaporator was able to compensate the performance degradation of the "*air source"* source evaporator caused by the low ambient temperature.

Keywords: Solar assisted heat pump, Hybrid photovoltaic/thermal panels, Dual Source, Domestic hot water, PVT, SAHP

1. Introduction

Multifunctional heat pumps are widely used for heating and cooling applications, as well as for the production of domestic hot water (*DHW*), by exploiting different heat sources (i.e., ground source, air source or water source). In particular, the coefficient of performance (*COP*) of air-source heat pumps depends on the ambient temperature, T_{amb} (viz. T_{amb} is related to the evaporating temperature, T_{eva}). As a consequence, in the winter season, when heating is needed and T_{amb} is lower, the system performance decreases, owing to the lower evaporating temperature. Conversely, considering a reversible heat pump in the summer season, when cooling is needed and T_{amb} is higher, the system performance decreases, owing to the higher condensing temperature. In this respect, the coupling between solar technologies and heat pumps—"*solar-assisted heat pumps*" (*SAHPs*)—is a promising technology to overcome the above-mentioned limitations, to reduce the consumption of energy resources and to meet the targets set by the recent regulations (i.e., European Union targets). Generally speaking, heat pumps can be coupled with photovoltaic (*PV*) panels, thermal collectors or hybrid photovoltaic/thermal (*PVT*) panels, as outlined in the literature surveys proposed by Kamel et al. (Kamel, Fung e Dash 2015) and by Mohantaj et al. (Mohanraj, et al. 2017). In practical applications, heat pumps are coupled with thermal or *PVT* panels, in direct or indirect expansion configurations. In direct expansion *SAHP*, the solar panel corresponds to the evaporator of heat pump; conversely, in indirect expansion *SAHP*, an intermediate heat exchanger is used to couple the solar system and the heat pump. In addition, *SAHP* systems can be classified into three sub-categories: (a) parallel systems, (b) series systems and (c) dual-source systems. In parallel systems, the heat pump receives energy from the ambient, and the solar energy is supplied directly for either space heating or for *DHW* production. In series systems, solar energy is supplied to the evaporator of the heat pump, thus raising the evaporating temperature (thus, increasing the *COP*) and cooling the solar collectors (thus, increasing the efficiency of the solar panels). In the dual-source systems, the evaporator can receive energy from either the atmosphere or from the solar energy, depending on the ambient conditions and system operation .

doi:10.18086/swc.2017.33.01 Available at http://proceedings.ises.org

This paper contributes to the existing discussion concerning multifunctional *SAHP* for heating and cooling applications, as well as for the production of *DHW*. In the last decades, different systems have been proposed and, in the following, a brief literature survey is proposed to better outline the framework of this research. Wang et al. (Wang, et al. 2011) experimentally investigated, in a laboratory-scale experimental setup, an indirect dual-source ("*air-source*" and "*water-source*" evaporators) *SAHP* for space heating and cooling and water heating. A storage tank, connected to thermal panels, was used to supply heat to the "*water-source*" evaporator or to produce *DHW*. They reported *COP* = 4, in the heating mode. Bridgeman and Harrison (Bridgeman e Harrison 2008) experimentally investigated, in a laboratory-scale experimental setup, the performance of an indirect series *SAHP* for water heating. They observed *COP* = 2.8 – 3.3, depending on the evaporator and condenser temperatures. Loose et al. (Loose, et al. 2011) performed field tests of various combined *SAHP* systems with different heat sources, for space heating and water heating. The system employed solar thermal collectors and geothermal heat pump with borehole heat exchangers. The collectors fed the storage tank directly when the sufficient solar radiation was available. Otherwise, low grade energy from the collectors would be used in the heat pump for space heating. Bakirci et al. (Bakirci e Yuksel 2011) investigated the performance of an indirect SAHP system for space heating. The solar collectors directly charged a storage tank which was linked to an evaporator to provide a heat source for the heat pump. They observed *COP* in the range of 3.3 – 3.8. Bai et al. (Bai, et al. 2012) theoretically studied, by using a TRNSYS model, an indirect combined hybrid *PVT SAHP* system for *DHW* production. Year round performance results were simulated under the different climatic conditions (Hong Kong and different locations in France) and an average *COP* = 4.9 has been observed.

From the above-mentioned literature survey, as well as from the literature surveys proposed by different authors (Hepbasli e Kalinci 2009, Ozgener e Hepbasli 2007, Parida, Iniyan e Goic 2011, Tian e Zhao 2013), it is observed that there is a lack of field studies concerning practical demonstration and fields studies concerning multifunctional dual source ("*air-source*" and "*water-source*" evaporators) *SAHP*. To this end, this paper presents the field tests of a novel solar-assisted dual-source multifunctional heat pump, installed in a detached house in Milan. The system couples hybrid *PVT* panels with a multifunctional and reversible heat pump. The paper is organized as follows. First, the experimental setup and methods are presented and described; second, the experimental results are commented and discussed; finally, main conclusions are drawn

2. Experimental setup and methods

In this section, the experimental setup and the experimental methods are presented and described. First, the multifunctional heat pump system and main characteristic of the components are presented and discussed (Section 2.1). Second, the details concerning the operation procedures are outlined (Section 2.2). Finally, the experimental techniques (Section 2.3) and performance parameters (Section 2.4) are described and commented.

2.1 Experimental setup

The multifunctional heat pump system (Fig. 1) has been designed and installed in a detached house (Fig. 2) located in Milan, at RSE Spa headquarter. The detached house has an heating/cooling area equal to 64 m^2, with a nominal load equal to 4 kW_{th} (indoor temperature equal to 20 °C and outdoor temperature equal to -5 °C). Fig. 1 displays the layout of the multifunctional heat pump, which is composed by five parts: (a) a solar system, (b) a *DHW* storage tank and an "*intermediate-temperature*" storage tank, (c) a reversible heat pump, (d) terminal heating and cooling systems (viz. fan coils) and (e) circulating pumps (Tab. 1). Further details concerning the different components of the system are provided in the following.

Solar system. The solar system consists in seven *PVT* panels and a *PV* panel (Fig. 2). The *PV* panel has the same size and cells characteristic of the *PVT* panels, to compare the performance of the two technologies. The seven *PVT* panels (south-oriented, 45° titled angle) have 1.75 kW_{el} nominal power and are of the roll-bond technology (Fig. 3a). They are composed by polycrystalline silicon cells, a steel heat-exchanger and a 0.002 m insulation. In the heat exchanger part of the *PVT*, water/ethylene glycol mixture has been used as working fluid, to prevent icing-related issues, with a nominal flow rate equal to 0.630 m^3/h. It is worth noting that the comparison between *PV* and *PVT* panels is not presented here and is a matter of ongoing research activities.

Storage tanks. The *DHW* storage tank (0.186 m^3 in volume) has been used to produce hot water; conversely, the "*intermediate-temperature*" storage tank (0.300 m^3 in volume, Fig. 3b) has been used as "*water-source*" from the heat pump, instead of the "*air-source*" one, to improve the performance in cold days and avoid defrosts and

reduce temperature fluctuations. Inside the "*intermediate-temperature*" storage tank water/ethylene glycol mixture has been used as working fluid, to prevent icing-related issues. The "*intermediate-temperature*" is connected to the heat pump, by a plate heat exchanger (Fig. 3c) and the maximum flow rate "*intermediate-temperature*" towards the "*water-source*" heat exchanger is 1.45 m^3/h.

Heat pump unit. The heat pump is a R410A reversible heat pump, 7 kW_{th} nominal heating capacity and 3.47 nominal COP (water leaving temperature equal to 35 °C and air temperature equal to 7 °C), equipped with an electronic expansion valve and a variable speed compressor.

Circulating pumps. As shown in Fig. 1, the experimental system includes circulating loops: (a) solar collector loops; (b) "*intermediate-temperature*" storage tank to heat pump; (c) indoor terminal fan-coil side loop and (d) *DHW* circulating loops. Details on pumps used are provided in Table 1.

P4	*DHW* circulating pump	WILO ZRS 12/7	86 (fixed speed)

2.2 Operation modes and control

The multifunctional heat pump has been tested starting from 17th January 2017 and the monitoring is still ongoing. The system has been tested in three operation modes in order to study the influence of the different operation parameters; each mode was controlled aiming to (a) minimize the electricity consumption by the heat pump, using solar thermal energy, and (b) maximizing the production of electricity of *PVT* panels keeping their operating temperature as low as possible. The operating principles for each mode are provided in the following.

- **Mode#1. Heating mode without *DHW* production (from 17/01/2017 to 13/03/2017).** The internal set-point temperature was set at $T_{set\text{-}point}$ = 22 °C, with night attenuation of 4 °C (from 22.00 to 7.30). In this operation mode, the temperature of the water produced by the heat pump and sent to the fan-coils was set by using a climatic curve: T_3 = 43 °C with T_{amb} = 0 °C and T_3 = 35 °C with T_{amb} = 15 °C. In this

operation mode, valve *V1* was set to deviate all thermal energy produced by the *PVT* panels to the "*intermediate-temperature*" storage tank. The "*intermediate-temperature*" storage tank, is used as the "*water-source*" for the heat pump when T_{amb}, is low and the resulting *COP* would decrease. Changes from "*air-source*" evaporator to "*water-source*" evaporator are obtained by switching on/off the pump *P2* and switching on/off the external "*air-source*" unit.

- **Mode#2. Heating mode with *DHW* production (from 13/03/2017 to 24/05/2017).** The operation mode *mode#1* has been modified as follows: (a) a daily profile of *DHW* production was set to produce 1*50 l* (corresponding to, approximately, 4 KWh); (b) valve *V1* was set to deviate the glycol-water mixture, at the outlet of the *PVT* panels, depending on the temperature of the storage tanks (a) towards the "*intermediate-temperature*" *DHW* storage ($T_{intermediate\text{-}temperature}$ < 38 °C), (b) towards the *DHW* tank ($T_{intermediate\text{-}temperature} \geq$ 38 °C) or towards the "*intermediate-temperature*" storage tank ($T_{DHW,tank} \geq$ 58 °C); (c) the *DHW* storage tank set-point temperature was set to $T_{DHW,set\text{-}point}$ = 48°C and its lower temperature has been set $T_{DHW,mantenance}$ = 42°C. In the case, the temperature of the *DHW* storage tank would fall below $T_{DHW,mantenance}$, the heat pump would be used been used to increase the *DHW* tank temperature.
- **Mode#3. Cooling mode with *DHW* production (from 24/05/2017, ongoing).** The internal set-point temperature was set at $T_{set\text{-}point}$ = 24 °C. In addition, the operation mode *mode#2* was modified as follows: (a) a daily profile of *DHW* production has been set to produce 1*50 l* (corresponding to approximately, 3 KWh; the DHW corresponding power is lower compared with the previous operation mode, owing to the higher inlet water temperature, T_1); (b) valve *V1* was set to deviate the glycol-water mixture, at the outlet of the *PVT* panels, depending on the temperature of the storage tanks towards the *DHW* storage tank ($T_{intermediate\text{-}temperature} \geq$ 36 °C) or towards the "*intermediate-temperature*" storage tank ($T_{DHW,tank} \geq$ 57 °C);).

2.3 Measurement system and procedure

All the main variables, to describe mass and energy balances, have been measured. The flow rate in each circuit has been measured by an electromagnetic flowmeter meter (E&H Promag P50, ±0.2% read value). All the inlet and outlet temperatures of the main equipments, the supply and return water temperatures of the different locations, were measured by RTD Pt100 4wire 1/5DIN, inserted inside the pipes. The indoor and outdoor (near the *PVT* panels) temperature and humidity were measured by an Pt100 4wire hygrometer (Siap+Micros). The solar radiation intensity has been measured by a thermopile pyranometers (pyranometer Kipp&Zonen CMP11), mounted at a 45° inclined angle near the *PVT* panels. The power consumption of the heat pump and the circulating pumps (solar pumps, intermediate-storage tank, fan-coil pump) were measured by multifunction electric meters (Shark 100, ±0.1%, and FRER MonoNano, ±0.5%). Evaporating and condenser pressures were measured by pressure transducers (Keller series 21Y). All the temperature probes were verified with a calibration procedure by using thermostatic batch, at RSE Spa. All data were recorded automatically at every 6 seconds interval in a data logger (Advantech ADAM 5000 and 4000 data logging devices) to be further post-processed.

2.4 Performance evaluation

The performance of the system has been evaluated based on the mass and energy balances, based on the recorded data (flow rates and temperatures). In particular, the energy fluxes across every component has been computed as follows:

$$Q = \dot{m} c_p (T_{inlet} - T_{outlet}) \quad \text{(Eq. 1)}$$

In Eq. (1), T_{inlet} and T_{outlet} refer to the inlet and outlet temperatures, m is the mass flow rate, c_p is the specific heat of water. Based on the heat fluxes and the electric power measured, the *COP* (during heating mode; *mode#1* and *mode#2*, Eq. (2)) and the *EER* (during the cooling mode; *mode#3*, Eq. (3)) have been computed as follows:

$$COP = \frac{Q_{HP \rightarrow fan-coil} + Q_{HP \rightarrow DHW-tank}}{P_{el}} \quad \text{(Eq. 2)}$$

$$EER = \frac{Q_{HP \leftarrow fan-coil} + Q_{HP \rightarrow DHW-tank}}{P_{el}} \quad \text{(Eq. 3)}$$

In Eqs. (2-3), P_{el} is the electric power provided to the systems; $Q_{HP \rightarrow fan\text{-}coil}$ and $Q_{HP \leftarrow fan\text{-}coil}$ is computed based on T_3 and T_4 and $m_3 = m_4$ (please refer to Fig. 1 for the location of the subscripts) and refer to the heat transfer from the heat pump towards the fan-coils and vice-versa; conversely, $Q_{HP \rightarrow DHW\text{-}tank}$ refers to the het flux provided from the heat pump to the *DHW* tank and is computed as follows:

$$Q_{HP \rightarrow DHW-tank} = \sum_{t=0}^{n=N} \rho V_{DHW,tank} c_p (T_{t=n} - T_{t=n-1}) \quad \text{(Eq. 4)}$$

In Eq. (4), $V_{DHW,tank}$ is the volume of the *DHW* tank, ρ is the density of water, and t is the time variable. Please note that Eq. (4) is computed under the following constrains: (a) the temperature of the *DHW* storage is below $T_{DHW,maintenance}$, (b) the temperature of the *DHW* storage tank is increasing with time; (c) heat pump status is ON.

To study the influence of the "*water source*" evaporator and the "*air-source*" evaporator, Eq. (2) has been modified as follows, based on the status of the storage tank circulating pump (pump *P2*, Fig. 1):

$$COP_{"water\text{-}source"} = \frac{Q_{HP \rightarrow fan-coil} + Q_{HP \rightarrow DHW-tank}}{P_{el}} \quad if\ pump\ P2 = ON \quad \text{(Eq. 5)}$$

$$COP_{"air\text{-}source"} = \frac{Q_{HP \rightarrow fan-coil} + Q_{HP \rightarrow DHW-tank}}{P_{el}} \quad if\ pump\ P2 = OFF \quad \text{(Eq. 6)}$$

3. Experimental results

In this section, the experimental results are presented and discussed. First, the ambient conditions in the monitored period are presented. Second, the performance of the heat pump are presented and commented with reference to the three different operating modes. Finally, the influence of the "*water-source*" and the "*air-source*" evaporators on the performance are commented.

3.1 Ambient conditions

In order to provide an overview of the heat pump working conditions, Fig. 4 displays the value of ambient conditions in the monitored period. In particular, Fig. 4 displays the daily averaged values of the ambient temperature and relative humidity. It is worth noting that the heat pump was operated in a quite broad range of operating conditions (i.e., daily averaged T_{amb} ranged between 0 and 33 °C; conversely, the instantaneous values of T_{amb} ranged between -5°C and 40 °C).

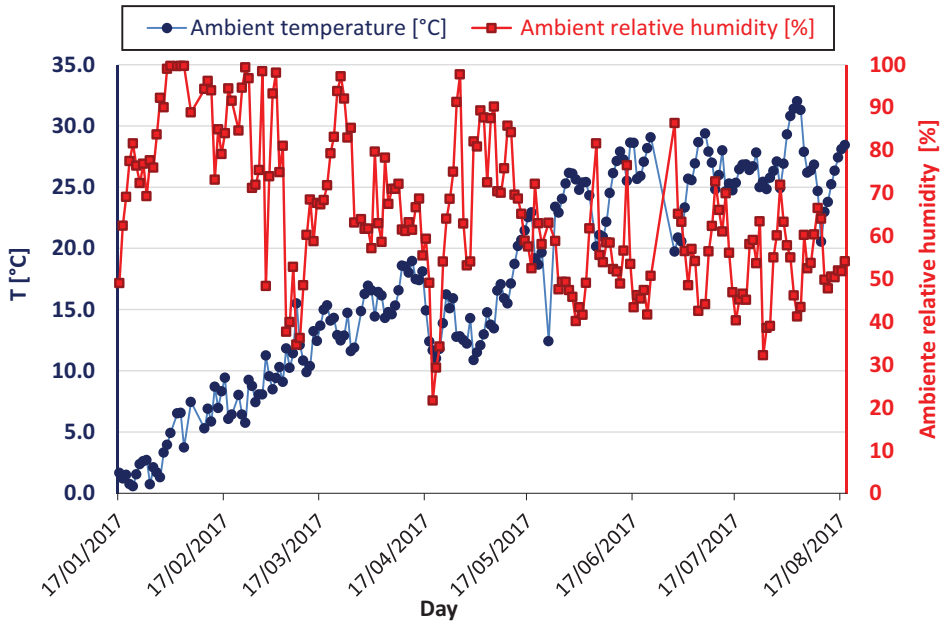

Fig. 4: Daily-averaged ambient conditions: ambient temperature and relative humidity

3.2 Seasonal performance

Fig. 5 displays the daily-averaged performance of the multifunctional heat pump in the three operating modes described in Section 2.2. In addition, in Fig. 5, T_{amb} is displayed for the sake of clarity. The performance of the multifunctional heat pump are computed by using Eq. (2)—the *COP*—and Eq. (3)—the *EER*. In the operation *mode#1*, the useful effect of the heat pump is $Q_{HP \rightarrow fan\text{-}coil}$ (there is no *DHW* production; $Q_{HP \rightarrow DWH\text{-}tank} = 0$); conversely, in the other operation modes (viz. *mode#2* and *mode#3*) the useful effect of the heat pump consists in both $Q_{HP \rightarrow fan\text{-}coil}$ and $Q_{HP \rightarrow DWH\text{-}tank}$. Please note that the electric consumption, P_{el}, considered in the evaluation of *COP* and *EER* does not account for the contribution of the auxiliaries (i.e., circulation pumps, stand-by consumption, etc…): (a) the solar circulating pump (its consumption was approximately 4.1 % of the total energy consumption); (b) the "*intermediate-temperature*" circulating pump (its consumption was approximately 1.2 % of the total energy consumption); (c) the Fan-coil circulating pump (its consumption was approximately 3.7 % of the total energy consumption), (d) the DHW circulating pump and all other auxiliaries (their consumptions were approximately 14.2 % of the total energy consumption).

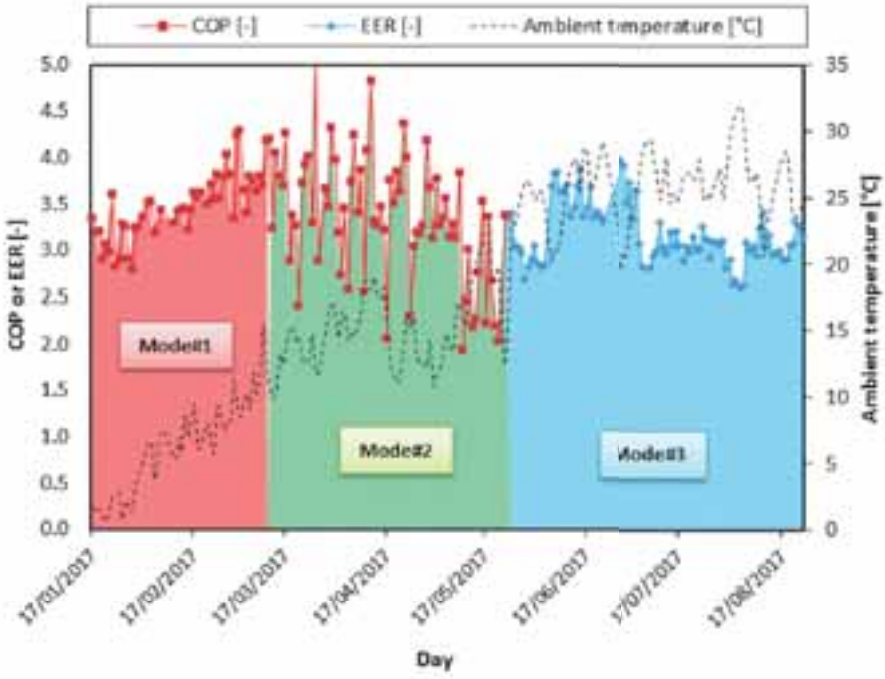

Fig. 5: Daily-averaged performance of the multifunctional heat pump depending on the operation mode and ambient temperature

In the operation mode *mode#1*, the daily-averaged *COP* is in the range of 3 and 4.5; as expected, *COP* increases with time, owing to the increasing daily-averaged T_{amb}. The relationship between T_{amb} and the heat pump performance can be further understood, by considering the layout of the system. Indeed, the performance of an heat pump may be related (for fixed component design), to the evaporating and condensing temperatures/pressures. In the present case: (a) the condensing pressure is related to the internal conditions, that, for a fixed set-point are periodical with time; (b) evaporating temperature T_{eva} is related to T_{amb}, owing to the variable speed compressor and the electronic expansion valve. Therefore, a variation in the ambient temperature, mainly affects T_{eva} and, thus, affect the performance of the system. To better discuss this concept, Fig. 6 displays the relationship between the variables of the heat pump (i.e., evaporator pressure and condensing pressure), T_{eva} and *COP*. The reader may refer to the studies proposed by Kuang and Wang (Kuang e Wang 2006) and Ma and Zhao (Ma e Zhao 2008) for a more detailed discussion on the role of variable speed compressors in heat pumps. In addition, in Fig. 6 is also displayed the influence of the "*water-source*" evaporator. This point is further discussed in Section 3.3. In the operation mode *mode#2*, the performance of the system, compared with *mode#1*, shows a larger variability and are slightly lower. This behavior can be explained based on the system operations as well as on the ambient conditions. First, in this period, beside DHW production, $Q_{HP \rightarrow fan\text{-}coil}$ is very low and, in some days, $Q_{HP \rightarrow fan\text{-}coil} \approx 0$, owing to the high T_{amb} (the internal set-point temperature can be achieved also with very low heat pump load). Therefore, *COP* is mostly related to $Q_{DHW\text{-}tank}$. Second, it should be noted that

$Q_{HP \rightarrow DHW\text{-}tank}$, is produced at higher temperature compared with $Q_{HP \rightarrow fan\text{-}coil}$; therefore the expected performance of the heat pump is reduced. In this respect it is well known that Eq. (2) does not take into account the grade of heat produced, as it is related to energy balances and neglect the entropy/exergy concept. In the operation mode *mode#3*, in the cooling mode with DHW production, the daily-averaged *EER* is in the range of 3 and 4.5. The discussion concerning the relationship between the ambient conditions and the system performance is similar to the above-discussion for the operation mode *mode#1*. It is worth noting that, owing to the high ambient temperature, in the summer season, the *PVT* panels are able to contribute to the maintenance temperature of the *DHW* storage tank, thus reducing $Q_{HP \rightarrow DHW\text{-}tank}$ and, thus, the energy consumption of the heat pump.

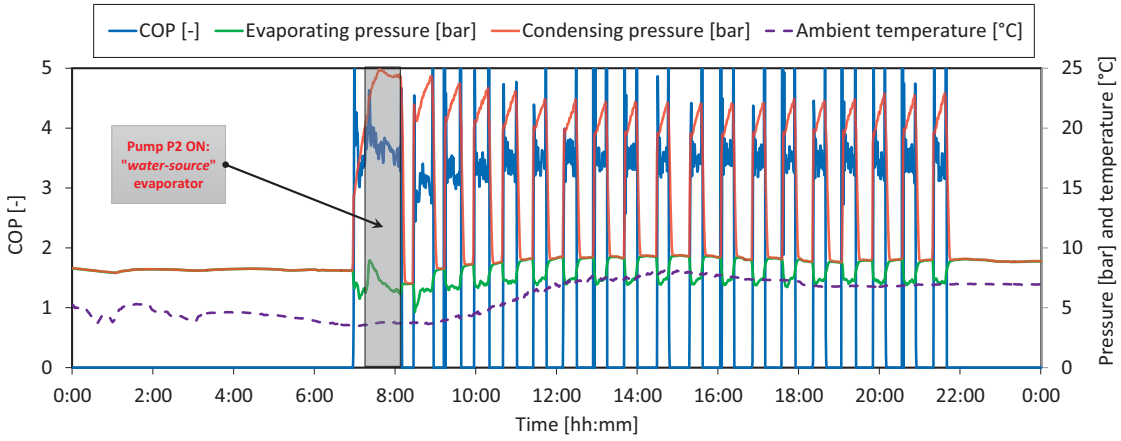

Fig. 6: Daily performance of the multifunctional heat pump: performance parameters (data obtained at 13/02/2017, *mode#1*)

3.3 Comparison between water source and air source

In this section, an insight in the performance of the system is proposed, by analyzing the contribution of the "*water-source*" evaporator and the "*air-source*" evaporator to achieve the averaged performance described in Section 3.2. To this end, by applying Eqs. (5-6) in the in the operation mode *mode#1*, the corresponding "*water-source*" the "*air-source*" performances have been obtained; the results of this analysis have been summarized in Fig. 7, in terms of daily-averaged values. Please note that in some days (viz. the data not displayed in Fig. 7), the "*water-source*" evaporator was not used. Applying the whole dataset, (in the operation mode#1) and applying Eqs. (5-6), an average *COP* increase approximately 35.5% from the "*air-source*" mode to the "*water-source*" mode has been observed. In order to better understand the relationship between "*water-source*"/"*air-source*" evaporators and the COP, Fig. 8 proposes three daily profiles of the heat pump operation.

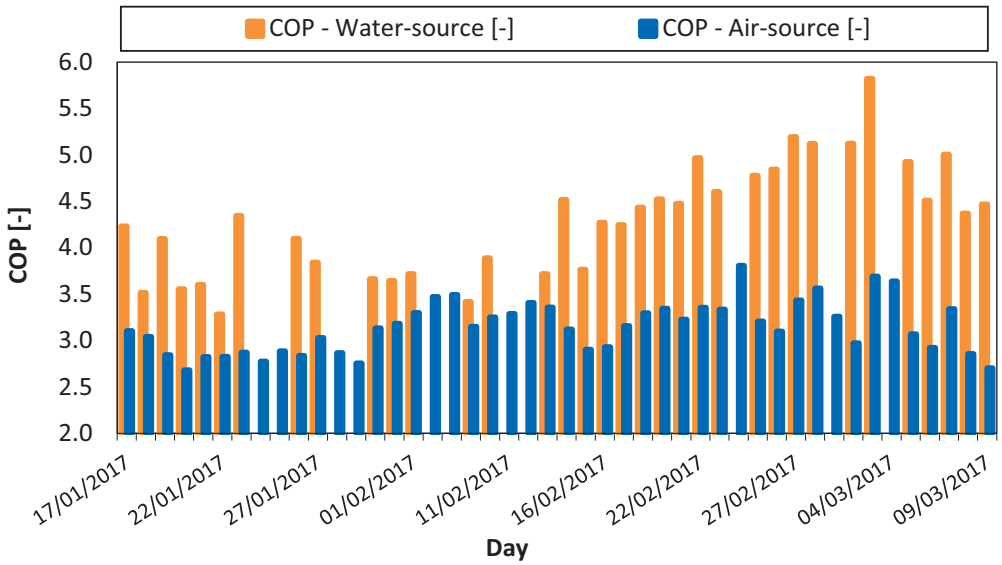

Fig. 7: Daily-averaged performance of the multifunctional heat pump: influence of "*water-source*" and "*air-source*" evaporators (data obtained during operation mode *mode#1*)

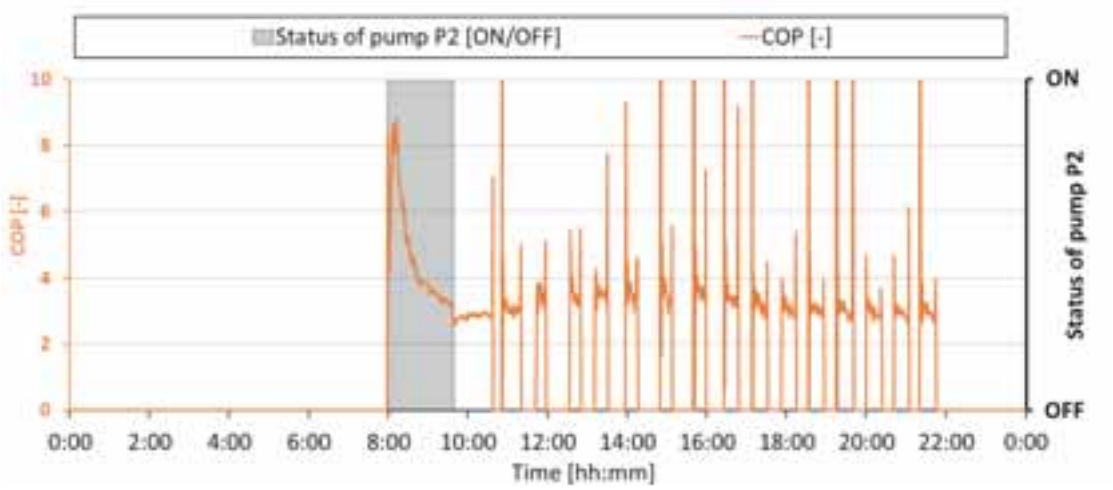
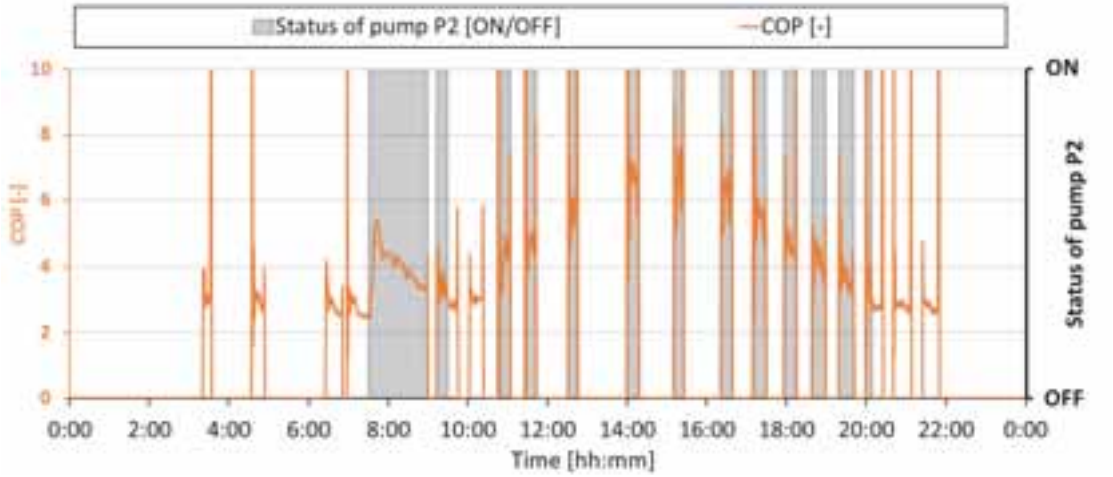
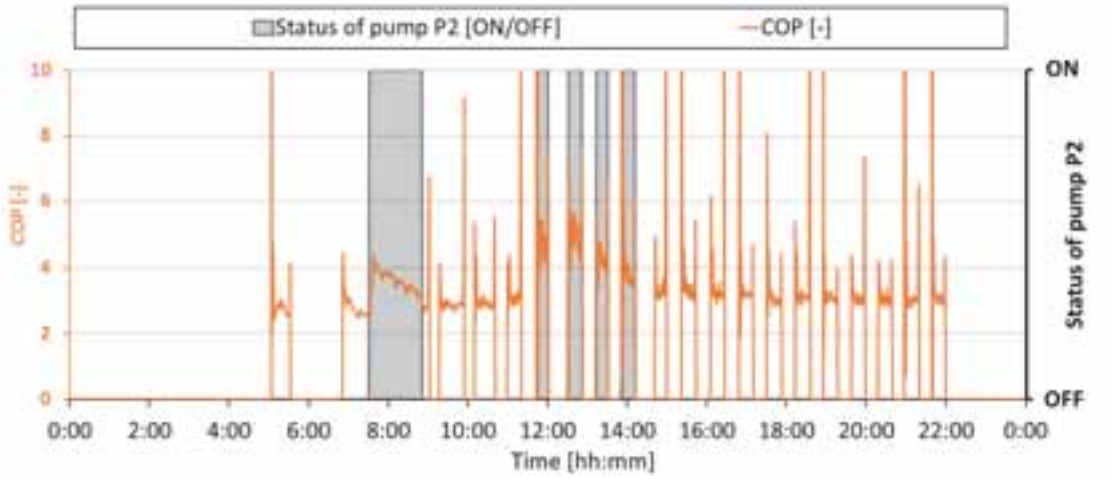


(a) data obtained at 17/01/2017, operation mode *mode#1*



(b) data obtained at 23/01/2017, operation mode *mode#1*



(c) data obtained at 27/01/2017, operation mode *mode#1*

Fig. 8: Daily performance of the multifunctional heat pump: influence of "*water-source*" and "*air-source*" evaporators

Fig. 8 clearly displays the significant increase of *COP*, owing to the use of the "*water-source*" evaporator. For example, it can be observed that, in Fig. 8a, by activating the pump *P2* at 8.00 AM the *COP* increases from 2.7 to 8 (instantaneous values). Similar considerations can be drawn for the other days displayed in Fig. 8b and Fig. 8c. It is important to emphasize that the "*water-source*" evaporator avoided the defrost cycles of the aerothermal heat pumps and the subsequent decrease in the performances. In this respect, the reader may refer to the defrost-related issues described by Zhang et al. (Zhang, et al. 2017). It should be noted that the *COP* obtained using water as source has been obtained in the most unfavorable conditions: the morning, when maximum building load and with the highest delivery water temperature. Unfortunately, the use of the water source is limited in time and depends on the thermal energy available in the "*intermediate-temperature*" storage tank. Future studies should be focused on alternative technical solutions for storage tanks (i.e., phase change material, *PCM*, storage tanks), to improve the availability of the "*water-source"*.

4. Conclusions, outcomes and outlooks

This paper presented the very first results of field study concerning a novel solar-assisted dual-source multifunctional heat, installed in a detached house in Milan. The system couples *PVT* panels with a dual-source ("*air source*" and "*water source"* evaporators) multifunctional and reversible heat pump. The multifunctional heat pump has been tested starting from 17th January 2017 (the monitoring is still ongoing) in three operation modes: (a) heating mode without *DHW* production; (b) heating mode with *DHW* (150 l) production; (c) cooling mode with *DHW* (150 l) production.

4.1 Conclusions and outcomes

The main results of the filed study are as follows:

- the averaged performance (*COP* and *EER*) of the multifunctional heat pump is approximately 3, in the three different operation modes;
- the thermal energy produced by the *PVT* panels have been successfully used to support the "water-source" evaporator in the winter/spring seasons;
- the thermal energy produced by the *PVT* panels have been successfully used to support the production of *DHW* in the summer period;
- the use of "*water-source*" evaporator allows to significantly increase the performance of the plant;
- the use of "*water-source*" evaporator allows to avoid defrost cycles;

4.2 Outlooks

Ongoing research as well as future studies may concern both experimental and numerical researches. On the experimental part, outlooks are as follows:

- extent the field study to the autumn ambient conditions, to provide a complete seasonal overview of the system operation;
- relate the daily and the seasonal operations, to provide a multi-scale evaluation of the heat pump performance;
- propose a comprehensive thermodynamic evaluation (energy and exergy evaluation) of the whole system;
- compare the performance of PV and PVT systems and provide insights in the relationships between operating conditions (i.e., temperatures, flow rates, ambient conditions) and the panels performances (i.e., thermal and electrical energy production);
- study alternative technical solutions for storage tanks (i.e., phase change material, *PCM*, storage tanks), to improve the availability of the "*water-source*".

On the numerical part, future studies would concern the testing and validation of a TRNSYS approach, to extend the results of the present experimental study to different climatic conditions and, finally, to assess the economic feasibility of the proposed system.

5. Nomenclature and abbreviation list

5.1 Acronyms

COP	Coefficient of performance
DHW	Domestic hot water
EER	Energy Efficiency Ratio
HP	Heat Pump
PV	Photovoltaic
PCM	Phase Change Material
PVT	Hybrid thermal-photovoltaic
SAHP	Solar-assisted-heat pump

5.2 Symbols

c_p	Specific heat of water	[kJ/kg K]
m	Mass flow rate	[kg/s]
N	Time discretization in Eq. (4)	[-]
$Q_{HP \rightarrow DWH\text{-}tank}$	Heat transfer from the heat pump to the *DHW* tank	[kW]
$Q_{HP \leftarrow fan\text{-}coil}$	Heat transfer from the heat pump to the fan-coils	[kW]
T	Temperature	[°C]
t	Time in Eq. (4)	[min]
$V_{DHW,tank}$	Volume of the *DHW* storage tank	[m^3]
$V_{DHW,tank}$	Volume of the *"intermediate-temperature"* storage tank	[m^3]
ρ	Density of water	[m^3/kg]

5.3 Subscripts

amb	Ambient conditions
el	Electrical energy
eva	Evaporator
inlet	Inlet condition
outlet	Outlet condition
th	Thermal energy

Abstract

The aim of the present paper is to analyze flat plates (FP) and capillary mats (CM) heat exchangers for solar-ice systems. The optimum heat exchanger area needed in the ice storage is based on energetic transient system simulations and on cost indicators. Solar-ice systems using ice storage volumes from 2 to 5 m^3 and selective uncovered collectors with 15 to 25 m^2 in the city of Zurich were able to achieve system performance factors SPF_{SHP+} ranging from 3.5 to 6 with both CM and FP in a single family house with 10 MWh yearly heating demand. Considering the cost of the system, only simulations with CM were able to achieve lower heat generation cost than that of a ground source heat pump (GSHP) with even higher SPF_{SHP+} (an SPF_{SHP+} of 4 was assumed for GSHP). For example a system with a collector area of 15 m^2 and 5 m^3 of ice storage volume can reach heat generation cost of 29 Rp./kWh, 0.5 Rp./kWh below the GSHP average reference cost, with an increase of SPF_{SHP+} of 20 % respect to the GSHP system. However, the targets can only be achieved using an appropriate heat exchanger area. The optimal heat exchanger area was found to be around 4 to 5 m^2 per m^3 of ice storage for CM and around 10 to 14 m^2/m^3 for FP. These heat exchanger ratios correspond to a distance between heat exchangers of around 12 - 17 cm for both CM and FP. These results were obtained assuming a conservative maximum ice fraction of 80 %.

Keywords: ice storage, heat exchangers, solar-ice.

1. Introduction

One of the main priorities of the European Commision is to decrease the annual greenhouse gas (GHG) emissions in 2050 by 80% compared to the status of 1990 (Europen Commision, 2012). In order to reach this ambitious goal, the energy supply system needs to be decarbonised. The heating and cooling demands in Europe are responsible of 40 % of the total energy demand. Therefore, the increase of system efficiency as well as raising the share of renewable energy in the heating and cooling sector is necessary to mitigate the climate change by reducing the GHG emmissions. A promising example for a heating system with a high share of renewable energy is the combination of solar thermal and heat pump systems with ice storages, the so-called solar-ice systems. The interest in solar-ice systems is growing in central Europe, where climatic conditions are appropriate for this technology. One of the reasons for the market push of solar-ice systems is due to the regulations established for drilling boreholes. For this reason, solar-ice systems have been established as an alternative to ground source heat pump (GSHP) systems.

Some of the advantages of solar-ice systems respect to GSHP (Carbonell et al., 2016b, 2015) are: i) usually not restricted to regulations of water and soil ii) no need to regenerate the ground as in regions densely populated with boreholes iii) the ice storage is accessible, allowing for solving leakages or replace heat exchangers, iv) the ice storage can be installed in the cellar when no ground space is available v) it is a flexible system able to adapt to building size restrictions, i.e. the same system performance can be reached with different combinations of collector area and ice storage volume and vi) higher performance compared to GSHP can be achieved while being cost competitive if direct solar heat is used extensively. However, solar-ice systems have some disadvantages respect to GSHP such as: i) higher number of hydraulic components, ii) added complexity

doi:10.18086/swc.2017.33.02 Available at http://proceedings.ises.org

of the control, iii) higher installation cost if the same performance is desired, iv) degradation of performance when ice grows, v) need of a back-up system to cover peak demands after long cloudy and cold periods.

Some of the frequently asked questions and answers concerning solar-ice systems are (Carbonell et al., 2017a):

- *"How can a solar-ice system, which is based on a 0 °C temperature source for the heat pump, perform better than a GSHP system which has usually a higher temperature source?"* The main reason is that a solar-ice system can also use solar heat directly without the need of the heat pump. During times when solar heat is used directly, the system performance in terms of heat provided divided by electricity consumed can be up to fifty times higher compared to a GSHP system (only pumps consume energy). Moreover, since solar collectors are also used directly as a source for the heat pump, the source temperatures in solar-ice systems when the sun is shining can be considerably higher than in a GSHP.
- *"Whats is the use of the ice? Can it be spared?"* The key aspect of the solar-ice system concept relies on reducing the need of the storage volume by making use of the high latent heat of fusion released when ice is formed. Icing a specific quantity of water releases the same energy as cooling the same amount of water from 80 °C to 0 °C. Thus, although remaining always above the solidification temperature of water would lead to higher system performance, the required storage volume would be prohibitively large for this concept.

The principal idea of a solar-ice system is shown schematically in Fig. 1.

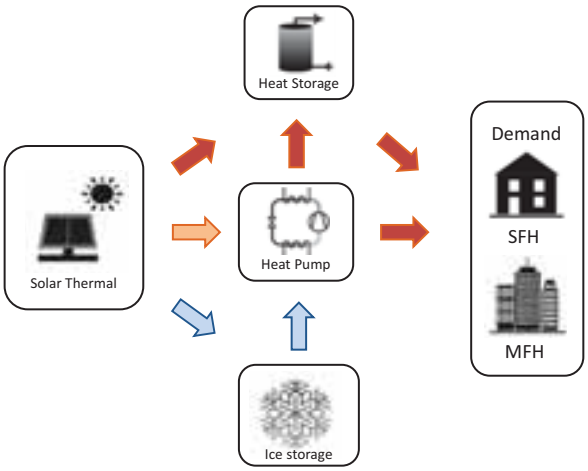

Fig. 1: Principle concept of solar-ice systems. The arrows show the heat fluxes that are on different temperature levels, i.e. red, orange and blue for high (>30 °C), medium (>10 °C) and cold (<10 °C) respectively.

Most of ice storages installed in Europe are based on ice-on-coil heat exchangers, and although other heat exchanger concepts exist on the market, their specific advantages and disadvantages remain unclear.

Several heat exchanger concepts for extracting the latent heat from water can be used. Each concept has to ensure that the ice layer on the specific heat exchanger reaches thicknesses that do not result in too high heat transfer resistance, and thus, in too low source temperatures for the heat pump. When ice grows on the surface of the heat exchanger the overall heat transfer coefficient of the heat exchanger decreases. If ice is not actively removed, the heat exchanger design has to ensure that the heat transfer capacity will be high enough at the maximum design mass ice fraction (ratio between mass of ice and total mass of water and ice) or ice thickness on the surface of the heat exchangers. For example, let's assume that flat heat exchanger plates covering all the height of the ice storage are installed with a distance of 10 cm between each heat exchanger plate. If the heat transfer capacity with 3 cm of ice on the surface is not high enough, the temperature of the heat transfer

fluid will drop until the minimum temperature accepted by the heat pump is reached and the heat pump will be stopped for security reasons. If this occurs, the ice thickness can not exceed 3 cm and part of the latent storage capacity will be lost as 2 cm out of the theoretical maximum of 5 cm will not be used. Thus, the maximum ice fraction will never grow above 60% and the desired maximum accepted ice fraction may not be reached.

In principle, two main strategies exist for the design of heat exchangers for ice storages (Philippen et al., 2015) i) ice-on-hx and ii) free-of-ice-hx. In ice-on-hx, large heat exchanger areas, homogeneously distributed throughout the whole storage volume, are necessary. Heat exchangers such as coils, plates or capillary mats can be used. In free-of-ice-hx, several concepts such as ice slurries (Kauffeld et al., 2005) or de-icing, e.g by hot gas in ice harvesting system (ASHRAE, 2007) or by solar thermal collectors (Philippen et al., 2012) can be used. From all these concepts, only the ice-on-hx concepts are established in the solar and heat pump heating market. In this paper, the ice-on-coil and ice-on-plate concepts will be analyzed from an energetic and economic point of view.

2. Methodology

Dynamic system simulations are used in order to assess the heat exchanger area and heat exchanger type on a system level. The simulations have been conducted with the simulation environment TRNSYS-17 (Klein et al., 2010). The basic components to model a solar-ice system are: collectors, heat pump, ice storage, sensible thermal storage, building, climate and control. The ice storage model has been developed and validated in Carbonell et al. (2017b), the remaining component models were provided in Carbonell et al. (2016b), where a complete solar-ice system based on a de-icing concept was validated with monitored data of a pilot plant.

The time step of yearly simulations is set to 120 seconds. As a verification process several systematic checks are done for all simulations. Heat balances are checked in all individual components, hydraulic loops and also from the system perspective. The convergence criteria from TRNSYS is set to 5e-4, which allows to achieve heat imbalances always below 1.% with respect to the total heat demand. Iteration problems are also checked for all simulations and are always below 10 time steps per year simulated. In most cases iteration problems are in the order of 1 - 5 per year.

2.1. Hydraulic scheme of the simulated system

The hydraulic scheme of the complete solar-ice heating system is shown in Fig. 2. The main components of the heating system are the collector field, the combi-storage, the heat pump and the ice storage.

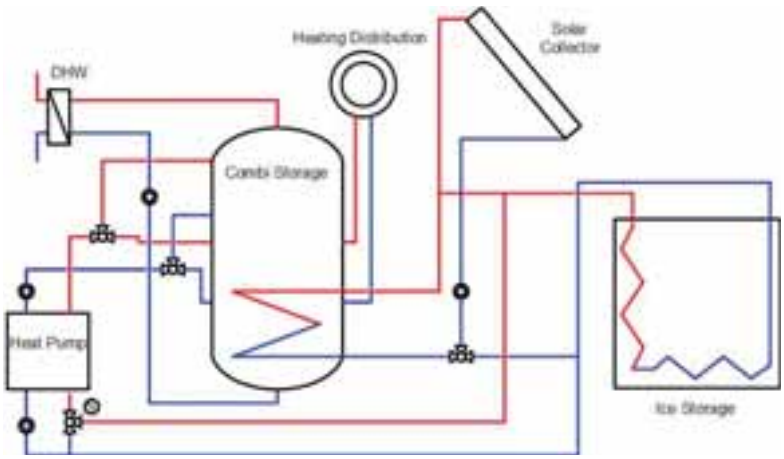

Fig. 2: Simplified hydraulic scheme of the analysed heating system.

The main energy source of the system is the solar irradiation. Some additional energy is extracted from the air, especially when uncovered collectors are used [1]. Part of the total solar irradiation is transformed by the collectors to useful heat for the system. This energy is transferred, either to the heat pump, to the ice storage, or to the combi-storage. When the heat pump is running, two operation modes are possible, depending on whether the collectors are able to provide energy or not: i) the heat pump uses the solar energy directly in a series operation mode, meaning that collectors are used as heat sources or ii) the heat pump uses only the ice storage as its source. With the hydraulic set-up proposed here, when the heat pump is running with solar energy as a source, the mass flow from the solar collector field is divided: one part goes to the heat pump and the other part goes to the ice storage. The split of the mass flow is basically controlled by each circulation pump, i.e. solar pump and heat pump evaporator pump. If these mass flows are not equal, its difference will flow to the ice storage. On these conditions, if more energy is available from the collector field than is needed by the heat pump, the ice storage is also loaded while the heat pump is running. On the contrary, if the collector output is lower than the heat pump needs, both, the ice storage and the collector field are used to provide heat to the evaporator of the heat pump. If none of these heat sources are available, which means that the ice storage is full of ice and the solar radiation and the ambient temperature are very low, the temperature of the heat pump evaporator drops below the minimum allowed value and the heat pump stops. In this case, a direct electric back-up is used. A method to reduce the need of back-up in winter times is to send the whole mas flow from the collector to the heat pump. The idea is to use the collectors even if the temperature is lower than 0 ^{o}C[2]. This can be achieved with the proposed hydraulic scheme by setting the mass flow from the collector equal to the one demanded by the heat pump. This tends to reduce the working temperature of the circuit and as a consequence decrease the heat pump COP. However, it reduces the times where the ice storage is used and thus the times where the direct electric back-up is used. Usually, reduction of the time use of the direct electric back-up is compensated by the loss of heat pump performance.

2.2. System control

The system part on the secondary side of the heat pump, i.e. the heating distribution and the DHW-preparation, and the heat pump itself are controlled in a standard way. The brine cycle on the primary side, on the other hand, needs some special operation modes to decide how to use the solar heat. The backup needs to be controlled too, such that it runs when there is a heating demand in the building and the ice storage is fully iced (no source available for the heat pump). Further, season-based priorities regarding the use of the solar heat are implemented. The solar-ice system has a global control with three main priorities in the following hierarchy:

1. Use of direct solar heat to provide the space heat to the building without switching on the heat pump.
2. Switching on the heat pump when not enough energy is available in the combi-storage in order to provide space heat. When heat pump is on, solar energy is prioritized as energy source.
3. Use solar heat to load the combi-storage and ice storage when the heat pump is off. Loading the combi-store is usually referred as direct solar heat. Direct solar heat is usually prioritized in spring, summer and autumn, but in winter the loading of the ice storage is prioritized.

The control has to cope with the fact that the ice storage is a cold sink for a long time during the year. Unless a logic is implemented, that switches to loading of the combi-storage when appropriate, the ice storage would be loaded predominantly. The control mode that actively stops the loading of the cold storage and tries to divert the solar heat on a higher temperature level to the combi-storage is called warm storage priority. If the warm storage priority is not active, the control mode cold storage priority is on, which loads the ice storage. For small sized systems regarding collector field and ice storage it is usually a better option to use a cold storage

[1] All results shown in this paper are obtained with selective uncovered collectors.
[2] In this case the ice storage would provide a higher temperature, i.e. around 0 ^{o}C.

priority in winter in order to avoid the time when the direct electric back-up is needed. As soon as there is no risk to fully ice the storage, then warm storage priority should be used.

2.3. Performance indicators

The main performance indicator for the systems is the System Performance Factor calculated as described in Malenkovic et al. (2012):

$$SPF_{SHP+} = \frac{Q_{DHW} + Q_{SH}}{P_{el,T}} = \frac{Q_D}{P_{el,T}} \quad (1)$$

Q is the yearly heat energy demand and $P_{el,T}$ the total yearly electric energy consumption. The subscripts SHP, DHW, SH and D stand for solar and heat pump, domestic hot water, space heating, and total demand respectively.

The total electricity consumption is calculated as:

$$P_{el,T} = P_{el,pu} + P_{el,hp} + P_{el,cu} + P_{el,back-up} + P_{el,pen} \quad (2)$$

where the subscripts pu, hp, cu, aux and pen refer to circulation pumps, heat pump, control unit, back-up and penalties respectively. The symbol "+" in the $SHP+$ from Eq. 1 refers to the consideration of the heat distribution circulating pump in the electricity consumption. Therefore, the system performance indicator used in this work includes all circulation pumps of the system and also all thermal losses/gains from storages and piping. Penalties for not providing the heating demand at the desired comfort temperature are calculated according to Haller et al. (2012). $P_{el,aux}$ is the energy used from the direct electric back-up system.

3. System energetic performance with varying heat exchanger type and area

Dynamic yearly system simulations have been carried out for different heat exchanger areas and for two types of heat exchangers, capillary mats (CM) and flat plates with stainless steel (FP-SS). Simulations have been performed for ice storage volumes of 3 m^3, 4 m^3 and 5 m^3 and collector areas of 15 m^2, 20 m^2 and 25 m^2. All simulations are carried out using a single family house building located in Zurich with approximately 9.5 MWh of total heating demand for SH and DWH.

Results for the SPF_{SHP+} are shown in Fig. 3 as a function of the ratio between the heat exchanger area and the ice storage volume and as a function of the distance between heat exchangers. The same distances between heat exchangers are used both for CM and FP-SS. However, since FP-SS have almost twice the area[3] compared to CM, results for FP-SS are shifted towards higher A_{hx}/V_{ice} axis. Both heat exchanger types are able to provide very high SPF_{SHP+}, up to 6 for the sizes used in these simulations. System performances above 4[4] are always achieved if the collector area is $\geq$ 20 m^2. For collector areas in the order of 15 m^2, an SPF_{SHP+} above 4 can be achieved with CM and $V_{ice} = 4$ m^3 and with FP-SS if $V_{ice} = 5$ m^3. Using a collector area of 15 m^2 and an ice storage volume of 5 m^3 both heat exchangers are able to provide an SPF_{SHP+} above 4.

Very high system performances, in the order of 5 to 6, can be achieved with different component sizes. These results confirm the flexibility of the system concept, i.e. the same SPF_{SHP+} can be obtained using different configurations of ice storage volume and collector area. This allows to achieve a specific SPF_{SHP+} even if there are restrictions such as small cellar capacity or available roof area. However, there is a limit on the lowest size of the collector field since the solar-ice system is based purely on solar energy as heat source. The system flexibility of solar-ice systems was discussed in Carbonell et al. (2014). Of particular interest are results with 4 m^3, since this storage volume could fit in many cellars of single family homes using two separated storages of 2 m^3 allowing to achieve an $SPF_{SHP+} \geq 5$ with collector areas of 20 m^2.

[3] The two faces of the flat plate heat exchanger are considered as heat exchanger area.
[4] As a reference GSHP is used with an SPF_{SHP+} of 4.

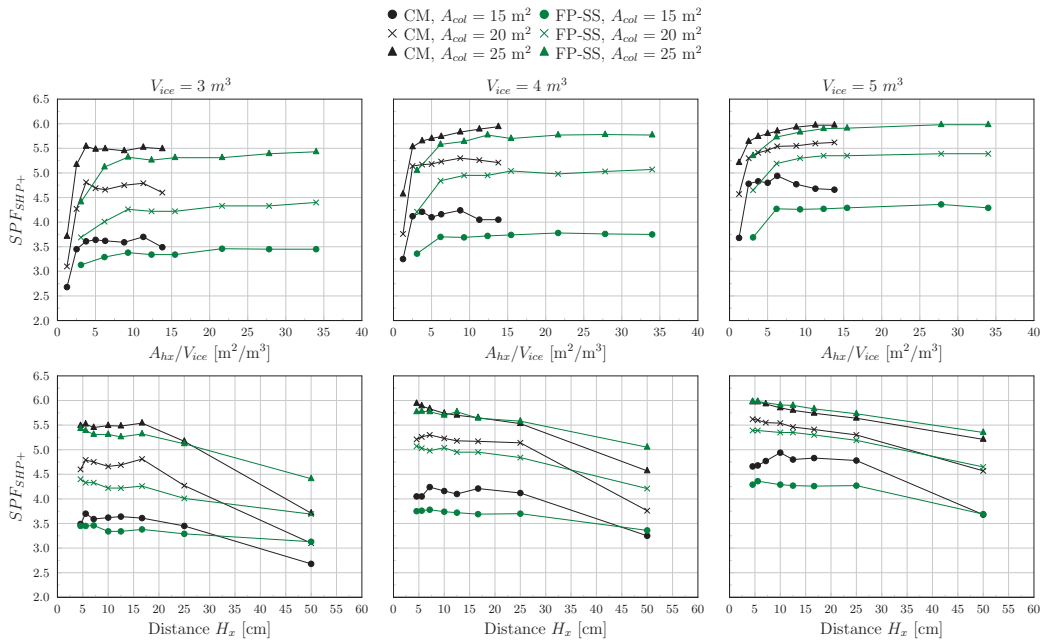

Fig. 3: Yearly system performance as function of (top) heat exchanger area divided by ice storage volume and (bottom) distance between heat exchangers for three ice storage volumes of (left) 2 m^3, (mid) 4 m^3 and (right) 5 m^3.

Regarding the heat exchanger type, the SPF_{SHP+} is usually higher for CM compared to FP-SS except for large distance between heat exchangers, e.g. $>$ 25 cm for V_{ice} =3 m^3. System performances for CM when distances between heat exchangers are small are higher because of the better heat transfer coefficient when icing at high ice fractions. The SPF_{SHP+} of CM is worse than that of FP-SS for cases where the distance between heat exchangers is way higher than that between the tubes in one CM. One can imagine a CM like a FP with empty spaces between tubes. Let's imagine the limit case where all tubes in one CM are in contact to each other. Under those circumstance CM would be worse than FP because of the higher resistance of polypropylene compared to stainless steel. When ice fills all the gaps between tubes, there is the added limitation that not all area is used due to the spaces between tubes.

Differences between FP-SS and CM are more prominent for low collector areas and low ice storage volumes. Results for 25 m^2 and 5 m^3 tend to an asymptotic solution where differences between CM and FP-SS are negligible. In those situations the direct electric back-up is not used because the system components are sized largely enough such that not all the latent heat capacity of the storage is necessary. The direct electric back-up is shown in Fig. 4 as a function of the ratio between A_{hx} and V_{ice}. Clearly, the increase of collector area and storage volume decrease the use of the direct electric back-up. The direct electric back-up is used exclusively in winter, when the ice storage if full (maximum ice fraction of 80 % has been assumed) and there is not enough solar energy to provide the heat for the evaporator of the heat pump. The use of the electric back-up is the dominant factor that influences the SPF_{SHP+}. In larger systems where the electric back-up is avoided, the system performance is quite independent of the heat exchanger area and less dependent on the collector area or ice storage volume. A SPF_{SHP+} value below 5.5 usually indicates the need of direct electric back-up.

In order to establish the optimum heat exchanger area in terms of SPF_{SHP+} it is of importance to investigate the maximum ice fraction achieved, as shown in Fig. 5. If the heat exchanger area is too low for the specific system design, some latent heat may not be used because the heat transfer coefficient will be too low at the maximum ice thickness achieved. This would lead to a situation where the heat pump would not be able to extract enough power from the ice storage while there is still liquid water present. For CM the maximum ice fraction of 80 % is reached approximately for ratios of A_{hx}/V_{ice} of 5-10 m^2/m^3. For FP the maximum ice fraction is reached at

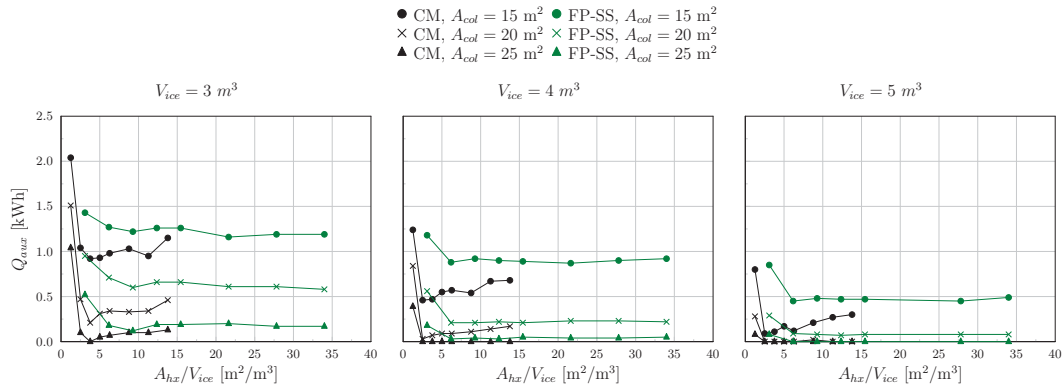

Fig. 4: Direct electric back-up as a function of heat exchanger area divided by ice storage volume for three ice storage volumes of (left) 2 m^3, (mid) 4 m^3 and (right) 5 m^3.

higher ratios of 10-15 m^2/m^3. For both cases these ratios correspond to a distance of around 7-12 cm between heat exchangers.

For some configurations, it is not possible to use all latent heat of the storage. For example for $V_{ice} = 5$ m^3 and $A_{col} = 25$ m^2, non of the heat exchangers setup can achieve an ice fraction of 80 %. This indicates that the system is oversized and either the ice storage or the collector area could be decreased and the system performance would not be penalized much. For example in Fig. 3 the $\text{SPF}_{\text{SHP+}}$ of $A_{col} = 25$ m^2 is almost the same if the storage volume is 4 m^3 or 5 m^3. Another way to make use of the latent heat and also to increase the $\text{SPF}_{\text{SHP+}}$ would be to give more priority to the warm storage loading.

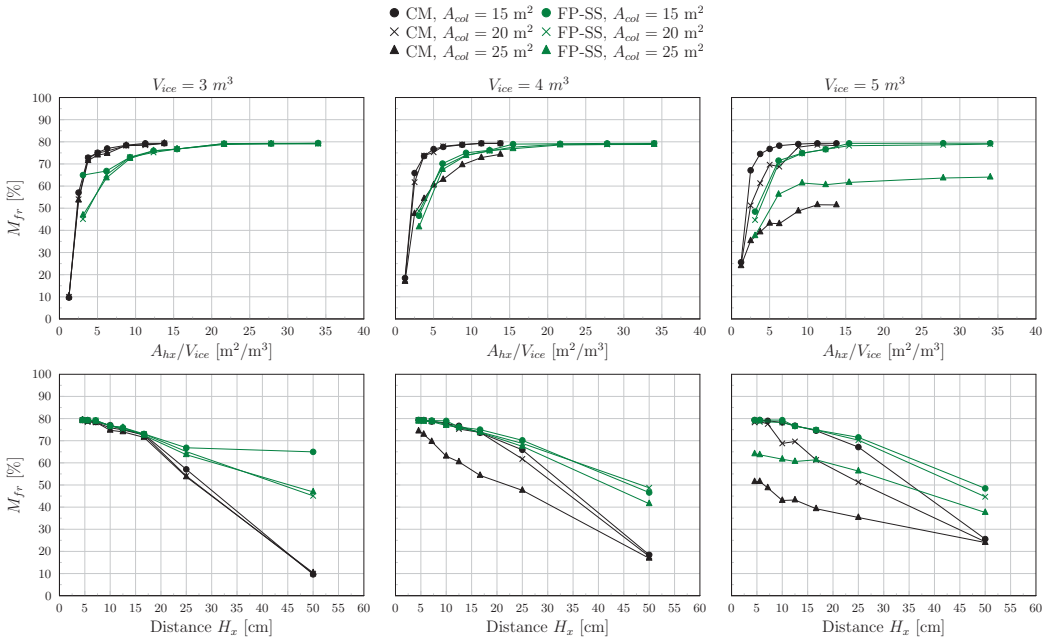

Fig. 5: Maximum yearly mass ice fraction as a function of (top) heat exchanger area divided by ice storage volume and (bottom) distance between heat exchangers for three ice storage volumes of (left) 2 m^3, (mid) 4 m^3 and (right) 5 m^3.

4. Cost analyses of solar-ice systems

In the section above the system performance in terms of energy has been provided. In this section, costs are taken into consideration in order to further evaluate different system designs. For all analyzed heating systems, investment costs and heat generation costs for prices of the Swiss energy market in 2016/2017 are calculated. The comparison of costs is used to find the optimum heat exchanger area considering both energetic system performance and a good value for the money.

The investment costs of the solar-ice systems are based on real costs that were gathered from several sources. Some data was obtained from the realization of two demonstration projects of solar-ice systems in Rapperswil-Jona, Switzerland. The data from the solar part was obtained from the SFOE project ReSoTech (Philippen et al., 2016). This data was used to derive cost functions per component. The cost functions are then used to calculate investment costs per specific system size simulated. All received cost functions were verified by a Swiss seller of heating systems in terms that they represent actual average market prices.

A ground source heat pump system is used as a reference to compare the system performance in terms of energetic efficiency and cost. Using a borehole length of 130 m for a single family house in the region of Zurich an SPF_{SHP+} around 4 is expected. Investment costs for GSHP are based on two offers of Swiss sellers for a GSHP system that supplies heat to a single family house (Causi, 2010). The cost functions were derived from average costs of the two offers. These two offers were used to estimate an uncertainty range on the heat generation cost. The average heat generation cost of a GSHP system based on the annuity is calculated as 39.6 $\pm$ 3.3 Rp./kWh.

For each system the present value of costs and the annuity are calculated following the methodology of VDI (2012) and Bangerter (1985) with some simplifications. Heat generation cost are calculated using the annuity factor. Main assumptions for the economic analysis are given in Table 1 and details for the calculation method were provided in Philippen et al. (2015). The electricity prices are taken from the price list of a regional Swiss utility and represent typical prices for small customers. The increase of electricity cost is based on the assessment of this utility. An interest rate of 2% is assumed, which represents an average interest used in credits for buying a house or for refurbishing it in Switzerland. An increase of the interest rate would shift all heat cost predictions to higher values, but differences between systems on the range of interest would be similar.

Tab. 1: Assumptions for calculation of heat generation costs.

Rate of interest	2.0 % p.a.
Analysis period	25 years
Yearly Maintenance	0.25 % of investment costs
Lifetime	25 years
Electricity costs (incl. VAT)	Fixed costs: 171 Fr. per year Variable costs: 0.13 Fr. per kWh
Increase of electricity costs	1 % p.a.

The system performance (top) and the heat generation cost (bottom) are shown in Fig. 6 as a function of the distance between heat exchangers for CM and FP-SS for $A_c = 15$ m^2 and all storage volumes analyzed in the section above. The SPF_{SHP+} is repeated here in order to compare directly graphs of SPF_{SHP+} and cost. The reference values for the GSHP system are included in all graphs. The objective is to achieve a solar-ice system with same or higher performance than GSHP and with similar heat generation costs. Therefore, the focus is on solar-ice systems with an $SPF_{SHP+} \geq 4$. It should be noted that cost calculations are based on offers for installations in single family houses that vary significantly among each other. Therefore, heat generation cost should be seen as orders of magnitude. To consider the large variation a 10% error band in the installation cost

has been assumed for all cases. The uncertainty range of the heat generation cost of the GSHP is estimated as 39.6 ± 3.3 Rp./kWh which can be visualized in Fig. 6 and 7 as a gray shadow area.

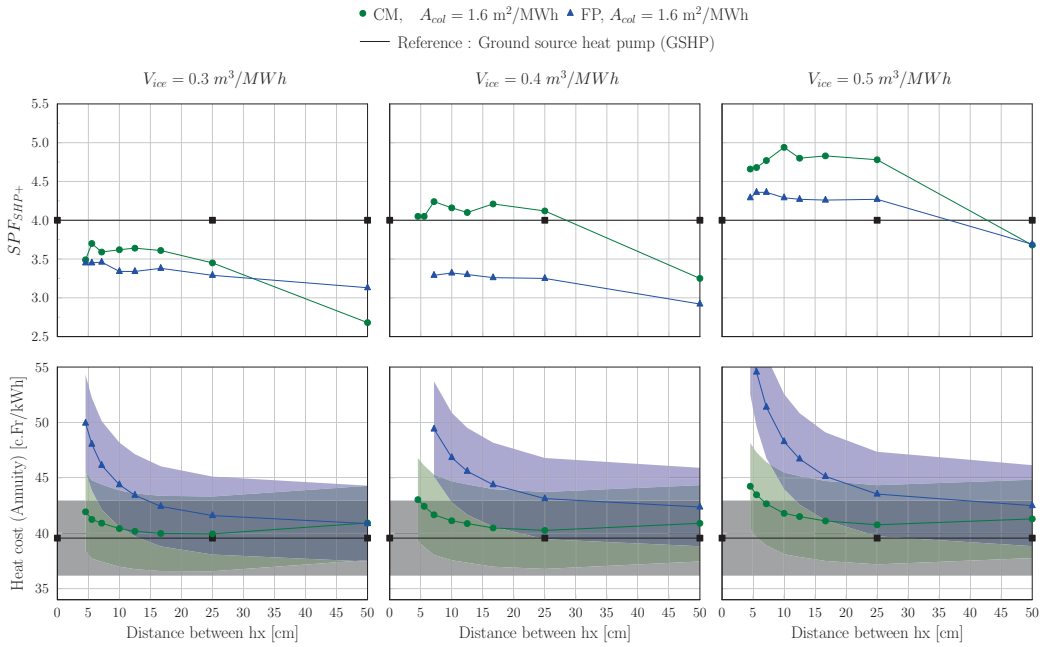

Fig. 6: System performance (up) and heat generation cost (bottom) as function of the distance between heat exchangers. Three ice storage volumes are used: (left) 3 m^3, (mid) 4 m^3 and (right) 5 m^3.

The heat generation cost calculated using the annuity factor are shown in bottom part of Fig. 6. There are two configurations where the $SPF_{SHP+} \geq 4$ and the heat generation cost are within the uncertainty range of the GSHP. Both configurations are using 15 m^2 of collectors, and 4 (CM) and 5 (CM and FP) m^3 storage volumes. These two system set-ups are of particular interest due to the cost comparable to GSHP and high efficiency. All systems using FP-SS show higher heat generation cost compared to CM. However, FP-SS are oxygen tight, and thus black steel can be used in the collector loop. In the other hand, CM made of polypropylene are usually installed with stainless steel pipes in the collector loop increasing its cost. Unfortunately, this cost difference has not been considered in the present calculation.

Using the cost function alone is not a good approach to decide on the heat exchanger area. For example, the lowest area seems to provide the cheapest system even when the energetic performance is relatively low. Thus, besides the cost function, the SPF_{SHP+} and also the maximum ice fraction achieved as shown in Fig. 5 should be used. Considering all these values it seems that the optimum heat exchanger area is in the order of 4-5 m^2/m^3 for CM and around 10-14 m^2/m^3 for FP-SS. Those ratios correspond to distances between heat exchangers of 12 - 17 cm for both heat exchanger types.

The heat generation cost along with the system performance are shown in Fig. 7 as a function of the collector area using a distance between heat exchangers of 16.6 cm. The heat generation costs increase linearly with collector area. The minimum of the cost function can not be observed with the simulated collector area.

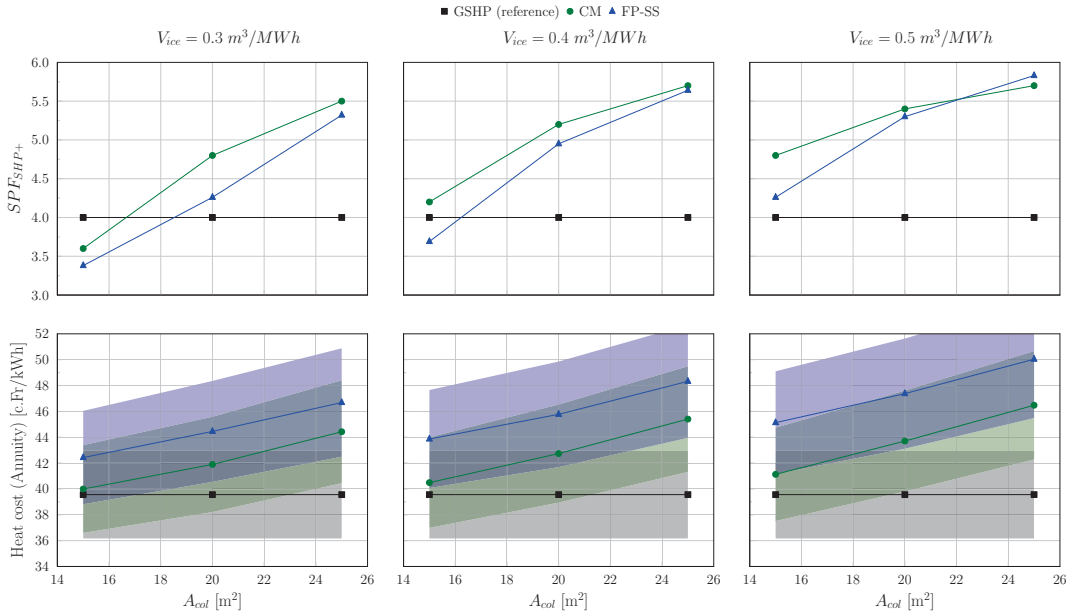

Fig. 7: System performance (up) and heat generation cost (bottom) as function of the collector area and ice storage volume for a distance of 16.6 cm between heat exchangers.

5. Conclusions

In this paper, the complete solar-ice system has been simulated with a well validated ice storage model from Carbonell et al. (2016a). From the system simulations the following conclusions can be drawn:

- A solar-ice system with ice storages volumes between 0.3 and 0.5 m^3/MWh (of total heating demand), and collector areas between 1.6 to 2.1 m^2/MWh can reach an SPF_{SHP+} in the range of 3.5 to 6 in Zurich for a single family home with 9.5 MWh total (SH + DHW) heating demand.
- Besides the sizes of the ice storage and collector field areas, the most relevant factor affecting the SPF_{SHP+} is the electric back-up necessary to run the system in winter periods. Control strategies should be focus on reducing it as a first target. When the electric back-up is minimized, control strategies should focus on the maximization of direct solar heat.
- Solar-ice systems can reach very high SPF_{SHP+} regardless of the heat exchanger type, but when the heat generation cost are included, capillary mats seem to be the most economic option. However, the heat exchanger area needs to be well design to reach these targets. An ice storage volume of 4 m^3 with capillary mats and 15 m^2 of collector area can reach an SPF_{SHP+} of 4.2, which represents an increase of SPF_{SHP+} of 5 % respect to GHSP with a similar heat generation cost.
- Considering both energetic and economic indicators, capillary mats are found to be the most promising solutions for solar-ice applications when compared to the other heat exchangers analysed along the project. Nevertheless, other factors could be used to choose other heat exchangers. For example, one may choose flat plates made of stainless steel instead of capillary mats due to the robustness of the heat exchanger, with a life time guarantee in the range of 25 years. Another reason to select stainless steel heat exchangers can be that they are oxygen tight and therefore an expensive stainless steel piping system in the collector loop can be avoided. The cost of the stainless steel piping system needed when plastic capillary mats are used could overcome the more expensive heat exchangers. However, this has not been considered in the cost calculations, where the piping system was the same for all heat exchangers.

- A strategy to reduce the direct electric back-up in small systems, e.g. using ice storages in the range of 0.3 - 0.4 m^3 per MWh of total heating demand and collectors areas in the range of 1.6 - 2.1 m^2/MWh, is to reduce the working temperature of the primary brine loop connecting the solar collectors, ice storage and heat pump. For those systems, priority should be set to use the collectors as primary source for the heat pump in winter, even that the working temperature decreases well below 0 ^oC. In those circumstances, the use of the ice storage would increase the instantaneous COP of the heat pump. However, it would increase the operating times of the direct electric back-up. The better instantaneous heat pump COP can hardly compensate the higher use of the electric back-up at a COP of 1. For larger systems, where the back-up is seldom used in winter, the control should give priority to the combi-storage. Those systems will have roughly an SPF_{SHP+} in the order of 5.5 or above. However, results form this paper suggest that only "small" sized systems with an SPF_{SHP+} around 4 - 4.5 could be cost competitive.

Combined solar thermal and heat pump systems within the funding program of large-scale solar thermal systems in Austria – Status investigation and progress report

Franz Helminger[1], Bernd Windholz[1], Christian Fink[2] and Samuel Knabl[2]

[1] Center for Energy/AIT – Austrian Institute of Technology GmbH, Vienna (Austria)

[2] AEE Intec, Gleisdorf (Austria)

Abstract

The Austrian "Klima- und Energiefonds" started 2010 a funding program for the development and further market penetration of large-scale solar thermal systems. The most interesting projects in terms of innovation were selected for a system monitoring, analysis and optimization of about 12 months by a scientific partner. Since 2010 about 25 combined solar thermal and compression heat pump systems (STHP systems) were selected within this framework and for eleven of these systems monitoring data is available. In this paper the selected systems are categorized and findings from the monitored systems are presented. Therefore, the performance of the systems is assessed with technical, economic and ecological parameters. In principle, the compression heat pump suits well to the solar thermal system to generate low temperature heat for space heating purposes and hot water preparation. The compression heat pump acts flexible and generates heat whenever the solar energy is not available. STHP systems show also a very positive effect for reductions of environmental impacts. But lack of standards for planning and realization leads to higher effort, higher risk and costs. Up to now the knowledge transfer by the scientific partners to the market players is essential for the further development of this technology.

Keywords: large-scale solar thermal system, compression heat pump, monitoring

1. Introduction

The Austrian "Klima- und Energiefonds" introduced a funding program for large-scale solar thermal systems in 2010 for innovative solar thermal concepts of between 100 and 2000 m² collector area. In this funding program the implementation of following concepts is addressed:

- Solar process heat applications
- Solar district heating systems
- Solar cooling applications (until 2015)
- Solar combisystems with high solar fractions of above 20 %
- Novel technologies and innovative concepts (since 2013)

A scientific consultancy in the application phase for the funding program ensures the high quality of the addressed systems. For the most interesting projects a system monitoring is done for a period of about 12 months. Therefore operating data is continuously recorded and analyzed. Based on this analysis the heat generation systems (solar thermal, heat pump, biomass, oil, etc.) and their controls as well as the heat distribution systems are optimized. Any existing cold supply is analyzed, as well. Conclusions of the system monitoring and optimizations are published.

Since 2010 about 25 combined solar thermal and compression heat pump systems (STHP systems) have been funded and selected for the monitoring. For eleven of these systems monitoring data of the entire period is available. In this paper the selected STHP systems are categorized and findings from the monitored STHP systems are presented. In chapter 2 an overview and categorization is given. In chapter 3 an assessment of the STHP systems by means of following parameters is shown:

- Specific solar gains
- Mean collector temperature

doi:10.18086/swc.2017.33.03 Available at http://proceedings.ises.org

- Seasonal performance factor (SPF) of the heat pump system
- Operation time and number of operating cycles of the compression heat pump
- Greenhouse gas impact measured by CO_2 equivalents and primary energy consumption

In chapter 4 the results are summarized and a conclusion is given.

2. Overview and categorization

Solar thermal systems and compression heat pumps can be combined in many ways. The possibilities how to combine these systems were analyzed and described within the IEA SHC Task 44 documented by (Paula 2014) and (Ruschenburg and Herkel 2013). The main categories are "parallel", "serial", "regenerative" and "complex" concepts. A short description of these four concepts is given in Tab. 1, Fig. 1 shows the energy flow schemes of the four concepts.

Tab. 1: Short description of different STHP concepts and their functionality

Concept	Short description
Parallel	Heat from the solar system and the heat pump is fed in one heat storage. The solar system and the heat pump work independent from each other, only coupled via the storage.
Serial	The solar system and the heat pump are hydraulically connected in a way, that the solar system delivers heat to the evaporator of the heat pump. This concept allows low temperatures in the solar system and the collectors act as air heat exchangers (ST+PV hybrid collectors and unglazed collectors).
Regenerative	The solar system delivers heat into ground heat exchangers to regenerate the ground. In that way heat from sunny periods is used in cold periods and the ground acts as seasonal storage.
Complex	Combination of parallel, serial and/or regenerative concepts.

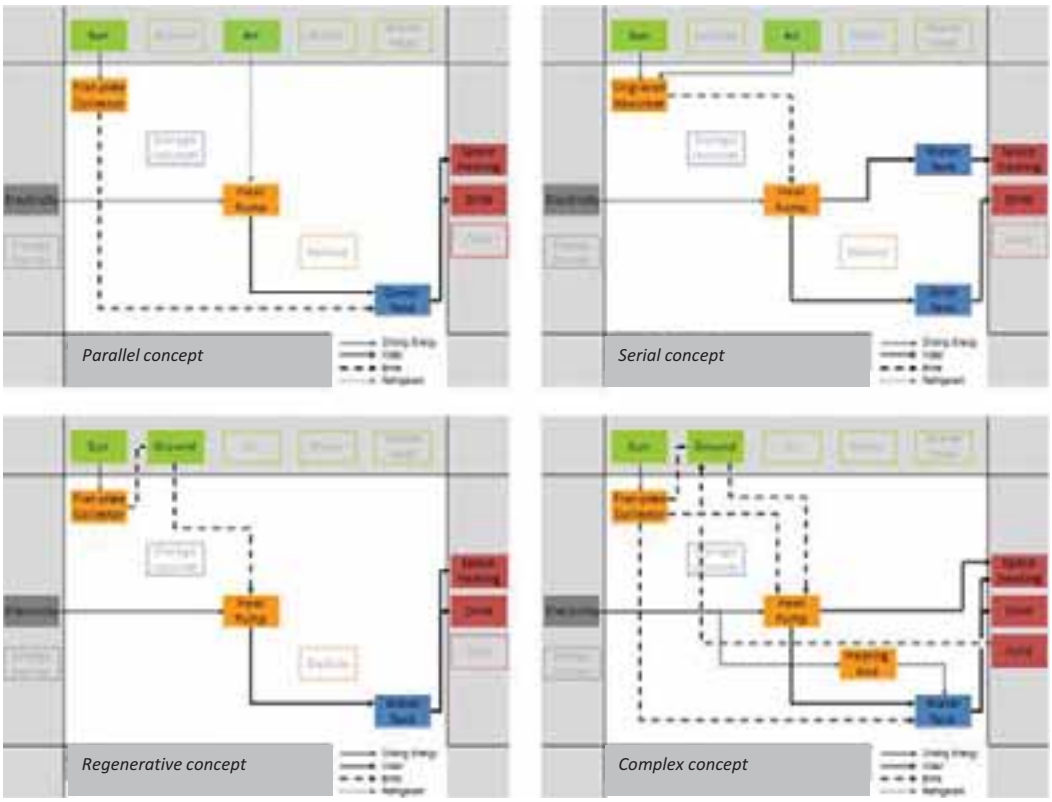

Fig. 1: Energy flow schemes of four STHP concepts by IEA SHC Task 44 (Paula 2014)

Of the 25 selected systems (sum of dark and light blue bars in Fig. 1), 19 (76%) STHP systems can be assigned as complex systems and six (24%) STHP systems as parallel systems. For eleven of the 25 selected STHP systems the monitoring is already finished and monitoring data of the entire period of 12 months is available (dark blue bars in Fig. 1). Ten of the monitored systems are complex systems and one system is a parallel system.

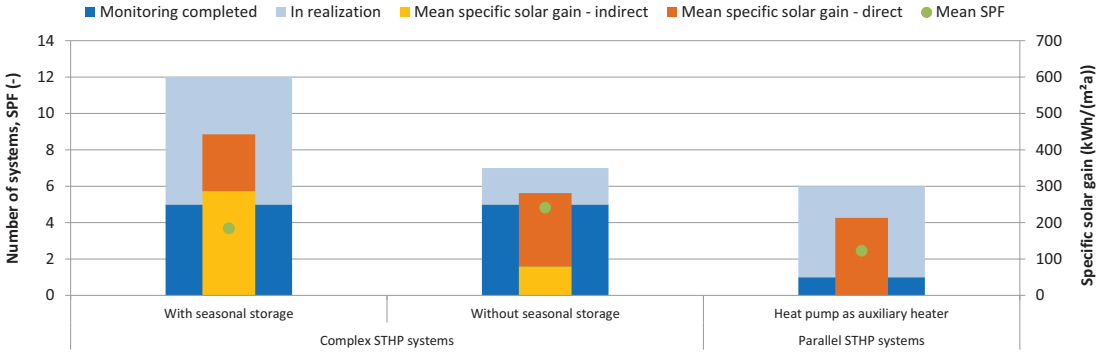

Fig. 2: Classification of selected STHP systems and overall results

For further distinction and better overview including the functionality following subcategories are established (see Fig. 1):

Complex STHP systems:

- Systems with seasonal storage
- Systems without seasonal storage

Parallel STHP systems:

- Systems with heat pump as auxiliary heater

The subcategory „systems with seasonal storage“ covers systems with horizontal ground collectors and depth probes. Heat from the solar system can be delivered to the ground and used by the heat pump. In “systems without a seasonal storage” systems are summarized where the combination of solar thermal and compression heat pump enables solar heat at the evaporator of the compression heat pump without a seasonal storage. Within the category “parallel systems” a (brine-to-water or air-to-water) heat pump acts as auxiliary heater to the solar system. 14 systems are in implementation (light blue bars in Fig. 1), seven of these systems are covered by the category “systems with seasonal storage”, two belong to “systems without seasonal storage” and five systems are “systems with heat pumps as auxiliary heater”. In three of five “systems with seasonal storage” with finished monitoring, the heat pump is used for heating and cooling and the seasonal storage is partly regenerated by the heat pump. The following assessment covers only heating mode of the systems.

3. Assessment

For the assessment of the specific solar gains and the mean collector temperature two different operating modes of the solar system are distinguished. The operating mode “direct” considers the solar gains and collector temperatures in periods where the heat is directly delivered to the respective use (e. g. space heating or hot water preparation) or to a short-term storage (i.e. buffer tank). The operating mode “indirect” includes solar gains and collector temperatures in periods where the heat is given to the evaporator of the compression heat pump or to a seasonal storage. The solar gains in the two operating modes are shown in Fig. 2, which also shows the mean seasonal performance factor (SPF) of the heat pump. The SPF is the ratio of the useful heat taken from the condenser of the compression heat pump divided by the electrical energy consumption of the compression heat pump. It is typically analyzed to assess the efficiency of a heat pump and gives also a value for the assessment of the economical operation. It was analyzed only for heating mode and not taking into account auxiliary devices like circulation pumps due to the fact that auxiliary devices need not to be measured regarding the funding scheme.

All STHP systems with completed monitoring are analyzed and the results are given at Fig. 3 to Fig. 5 for each subcategory. This graphs show the specific solar gains (direct and indirect operating mode), the mean collector temperature (direct and indirect operating mode) and the SPF as most significant parameter of the heat pump.

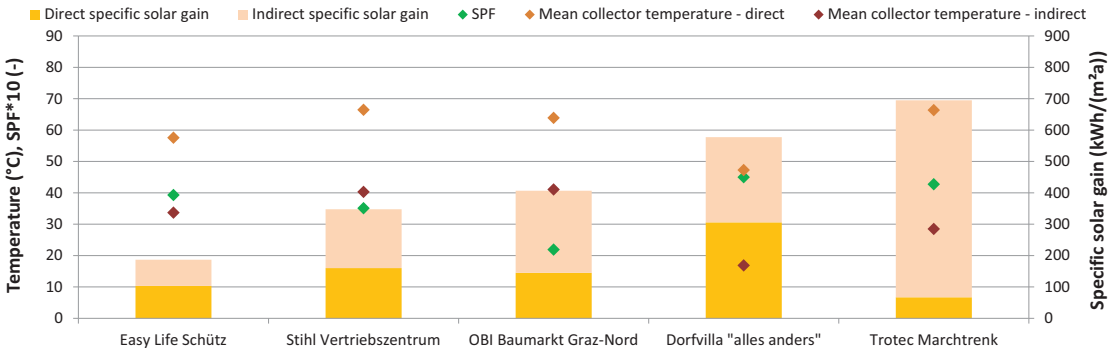

Fig. 3: Results of complex systems with seasonal storage

By means of the specific solar gains in ”direct” and ”indirect” operating mode different behavior of each STHP system is presented. In all STHP systems heat from the solar system in ”direct” operating mode is generated at a higher temperature level than in ”indirect” operating mode. The average of the mean collector temperature in ”indirect” operating mode is about 25 K lower than in ”direct” operating mode. With lower collector temperatures the efficiency of the solar collector and the solar gain increases. In many cases heat at lower temperature cannot be used directly and needs to be lifted by the compression heat pump. This operating mode causes an electrical energy demand. The higher the difference of the temperature of the heat source to the heat sink of the heat pump, the higher the electrical energy demand and lower the SPF.

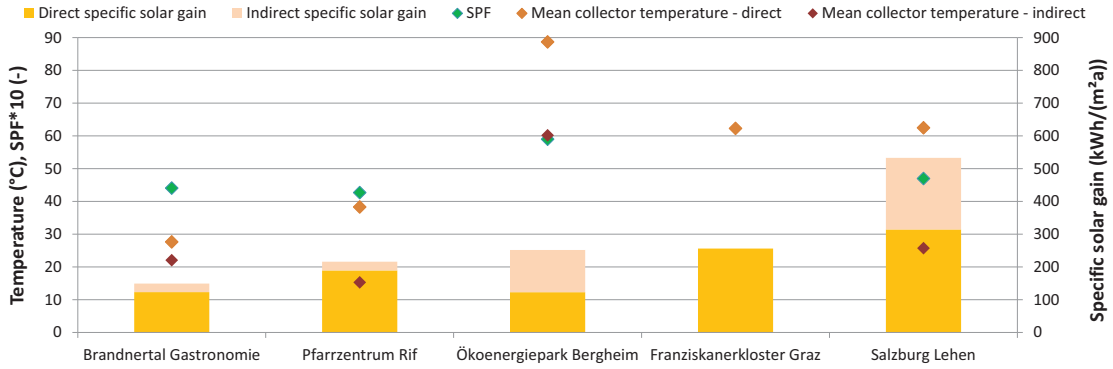

Fig. 4: Results of complex systems without seasonal storage

An optimization of the respective STHP system in consideration of diametrical optimization criteria (minimum electrical energy costs, maximum reduction of CO_2 emissions, etc.) is a sophisticated task and done by the operators with different optimization targets and different framework conditions (e.g. storage sizes, collector area, energy prices, etc.).

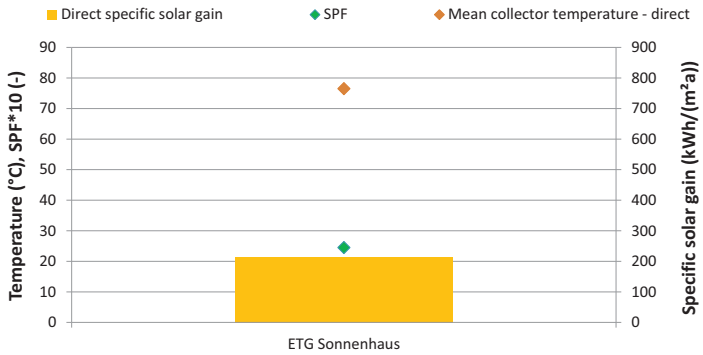

Fig. 5: Results of parallel systems with heat pump as auxiliary heater. In this specific case an air-to-water heat pump is used.

The specific solar gain differs significantly within each category. Even if the configuration of the STHP systems is similar within one category, each STHP system is planned, realized and operated individually (collector area, storage size, orientation of solar collectors, heat demand, temperature level of consumers, etc.). Therefore, it is not possible to give clear conclusions and generally applicable recommendations.

The monitoring results of the compression heat pumps are very good for almost all STHP systems, only at „OBI Baumarkt Graz-Nord“ and „ETG Sonnenhaus“ the SPF is low. At these two STHP systems, the operating conditions for the compression heat pumps are very unfavorable and therefore, a higher SPF cannot be reached. At the STHP system „OBI Baumarkt Graz-Nord“ the ground collectors are placed below a parking area and are not sufficiently insulated against outside air. The operating temperature of these ground collectors is very close to the outside temperature and especially in winter lower than expected. At the STHP system „ETG Sonnenhaus“ the air-to-water heat pump is operated only in December and January with a very high temperature lift from outside temperature to the heat delivery system.

The compression heat pump at the STHP system „Franziskanerkloster Graz“ was not operated during the monitoring period and therefore, the SPF can not be calculated.

A continuous operation of the heat pump is generally an advantage for an economical use. To assess the continuity of the heat pump operation of the STHP systems the yearly operation period, the mean operation period per activation in the monitoring year, the mean operation period per activation in the month with longest operation period and the number of activations per year are compared in Tab. 2. The mean operation period per activation in the monitoring year is between ten minutes and about ten hours. Very short operation periods per activation have negative consequences for the lifetime of the compressor(s) of the heat pump (lubrication gap has to be built up), and for the SPF, because on start up (takes at least one minute) the efficiency is lower than in steady state operation. Mean operation periods below 30 minutes are disadvantageous, but can not be avoided due to varying energy demands.

Tab. 2: Analysis of activation periods and number of activations of the compression heat pump

		Yearly operation period (h)	Mean operation period per activation in the monitoring year (min)	Mean operation period per activation in the month with longest operation period (min)	Number of activations per year
Systems with seasonal storage	Easy Life Schütz	2790	90	62	1868
	Stihl Vertriebszentrum	790	44	63	1074
	OBI Baumarkt Graz-Nord	313	14	21	1349
	Dorfvilla "alles anders"	1887	176	206	644
	Trotec Marchtrenk	1113	43	69	1536
Systems without seasonal storage	Brandnertal Gastronomie	570	10	10	3552
	Pfarrzentrum Rif	1067	24	32	2721
	Ökoenergiepark Bergheim	3055	114	371	1609
	Franziskanerkloster Graz	No heat pump operation during monitoring period			
	Salzburg Lehen	3744	567	781	396
Heat pump as auxiliary heater	ETG Sonnenhaus	146	194	182	45

Fig. 6 shows the results given in Tab. 2 and emphasises that due to different applications of the STHP systems and different share of energy from the solar system and the compression heat pump, a wide range of operation periods occured in the monitored systems. An example with continuous operation of the heat pump is given in

”Salzburg Lehen”, where the yearly operation period is long (3750 hours, about 5 month). The main reason for this behavior is that the capacity of the STHP system is very low compared to the energy demand. The STHP system covers a part of the base load, therefore, it is activated continuously.

During monitoring periods numerous improvement measures were implemented in the considered STHP systems. In some cases, due to planning mistakes (e.g. dimensioning of storage), just small improvements were possible. High effort would be necessary to correct such planning mistakes. In some STHP systems the heating capacity of the compression heat pump is too high compared to the energy demand or the storage size. This leads to short activation periods of the compression heat pump, because the compression heat pump is deactivated when the storage is loaded and no heat is needed. The dimensioning of the compression heat pump has to be done according to standards and is calculated to cover the energy demand at the coldest day of the year. To compare STHP systems the mean operation period per activation is assessed, on the one hand for the monitoring year and on the other hand for the month with the longest operation period. The mean operation period of the month with the longest operation period is normally longer than the mean operation period of the monitoring year. Only for the STHP systems „Easy Life Schütz“ and „ETG Sonnenhaus“ the mean operation period of the monitoring year is longer than the mean operation period of the month with the longest operation period. At both STHP systems the reason is the specific use of the buildings. The mean operation period should be longer than about 45 to 60 minutes. Otherwise, a compression heat pump with less capacity would be sufficient to cover the energy demand. Looking at the past years, the lowest outside temperature of each year was rising. Therefore, the nominal capacity of the overall heating system is rarely needed, the heating system is operated in partial load, and operating periods are shorter. A bigger but more expensive energy storage could improve the situation and lead to lower electrical energy demand of the heat pump.

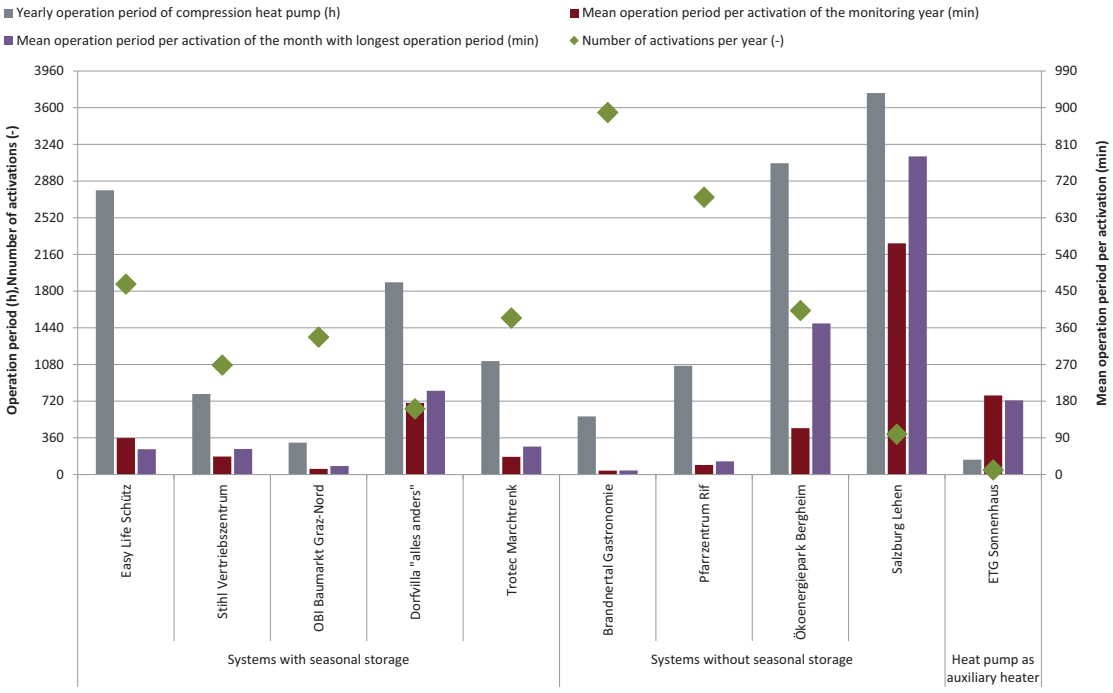

Fig. 6: Operation periods and activations of compression heat pump

STHP systems enable a reduction of negative environmental impacts (CO_2 emissions, primary energy consumption, etc.) compared to heating systems operated with fossil fuels. An ecological assessment of the yearly reduction of CO_2 equivalents and primary energy consumption was done by comparing the monitoring results to a reference scenario. Therefore, following assumptions were made:

- As reference scenario a gas boiler with 96 % efficiency was chosen.
- At STHP systems without any additional heating system (listed below) it was assumed that the gas boiler delivers the overall energy demand without storage losses.

Easy Life Schütz	Stihl Vertriebszentrum	OBI Baumarkt Graz-Nord
Dorfvilla "alles anders"	Trotec Marchtrenk	Pfarrzentrum Rif
ETG Sonnenhaus		

- At STHP systems with additional heating systems (listed below) it was assumed that just the energy delivered from the solar system and the heat pump is compared to the reference.

Brandnertal Gastronomie	Ökoenergiepark Bergheim	Salzburg Lehen

  This assumption neglects that the behavior of the additional heating systems is affected by the operation of the STHP system and the reference. At these STHP systems the heat pump operates as a booster and lifts low temperature heat to heat at temperature levels used by the heat consumers. It is neglected that the additional heating systems have an influence to the ecological emissions. As this paper wants to present the effect of the STHP systems, all these neglections cause a simplification of the analysis.
- The electrical energy consumption of auxiliary devices of the STHP systems was estimated out of the monitoring results as it was not measured. The electrical energy consumption of the auxiliary devices was assumed to be 3.5 % of the electrical energy consumption of the compression heat pump of each STHP system.
- At the STHP system “Franziskanerkloster Graz” the heat pump was not activated during the monitoring period. As there is an additional heating system, just the solar heat delivered to the entire system is compared to the reference. The electrical energy consumption of the auxiliary devices was assumed to be 3.5 % of the solar heat delivered to the entire system.

The CO_2 equivalents and primary energy consumptions for Austria and EU-25 (abbreviated EU) were determined for the reference scenario and the monitored STHP systems (see Tab. 3 and Tab. 4). Following factors from (Öko-Institut Freiburg) were used:

- Greenhouse gas emissions to air – CO_2 equivalent for natural gas in Austria
- Greenhouse gas emissions to air – CO_2 equivalent for natural gas in EU
- Greenhouse gas emissions to air – CO_2 equivalent for electrical energy in Austria
- Greenhouse gas emissions to air – CO_2 equivalent for electrical energy in EU
- Resource requirements – primary energy consumption ratio for natural gas in Austria
- Resource requirements – primary energy consumption ratio for natural gas in EU
- Resource requirements – primary energy consumption ratio for electrical energy in Austria
- Resource requirements – primary energy consumption ratio for electrical energy in EU

Tab. 3: Yearly reduction of CO_2 equivalents using emission factors for Austria and EU, respectively

		Yearly reduction of CO_2 equivalents (t)	
		Austrian energy mix	EU energy mix
Systems with seasonal storage	Easy Life Schütz	7.58	6.59
	Stihl Vertriebszentrum	44.05	38.34
	OBI Baumarkt Graz-Nord	91.01	73.94
	Dorfvilla "alles anders"	14.30	14.55
	Trotec Marchtrenk	38.14	40.47
Systems without seasonal storage	Brandnertal Gastronomie	4.07	3.65
	Pfarrzentrum Rif	9.71	9.83
	Ökoenergiepark Bergheim	312.18	311.55
	Franziskanerkloster Graz	20.10	21.27
	Salzburg Lehen	239.60	242.02
Heat pump as auxiliary heater	ETG Sonnenhaus	3.93	4.05

Tab. 4: Yearly reduction of primary energy consumption using consumption factors for Austria and EU, respectively

		Yearly reduction of primary energy consumption (MWh)	
		Austrian energy mix	EU energy mix
Systems with seasonal storage	Easy Life Schütz	29.82	19.46
	Stihl Vertriebszentrum	173.35	113.07
	OBI Baumarkt Graz-Nord	336.16	165.41
	Dorfvilla "alles anders"	65.06	63.91
	Trotec Marchtrenk	180.44	191.94
Systems without seasonal storage	Brandnertal Gastronomie	16.47	11.81
	Pfarrzentrum Rif	43.95	42.70
	Ökoenergiepark Bergheim	1394.78	1316.76
	Franziskanerkloster Graz	94.84	100.40
	Salzburg Lehen	1082.62	1048.22
Heat pump as auxiliary heater	ETG Sonnenhaus	18.09	18.22

The results of the assessment shown in Tab. 3 and Tab. 4 vary in a wide range due to the fact that the heat demands of the STHP systems are very different. The ecological improvement was additionally analysed by a comparison of relative improvements of each STHP system. Therefore, the ratio of the yearly reduction of emissions and primary energy consumption of the monitored STHP systems to the CO_2 emissions and primary energy consumption of the reference scenario was determined and is shown in Fig. 7 for CO_2 equivalents and in Fig. 8 for primary energy consumption. In both graphs the grey bars represent the reduction, if the STHP system was powered by the EU energy mix and the dark red bars represent the reduction, if the STHP system was powered by the Austrian energy mix. The reduction of CO_2 equivalents is between 40 % and 96 % for the EU energy mix, and between 53 % and 97 % for the Austrian energy mix. The reduction of primary energy consumption is between 19 % and 95 % for the EU energy mix, and 41 % and 96 % for the Austrian energy mix.

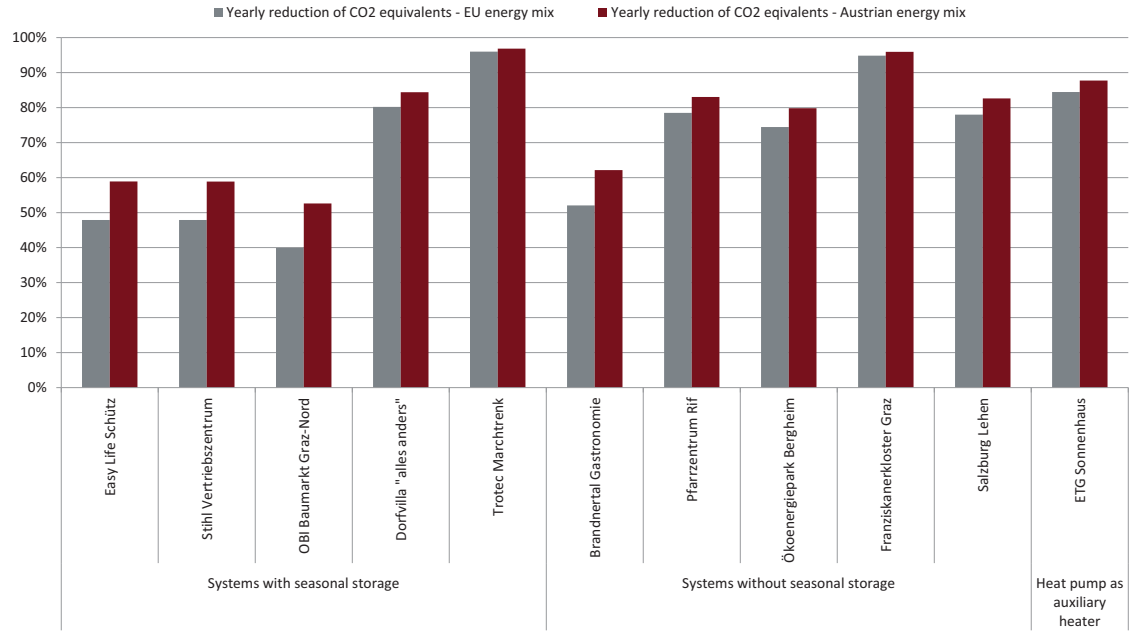

Fig. 7: Yearly reduction of CO_2 equivalents (Austrian and EU energy mix, respectively) by use of STHP systems compared to a gas boiler

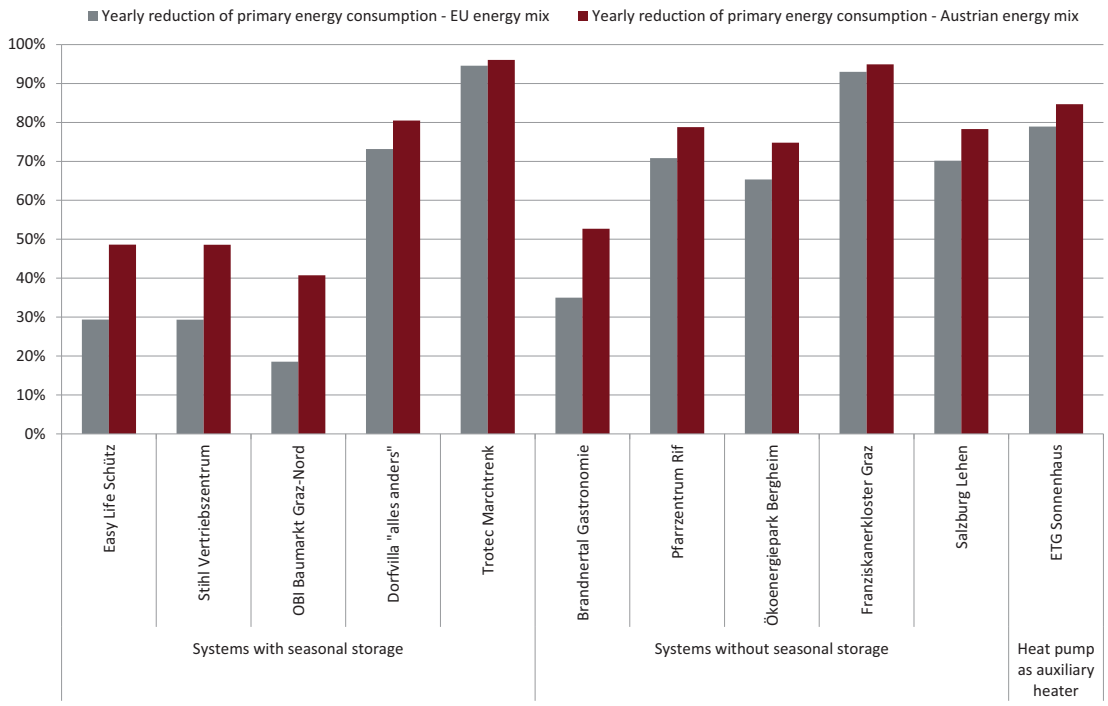

Fig. 8: Yearly reduction of primary energy consumption (Austrian and EU energy mix, respectively) by use of STHP systems compared to a gas boiler

4. Conclusion

The number of STHP systems within the framework of the funding program for large-scale solar thermal systems was increasing in recent years. Eleven systems are realized and monitoring results are available, additional 14 systems are selected and should be realized within coming years.

In principle, the compression heat pump suits well to the solar thermal system to generate low temperature heat for space heating purposes and hot water preparation. The compression heat pump acts flexible and generates heat whenever the solar energy is not available. STHP systems show also a very positive impact for reductions of environmental impacts.

Although experience in STHP systems is available for planers, installers, operators, and owners, the lack of standards for planning and realization leads to higher effort, higher risk and costs. Up to now the knowledge transfer from the scientific partners to the market players is essential for the further development of this technology. Within the framework of the funding program some planers with long-time experience apply for funding, but also planers with no or nearly no experience take part. For both groups tools, standards and guidelines for STHP systems would lower costs and risks. As the STHP systems are mainly composed for the individual situation, a detailed simulation is advantageous. Some of the planers do not take care of this and therefore the risk for mistakes and dissatisfaction occurs.

Abstract

Silicon enriched zeolites of type DAY (dealuminated Y) have been investigated by BET-Isotherm measurements, infrared spectroscopy, thermogravimetric and water sorption measurements with respect to their characterization of crystal state and water uptake properties. Variation of the adsorption behavior of samples is a result of a steaming process at different temperatures in dependence of time. It was found that different Si/Al ratios affects the typical characteristic of the silicon enriched zeolites, relating to their ad- and desorption temperatures. In comparison with other usual DAY zeolites it was found a different microporous and mesoporous hierarchy of the pore system. As a result of the steaming process, the silicon enriched zeolites enable more possibilities of low temperature application under specific conditions.

Keywords: dealumination; water adsorption; zeolites; adsorption heat pump; thermal adsorption storage

1. Introduction

In recent years more and more new materials have been developed which are specifically adapted for applications in solar driven heat pumps or thermal adsorption storage processes. But actually low-temperature heat pumps gain in importance, due to the increasing necessity to provide cold in industrial processes. It is well known that thermally driven heat pumps are ecological much more efficient in comparison with electrically operated heat pumps. In conjunction with the use of renewable energies it is even possible to develop such a system as carbon-neutral alternative. Quite expensive materials such as silicoaluminophosphates (SAPO) find application in adsorption heat pumps which depend upon low-temperature heat for regeneration aluminiumphosphates (ALPO) have proven their operational capability in low-temperature heat pump applications, too. But silica gel is still most commonly used in those applications due to its low price. On basis of previous results, which have shown that dealuminated Y zeolites [1, 2] are possible substitutes for SAPO's and ALPO's, we redesigned the adsorption affinity of DAY zeolite to a bigger operating range for water vapor pressures level and capacity that it is actually needed in the process. This way offers the possibility to substitute materials of nearby all types.

From catalysis it is well known that a post-synthesis modification of zeolites by hydrothermal treatment [3] reduces the lattice aluminum concentration and improves the thermal stability and catalytic performance. A partial dealumination of the parent zeolite Y by steaming reduces the hydrophilic character of the zeolite as well as leads to a lower energy for water desorption. The observed healing process of the aluminium framework defects by silicon building units reduces the loss of microporous sorption volume.

The aim of this contribution is therefore to describe more in detail the steaming process and its influence on the water adsorption properties of DAY with respect to optimized adsorption/desorption heats and the influence on the secondary pore system hierarchy.

doi:10.18086/swc.2017.33.04 Available at http://proceedings.ises.org

2. Methods and materials

The adsorption properties of the potential heat pump application materials have been studied by different thermogravimetric methods (TG/DTA), the TG-programs for the H_2O desorption measurements started at 298 K and then followed by a heating range with 3 K/min up to temperature of 723 K, in permanent N_2 current of 1l/h. The samples where preconditioned for 48 h, at temperature of 298 K in a p/p_s=0,33 water atmosphere.

The investigated samples were also studied by gravimetric isotherm measurements using a McBain-Bakr quartz spring balance (tempered at 303 K). The high vacuum glass apparatus works in a pressure range between 10^{-5} up to 1013 mbar and in a temperature range between - 253K up to + 368K (± 0.1K). The apparatus has a measuring sensitivity of 4 mg / mm, with a amplitude of 0.01 mm measured with a Cathetometer. The minimum sample value is between 150 and 100 mg.

The BET nitrogen isotherms of the different DAY and parental NaY samples were measured with a Quantachrome NOVAe 2000e after outgassing the samples at a temperature of 623 K for minimum 2h.

The DAY samples were obtained by a steam treatment at 1 bar water pressure and temperatures of 673 K up to 973 K in dependence on time (1-5 h). The parent NaY zeolite with a framework Si/Al ratio of 2.6 was introduced into the active NH_4Y modification by ion-exchange. The resulting framework Si/Al ratios were characterized by infrared spectroscopic measurements using the specific double-ring vibration band at 278 cm^{-1} for the parent NaY sample for calculation.

3. Results and discussions

In Table 1 the chemical composition and adsorption capacity of the DAY samples are presented. For better overview and understanding the results of the parent zeolites NaY (Grace), SAPO-34 and Silica gel are included are presented, too. A moderate dealumination up to Si/Al=3.4 doesn't have a strong influence on the adsorption capacity, which is still comparable the reference materials that are used for heat pump applications actually. At higher Si/Al-ratios the water sorption capacity is reduced, for desorption temperatures up to 523 K. In contrast, the influence on the BET surface is quite strong. It depends on the operating temperature and healing time that is given during the synthesis. For the optimized synthesis condition process it is necessary to find a perfect combination of the three conditions temperature, healing time and Si/Al ratio.

Tab. 1: Si/Al-ratio and adsorption capacity of 48h in RH=33% (p/ps=0.33; 20.45 mbar partial water vapor pressure) conditioned samples, desorbed up to a temperature of 723 K, BET Surface.

Sample	Dealumination conditions	Si/Al	Adsorpt. capacity in g/g	BET Surface in m²/g
DAY1	673K; 1h	2.8	0.32	
DAY2	673K; 3h	3.1	0.31	
DAY3	773K; 1h	3.4	0.30	623
DAY4	773K; 3h	3.8	0.29	578
NaY		2.6	0.32	684
SAPO-34		-	0.30	630 - 650
Silica gel		-	0.20	600 - 700

From Fig.1 (see below) it is easy to find out, that the steaming process has a positive influence on the desorption capability of the modified Y-type zeolites. In spite of the difference of the desorption level that is reachable at 120°C by DAY2 and SAPO-34, the desorption kinetics of DAY2 seems to be better, due to the steeper slope of the TG-curve at the beginning.

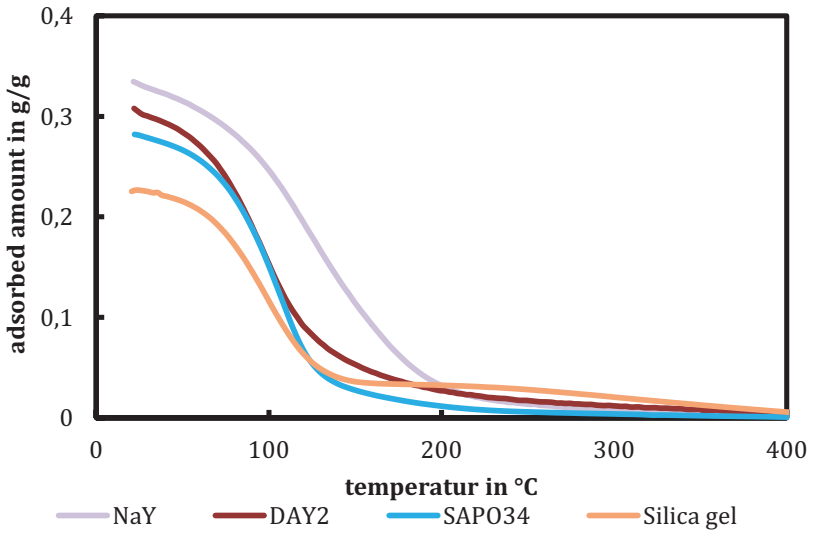

Fig. 1: Thermogravimetric profiles of the parent Y-zeolite, the dealuminated forms of Y-zeolite (DAY2) , SAPO34 and silica gel.

The low angel of the presented thermogravimetric profiles at a temperature above 200 °C is without interest for the relevant regeneration temperatures of those materials. But the clear shift from the light purple parental NaY to the dark red DAY2 curve shows that the dealuminating steaming process gives the opportunity to lower the regeneration temperature level and related to that the desorption time and performance of such a material.

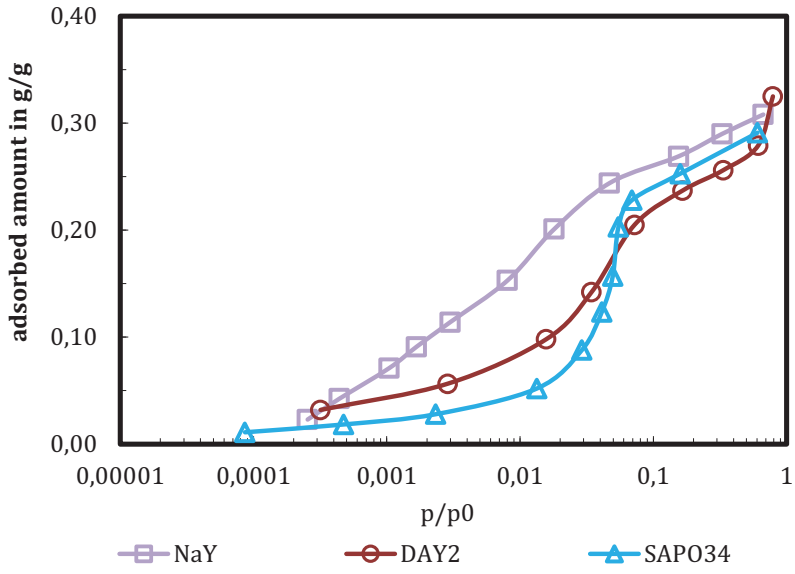

Fig. 2: Water isotherms of zeolite NaY, the dealuminated form of a Y-type zeolite and the zeotype SAPO-34 at 298 K.

The adsorption isotherms shown in Figure 2 of DAY2 and SAPO-34 show a similar beneficial steep rise in the usual working range for low temperature heat pimp applications. This results through the dealumination of the parental Y type zeolite (NaY). The Figure 2 gives also information about the position of the water isotherms of the dealuminated zeolite and the SAPO-34 compared with the parent NaY. As it can be seen, the DAY2

isotherm is shifted towards the SAPO-34 isotherm into the pressure interval between 0.01-0.3 mbar as the heat pump needs for low temperature applications.

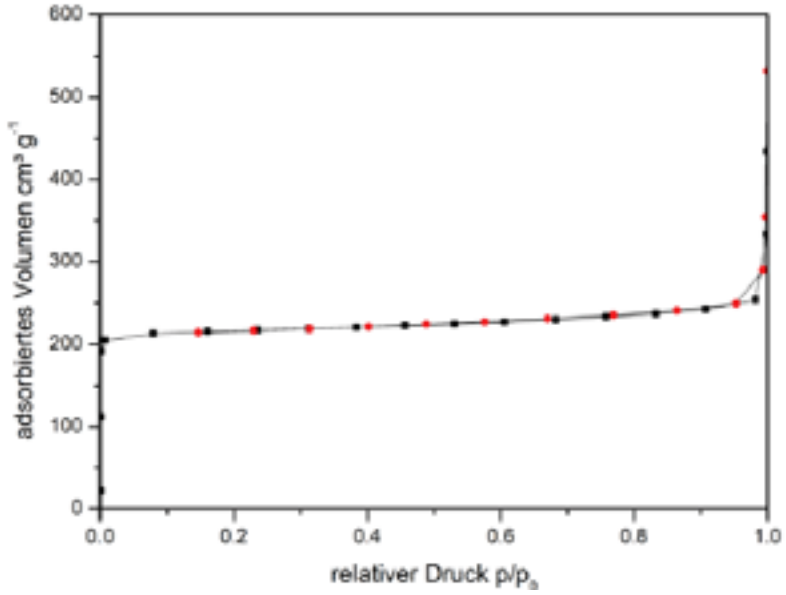

Fig. 3: Nitrogen isotherm of the parental NaY zeolite measured with a Quantachrome NOVAe 2000e after outgassing the samples at a temperature of 623 K for minimum 2h.

The influence of the dealuminting steaming process on the inner pore system of the Y-type zeolite is proven with the measurements given in Fig. 3 and 4 and the results illustrated in Table 2.The microporous inner pore structure is dissolving partly, through the influence of free H_3O^+ molecules, provided by the steaming process. Those molecules are able to remove the alumina part of the faujasite structure, in result the adsorption capacity is degrades slightly (see Tab. 1), the transformation of secondary pore system at the surface to a larger average diameter, has a positive influence on the mass transfer in and out of the material itself. Which explains the observed shift of the desorption temperature to the lower temperatures in Fig. 1. and a previous observation that the dealumination process improves the adsorption kinetic (not shown).

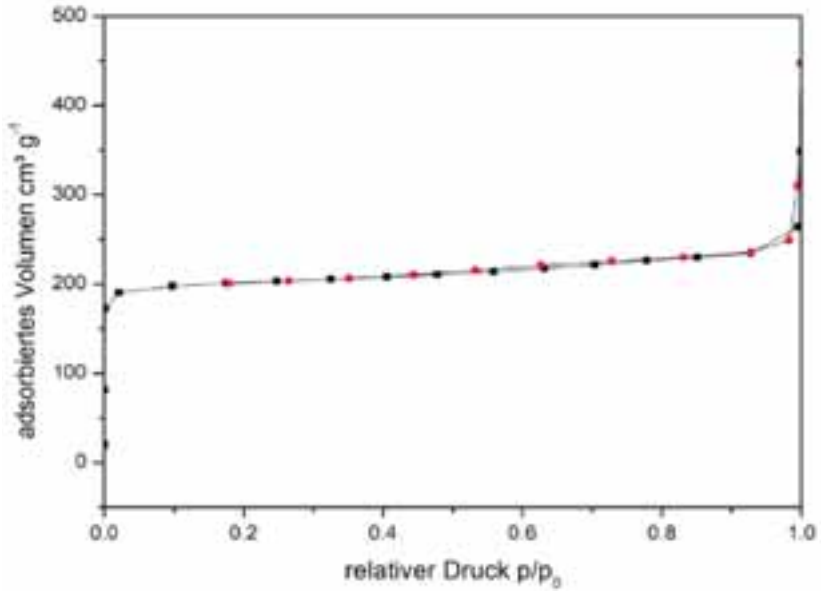

Fig. 4: Nitrogen isotherms of DAY3 zeolite measured with a Quantachrome NOVAe 2000e after outgassing the samples at a temperature of 623 K for minimum 2h.

Tab. 2: BET surface, pore diameter (BJH), pore volume (BJH), pore volume (p/p_0 = 0.97), micropore volume (t-Plot) micropore surface (t-Plot)

parameter	NAY	DAY3	DAY4	unit
BET surface	684 ± 20	623 ± 20	578 ± 20	$m^2\ g^{-1}$
pore diameter (BJH)	3,6	4,0	3,8	nm
pore volume (BJH)	0,49	0,40	0,48	$cm^3\ g^{-1}$
pore volume (p/p_0 0,97)	0,39	0,41	0,38	$cm^3\ g^{-1}$
micropore volume (t-Plot)	0,31	0,28	0,23	$cm^3\ g^{-1}$
micropore surface (t-Plot)	629	539	463	$m^2\ g^{-1}$

As it is shown in Table 2 the influence of the streaming process on the BET surface is quite strong. It depends on the operating temperature and the so called healing time (time for regenerating the disturbed inner lattice structure) that is given during the dealumination. For the optimized synthesis condition process it is necessary to find a perfect combination of the three conditions temperature, healing, time and Si/Al ratio (see Table 1).

4. Conclusions

The optimized post synthesis steaming process seems to be a powerful tool to tailor the hydrophilic character and the inner structure of Y-type zeolites and to reach the special needs of nearby all kind of heat pumps and storages.

Abstract

The combination of solar thermal and heat pump (STHP) systems is a promising hybrid concept for the efficient and sustainable energy supply of buildings. In general, the modeling and simulation of such complex energy systems is a challenging task as it requires expert knowledge in modeling as well as in the behavior of the real systems. As an alternative to the complex and lengthy general modeling process, a TRNSYS-based stand-alone tool is presented which enables users to analyze different predefined SHP concepts with hardly any knowledge in modeling and simulation itself. The predefined STHP concepts are explained in detail and the simulation results for a comparison of the performance of different system concepts are presented. The predefined systems are ground or air source heat pump systems with or without parallel integration of solar thermal collectors. In addition to earlier work, these system concepts are extended by solar thermal and ice storage heat pump systems. On the one hand, the simulation results show that in case of moderate climate and new as well as renovated buildings, solar thermal and air source heat pump systems can compete with ground source heat pump systems without solar integration and can achieve the same or even higher values of seasonal performance factors. On the other hand, the results show that solar thermal and ice storage systems are efficient solar thermal heat pump systems, which can achieve higher SPFs than air source heat pump systems and for new buildings even SPFs in the range of ground source heat pump systems. Furthermore, this contribution shows the advantages and the possible performance improvements by parallel integration of solar collectors in different system concepts.

Keywords: modeling, simulation, solar thermal, heat pumps, combined systems, performance, TRNSYS

1. Introduction

The combination of solar systems and heat pumps (HP) is a promising hybrid concept for the efficient energy supply of buildings. The notion combined solar and heat pump (SHP) system comprises basically all combinations of these systems, including photovoltaic (PV) and solar thermal (ST) systems. Combined solar thermal and heat pump (STHP) systems only comprise combinations with ST integration. Depending on the heat source of the HP, STHP systems can be divided in systems with ground source (SGSHP), air source (SASHP), ice storage (SISHP) and others, like combined solar and water source or waste heat source HP systems. Independently of the heat source of the HP, the systems can be classified in parallel, serial and regenerative system concepts by the interaction between ST system and HP (Frank et al., 2010). Parallel systems (fig. 1a) are systems with independent supply of useful energy for space heating (SH) and/or domestic hot water (DHW) preparation by the ST system and the HP. Serial systems (fig. 1b) are systems in which the ST system is used as heat source of the HP. Regenerative system concepts (fig. 1c) are systems in which the ST system is used for the regeneration of the main source of the HP, usually the ground. Furthermore, there is the possibility to combine these system concepts, as individual concepts do not exclude each other (Frank et al., 2010; Ruschenburg and Herkel, 2015). The classification in parallel, serial and regenerative system concepts (or combinations) can be indicated with -P, -S and -R at the end of the abbreviation of the general STHP concept, e.g., SGSHP-P means parallel combined solar thermal and ground source heat pump systems.

doi:10.18086/swc.2017.33.05 Available at http://proceedings.ises.org

During the past decade, a wide range of combinations of these systems entered the market. A statistical analysis on market-available STHP systems can be found in Ruschenburg et al. (2013) and Ruschenburg and Herkel (2013, 2015). As a main result, parallel systems were identified as the market-dominating system concepts with a proportion of 61% of the surveyed systems (Ruschenburg et al., 2013). Hence, the following investigations will focus mainly on parallel STHP systems with ground or air source HP and on HP systems without ST collectors. As addition, (serial and serial plus parallel) concepts with ice storage systems will be considered as solar only concept without additional heat source.

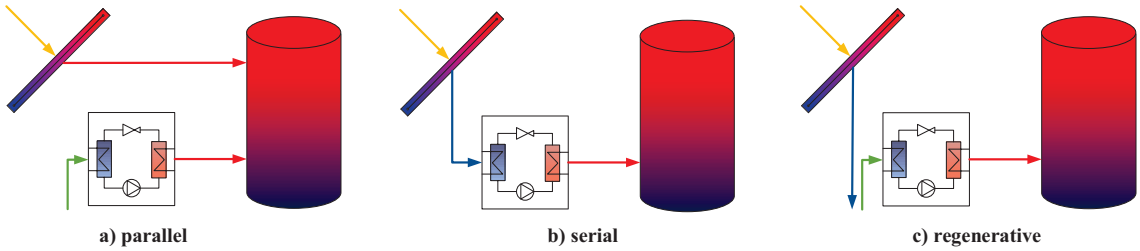

Fig. 1: Classification of solar thermal and heat pump systems in parallel, serial and regenerative system concepts

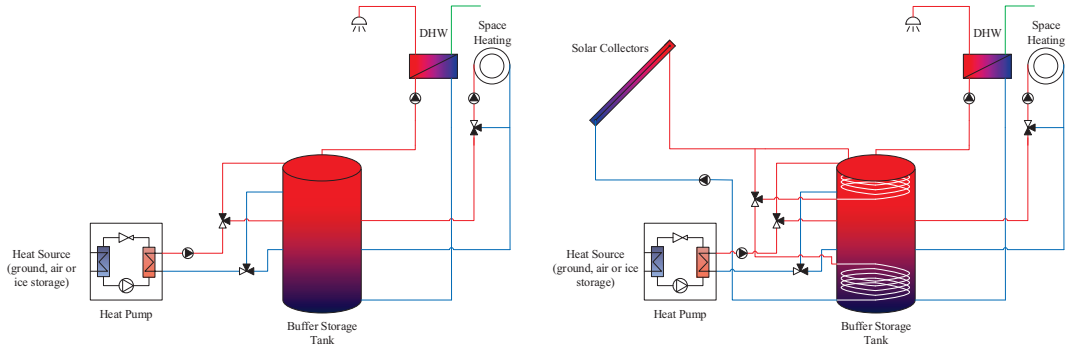
The variety of possible investigations on SHP systems requires well-validated simulation tools. One possibility to simulate these systems is the use of the simulation environment TRNSYS. Model design in TRNSYS is a complex task, which requires expert knowledge in different fields. The objective of this work, based on the former contributions published in Jonas et al. (2017a, 2017b, 2017c), is the development of a user-friendly TRNSYS-based simulation tool (SHP-SIMFRAME) which can be used for the simulation and the model-based analysis of different SHP concepts. In Dott et al. (2013) and Haller et al. (2013a), the International Energy Agency (IEA) Solar Heating and Cooling Programme (SHC) Task 44 / Heat Pump Programme (HPP) Annex 38 defined boundary conditions for a better comparability of results of STHP system simulations, which are also implemented in the simulation tool of this contribution (see section 3). At present, the tool contains four predefined STHP systems (GSHP, ASHP, SGSHP-P, SASHP-P). However, it will be expanded by SISHP systems and PV systems to analyze SHP concepts for heat and electricity supply of buildings. Overviews of simulation results of STHP systems within the IEA SHC Task 44 / HPP Annex 38 were provided by Haller et al. (2014, 2015). The authors presented summaries of simulations which were performed by different authors and different simulation platforms using the boundary conditions of IEA SHC Task 44 / HPP Annex 38. Investigations focused on SGSHP-P and SASHP-P systems can be found in Carbonell et al. (2014a, 2014b), Jonas et al. (2017a) and Poppi et al. (2016).

In the following sections, the system concepts (section 2) and the model design in TRNSYS as well as the developed TRNSED application (section 3) will be explained in detail. This is followed by a simulation study of the considered STHP concepts (section 4). Finally, section 5 provides the main conclusions and an outlook on further work.

2. System concepts

Fig. 2 shows the considered system concepts without ST collector integration (fig. 2a) and with parallel ST collector integration (fig. 2b) regardless of the heat source of the HP. The GSHP system consists essentially of a brine/water HP with borehole heat exchanger as heat source and a buffer storage tank as heat sink of the HP. The buffer storage tank is used for the energy supply of the SH system and the heat exchanger for DHW preparation. The HP charges the buffer storage tank in two different zones. The lower and middle zones of the storage are used for the SH circuit, the upper zone supplies the DHW circuit on a higher temperature level. Depending on the current demands, the heating by the HP is switching to the different zones with priority on DHW preparation. The SGSHP-P system corresponds to the GSHP system with additional solar loop. The solar collectors supply the buffer storage with solar energy via two internal heat exchangers depending on the current solar collector outlet temperature. If the temperature of the solar collectors is high enough, the upper heat exchanger is charged and the return of the upper heat exchanger is used as input for the lower heat exchanger. Otherwise, the solar collectors supply only the lower heat exchanger with solar energy. The advantage of this solution is to supply the upper

DHW zone of the storage with solar energy on a high temperature level, if possible, and thus avoid storage mixing and exergy losses and achieve better storage stratification. The ASHP system and the SASHP-P system correspond to the GSHP and SGSHP-P systems with a replacement of the GSHP by an ASHP. The SISHP-S systems correspond to the GSHP system with a replacement of the borehole heat exchanger by an ice storage, which is charged by solar absorbers, as heat source of the HP. The SISHP-S+P concept corresponds to the SISHP-S system with additional solar loop using solar collectors for the direct supply of the buffer storage tank (indicated by "-S+P" instead of "-S,P" which could be used for concepts with switching of solar absorbers from heat source to direct buffer storage (heat sink) charging).



a) GSHP, ASHP and SISHP-S **b) SGSHP-P, SASHP-P and SISHP-S+P**

Fig. 2: STHP system concepts

According to the approaches in Frank et al. (2010) and Ruschenburg and Herkel (2015), visualizations of the energy flows of the considered STHP system concepts are shown in fig. 3. At this, flows of final energies, which are obtained externally (like electricity as driving energy for the HP), are shown on the left boundaries of the flow charts. The environmental energy sources (like sun, ground or ambient air) of the HP and the ST systems are shown on the upper boundaries. The useable energy output of the system (e.g. for SH or DHW preparation) is placed on the right boundaries. The system components (like HP, ST collectors or absorbers, thermal storages on the source or sink side of the HP and backup heating systems) have fixed positions and are highlighted if existing in the respective concepts. In case of the considered system concepts, the ST collectors (flat-plate collectors), the solar absorbers (uncovered collectors), the source side storage (ice storage), the HP and the sink side storage (buffer storage) are highlighted as well as the used environmental energy sources (sun and ambient air or ground). In addition, the electricity used as driving energy for the HP is highlighted as well. The energy flows between the components are shown as connections in the flow chart. The distinction between various carrier media is indicated by different types of lines.

3. Model design and simulation framework

3.1 Background

The aim during the development of the TRNSED application SHP-SIMFRAME was to create a tool, which can be used for the simulation of SHP systems with hardly any knowledge in modeling or programming. The tool should be a user-friendly framework which can be used to perform parameter studies and analyses of SHP systems (e.g. for different locations and/or buildings) or test individual components (e.g. ST collectors or HPs) for the use in SHP systems by editing the component specific parameters and data sets. In its latest version, SHP-SIMFRAME contains GSHP, ASHP, SGSHP-P and SASHP-P system models. In future work, the tool will be expanded by SISHP systems including the TRNSYS models used for the simulation study of this contribution. Furthermore, as the name "SHP"-SIMFRAME implies, it will be extended by electrical solar energy (PV and PV thermal) systems to analyze SHP concepts for the heat and the electricity supply of buildings.

3.2 TRNSYS models

The simulation models of the main system components, especially the SHP system components, in TRNSYS are summarized in tab. 1. For a better structure and a higher level of modularity and flexibility, the TRNSYS model is divided in the subsystems *Reference System and Storage*, *SHP* and *SHP Control*. The subsystems include TRNSYS equation blocks, which are used as inputs and outputs of the subsystems for their connection via variables (see Kuethe et al., 2008). The subsystem *Reference System and Storage* include the reference system of the IEA SHC Task 44 / HPP Annex 38 (including boundary conditions and building model) and the Multiport-Store Model Type 340. General boundary conditions contain weather data for three different locations which represent warm (Athens), moderate (Strasbourg) and cold (Helsinki) climates (Meteonorm, 2009)[1] and ground properties for the simulation of ground coupling losses of the building and ground heat exchangers (Haller et al., 2013a). Within the reference framework, three different buildings are defined. The different buildings represent single-family houses (SFH) with heat loads for SH of 15 kWh/m²a (SFH15), 45 kWh/m²a (SFH45) and 100 kWh/m²a (SFH100) for the climate of Strasbourg. SFH15 represents a new building with very high energetic quality, SFH45 a renovated building with good thermal quality of the building envelope and SFH100 a non-renovated existing building. The boundary conditions also include the design supply and return temperatures of the heat distribution system for SH for the different locations and buildings (Dott et al., 2013) as well as the DHW draw off profiles. The DHW draw off profiles correspond to an average draw off of 140 l per day with a draw off temperature of 45 °C and are equivalent to an energy consumption for DHW preparation of 5.845 kWh/d with a cold water temperature of 10 °C. According to the boundary conditions of IEA SHC Task 44 / HPP Annex 38, the borehole heat exchangers are simulated as double-U pipes. The main properties of the borehole heat exchangers

[1] The permission of Meteotest for using Meteonorm climate data for simulations within the IEA SHC Task 44 / HPP Annex 38 is gratefully acknowledged.

are also defined within the framework (Haller et al., 2013a). The annual heat loads for SH (Q_{SH}) and DHW preparation (Q_{DHW}) for the climate of Strasbourg and the different buildings are summarized in tab. 2. Further information on the reference system, boundary conditions and building models can be found in Dott et al. (2013) and Haller et al. (2013a, 2015).

Tab. 1: TRNSYS models of the main system components

Component	TRNSYS Model
Building	Type 56 (TRNSYS, 2014)
Solar collector / absorber	Type 832 (Haller et al., 2013b)
Compressor HP	Type 401 (Wetter and Afjei, 1997)
Borehole heat exchanger	Type 557a (TESS, 2014)
Buried ice storage tank	Type 343 (Hornberger, 2006)
Multiport storage tank	Type 340 (Drück, 2006)
Single speed pump	Type 3d (TRNSYS, 2014)
Variable speed pump	Type 803 (Heimrath and Haller, 2007)
Pipe	Type 31 (TRNSYS, 2014)
Bi-directional noded pipe	Type 604a (TESS, 2014)
Buried noded pipe	Type 952 (TESS, 2014)
Flow diverter	Type 11f (TRNSYS, 2014)
Tee-piece	Type 11h (TRNSYS, 2014)

Tab. 2: Annual heat loads for SH and DHW preparation

Location	Building	Q_{SH} [kWh/a]	Q_{DHW} [kWh/a]
Strasbourg	SFH15	2474	2076
	SFH45	6476	2076
	SFH100	14031	2076

In general, the *SHP* subsystem includes the HP and the heat source models. In case of *GSHP* systems, the subsystem contains the components for the heat source circuit, the brine/water HP, the pump for buffer storage charging and the pipes from the HP to the storage. The heat source circuit consists of the vertical borehole heat exchanger, the heat source pump, buried pipes and an additional circuit with adiabatic pre-pipe in front of the input of the borehole heat exchanger. The adiabatic pre-pipe is used for a better representation of the short-term behavior of the borehole heat exchanger in the simulation due to missing short-term heat capacity effects of Type 557. More information on the pre-pipe concept, the model validation and parameterization rules can be found in Bertram (2015) and Pärisch et al. (2015). In case of *ASHP* systems, the subsystem includes the air/water HP, the pump for buffer storage charging and the pipes from the HP to the storage. In case of *SISHP-S* systems, the subsystem contains the components for the heat source circuit, the brine/water HP, the pump for buffer storage charging and the pipes from the HP to the storage. The heat source circuit consists of the buried ice storage tank model, the heat source pump to the HP, buried pipes and an additional solar absorber circuit with solar absorber circuit pump and pipes from the solar absorber to the ice storage tank for ice storage charging. Furthermore, in case of systems with parallel ST (flat-plate collectors) integration (*SGSHP-P*, *SASHP-P* and *SISHP-S+P*), the subsystems contain an additional solar loop with ST collectors, solar circuit pump and pipes from the solar collectors to the buffer storage. Using the example of a SGSHP-P (fig. 4a) and a SISHP-S (fig. 4b) system, the subsystem SHP is shown graphically in fig. 4. The subsystem *SHP control* includes the control of the HP and ST system and consists of a combination of differential controllers (Type 2b) and equation blocks. Due to their simplicity, the subsystems of SHP control are not shown graphically. The used control strategies and parametrization possibilities are described in section 3.3.

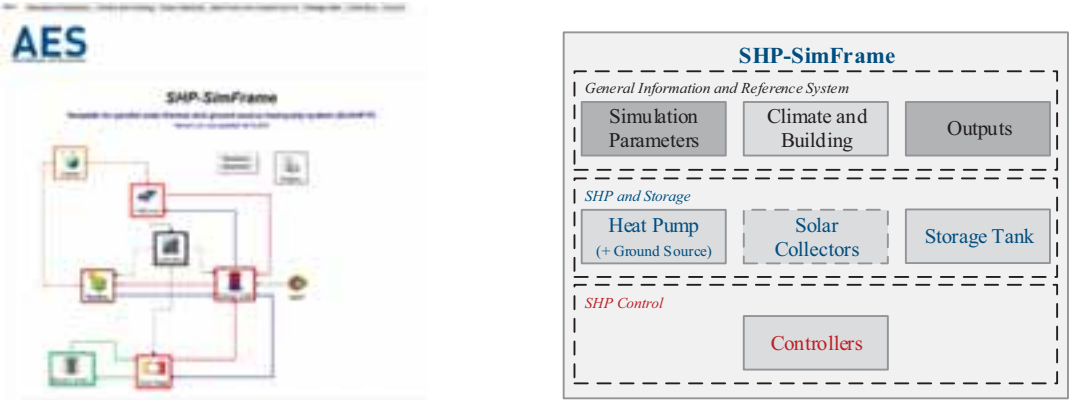
3.3 TRNSED application

The developed TRNSED application for the simulation of SHP systems are based on the TRNSYS models illustrated in section 3.2. In addition to a navigation page (see fig. 5a) as initial interface, the tool consists of the submodules *Simulation Parameters*, *Climate and Building*, *Solar Collectors* (in case of ST integration), *Heat Pump* (*and Ground Source* in case of GSHP, SGSHP-P), *Storage Tank*, *Controllers* and *Outputs* for the parameterization of the simulation models. The submodules of the tool and the assignments to the TRNSYS subsystems mentioned before are illustrated in fig. 5b. In future work, an Ice Storage submodule will be added for the simulation of SISHP-S and SISHP-S+P systems.



a) Navigation page, example: SGSHP-P **b) Submodules**

Fig. 5: TRNSED application as stand-alone tool

The submodule *Simulation Parameters* can be used to set general simulation parameters like the simulation time step and length depending on the simulation requirements. The submodule *Climate and Building* allows the user to choose the pre-defined climate data (Helsinki, Strasbourg and Athens) and the building type (SFH15, SFH45, SFH100) from a pull-down menu. The *Outputs* submodule contains a selection of predefined outputs, which can be selected for the graphical (plotter) and data file (printer) based evaluation of the simulation results. The *Storage Tank* submodule is used to set the general thermal storage parameters (volume, initial tank temperature, insulation thickness and additional loss factors) and the relative heights of the temperature sensors for the control of the SHP system. This includes temperature sensors for storage protection, for collector loop control as well as for charging of the DHW zone and the SH zone. In addition, within this submodule, the user can specify the relative heights of the storage tank connections. This includes in general the relative heights of the HP connections (for reheating the SH zone and DHW zone) and the SH and the DHW supply connections. In case of ST integration, the submodule also includes the relative heights of the connections to the solar loop. In general, the *Heat Pump* submodule contains a pull-down menu to select data sets, which are used in Type 401 for the HP modeling, and the definition of HP parameters like power, heat exchanger temperature differences of the HP, mass flow rates, set points of low-pressure and high-pressure thermostat or heat-up and cool-down constants. In addition, within this submodule, the user can specify the piping between the HP and the storage tank. In case of ASHP systems, the user has the possibility to define additional parameters for a better consideration of icing and defrosting effects. Furthermore, in case of GSHP systems, this submodule allows the user to define ground properties and borehole properties like number and depth of the boreholes, space between boreholes or the length of buried pipes between ground heat exchanger and HP. In case of STHP systems, SHP-SIMFRAME includes the submodule *Solar Collectors*. This module allows the user to define the solar collector field (area, tilt, azimuth and specific mass flow) and the collector loop pipes properties as well as the solar collector efficiency parameters. The submodule *Controllers* can be used to set the control parameters for the solar loop and the reheating of the storage tank for SH and DHW preparation by the HP. The set point calculation of the supply temperature $T_{Set,SH}$ for SH depends on different factors (e.g. the ambient temperature or the design heat load of the specific building and location) and is described in Dott et al. (2013). The HP buffer storage charging for SH is turned on if the difference between the storage temperature sensor for SH ($T_{S,SH,up}$) and the set point for the supply temperature $T_{Set,SH}$ for SH falls below $\Delta T_{SH,on}$

(predefined: 0 K) until the temperature difference is higher than $\Delta T_{SH,off}$ (predefined: 3 K). The buffer storage charging for DHW depends on the value of the storage temperature sensor for DHW preparation ($T_{S,DHW}$) and is turned on if the temperature falls below $T_{DHW,on}$ (predefined: 53 °C) until it reaches $T_{DHW,off}$ (predefined: 55 °C). In SGSHP-P and SASHP-P systems, the solar loop is switched on if the difference between the supply temperature of the ST collectors (T_{Sol}) and the storage temperature sensor ($T_{S,c}$) is higher than $\Delta T_{Sol,on}$ (predefined: 5 K) and will remain on until the temperature difference falls below $\Delta T_{Sol,off}$ (predefined: 2 K). If the difference between T_{Sol} and $T_{S,DHW}$ is higher than $\Delta T_{Sol,DHW,on}$ (predefined: 5 K), the upper heat exchanger is additionally charged by the solar loop and the return of the upper heat exchanger is used for the supply of the lower heat exchanger (DHW mode) until the temperature difference falls below $\Delta T_{Sol,DHW,off}$ (predefined: 2 K). Otherwise, the ST collectors supply only the lower heat exchanger with solar energy (SH mode). In addition, for storage protection, a maximum storage temperature ($T_{Set,S,max}$, predefined: 80 °C) of the storage temperature sensor for storage protection ($T_{S,sp}$) is defined (storage protection mode). Furthermore, a high limit cut-out for the ST collector temperature is defined in the controller to avoid damage of the components in the solar circuit if the supply temperature of the ST collectors (T_{Sol}) reaches $T_{Set,Sol,max}$ (predefined: 130 °C). In this case (ST protection mode), the solar loop is turned off until T_{Sol} falls below a defined temperature $T_{Set,Sol,max,off}$ (predefined: 120 °C).

4. Simulation study

4.1 Parameter

An exemplary application of the model-based analysis of STHP systems is the investigation of the influence of system concepts on the seasonal performance factor (SPF, see section 4.2). The performed TRNSYS simulations consider GSHP, ASHP, SGSHP-P and SASHP-P (using SHP-SIMFRAME) as well as SISHP-S and SISHP-S+P systems. The simulations were performed for SFH15, SFH45 and SFH100 and the climate of Strasbourg with variations of the solar collector area (or absorber area in case of SISHP systems) with a maximum available roof area of 25 m². The main model parameters for the simulation of the HP, the solar collectors and the solar absorbers are summarized in tab. 3-6. In case of SFH100, characteristics of market available air/water HPs and brine/water HPs were used as data basis for the parameterization of the HP models. In case of SFH15 and SFH45, the power data was down-scaled to a nominal heating power of 6 kW due to a better fitting of the design heat loads.

Tab. 3: Key values of brine/water heat pump models, performance data based on data sheets of Viessmann BW301.B10 (Viessmann, 2017)

Parameter	Value
COP at B0/W35 [-]	5.01

first order IAM b_0 [-]	0.0327
IAM for diffuse radiation K_d [-]	1.00

For the control of the systems, the predefined control parameters from section 3.3 were used. In case of SISHP systems, an additional controller for the charging of the ice storage is needed. In these system concepts, the solar absorber loop is switched on if the difference between the supply temperature of the solar absorbers ($T_{Sol,abs}$) and the ice storage temperature sensor ($T_{S,ice,c}$) is higher than $\Delta T_{Sol,abs,on}$ (predefined: 3 K). The solar absorbers loop will remain on until the temperature difference falls below $\Delta T_{Sol,abs,off}$ (predefined: 1 K). In addition, a maximum ice storage temperature ($T_{Set,S,ice,max}$, predefined: 15 °C) of the ice storage temperature sensor ($T_{S,ice,c}$) is defined. If the ice storage temperature reaches this value, the solar absorber loop is turned off until $T_{S,ice,c}$ falls below a defined temperature $T_{Set,S,ice,max,off}$ (predefined: 14 °C). In case of SISHP-S+P systems, the predefined control concept from section 3.3 was used for the control of the ST collector loop.

4.2 Performance figures

The SPF quantifies the final energy efficiency of a whole SHP system and is defined as the overall useful energy output to the overall driving final energy input for an adopted system boundary over a period of one year (Malenković et al., 2013). In some cases, the systems may not permanently provide the DHW tapping temperatures or the room temperature of the building. For a better comparison between simulation results, penalty functions are defined as direct electric heating for times in which the system does not reach the required comfort criteria (Heimrath and Haller, 2007; Jordan et al., 2003). The SPF of the overall SHP system with penalties ($SPF_{SHP+,pen}$) is defined as the amount of useful energy for SH (Q_{SH}) and DHW preparation (Q_{DHW}) divided by the amount of electric energy consumption ($W_{el,SHP+,pen}$) of the overall SHP system (including all electrical consumptions of the SHP system and penalties) (Haller, 2013):

$$SPF_{SHP+,pen} = (Q_{SH}+Q_{DHW}) / W_{el,SHP+,pen} \quad \text{(eq. 1)}$$

For the comparison of simulation results of SHP systems with a defined reference system (e.g. without ST collectors) the relative increase $\Delta SPF_{SHP+,pen}$ is defined as:

$$\Delta SPF_{SHP+,pen} = (SPF_{SHP+,pen} - SPF_{SHP+,pen,ref}) / SPF_{SHP+,pen,ref} \quad \text{(eq. 2)}$$

where $SPF_{SHP+,pen}$ is the SPF of the considered system and $SPF_{SHP+,pen,ref}$ is the SPF of the corresponding reference system. Another figure for the comparison of system concepts to a reference system are the absolute electricity savings $W_{save,el}$, defined as difference between the electric energy consumption of the defined reference system $W_{el,SHP+,pen,ref}$ and the considered system configuration $W_{el,SHP+,pen}$:

$$W_{save,el} = W_{el,SHP+,pen,ref} - W_{el,SHP+,pen} \quad \text{(eq. 3)}$$

4.3 Results and discussion

The results of the evaluation of SPFs for the different STHP systems concepts and buildings are shown in fig. 6 and are summarized, with respect to the used collector / absorber areas and storage sizes, in tab. 7. In general, SGSHP-P systems achieve the highest SPFs for all types of building, which are in the range of 4.3 to 6.2 (SFH15), 4.9 to 6.7 (SFH45) and 4.5 to 5.4 (SFH100). For GSHP systems without ST integration, the SPFs are 3.1 (SFH15), 4.0 (SFH45) and 4.1 (SFH100). ASHP systems without ST collectors achieve the smallest SPFs, which are 2.6 (SFH15), 3.1 (SFH45) and 2.9 (SFH100). SISHP-S systems achieve higher values of SPF than ASHP systems for all types of building and in case of SFH15 even the same values as GSHP systems, which are in the range of 3.0 to 3.1 (SFH15), 3.6 to 3.7 (SFH45) and 3.4 (SFH100). The smaller values of SPF in case of SFH15 buildings with high fraction of DHW demand (46 %) show the impact of demand on high temperature level for DHW and as a result a lower performance of the HP in all system combinations without ST collectors. Additionally, the SH demand occurs predominantly in winter season with low ambient / source temperatures, especially in case of ASHP systems, and the HP runs with a lower performance. The simulation results show that the SPF can be

increased for all system concepts by adding a parallel ST collector system. Due to the direct use of solar thermal energy, SASHP-P systems can even reach higher SPFs than GSHP systems without ST integration. In case of SFH15 with a minimum collector area of 5 m² (SPF: 3.4) and in case of SFH45 with a minimum collector area of 10 m² (SPF: 4.2). However, in case of SFH100 the simulated SASHP-P systems cannot reach the performance of GSHP systems.

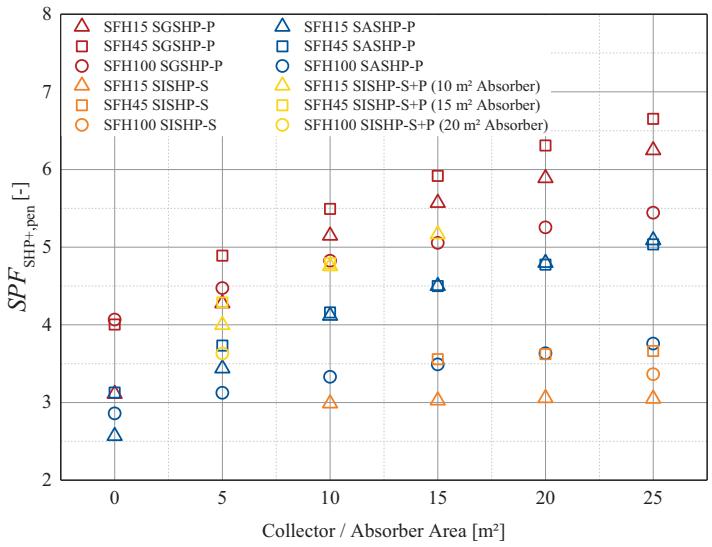

Fig. 6: SPF for Strasbourg depending on ST collector area (SGSHP-P, SASHP-P and SISHP-S+P) or absorber area (SISHP-S). SGSHP-P includes GSHP systems and SASHP-P includes ASHP systems (collector area = 0 m²).

The SPFs of SISHP-S systems can also be increased by adding small areas of ST collectors and can reach higher SPFs than GSHP systems without ST integration with a minimum collector area of 5 m² for SFH15 (SPF: 4.0) and SFH45 (SPF: 4.3). In case of SFH100, the simulated SISHP-S+P systems cannot reach the performance of GSHP systems. In case of SISHP systems, the benefit of adding flat-plate collectors to a SISHP-S system with design absorber area is higher than adding additional solar absorbers. If the roof area is limited to 25 m², this is shown by an increase of the SPF in the range of 33.8 % to 72.9 % in case of SFH15 and 20.5 % to 34.7 % in case of SFH45. In comparison, the maximum increase of SPF by adding additional solar absorbers is 2.0 % for SFH15 and 3.0 % for SFH45.

5. Conclusions and outlook

This contribution presented the TRNSYS-based stand-alone tool SHP-SIMFRAME for the simulation of STHP systems and a performance evaluation of different STHP system concepts. The main advantages of the tool for the end-users are the possibility to analyze different predefined SHP concepts without any knowledge in modeling and simulation itself as well as the related time saving and error prevention for model-based system design or system analysis by simulation. On the one hand, the performance evaluation shows that in case of moderate climate and new as well as renovated buildings, SASHP-P systems can compete with GSHP systems without solar integration and can achieve the same or even higher values of SPF. On the other hand, the results show that SISHP-S systems are efficient STHP systems, which can achieve higher SPFs than ASHP systems and for new buildings even SPFs in the range of GSHP systems. Furthermore, SISHP-S+P systems with parallel integration of solar collectors can achieve higher values of SPF for new as well as for renovated buildings than GSHP systems and even than SASHP-P systems with same ST collector area. However, the highest performance in the simulations can be reached by SGSHP-P systems for all type of buildings and in case of the considered non-renovated building, the SPFs of GSHP systems cannot be reached by the considered SASHP-P and SISHP-S+P systems with a limited available roof area of 25 m². In addition, the results illustrate the need of simulation tools to design SHP systems depending on the boundary conditions of the specific application and the comparison of

different system concepts. In future work, SHP systems with electrical solar energy (PV and PV thermal) systems will be investigated and integrated in the simulation framework.

Acknowledgements

This work was partially funded by the Saarland State Chancellery (Department WT/2). The authors are grateful for this support and thank the project partners, Viessmann Heizsysteme GmbH and SEG Kioto GmbH, for their support and cooperation. The authors would also like to express their gratitude to the participants of the IEA SHC Task 44 / HPP Annex 38 for the provision of the reference framework for system simulations.

SolarHybrid Heating And Cooling – An Environmental Friendly And Economic HVAC Solution

Daniel Neyer[1, 2], Manuel Ostheimer[2], Florian Gritzer[2]

[1] daniel neyer brainworks, 6700 Bludenz (Austria)

[2] University of Innsbruck, 6020 Innsbruck (Austria)

Abstract

Due to increasing living comfort and climate change, an increase in building air-conditioning demand can be expected. Solar air-conditioning is intuitively a good solution, because of the coincidence of solar irradiation and cooling demand. The Austrian research project SolarHybrid deals with the systematic processing and optimization of solar thermal and photovoltaic driven cooling technologies, especially in order to design promising (solar-) hybrid solutions. The project includes the construction and measurements of functional models of a single/half effect NH_3/H_2O absorption chiller and a NH_3 vapour compression chiller. The system design and optimization is carried out by means of annual dynamic system simulations for three load profiles.

The combination of the absorption chiller and the vapour compression chiller represent an interesting initial position for effective and economic attractive solar driven HVAC solutions. Under the considered boundary conditions the solar thermal configurations appear to be more efficient and more cost competitive than the PV or PVT variations. Solar heating and cooling can become cost competitive when systems are designed clever with simplified HVAC layouts, advanced control strategies and high efficient components.

Keywords: ammonia vapour compression chiller, absorption chiller, hybrid system, solar cooling

1. Introduction

The supply of heat and cold in the building and industrial processes has a large potential for non-renewable primary energy savings. However, the substitution of non-renewable energy sources should always follow the basic premise of firstly reducing energy demands before applying renewable systems. High solar fraction and thus high non-renewable primary energy saving can be achieved with solar thermal (ST) or solar electric (PV) supported systems. However, there is a controversial discussion about these two technologies and their technical and economic aspects ongoing. Both solar technologies can offer energetic and/or economic advantages depending on the boundary conditions and the ratio of heating to hot water demand.

Within the project SolarHybrid different hybrid concepts for solar heating and cooling (SHC) are investigated. The major challenge for introduction of SHC systems to the market are the initial investment costs. Therefore, one focus of this project is the radical reduction of system components (e.g. no storage, etc.). The approach to achieve this goal is (i) to define possible system configurations, (ii) to examine them in software simulations, (iii) to test the real components in Hardware-in-the-Loop (HiL) tests, (iv) to validate the simulations with the measured data and run annually simulation studies and (v) to evaluate the results in terms of technical and economic performance.

Both technologies (ST, PV) but also the combined one (PVT) are investigated, their applications in HVAC system are optimized and new solar hybrid systems are developed. The aim is to improve the efficiency of individual components and the overall HVAC systems. The systems are optimized in order to increase primary energy efficiency and economic feasibility in respect to entire load profiles. The optimized components are integrated into system solutions resulting in innovative, radically minimized solar hybrid solutions.

doi:10.18086/swc.2017.33.06 Available at http://proceedings.ises.org

The economic and energetic optimization of the solar thermal concepts is achieved by means of adapted hydraulic layouts, radically minimized number of components and improved, more efficient control strategies. The technical as well as the economic potential is assessed by means of the T53E4 Tool (Neyer 2016). Extensive sensitivity analyses are used to determine the impact of changing technical and economic boundary conditions on key performance indicators (KPIs).

In the course of the project two components were built and optimized for the hybrid operation; (i) a vapour compression chiller (VCC) and (ii) an absorption chiller (ACM). The ammonia/water ACM, developed in the research project DAKTris (2013), has been further optimized in SolarHybrid, and was driven in hybrid operation with the ammonia VCC in Hardware-in-the-Loop laboratory measurements.

The project is based on detailed research of the components and systems, their modelling and the different load profiles. The systematic analysis of the simulation approaches and the individual models with their part load behaviour and application limits are an essential base for modelling. Through the appropriate choice of the models, dynamic system simulation models are created. Further investigations are carried out with suitable dynamic simulation models, which were adapted according to the laboratory measurements. Three profiles are investigated; an office building, a hotel and a potential study. The hybrid systems are optimized regarding non-renewable primary energy savings and economics. Figure 1 is showing the overall methodological approach of the project.

Fig. 1: Methodological approach and workflow of SolarHybrid

This paper is focusing on the simulation results of the hotel profile and the potential study of the hybrid ACM and VCC operation.

2. Methodology

Three main methods are described here. The assessment and its key performance indicators, the steady state and dynamic laboratory measurements and the simulation study for the hotel and the potential study. Table 1 summarizes the main nomenclature and subscripts.

Table 1: Nomenclature and Subscripts

ACM SE	Absorption chiller, Single effect	f_{sav}	Savings	PV	Photovoltaic
C	Cooling	in	Input	Q	Energy [kWh]

EC	Energy Carrier	NRE	Non-renewable	sys	System
el	Electrical	out	Output	VCC	Vapour compression chiller
equ	Equivalent	PER	Primary Energy Ratio	WD	Water Distribution

2.1 Assessment – T53E^4-Tool

The performance assessment of SHC systems can be complex. Performance indicators can be determined in numerous ways by taking different system boundaries into account or using different energy quantities. Performance evaluation of integrated SHC systems distinguish in the distribution of collected solar heat and backup energy sources to space heating (SH), domestic hot water (DHW) and cooling (C) applications.

The assessment is performed with the techno-economic evaluation tool of IEA SHC Task 53. The T53E^4-Tool offers a database of primary energy factors (ε), efficiencies and economic data for all main SHC components. The evaluation is based on non-renewable primary energy for electricity and all energy carriers. Electricity exported towards the grid does not reduce the primary energy effort of the system, but the economic benefits is considered. The most important key figures are briefly discussed, the according equations are shown in Table 2. The key figures are fully discussed and defined in the IEA SHC Task 53 (Neyer et al. 2016).

- Non-renewable Primary Energy Ratio (PER_{NRE})

The evaluation is carried out based on non-renewable primary energy (NRE). The PER_{NRE} quantifies the non-renewable primary energy efficiency of the system (eq. 1). The primary energy factors (ε) required for the conversion are depending on type of energy, the location of the plant and the season.

- Non-renewable primary energy savings ($f_{sav.NRE}$)

The primary energy of the entire SHC system is compared with a reference system. The standardized Task 53 reference system is an air-cooled compression chiller (VCC) and a natural gas boiler and its primary energy ratio $PER_{NRE.ref}$ is calculated according equation 2. Applying both PERs (SHC and ref) the savings can be calculated according to equation 3.

- Equivalent Seasonal Performance Factor (SPF_{equ})

The SPF_{equ} is the ratio of useful energy (supplied to satisfy the needs of the building) to consumed energy from external sources (eq. 4). The energy inputs are converted into electrical equivalents units according to the primary energy factor of electricity (ε_{el}).

- Cost Ratio (CR)

The cost ratio is determined with the levelized costs of energy for the SHC system ($C_{use.SHC}$) and the levelized costs of energy for the reference system ($C_{use.REF}$). These costs include investment, replacement, maintenance, electricity, energy, water as well as feed-in tariffs. The costs are discounted according to the annuity method and are summed up on a yearly basis. If the CR equals one cost equity is reached for the SHC system compared to the reference system.

Table 1: Overview technical and economic key performance figures defined in IEA SHC Task 53

Non-renewable Primary Energy Ratio	$PER_{NRE} = \frac{\sum Q_{out}}{\sum\left(\frac{Q_{el,in}}{\varepsilon_{el}} + \frac{Q_{in}}{\varepsilon_{in}}\right)}$	(eq. 1)
	$\mathrm{PER_{NRE.ref}} = \frac{\sum \mathrm{Q_{out}}}{\sum\left(\frac{\mathrm{Q_{out.heat}+Q_{loss.ref}}}{\varepsilon_{\mathrm{in}}*\eta_{\mathrm{HB.ref}}} + \frac{\mathrm{Q_{out.cold}}}{\mathrm{SPF_{C.ref}}*\varepsilon_{\mathrm{el}}} + \frac{\mathrm{Q_{el,ref}}}{\varepsilon_{\mathrm{el}}}\right)}$	(eq. 2)
Non-renewable primary energy savings	$f_{sav.NRE} = 1 - \frac{PER_{NRE.ref}}{PER_{NRE.sys}}$	(eq. 3)
Equivalent Seasonal Performance Factor	$SPF_{equ.sys} = \frac{PER_{NRE.sys}}{\varepsilon_{el}}$	(eq. 4)
Levelized Costs of energy	$C_{use} = \frac{C_{an}}{\sum Q_{out}}$	(eq. 5)
Cost Ratio	$CR = \frac{C_{use,SHC}}{C_{use,REF}}$	(eq. 6)

2.2 Measurements & Hardware-in-the-Loop

Two chiller prototypes were tested in the laboratories; (i) an ammonia/water (NH_3/H_2O) absorption chiller (ACM)

and (ii) a vapour compression chiller (VCC). The ACM was developed in the research project DAKTris (2013), it has a nominal cooling capacity of 20 kW and enables the possibility to switch from single- to half-effect (SE/HE). This permits the possibility of high heat rejection temperatures (up to 45°C), the use of a dry cooling tower and the possibility of high useful temperatures in heat pump mode. Within this project, the ACM is adapted and optimized concerning the findings in DAKTris and the requirements of SolarHybrid (e.g. automation of the solvent compensation, etc.). In consideration of the hybrid operation of both chillers the cooling capacity of the VCC is also 20 kW (at evaporation temperature 4°C, condensing temperature 50°C) and the chosen refrigerant is ammonia (R717). The main components of the vapour compression chiller are a frequency controlled piston compressor, a flooded evaporator and a hot gas bypass.

In a first step steady state performance of both chillers are measured and characteristic curve diagrams are generated. Further dynamic Hardware-in-the-loop (HiL) tests of the components integrated in the simulated overall systems and the evaluation of the results are carried out.

- Laboratory infrastructure

The Unit for Energy Efficient Buildings at the University of Innsbruck provides the lab infrastructure for various tests of HVAC components. The infrastructure contains a heat-sink and -source facility. The sink is cooled by a vapour compression chiller (50 kW cooling power) and offers, depending on climatic conditions, the possibility of free-cooling. Three immersion heaters supply the heat for the source, each with a capacity of 15 kW. The temperature ranges up to 95°C for the source and down to -10°C for the sink. Four test benches with a capacity of 10 kW and 30 kW respectively are affiliated.

A multifunctional software is developed with the software platform LabView (National Instruments – NI) to provide the control of the laboratory. It is working on compactRIO (NI) real time devices and enables flexible and easy configurable tests. The communication is based on a dynamic link library, which offers the possibility to connect arbitrary software (TRNSYS, Matlab, Excel, BCVTB, etc.) to the lab.

- Steady state measurements

Steady state measurements are used to identify the performance at several conditions. The settings are adjusted accordingly considering the settling time and the measurement period to calculate a representative mean value and the corresponding deviation.

The measurements of the ACM and the VCC are executed at a wide range of operating conditions. The absorption chiller is tested in SE and HE mode, various volume flows (LT: 1.5–3, MT: 4.25–6, HT: 3–4.5 m³/h) and inlet temperatures (LT: 6–22, HT: 80–90, MT: SE 20–35, HE 20–45°C). The compression chiller capacity is varied through the compressor speed and with the hot gas bypass as well as variable volume flow rates (LT: 2–3.5, MT: 3.5–6 m³/h) and inlet temperatures (LT: 12–22, MT: 25–45°C).

- Dynamic measurements

Overall system performance and components interaction can be evaluated by dynamic measurements. Building up complex systems is time and cost intensive, therefore Hardware-in-the-Loop (HiL) tests are a promising alternative. HiL tests combine system simulations and real component testing. The overall system is designed in an adequate accuracy with a software (here TRNSYS) and the investigated components are connected to the lab. This coupling of simulation and lab in real time enables the determination of the overall system performance.

Based on the steady state results (limiting boundary conditions) and defined system configurations (see next paragraph) a simulation model is set up in TRNSYS. Each configuration is measured under the boundary conditions of two significant days (one sunny, one cloudy) at the chosen location in different variations (different temperatures, mass flows, control strategies, machine modes, etc.).

Following description is one variation of the combined chiller and heat pump mode of ACM and VCC (configuration c). The main purpose of this system is the supply of heat and simultaneously the optional allocation of cooling energy. The defined temperature levels are 12/6°C for LT circuit, 14/40°C for MT circuit and variable HT input (60~95°C). HT (4.5 m³/h) and LT (3.5 m³/h) volume flows are fixed, MT (min. 0.5 m³/h) volume flow is controlled to reach set outlet temperature (40°C). The ACM delivers as much as possible (depends on solar irradiation) and the VCC is complementing to deliver the set LT outlet temperature.

Subsequent to the measurements the evaluated data and energy balances are used to fit the simulation model of the ACM and VCC. Annual simulation studies are carried out accordingly.

- System configurations for Hil tests

As a consequence to the idea of minimized and reduces number of components the measured configurations are defined accordingly as direct solar thermal driven systems. The climatic conditions are simulated for different locations (Innsbruck, Sevilla, etc.). The solar collector field, the cooling tower and the other components are designed accordingly. The grid provides the required electrical energy.

a) Chiller-mode ACM and VCC: The generator (HT) circuit of the ACM is directly connected to a solar collector field (ST), re-cooling (MT) circuits of both machines are connected in parallel with a dry cooling tower and the chilled water (LT) outlet of the ACM is connected in serial to the inlet of the VCC.

b) Heat pump-mode ACM (SE and HE): HT circuit of ACM is directly connected to the collector, MT mass flow is controlled to reach the desired temperature at the MT outlet of the ACM and the chilled water could be used optionally.

c) Combined chiller- and heat pump-mode ACM and VCC: HT circuit of ACM is directly connected to the ST, MT and LT circuits of the ACM are connected in serial to the VCC, MT mass flow is controlled to deliver the defined temperature and VCC capacity is controlled to reach set LT temperature.

2.3 Simulation studies

The simulations are set up in TRNSYS and base on a load file approach. This concept enables the separation of building- and HVAC-simulation.

- HVAC simulation models

The individual models (ACM, VCC, cooling tower, etc.) have been investigated and improved on their partial load behaviour. The ACM and VCC are built up as characteristic curve models and are adjusted to the measured steady state and dynamic data.

The ACM model (Type 1005, Neyer et al., (2015b)) is based on semi-physical models of a single-effect (SE) ACM (Hannl et al., 2012) and a half-effect (HE) ACM (Zotter et al., 2015). The model can switch between the two operating modes (SE/HE) and its nominal capacity is scalable. A new characteristic curve model has been developed for the VCC. It's also based on a semi-physical simulation model (Luger 2017) that was fitted to the according measurements. The deviation between the simulation model and the daily dynamic measurements is smaller than 3% of the total energy balance.

- Load profile

The building simulation of a four-star hotel was set up in TRNSYS. This hotel has a capacity of 240 beds and an area of 10'080 m². Internal loads and geometry are based on different standards (e.g. SIA, etc.). The south oriented building has a high quality thermal envelope. Shading is achieved by construction and active shading elements. The hotel includes the following zones: accommodation, reception, lobby, bar/restaurant, kitchen and spa area with a pool. Geometry, design and control strategies determine the load profiles and energy demand for space heating, pool heating, domestic hot water and cooling accordingly. The ventilation includes heat recovery in winter and the air change rates and specified temperatures correlate with each usage.

In table 3 the annual energy demands and maximum loads for the locations Innsbruck and Sevilla are summed up.

Table 3: Energy demand and loads for the hotel profile in Innsbruck and Sevilla

	Innsbruck		Sevilla	
Application	Demand [MWh]	Load [kW]	Demand [MWh]	Load [kW]
Space heating (SH)	271.2	190	7.1	38
Pool heating (pool)	274.8	208	227.8	205

Domestic hot water (DHW)	562.5	260	562.5	260
Air–conditioning (C)	85.7	80	315.5	135

The load profiles are used individual and in several combinations: DHW only, DHW+C, DHW+C+SH+pool.

- HVAC layouts for the hotel

Six HVAC layouts are compared in detail for the hotel profile and are briefly described here.

REF: The standard Task 53 reference system consists of a modulating natural gas boiler and an air-cooled vapour compression chiller.

ST: The solar thermal collector field (ST) feeds a hot water storage tank, which is used to ensure the heat supply and operation of the ACM. A natural gas backup boiler is used for DHW and SH only. The ACM is used to cover the base load (19 kW) and the conventional VCC (70 kW) covers the remaining demand using grid electricity. Both chillers operate with a dry cooling tower.

HP: A heat pump operates reversible and feeds the hot water storage tank for domestic hot water usage and a cold water storage. Groundwater is used as the source for the heat pump.

HP+PV: A PV area, which is dimensioned for the operation of the reversible heat pump, complements the system. The HP is not controlled specifically, thus the coincidence of HP operation and PV electricity results from the simultaneousness from load and irradiation. The demand of electricity from the grid and the excess of PV electricity result correspondingly.

PVT: The system consists of a solar thermal collector field for domestic hot water purpose with a natural gas backup. The PVT collector is used to preheat the fresh water for the pool heating and to cool the PV accordingly. The cooling is supplied by a water-cooled conventional VCC (dry cooler).

PVT(P2H): in this variation the surplus PV electricity is used to heat up the hot water storage (power to heat).

PV(P2H): The reference system is equipped with PV. The PV is only used to heat up the hot water storage (power to heat).

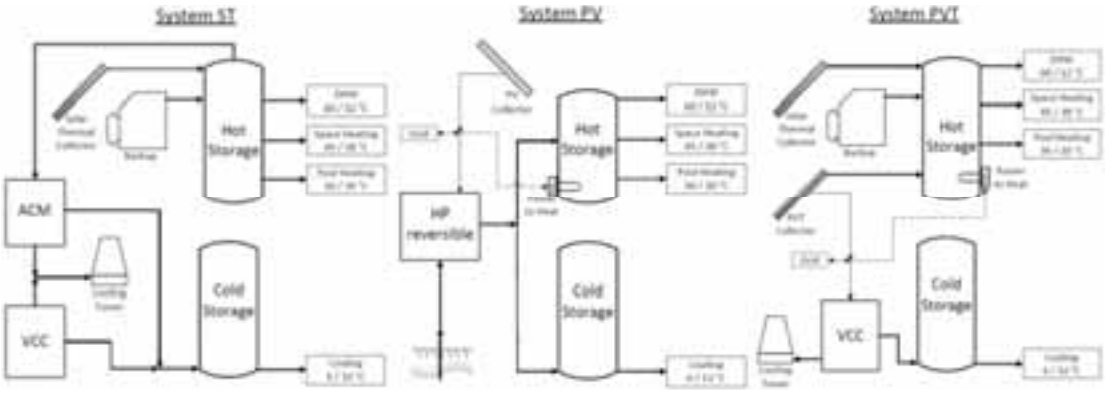

Fig. 2: Principle schemes of three solar hybrid HVAC solutions

The collector area for the entire system was varied during the simulation study: solar thermal (ST: 220, 420, 720, 820, 920, 1'120 m²) and photovoltaic (PV: 26, 49.5, 73, 84.5, 94, 130 kWp), PVT (420m² ST + 5, 12.5, 25, 50, 75, 100 kWp) and PV(P2H) (25, 46, 100, 150, 100, 200, 300 kWp).

- Potential study

The same configurations that are measured in the dynamic Hardware-in-the-Loop test are investigated in annual simulations. The system configurations are described above (cf. configurations a, b, c for HiL tests). The absorption chiller (in different modes) is directly solar driven, no hot water storage is included. Due to the design of the system the collector can deliver sufficient generator power to run the ACM if the solar irradiation is greater than 200 W/m². The maximum potential is investigated by means of constant return temperatures of LT- and MT-circuit and the operation through the entire year as soon as there is sufficient radiation available.

Selected boundaries for configuration (c) are presented in table 4. Three operation modes are analysed in order to reach different solar fractions: the ACM in single operation (without LT outlet temperature set point), the ACM with controlled VCC support (to reach the set LT temperature) and the ACM with maximum capacity VCC. The MT inlet temperature (returned to the chiller) is kept constant at 14°C and controlled to reach 40°C outlet (useful) temperature. The LT inlet is kept constant at 12°C or at ambient temperature plus 3 K to simulate an air source heat pump. The measurements are executed for the location of Innsbruck and Sevilla and are distinguished between the use of MT only and the simultaneous MT and LT usage.

Table 4: matrix of boundary conditions of the annual simulation for configuration (c)

Use	Location	LT return	MT temp	LT set temp.	Operation mode
MT MT+LT	Innsbruck	Amb. +3 K	14/40°C	Free floating	ACM only
	Innsbruck Sevilla	12°C		6°C	ACM + VCC controlled
				Free floating	ACM + max VCC

3. Results

This paper only shows a short selected survey of measured and simulated results. More details can be found in the final report of the project SolarHybrid (Neyer 2017).

3.1 Measurements & Hardware-in-the-Loop

- Characteristic curves vapour compression & absorption chiller

The steady state measurements of ACM and VCC are executed according to the defined measurement matrix. Figure 3 shows the performance maps of ACM (left) and VCC (right).

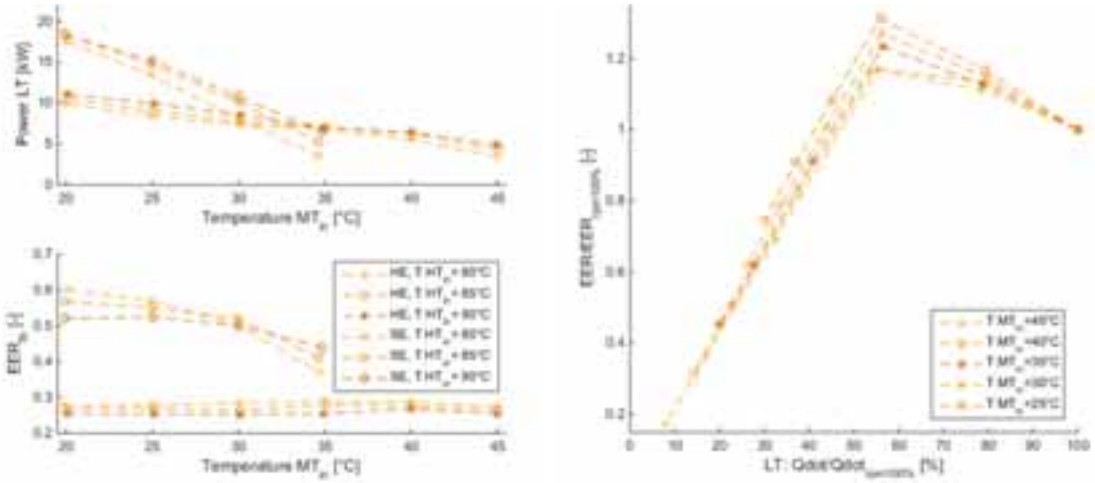

Fig. 3: Performance maps of ACM (left) and VCC (right), LT_{out}=12°C, $\dot{v}_{MT}$=6.5m³/h, $\dot{v}_{LT.ACM}$=3m³/h and $\dot{v}_{LT.VCC}$=3.5m³/h

The LT inlet temperature is kept at 12°C for both cases (left ACM, right VCC). The MT volume flow is 6.5 m³/h, LT volume flow is 3 m³/h for the ACM and 3.5 m³/h for the VCC measurements. The upper diagram of the ACM map shows the LT capacity and the lower diagram the Energy Efficiency Ratio (EER_{th}) in dependence on the MT_{in} inlet temperature. The different lines represent different modes (SE/HE) and different HT inlet temperatures. In SE mode recooling temperatures up to 35°C are possible; HE modes enables recooling temperatures up to 45°C, but at nearly half EER (caused by double generator power). In terms of energy production, switching from SE to HE could be reasonable at a MT inlet temperature higher 32°C (cf. upper diagram).

The VCC map shows values in relation to the nominal capacity, x-axis indicates the relative LT capacity and y-axis the relative EER. The lines represent different MT inlet temperatures, the capacity is first reduced by controlling rpm (100, 75, 50% – right three points of each line) and second on the basis of opening hot gas bypass (left three points of each line). The EER of the VCC is maximized at minimal rpm with closed hot gas bypass,

caused by better heat transfer in condenser and evaporator.

Both machines show a good performance, especially under consideration of the prototype status. The adaptations of the ACM show the expected impact and improve the performance significant. The VCC show EERs far above average small-scaled chillers and enables a capacity control for a large range.

- Dynamic measurements

Following the results of the described configuration (c) – combined chiller and heat pump mode of ACM and VCC – are discussed. The measurements are analysed visually, energies are summed up and characteristic numbers (e.g. electrical/thermal seasonal performance factor – SPF) are calculated.

Figure 4 shows the course of the cloudy day (Innsbruck); the upper diagram shows the capacities (HT, MT, LT, electrical) of ACM and VCC and the irradiation (multiplied with factor 10) on the collector field; the lower diagram shows the corresponding temperature (MT, LT in- and outlet; HT inlet temperatures multiplied with factor 0.1; ambient temperature)

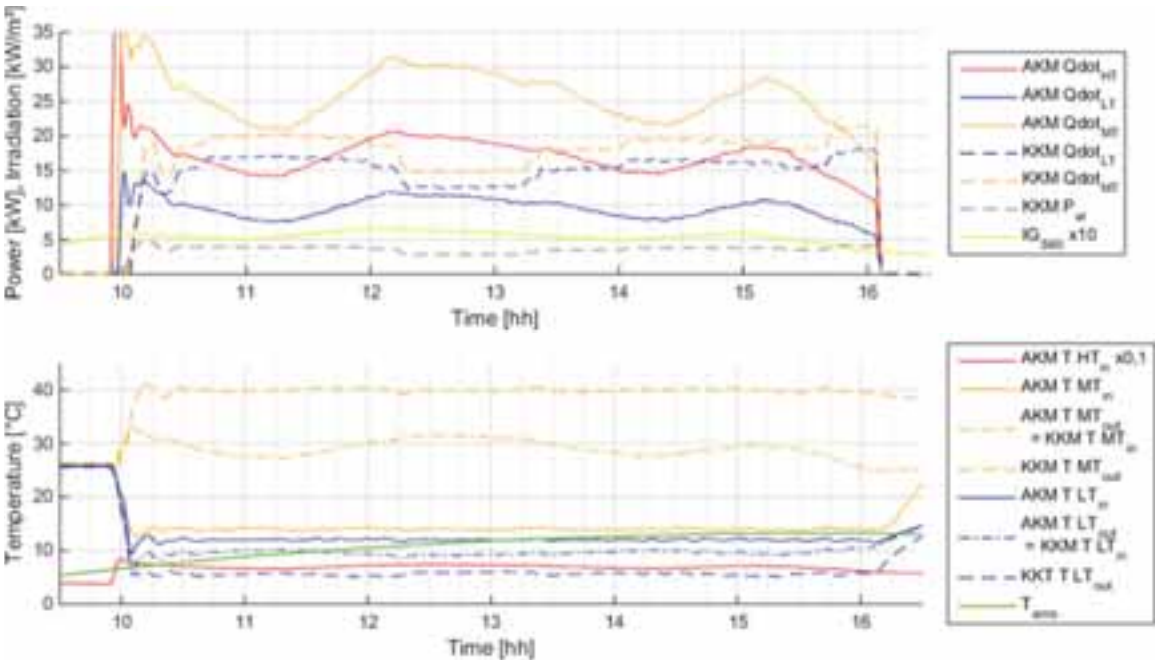

Fig. 4: Combined chiller and heat pump mode of ACM and VCC – trend over the cloudy day (upper diagram: powers and irradiation; lower diagram: temperatures)

The power devolution shows the correlation between ACM and VCC, as soon as the ACM delivers less power the VCC increases the capacity to reach the set point. This results in a constant LT outlet temperature (cf. Figure 4 lower diagram), constant MT outlet temperature is reached by means of controlled MT mass flow.

Table 5 shows the energy balances and system SPFs over the daily courses (sunny and cloudy day). The SPFs are distinguished in used energy (MT or MT+LT); the thermal SPF (SPF_{th}) represents the ratio of delivered energy (MT, MT+LT) to provided thermal energy (HT); SPF_{el} (electrical) shows the ratio of delivered energy to electrical energy (all circuit pumps, ACM solvent pump, VCC compressor).

Table 5: Energy Balances and SPFs of combined chiller and heat pump mode of ACM and VCC

	Energy ACM [kWh]			**Energy VCC** [kWh]			**ACM+VCC** [kWh]		**System SPF [-]**			
									MT+LT		**MT**	
	Q_{HT}	Q_{LT}	Q_{MT}	Q_{MT}	Q_{LT}	Q_{el}	Q_{MT}	Q_{LT}	SPF_{th}	SPF_{el}	SPF_{th}	SPF_{el}
Sunny day	233	125	349	96	80	21	445	205	2,03	20,19	1,50	13,82
Cloudy day	102	57	152	102	86	21	254	143	2,04	12,33	1,49	7,89

The configuration with the ACM and VCC used as heat pump reaches in all cases electrical efficiencies of >8. The difference between sunny and cloudy day get obvious but still provide optimization potential as the pumps are all calculated with constant power, including further speed-controlled auxiliaries enables systems with electrical performance of > 10.

3.2 Simulation studies results

- Hotel profile

Table 6 shows the most important results of all six simulated HVAC systems for the entire building load (DHW+C+SH) and the location of Innsbruck.

The solar yield is highest for ST (423 MWh), the PVT variation consist of ST+PVT_{th} (220+46 MWh) and PVT_{el} (61 MWh). The PV variation yield is 112 MWh. The demand for backup (natural gas) and/or grid electricity is reduced according to the yield. The surplus PV electricity is fed into the grid for the PV/PVT variations. A corresponding non-renewable primary energy input (PE_{NRE}) is resulting and expressed as savings ($f_{sav.NRE}$) in relation to the reference system.

Table 6: Comparison energy balances, costs and savings for maximum building load (DHW+C+SH/562+82+542 MWh/a) for each system

	Unit	REF	ST	HP	HP+PV	PVT	PV(P2H)
Collector area	m²	-	720	-	720	420 (ST)+ 326 (PVT)	652
Solar yield	MWh/a	-	423	-	112	ST:220, PVT_{th}:46, $_{el}$:61	113
Gas	MWh/a	1210	795	-	-	880	1071
Electricity supply	MWh/a	48	32	518	408	33	30
Electricity feed in	MWh/a	-	-	-	2	39	-
Sum Primary Energy	MWh/a	1498	963	1295	1020	1060	1265
Spec. Investment	€/kW	330	1200	500	890	1397	890
Investment ratio SHC/REF	-	-	3.6	1.5	2.7	4.2	2.7
$f_{sav.NRE}$	-	-	0.35	0.12	0.30	0.295	0.16
Cost Ratio (CR)	-	-	0.36	1.04	1.05	1.05	1.04

To analyse the costs, the specific investment costs are listed in Table 6. These were calculated with the standardized values of the T53E[4]-tool. The ratio of the investment costs of the entire system compared to the reference ranges from 1.5 for the heat pump up to 4 for the PVT variation. In addition to the investment costs, the costs for replacement, consumption-related costs (electricity, gas, water), maintenance costs and feed-in tariffs are reported. Figure 5 shows a comparison of the distribution of these cost categories in relation to the reference costs.

In case of the reference system, the energy costs for natural gas (73%) are dominant, while the proportion of investment is increasing significantly in the case of all renewable variations. In case of the solar thermal systems, the costs for natural gas; for the heat pump systems, the cost of electricity are the largest cost drivers.

All results of the techno-economic analysis are summarized in Figure 6 (left: Innsbruck, right: Sevilla). The cost ratio (CR) and the non-renewable primary energy savings ($f_{sav.NRE}$) are mapped. The markers represent the simulated variations, which are distinguished by collector size, by application (DHW only, DHW+C, DHW+C+SH) and by the system configuration (ST/PV/PVT). In general, it is obvious that the larger the collector size the larger the non-renewable primary energy savings can get but simultaneously rising cost ratios (CR) are observed.

Figure 6 shows the difference between the individual profiles as well as the system variations and the two locations. With the pure DHW systems, the highest savings ($f_{sav.NRE}$) are achieved (lowest energy quantity, highest solar coverage for the same area). The profile DHW+C+SH leads to the flattest curves (maximum energy quantity).

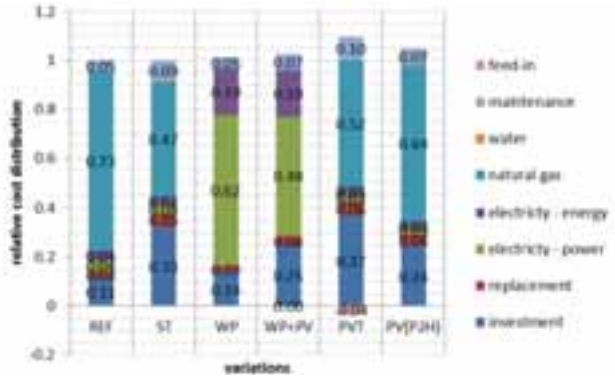

Figure 5: Relative cost allocation for the total building load (DHW+C+SH/562+82+542 MWh/a) relative to the reference (REF) for each system

With increasing collector size, the PVT quickly reaches a maximum of savings ($f_{sav.NRE}$) despite further rising of costs. This is due to the fact that, from a certain size, the user's self-consumption is no longer increased as the electricity consumption and the coincidence is low. On the other hand, increased PVT areas lead to larger ratios to preheat the DHW and thus the average collector temperature increases. Since uncovered PVT collectors usually have comparatively low stagnation temperatures, rising temperature can lead to a further reduced thermal yield.

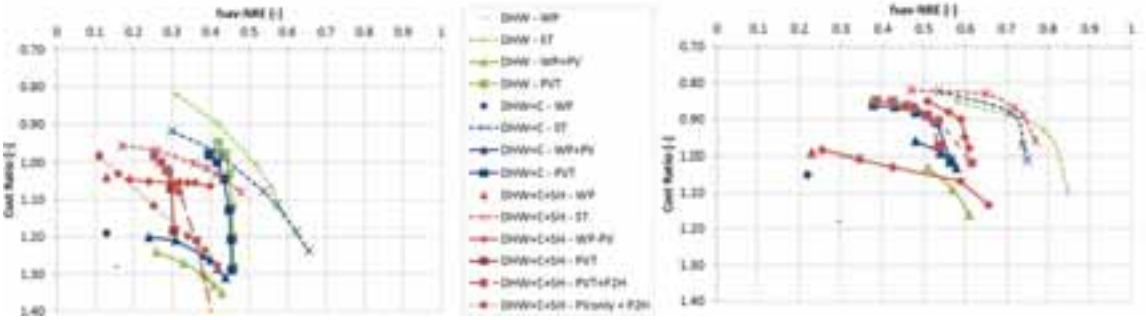

Figure 6: Technical and economical comparison of plant configurations: ST, HP, HP+PV, PVT, PV (P2H) for Innsbruck (left) and Sevilla (right)

Compared to the reference, the heat pump achieves $f_{sav.NRE}$ up to 15% (20% for SEV) with additional costs up to 28% (only DHW, IBK). The higher the energy demand the more favourable the HP. A CR of 1.04 (1 for SEV) can be achieved with the complete profile. The ratio of the investment costs to the energy costs, which account for 80% (IBK, cf. Fig.5) of the total profile, is decisive here. The cost can be reduced with high efficient solution accordingly.

If the heat pump is expanded by the PV, small increases in the CR will result for Innsbruck, but pays off in case of SEV immediately. If the PV area is increased, the costs increase accordingly. This result can essentially be attributed to the uncontrolled self-consumption and the trend of the profile.

The ST variations show the largest differences between the profiles as well as the different collector sizes. In the case of small areas, the savings in non-renewable primary energy are lower than in PV and PVT variations, but at lower costs (IBK). In Sevilla all variations of the ST show higher savings than the other solutions. The results (CR, $f_{sav.NRE}$) coincide with analyses of other measured and simulated plants in SHC Task 53 (Neyer 2016).

In sum, depending on the design and boundary conditions, ST, PV or even PVT could be preferred. Under the chosen boundary conditions, the ST systems can achieve the best results regarding costs and non-renewable primary energy savings due to the existing buffer storage and the time resolution and evolution of the profile.

- Potential study

The results of all five case studies of the potential study are shown in Figure 7. Each curve represents the three possibilities in operation mode (c.f. table 4). The ACM only operation mode can thus be found on the right hand side showing the highest savings. They are almost 100%, only a small electricity demand is lowering the $f_{sav.NRE}$ accordingly. The more the VCC is supporting the lower the solar fraction und consequently the lower the savings. At the same time the CostRatio drops rapidly as more energy can be delivered and the domination of investment is reduces. Worst performance is presented by the air-heat pump mode (AMB-14-40, only calculated for IBK). The lower the source temperature (especially in winter) the lower the efficiency and thus lower the savings and the CostRatio. If both LT and MT can be used the performance increases accordingly. Due to the higher solar yield the results for Sevilla are improved compared to Innsbruck.

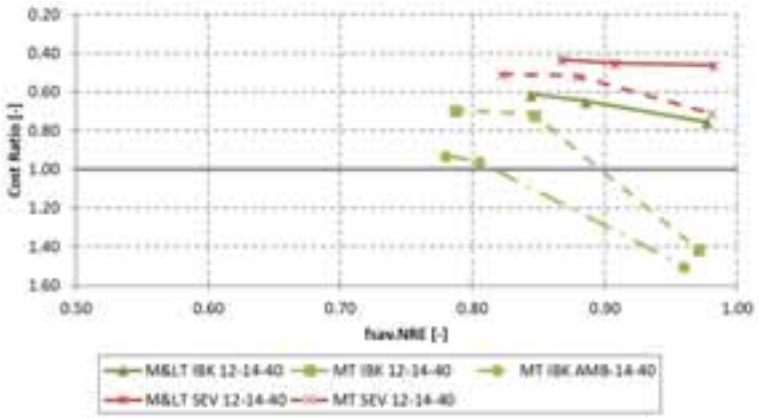

Figure 7: Comparison of the simulation results for Seville and Innsbruck for the heat pump cases with 12/6°C cold water (evaporator) and 14/40°C hot water (condenser) temperature; nomenclature: use(MT, MT+LT) Location LT return, MT in/out

Summing up the potential study illustrates that non-renewable primary energy savings >80% and CostRatio's mostly below 0.8 and as far as 0.4 can be reached. As the economic performance is still investment cost dominated a sensitivity analysis on different parameters was performed.

- Sensitivity analysis

The effect of the sensitivity analysis is shown by means of the shift of the trend lines. The parameters that are varied are the total investment costs, the electricity price, the electrical and thermal efficiency of the systems, as well as the reference performance.

Figure 8 is showing the summary of the sensitivity analysis (left; MT IBK 12-14-40, ACM+VCC) and for one curve of Figure 7 (MT IBK 12-14-40). The investment costs show the largest gradient and thus present the highest influence on the cost performance followed by the performance of the reference system and the entire electrical efficiency.

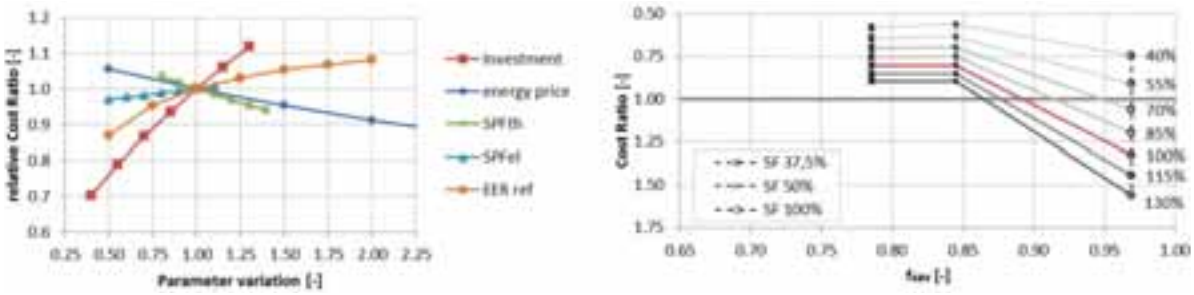

Figure 8: Sensitivity analysis for the heat pump case (MT IBK 12-14-40) as overview (left) and on investment costs variation from 40% to 130% of the Task 53 standard values (right); SF: solar fraction

Figure 8 (right) shows that if the invest costs could be reduced by roughly 35% the 100% solar driven ACM would reach a CostRatio below one and thus represent a highly primary energy savings solution that is cost competitive.

4. Summary & outlook

In SolarHybrid solar heating and cooling systems were investigated intensively by means of simulations, measurements of prototypes and the assessment & benchmarking against conventional system and other solar solutions.

- The combination of the single/half-effect ammonia/water absorption chiller and the ammonia vapour compression chiller represent an interesting initial position for effective and attractive solar driven HVAC solution
- Under the considered boundary conditions, the solar thermal configurations appear to be more efficient and more cost competitive than the PV or PVT variations.
- Solar heating and cooling can become cost competitive when systems are designed clever with simple HVAC layouts, advanced control strategies and high efficient components.

5. Acknowledgment

The presented work refers to the project SolarHybrid, which is carried out in collaborative work by the University of Innsbruck, FH OÖ Forschungs und Entwicklungs GmbH and the companies Engie Kältetechnik GmbH and Pink GmbH. The project is funded by the Austrian Climate and Energy Fund and is carried out within the framework of the Energy Research Program 2013.

Abstract

In this study, a detailed model of a single-family house with exhaust air heat pump, PV system and energy hub developed in the simulation software TRNSYS 17 is used to evaluate energy management algorithms that utilize weather and electricity price forecasts. A system with independent PV and heat pump is used as a base case. The three smart and predictive control algorithms were developed with the scope to minimize annual cost of bought electricity by the use of the thermal storage of the building, the hot water tank and electrical storage. The results show reduction of the final energy of 26.4%, increase of the self-consumption to 60% and decrease of the net annual cost for electricity of 15% when using the forecast services in combination with thermal and electrical storage compared to the base case.

Keywords: photovoltaics, heat pump, forecast services, thermal storage, electrical storage

Nomenclature

DHW	Domestic hot water
FE	Final energy
HP	Heat pump
PV	Photovoltaics
NCOE	Annual cost of electricity
SC	Self-consumption [%]
SH	Space heating

1. Introduction

Sophisticated control of HPs can provide the flexibility to match the onsite PV electricity production with the household load for space heating (SH) and domestic hot water (DHW). Batteries have the advantage of being able to store electricity for later use and are a suitable option for short term storage of PV electricity in buildings (Luthander et al., 2015), while thermal storage has also been studied in combination with heat pumps. For example, according to Fischer and Madani (2017), rule based approaches lead to cost reduction by 2 to 4%. Salpakari and Lund (2016) studied the optimal cost control for PV systems with thermal and electrical energy storage based on the electricity price and Thygesen and Karlsson (2016) proposed a control strategy based on a perfect short-term weather forecast for a PV system with a heat pump and thermal and energy storage that showed low profitability. Strategies for improving PV self-consumption in residential buildings with energy storage and

doi:10.18086/swc.2017.33.07 Available at http://proceedings.ises.org

the various control approaches, including rule based and predictive control have been reviewed thoroughly by Luthander et al., (2015) and Fischer and Madani (2016) respectively. The majority of the studies that focus on PV are in combination with battery storage but heat pumps plus hot water storage have shown increasing interest in recent years (Binder et al., 2012; Hesaraki and Holmberg, 2013; Thygesen and Karlsson, 2014; Luthander et al., 2015; Hirvonen et al., 2016; Fischer et al. 2017). This study evaluates predictive control measures for systems with PV and heat pumps for a single-family house in Sweden. For the base case, a detailed model of a new single-family house with a grid-connected PV system, exhaust air heat pump and hot water storage is used. In this base case scenario, the heat pump is not controlled to increase the internal use of the PV electricity. The model is further developed to include electrical storage.

1.1 Aim of study

The objective of this study is to develop and evaluate algorithms that use forecasts of weather and electricity price on hourly basis in order to reduce the annual final energy and net cost of electricity. In a previous study, Psimopoulos et al. (2016) developed control algorithms to utilize more effectively the excess PV electricity production. The previous results have focused on energetic improvement such as to increase the self-consumption (SC) and to reduce the bought electricity from the grid, namely final energy (FE). In the follow-up study presented here, a simplified economical evaluation of the running cost and revenue is used as for generating the net cost of electricity that is used for the optimization. In Sweden, it is already possible for house owners and PV micro producers to have an electricity tariff coupled with the Nord Pool spot market price, with tariffs on hourly basis (Sommerfeldt and Madani, 2015). What is new in this work is the proposed operational control strategies in addition to the short time-step weather data and load profiles for both domestic hot water (DHW) and electricity demand. Another difference to other studies is that the exhaust air heat pump, very common in Sweden, cannot supply the full heating rate required and thus control of the electrical auxiliary heater is important and also modelled in detailed in this study.

The scope of the study is for a modern single family house with exhaust air heat pump located in Sweden. The stochastical load patterns are based on monitoring data for single family houses described in Widén et al., (2012, 2009). All these are implemented in the simulation software TRNSYS 17, where the components in the model are parameterized to match the specifications of existing products on the market. Net cost of energy is considered in the analysis based on spot market price and no feed-in subsidies. A full economic evaluation including investment cost is out of scope of this paper, rather the focus is on impact of advanced control algorithms assuming the system already exists.

2. Methodology

2.1 Boundary conditions for the system

The system with heat pump supplies a typical Swedish single family house (SFH) with a gabled roof of one floor that has an overall U-value of 0.2 W m^{-2} K^{-1} and 143 m^2 heated floor area. A detailed model of the house with six zones, developed in the simulation software TRNSYS, is described in detail and validated by Persson and Heier (2010). TRNSYS' type 56 is used for the house model. Three zones (rooms) have a set temperature of 20°C, while two zones have 21°C and one zone has 22°C as set temperatures (Persson and Heier, 2010). The location of the house is Norrköping, Sweden (58.6°N, 16°2E). Measured high-resolution (one minute) meteorological data by the Swedish Meteorological and Hydrological Institute (SMHI) from the year 2011 in Norrköping is used in the simulations. The weather data is used both for calculation of the PV electricity production and for calculations of energy gains and losses in the house. Fresh water temperature, which affects the heating demand, is dependent on the time of the year and modelled using a function described by Heimrath and Haller (2007). Two adults and two children are living in the house, and the internal heat energy gain, assumed to be the same as the electricity demand for appliances, is calculated using a Markov-chain model for occupancy and energy use as described in Widén et al. (2009). The DHW demand is derived from the MacSheep project and adjusted for this study (Bales et al., 2015), see Table 1. Domestic electricity and DHW loads have a 2 minute resolution over the period of one year.

Tab. 1: SH, DHW and appliance data

2979	**Discharge energy [kWh year^{-1}]**
70.9	Discharge DHW volume [m^3 year^{-1}]
45	Discharge DHW temperature [°C]
194.2	Daily Average DHW draw-off [kg]
2.44 – 972.2	DHW flow [kg h^{-1}]
3437	Electricity for appliances [kWh year^{-1}]
14046	Space heating load [kWh year^{-1}]
5650	Max load for appliances [W]

2.2. Hot water storage tank, heat pump and auxiliary heater

A variable speed, exhaust air HP delivers heat both for SH and DHW but cannot supply them both at the same time. The HP model is based on the performance map of the HP, with heat capacity and power input as dependent variables together with inlet air temperature, inlet air flow rate and compressor speed as independent variables. A hot water storage tank of 180 litres is used for DHW whereas the SH is supplied by the HP through a buffer store of 25 litres. The HP is activated according to a heating curve and compensatory control algorithm dependent on the SH supply temperature. An electric auxiliary heater is activated when the thermal power provided by the heat pump is insufficient to meet thermal power need. The auxiliary heater is turned off during the predefined summer period. Table 2 shows the values used in this study for the DHW storage, heat pump and auxiliary heater. The models for the HP, DHW storage and internal control algorithms are based on common commercial products on the market. The performance characteristics as well as detailed control algorithm are based on those for a commercial integrated product with heat pump and DHW store as one 60x60 cm appliance unit.

Tab. 2 : Specifications of hot water storage tank, exhaust air heat pump and auxiliary heater

Preference	Quantity
DHW storage tank capacity [litre]	180
Electric compressor power [kW]	0.27-2.05
Thermal power of HP [kW]	1.14 – 4.99
Heat pump COP	2.4 – 4.7
Electric auxiliary heater [kW]	0.5 – 6.5

2.3. Battery storage and PV system

Three PV system sizes and three battery storage sizes are used to study the impact on the energetic and economic performance in terms of self-consumption, and final energy, with details described in Table 3. The tilt angle is defined by the roof of the building whereas the azimuth angle is chosen to optimize the yearly PV electricity production. The PV panels, inverter and lithium-ion batteries are modelled according to the specification of products available on the market.

Tab. 3: Specifications of the PV system and battery storage

Preference	Quantity/name
Capacity PV [kW]	3.12, 5.7, 9.36
Inverter efficiency [%]	97.7
PV tilt [°]	27
PV azimuth [°]	0
Capacity battery [kWh]	3.6, 7.2, 10.8
Round-trip battery losses [%]	10%

2.4. Electricity tariff

Figure 1 shows the annual variation of the Nord Pool spot market price for year 2011 in central Sweden. The purchased electricity price that is used for this study includes the following: the spot market price, the grid fee, the electricity certificate and the value added tax. For the case of the feed-in electricity to the grid, only the spot market price and the electricity certificate without the current tax reduction subsidy available in Sweden are considered. For the end user, this results in a mean value of 0.08 €/kWh of various fees is added to the hourly spot market price for the purchased electricity and 0.015 €/kWh is added to the hourly spot market price for the excess electricity fed to the grid. The added values are derived from 2011 market data (Nord Pool, 2016).

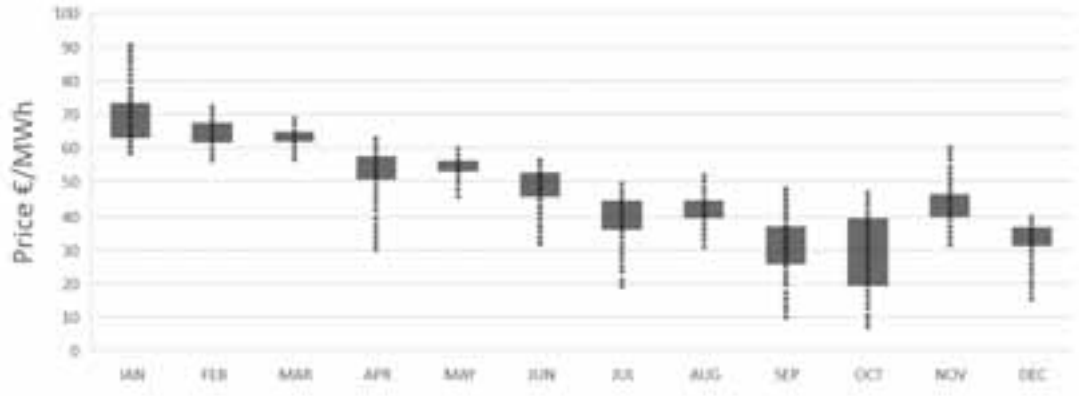

Fig. 1: Spot market electricity prices for Sweden in year 2011. Boxes include 50% of the values for each month

2.5 Sensitivity analysis of electricity tariff

Since the dynamic (spot) price is a small fraction of the end user price, this study also evaluates the potential of the amplified electricity price deviation that is shown in Figure 2, by investigating to what extent the applied algorithm based on the price forecast is sensitive to the hourly and daily price oscillation. To do that, data from 2011 were amplified by applying a factor of 2 to the deviation from the twenty four hours running average.

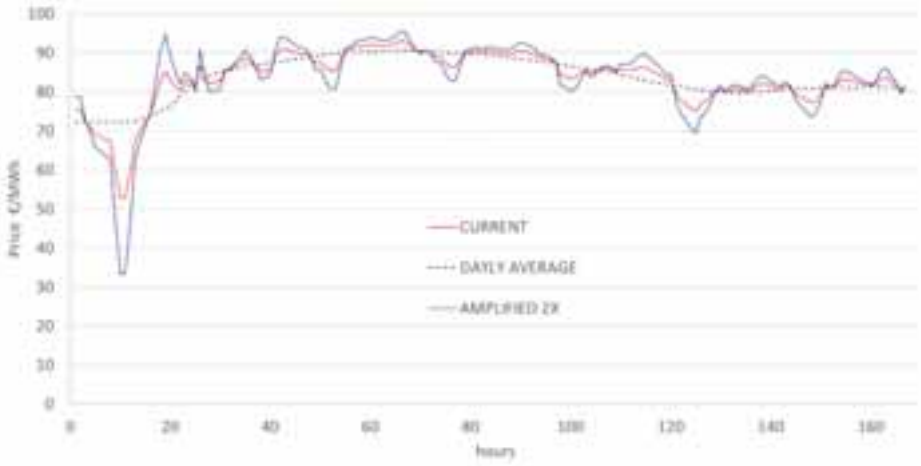

Fig. 2: Amplified electricity price deviation from the 24h running average (example of the first week in January 2011)

2.6 Performance indicators

The key figures for this study that are used to evaluate the energy and economic performance of the residential PV system are: final energy and self-consumption, annual electricity demand and annual net cost of electricity for the heating system and appliances. A mathematical description of self-consumption can be found in Luthander et al. (2015). If $L(t)$ denotes the instantaneous electric load including appliances, heat pump and auxiliary heater, and $P(t)$ is the instantaneous power from the PV system, the directly consumed PV power $M(t)$ can be defined as:

$$M(t) = \min\{L(t), P(t)\} \quad \text{(eq. 1)}$$

if no electric storage is used. When adding battery storage to the system, this can be extended to

$$M(t) = \min\{L(t), P(t) + S(t)\} \quad \text{(eq. 2)}$$

where $S(t) < 0$ denotes power to storage (charging) and $S(t) > 0$ denotes power from storage (discharging). The final energy for the simulation period (FE) is equal to the electric load that cannot be supplied by PV electricity:

$$FE = \int_{t_1}^{t_2} L(t)\, dt - \int_{t_1}^{t_2} M(t)\, dt \quad \text{(eq. 3)}$$

Self-consumption can then be defined as:

$$SC = \frac{\int_{t_1}^{t_2} M(t)\, dt}{\int_{t_1}^{t_2} P(t)\, dt} \quad \text{(eq. 4)}$$

The annual net cost of electricity (NCOE) can be defined as in equation 5. The cost of the purchased electricity is equal to the added values denoted as fixed fees C_{fixed} per kWh and the spot market price C_{sp}. The revenue consist of the spot price C_{sp} and the electricity certificates C_C:

$$NCOE = Cost - Income \quad \text{(eq. 5)}$$

$$Cost = \int (C_{sp} + C_{fixed}) P_{from\ grid}\, dt \quad \text{(eq. 6)}$$

$$Revenue = \int (C_{sp} + C_C)\, P_{to\ grid}\ dt \quad \text{(eq. 7)}$$

$P_{from\ grid}$ and $P_{to\ grid}$ are the power that the system requires from the grid or feed in to the grid, respectively.

3. Control strategies with forecast services

Smart control strategy is beneficial to demand response of the HP system and the optimal utilization of the thermal and electrical storage by the PV electricity production. One control action on the heating system based on electricity prices is to limit the need to purchase of energy when it is expensive. In those periods, if PV production is not sufficient to cover the total energy need, the storage system has a crucial role. In this study the price is defined as high or low by comparing the current price with the average price in a near-future interval of time. That means that the price is considered low or high relatively to what occurs in the hours ahead, and is not related to the average cost over the year. Figure 3 explains the logic that determines whether the current price is low or high.

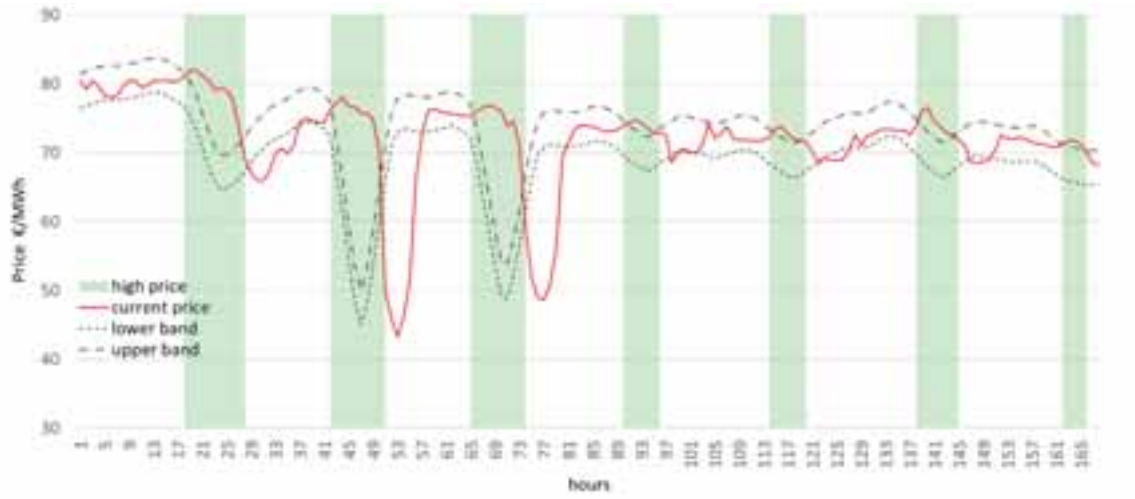

Fig. 3: Example of high price periods (data from a week in January 2011)

In Figure 3, the highlighted intervals are the hours when the price is high, i.e. when the current price is higher than the upper limit. The next day spot market data are obtained by using a perfect forecast, which is derived from the same electricity price data input file shifted one day ahead. The upper and lower limits are obtained by calculating the running average of the near future. The band width is therefore another parameter of this algorithm.

The weather forecast can be used for various applications. In this study the day-ahead global irradiance and the beam component are used as input to the PV model. A perfect forecast is used by shifting the original weather data file one day ahead in order to forecast the PV electricity production. A forecast of space heat demand is not generated or used.

Three algorithms were developed, utilizing either thermal storage by means of the thermal mass of the house (Algorithm 1) or the DHW tank storage, with the electrical storage (Algorithm 2) as well as a combination of using thermal mass storage and the electrical storage (Algorithm 3). The main objective is to control the temperature set points in the room regulators for the space heating using the variable spot market price and the set point in the DHW tank by the day-ahead of PV electricity forecast based on irradiance forecast and a night saving mode. The thermal comfort of the living space (room air temperature) and the availability of DHW were maintained between strict limits. A penalty function for both the SH and the DHW was implemented and monitored for deviations from the base case standards. For the room temperatures a minimum limit was defined as 19.5°C in the largest zone of the house and a minimum of 45°C in the tap. The penalty functions are based on the guidelines of the IEA SHC Task 32 and based on IEA Task 26 handbook (Weiss 2003). Both strategies are combined with overheating the zones of the house and the DHW tank when excess PV electricity is available. Constraints are also implemented to prevent increasing the cost and to prevent discomfort when the heating demand is high. Constraints of the control decisions that are not listed in the Table 4 are:

- The auxiliary heater is not allowed to be activated when overheating occurs.
- To prevent discomfort and probably use of auxiliary heater for reheating, it is not allowed to lower the zones' temperature set point when ambient temperature drops below 0 °C and high price occurs.
- It is not allowed to overheat the zones when the ambient temperature exceeds 10°C and low price occurs.

The developed control strategies are described as follows:

- The base case includes the house equipped with a PV system and a heat pump for DHW storage and SH. The HP is controlled solely by the need of SH and the temperature in the DHW storage tank. There is no active use of storage to optimize self-consumption/costs. For a more detailed comparison for the cases with the algorithms that combine both electrical and thermal storage the base case is also simulated with batteries and expressed as ALGb.
- In the first control algorithm (ALG1), the aim is to control the heat pump providing the SH load by the low and high dynamic price and to utilize the excess PV production to reduce net cost and to increase self-consumption. The control is implemented as follows: when high price occurs the room regulators lower the temperature by 0.5 K whereas the set point temperatures in all the zones are increased by 0.5 K during periods with low price. ALG1 is implemented with two variations ALG1 and ALG1a.The ALG1a difference includes the amplified dynamic price explained in section 2.5 but with the same control strategy.
- The second control algorithm (ALG2) is applied to the base case system with an additional electrical storage in batteries. The temperature set point of the DHW tank is triggered by the day-ahead weather forecast. The task of the saving function is to limit the cost for charging the DHW tank to the reference value which is compensated later by PV electricity. The time period during which this control is active if from hours 00:00 until hour 06:00. A precondition is that the PV power production between 07:00 and 08:00 exceeds a minimum threshold. Charging of the batteries is controlled by excess PV production to increase self-consumption whereas the HP is controlled solely by the need of SH and temperature in the DHW storage tank.
- The aim of the third control algorithm (ALG3) is to combine the energy storage in the thermal mass of the house, in the DHW tank and in the batteries together with a combination of price forecast and a forecast of the PV power production. The task is to use the batteries to reduce the final energy and to increase self-consumption. The HP is switched on when there is excess PV power production, otherwise it is controlled by the low and high dynamic price signals. The priority is to supply first the electrical loads and then the charging of the battery if there is additional excess PV power.

It should be noted that the battery charging is only allowed during times with excess PV power production after the desired set points in the DHW storage tank have been reached (algorithm 2) or if the SH overheating set point is reached (ALG3). The priority is given to the thermal storage in the course of any day. Table 4 lists the control schemes for on-off control of the HP for the three cases. For ALGb, the main control is that the battery charging is allowed only when excess PV power occurs.

Tab. 4: Control schemes for on-off control of the HP for the three algorithms

		ALG1	ALG2	ALG3
Spot price forecast	High price	Lower set point 0.5 K for SH	None	Lower set point 0.5 K for SH
	Low price	Increase set point 0.5 K for SH	None	Increase set point 0.5 K for SH
PV forecast	Threshold 500 Wh	-	$E_{PV} > 500$ Wh	-
Night saving	00:00-06:00	-	Lower set point 5K for DHW	-
PV excess $P_{PVe} > 320W$	Threshold 320W	Increase set point 1 K for SH	Increase set point 6 K for DHW	Increase setpoint 1 K for SH
PV excess $P_{PVe} > 0W$	Threshold 0W	-	Battery charging	Battery charging
Upper limits		$T_{zones} < 23$ °C	$T_{DHW\ tank} < 54$ °C	$T_{zones} < 23$ °C
		T_{set} DHW reference 48 °C ± 2 K hysteresis		

4. Results

In this section the results for the key performance indicators, i.e. FE, SC and NCOE, are presented. The developed control strategies are evaluated and compared to the base case with and without batteries. The system was simulated for the base case and each of the algorithms with the three different PV sizes, each with its own battery storage size chosen according to the PV capacity (3.1 kW PV and 3.6 kWh battery, 5.7 kW PV and 7.2 kWh battery, 9.3 kW PV and 10.8 kWh battery). Table 5 shows a summary of the key figures for the base case of 5.7 kW PV system without any smart control and with the implementation of the three control strategies. ALG1 is implemented with two variations, ALG1 and ALG1a. ALG1a uses the amplified dynamic price and is compared to the base case with the amplified dynamic price. Moreover ALGb refers to the base case with electrical storage and respectively ALG2 and ALG3 are also compared to ALGb.

Tab. 5: Key figures for the 5.7 kW PV and the three algorithms plus ALG1a (for all cases appliances use 3437 kWh year^{-1} and the PV array produces 6285 kWh year^{-1})

	Base case	ALG1	ALG1a	ALGb	ALG2	ALG3
Space heat [kWh year^{-1}]	14046	14385	14373	14050	14152	14382
DHW [kWh year^{-1}]	3657	3653	3652	3658	3711	3653
Heat pump electricity [kWh year^{-1}]	5932	6242	6695	5937	6375	6620
Aux heater electricity [kWh year^{-1}]	1568	1267	990	1595	1546	1101
PV self-consumption [%]	31	35	42	47	57	60
Final energy [kWh year^{-1}]	8994	8710	8467	8080	7728	7364
NCOE [Euros]	958	947	934	909	920	883

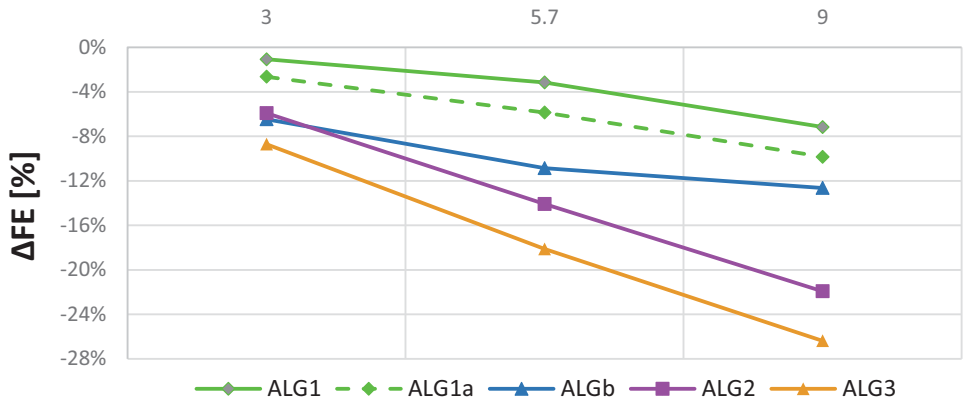

Fig. 4: Comparison of the change in final energy between the base case and the control algorithms ALG1, 2 and 3. ALG1a is shown with the dashed line and refers to the case with the amplified dynamic spot market price and ALG1b refers to the base case with batteries.

Figures 4, 5 and 6 compare the changes between base case and the three algorithms for the three key figures of final energy (ΔFE), net cost of energy (ΔNCOE) and self-consumption (ΔSC) respectively. All algorithms give greater cost and final energy savings the greater the PV system that is installed. ALGb, 2 and 3 including the electrical storage give higher savings in final energy as well as net costs than ALG1, which only uses thermal storage. ALG3 gives the highest reduction in final energy, saving 828, 1630 and 2278 kWh compared to the base case for the 3.1, 5.7 and 9.3 kW PV sizes respectively. Compared to ALGb the savings are 213, 654 and 1186 kWh respectively.

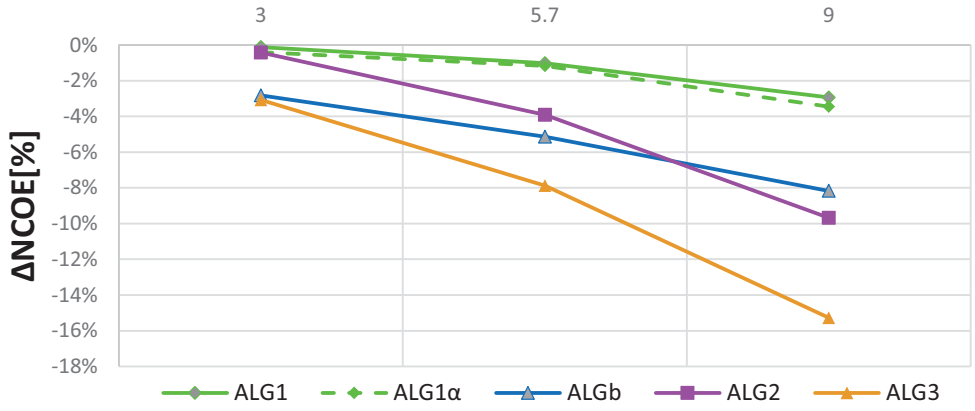

Fig. 5: Comparison of the Annual cost of electricity of the household between the base case and the control algorithms ALG1, 2 and 3. The electrical load for the household appliances is considered constant. ALG1a refers to the case with the amplified dynamic spot market price and ALG1b refers to the base case with batteries.

ALG1 gives gives small net cost savings even with the amplified dynamic price variation (ALG1a), while savings in final energy are larger as are the differences between ALG1 and ALG1a. The net cost savings for ALG3 is 36, 75 and 108 Euros for the small, medium and large PV systems respectively. The NCOE for the two variations of the ALG1 shows no difference even if the SC and final energy show benefits. It is also shown in Figure 5 that ALG2 gives higher cost savings than the base case with batteries, ALGb, only for the largest PV size whereas ALG3 has highest cost savings for all sizes.

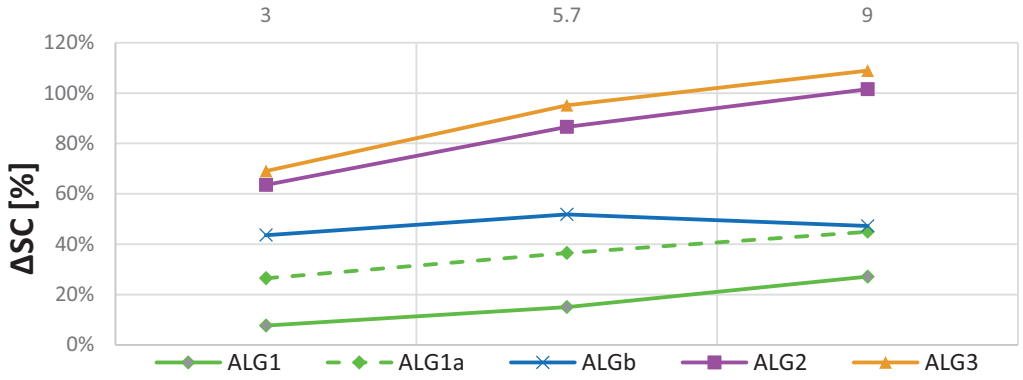

Fig. 6: Comparison of the increase of self-consumed electricity between the base case and the control algorithms ALG1, 2 and 3. Alg1a refers to the case with the amplified dynamic price and ALG1b refers to the base case with batteries.

ALG2 and 3 give twice as large an increase in self- consumption for the system with 9.3 kW PV compared to the base case. It should be pointed also that for the case of the ALG1a the increase in self-consumption is also more than twice as large between the ALG1 and ALG1a. In terms of absolute values the self-consumption for the medium system is 35.6% up to 60.4%, while the highest occur for the smallest size system and is 74.7%. Analyzing the results of the two scenarios of the electricity tariff for the base case, the comparison between the base case with the amplified dynamic price and ALG1a, it is found that the net cost is not affected by the amplified dynamic prices. Even if the cost is decreasing the revenue's decrease in this case results in a near zero change in the net cost. Table 6 lists the costs and revenues of the comparison of the base case and ALG1 and ALG1a while Table 7 lists the costs and revenue using ALG2 and ALG3 compared to ALGb. Both tables also give the average annual tariffs for buying and selling electricity. The tariff for buying is nearly double that for selling and does not vary with the algorithm, while that for selling varies slightly due to the different times of selling resulting from different algorithms.

Tab. 6: Cost and revenue and average tariffsfor base case and ALG1 and ALG1a

	Base case	**ALG1**
Cost (tariff)	1225 € (0.136 €/kWh)	1184 € (0.136 €/kWh)
Revenue (feed-in tariff)	267 € (0.065 €/kWh)	237 € (0.064 €/kWh)
	Base case Amplified	**ALG1a**
Cost (tariff)	1223 € (0.136 €/kWh)	1154 € (0.136 €/kWh)
Revenue (feed-in tariff)	259 € (0.068 €/kWh)	220 € (0.067 €/kWh)

Tab. 7: Cost and revenue and average tariffs for the base case with batteries ALG1b compared to ALG2 and ALG3

	ALGb	**ALG2**	**ALG3**
Cost (tariff)	1098 € (0.137 €/kWh)	1058 € (0.137 €/kWh)	1007 € (0.137 €/kWh)
Revenue (feed-in tariff)	188 € (0.066 €/kWh)	137 € (0.066 €/kWh)	124 € (0.065 €/kWh)

5. Discussion

The inclusion of forecast services in the control decisions increases the complexity of the rule-based decision.

In the current scenario in Sweden, there is a subsidy for feeding in excess electricity to the grid in order to motivate households to become micro producers and prosumers. With the feed-in subsidy, the revenue of selling electricity is very close to the savings from self-consuming the electricity. Increasing the self-consumption would, therefore, have a minor effect on the total costs. It is, however, not decided how long this subsidy will last, which makes it important to study ways to increase the revenue when the subsidy does not exist anymore. The chosen scenario of this study is therefore one where there is not feed-in subsidy and thus a large difference in tariffs for buying and selling, nearly a factor two. From the evaluation of the economic performance, it can be seen that the revenues of the excess electricity fed into the grid have an impact on the annual cost. Especially when cost saving decisions are implemented, there the cost reduction is partly cancelled out by the the reduction of the revenues, which limits the reduction in net annual costs. The limitation of rule-based algorithms for solving the multi-objective control tasks derives from the need to adjust the control decision seasonally and to develop logical solutions with constraints and priorities that are predefined and not updated throughout the course of the year.

One other point to be considered in the evaluation of the results is the use of a perfect forecast both for the weather forecast and also for the dynamic price. Using a real weather forecast, which includes uncertainties, the actual savings and benefits will be even lower than the ones from this study. In Sweden, the price for the coming 24 hours is decided at noon, and a perfect forecast is thus available.

6. Conclusion

This study shows the benefits of smart control using weather and electricity forecast services for decreasing annual net cost of electricity and final energy with the developed algorithms and for increasing the self-consumption. The improvements tend to increase with the larger system sizes. With the largest PV system the annual net cost is decreasing faster for all the algorithms than for the smaller PV systems, with highest cost savings forALG3 (thermal and electrical storage as well as predictive control). For ALG3 and largest PV array the following improvements compared to the base case system (without battery) with same PV array size are achieved: 26% reduction in final energy; self-consumption is nearly doubled to 60% ; and 15% decrease in net annual cost of electricity. For the same PV size and algorithm, the improvements compared to the base case system with battery are lower, namely: 16% reduction in final energy; 42% increase in self-consumption; and 8% decrease in net annual cost.

Using a battery (ALGb) gives greater savings than using thermal energy storage only (ALG1), for the battery and hot water store sizes used in the study. With the medium-sized PV system of 5.7 kW ALG1 gives only a small reduction in netannual cost but with electrical storage the reduction in net costs for electricity are 4 to 8% depending on algorithm used. The final energy can be decreased by 283 kWh (ALG1) up to 1630 kWh (ALG3). With the chosen scenario in this study, the proposed algorithms result in small improvements for cost savings up to 3 % for the smallest system of 3.1 kW when thermal and electrical storage are combined. Final energy is also reduced for this system by 101 kWh (ALG1) up to 828 kWh (ALG3).

MODELING OF SOLAR ASSISTED HEAT PUMPS COMBINED WITH PHOTOVOLTAIC THERMAL MODULES

Riccardo Simonetti, Luca Molinaroli and Giampaolo Manzolini
Department of Energy, Politecnico di Milano, Via Lambruschini 4, 20156 Milano, (Italy)

Abstract

This work summarizes the performance of a Solar Assisted Heat Pump integrating Photovoltaic thermal (PV/T) modules. This configuration reduces the disadvantage of low temperature heat recovery typical of PV/T modules as the fluid temperature is used to drive the heat pump evaporator instead of an end-user and, consequently, can be close to the ambient one. A detailed model featuring real components is developed in MATLAB® to correctly predict the SAHP performance as function of the design parameters (number of PV/T modules) and ambient conditions (solar irradiance and ambient temperature). In addition, an optimization tool was combined with the model to maximize the COP (Coefficient of Performance) by varying the water flow rate circulating in the PV/T panels. Results outline the benefits of this concept with respect to conventional air/water heat pumps in particular when the ambient temperature is below zero as the frost formation issue is not present. COP reaches high values, between 2.5 and 4.9 in the case with 12 PV/T panels and between 2.2 and 6.2 with 24. Advantages in terms of electricity production are outlined as well, with an increasing of 8-9% of the power produced.

Keywords: Solar Assisted Heat Pumps, Photovoltaic Thermal modules.

1. Introduction

Photovoltaic thermal (PV/T) modules combine thermal and electricity production. The main drawback of this technology is the low thermal efficiency and stagnation temperature because of the high thermal losses (Aste, et al., 2014; Zondag, et al., 2003). Insulation systems like vacuum chamber or the adoption of concentrators can be considered but require the installation of auxiliary rejection systems to control the PV cell temperature when the heat demand is absent (Kumar, et al., 2015). Another option to exploit the PV/T potentiality without increasing the module complexity consists of their integration with a heat pump (HP) leading to the so-called solar-assisted heat pump (SAHP) concept: the heat recovered by the PV/T modules supplies the heat duty of the HP evaporator (Ji, et al., 2008). A detailed study over this system was conducted by (Nuntaphan, et al., 2009) that has experimental analyzed the performance of an indirect SAHP coupled with solar flat collectors including a hot water storage of 300 dm^3. Results demonstrate higher system efficiency with respect to traditional configurations (air/water HP or thermal panels), with a gain that reaches 40%. (Li, et al., 2014) has analyzed an indirect SAHP with flat solar collectors for residential heating. The study was done with a model developed in TRNSYS and results demonstrated that 68.1% of the heating and domestic hot water demand was covered by the SAHP. Moreover, the performance is increased by 140% respect of a standard HP and the energy saving is close to 52%. (Liu, et al., 2014) has investigated a system with a SAHP and vacuum solar collectors for residential use. An experimental set-up is used to validate a model built in TRNSYS. The study shows that, considering a system designed for a solar fraction of 20%, about 66% of the thermal load can be covered in the worst month and it is possible to reduce the energy consumption by 55% with respect to a traditional layout with a boiler . (Calise, et al., 2016) has studied the performance of a three-generation system composed by an indirect SAHP integrating PV/T solar panels for heating/cooling loads in a residential application. The model, developed in TRNSYS, shows that the system can cover the entire thermal load and the average performance is 30% higher than a standard HP. The SAHP configuration fixes the PV/T low stagnation temperature issue as the PV/T operating temperature can be close to the ambient one. In addition, the PV power output increases with respect to conventional PV module because of the PV cell cooling effect (Migliorini, et al., 2017). In this work, a detailed modeling of the SAHP concept is carried out to assess the system performance and power output as function of the ambient conditions (irradiance and ambient temperature) and the design specification (number of PV/T modules and thermal efficiency). Physical behavior of all the components of the system are completely characterized, heat transfer coefficients and pressure drops are determined using typical correlation referenced in literature and a solver for a

doi:10.18086/swc.2017.33.08 Available at http://proceedings.ises.org

system with non-linear equations is used. An optimization tool is also implemented to maximize the performance in each different ambient condition, varying the volumetric flow rate that flows in the PV/T panels. With this comprehensive tool, developed in MATLAB®, it is possible to automatically obtain optimized performance maps for a variable number of PV/T modules.

The paper is structured as follows. Section 2 describes the concept and the layout of the system studied. In Section 3 models of the components are explained. Section 4 presents the methodology proposed to define design condition and the optimization method used. In Section 5 main results of the paper are presented and discussed. Finally, in Section 6 conclusions are drawn.

2. The Concept

A schematic of the concept modelled in this work is reported in Fig. 1.

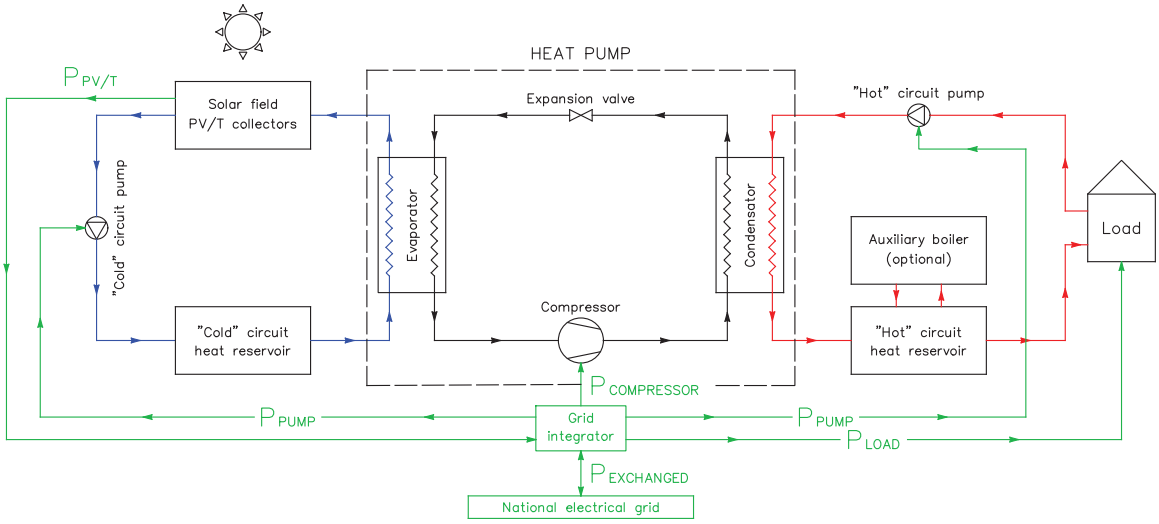

Fig. 1: Schematic of the system modelled in this work

The system consists of a water-to-water HP, PV/T modules and a thermal storage, being the latter component mandatory to decouple the solar energy availability with the thermal load. PV/T modules convert solar energy in thermal and electric ones: the first of them is used in the evaporator of the HP; the electric energy can be used to reduce/cover the HP electric energy demand together with the house ones. PV/T connection to the national grid is considered to account for the electricity excess/deficit with respect to the HP and house loads. The SAHP system considered in this work is designed to cover both Domestic Heat Water (DHW) and Space Heating (SH) consumptions of a single-family house. The heat pump nominal heating capacity and COP are equal to 8.52 kW and 3.19 respectively, whereas PV/T module performance feature commercially available ones (SoLink, 2017). The HP is modelled in MATLAB® considering the governing equations of each component as detailed in the next section, whereas the PV/T are modelled combining datasheet information and experimental measurements carried out at SolarTech^{Lab} of Politecnico di Milano (Bombarda, et al., 2016).

3. Mathematical Model

The SAHP model solves heat and mass balances assuming stationary conditions, neglecting the transient effect of solar radiation (G) variation and the thermal energy storage balance heat load variations. All the components of the HP (compressor, condenser, evaporator and expansion valve) and PV/T modules are considered as black-boxes, with governing equations to describe their physical behavior. The aim is to have a complete model that correctly describes the considered system within limited computational time to perform a detailed analysis in different ambient conditions and with a different number as well as typology of PV/T modules. Fig. 2 shows the refrigerant loop, the domestic water loop (as called primary circuit) and the water-glycol loop (as called secondary circuit). Glycol is used to prevent water freezing in winter time. HP operating points are numbered starting from the inlet of the compressor following the refrigerant fluid.

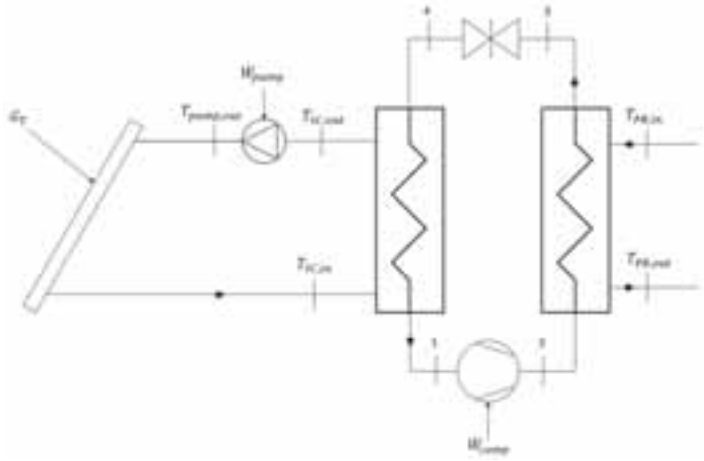

Fig. 2: Schematic of mathematical model

3.1. Compressor

The behavior of the compressor is described with polynomial equations to determine the refrigerant flow rate $\dot{m}_{refr}$ and the electric power consumption $\dot{W}_{comp}$ as functions of condensation and evaporation temperatures T_{cond} and T_{evap}. The 10 coefficients of the polynomial equations are provided by manufacturers (eq. 1 and eq. 2).

$$\dot{m}_{refr} = a_0 + a_1 T_E + a_2 T_C + a_3 T_E^2 + a_4 T_E T_C + a_5 T_C^2 + a_6 T_E^3 + a_7 T_E^2 T_C + a_8 T_E T_C^2 + a_9 T_C^3 \qquad \textit{(eq. 1)}$$

$$\dot{W}_{comp} = b_0 + b_1 T_E + b_2 T_C + b_3 T_E^2 + b_4 T_E T_C + b_5 T_C^2 + b_6 T_E^3 + b_7 T_E^2 T_C + b_8 T_E T_C^2 + b_9 T_C^3 \qquad \textit{(eq. 2)}$$

Coefficients a_i and b_i are evaluated by manufacturers at defined conditions. The compressor used in this work (**Emerson ZH30K4E-TFD**) (Emerson, 2017) has superheating temperature set to 5K, eq. 3 and eq. 4 determine the refrigerant flow rate and the electric power consumption with a different superheating:

$$\dot{m}_{refr}\big|_{\Delta T_{sh}} = \dot{m}_{refr}\big|_{\Delta T_{sh}=5K} \cdot \frac{\rho(p_{evap}, T_{evap}+\Delta T_{sh})}{\rho(p_{evap}, T_{evap}+5K)} \qquad \textit{(eq. 3)}$$

$$\dot{W}_{comp}\big|_{\Delta T_{sh}} = \dot{W}_{comp}\big|_{\Delta T_{sh}=5K} \cdot \frac{\rho(p_{evap}, T_{evap}+\Delta T_{sh})}{\rho(p_{evap}, T_{evap}+5K)} \qquad \textit{(eq. 4)}$$

However, part of the electric power absorbed by the compressor is dissipated as heat to the environment. This heat is assumed to be 10% of the total power, and this assumption is taken into account by means of eq. 5:

$$h_2 = h_1 + 0.9 \cdot \frac{\dot{W}_{comp}}{\dot{m}_{refr}} \qquad \textit{(eq. 5)}$$

The refrigerant at point 2 is superheated vapor and enters the condenser. The set of the compressor operating conditions is defined by the envelope, as shown in Fig. 3.

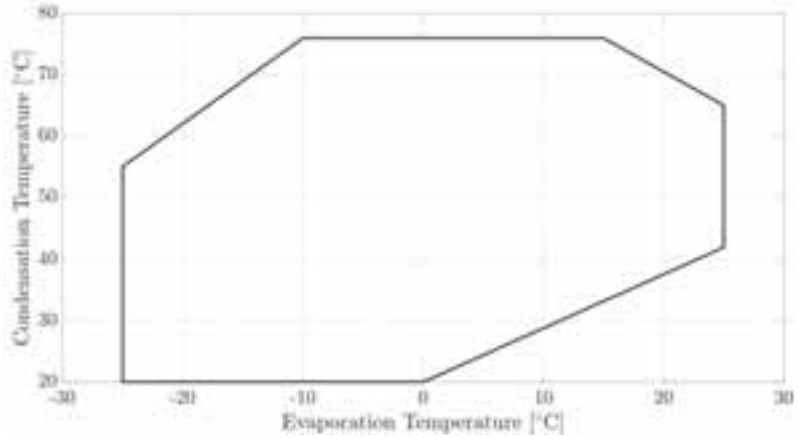

Fig. 3: Operating field of the compressor

3.2. Condenser

The condenser is a plate heat exchanger that transfers heat from the working fluid of the heat pump to the domestic water. This component is modelled by means of the eq. 6:

$$\dot{Q}_{condenser} = \sum_{i=0}^{zones} U_i \cdot A_i \cdot LMTD_i \qquad \textit{(eq. 6)}$$

Where$LMTD_i$ is the logarithmic mean temperature difference of each zone. The condenser is divided into two parts: the de-superheating zone and the condensation zone. Subcooling zone is neglected because of its negligible impact on the condenser's energy balance. For the two modelled sections, thermal transmittance (U) is calculated as the sum of the heat transfer contributions related to the refrigerant fluid, the domestic water and the thickness of the plate between them, as shown in eq. 7.

$$U = \left(\frac{1}{h_{conv,refr}} + \frac{s_{PLATE}}{k_{PLATE}} + \frac{1}{h_{conv,water}}\right)^{-1} \qquad \textit{(eq. 7)}$$

The conductive heat transfer coefficient h_{conv} is determined using the correlation of Kim (Kim, 1999) for single-phase fluids (superheated refrigerant vapor and liquid water) and the modified correlation of Shah (Shah, 1979) for the two-phase refrigerant fluid, as shown in eq. 8 and eq. 9 respectively:

$$Nu = 0.295 \cdot Re^{0.64} \cdot Pr^{0.32} \cdot (\pi/2 - \beta)^{0.09} \qquad \textit{(eq. 8)}$$

$$h_{conv} = \int_0^1 0.2092 \cdot Re_{LS}^{0.78} \cdot Pr_{LS}^{0.33} \cdot \frac{k_{LS}}{D_H} \cdot \left[(1-x)^{0.8} + \frac{3.8 \cdot x^{0.76} \cdot (1-x)^{0.04}}{\left(\frac{p_{SAT}}{p_{CRIT}}\right)^{0.38}}\right] dx \qquad \textit{(eq. 9)}$$

where $Nu = \frac{h_{conv} \cdot D_H}{k}$ is the Nusselt number, $Re = \frac{G \cdot D_H}{\mu}$ is the Reynolds number, $Pr = \frac{\mu \cdot C_p}{k}$ is the Prandtl number, $G = \frac{\dot{m}_{refr}}{N \cdot B \cdot t}$ is the specific flow rate of a single channel, $D_H = 2 \cdot t$ is the hydraulic diameter, $\beta = 65° \cdot \frac{\pi}{180°}$ is the Chevron angle and $N = \frac{N_{condenser}-1}{2}$ is the number of channels for the refrigerant flow. B and t are set as 0.08 m and 0.00205 m. Thermophysical properties are evaluated at mean temperature of the zone for the mono-phase fluids. The two areas of the heat transfer result from the model solution while the overall condenser surface defined at design condition, will be assumed constant in any other operating point, as discussed in next section.

With the aim of enhancing model accuracy, pressure drops are considered. Longo correlation (Longo & Zilio, 2013) is used to represent the physic behavior of the condensation, as shown in eq. 10.

$$\Delta p = \frac{15}{8} \cdot KEV \qquad with\ KEV = \frac{G^2}{2 \cdot \bar{\rho}} \qquad \textit{(eq. 10)}$$

For the de-superheating part, Martin correlation (Martin, 1996) is implemented in eq. 11 and eq. 12.

$$f = \left[\frac{\cos\beta}{\left(0.18 \cdot \tan\beta + 0.36 \cdot \sin\beta + \frac{f_0}{\cos\beta}\right)^{0.5}} + \frac{1-\cos\beta}{(3.8 \cdot f_1)^{0.5}}\right]^{-2} \quad with \begin{cases} \begin{cases} f_0 = \frac{64}{Re} \\ f_1 = \frac{597}{Re} + 3.85 \end{cases} & Re < 2000 \\ \begin{cases} f_0 = (1.8 \cdot log_{10}\, Re - 1.5)^{-2} \\ f_1 = \frac{39}{Re^{0.289}} \end{cases} & Re \geq 2000 \end{cases} \qquad \textit{(eq. 11)}$$

$$\Delta p = f \cdot \frac{L}{D_H} \cdot KEV \qquad \textit{(eq. 12)}$$

3.3. Expansion Valve

The working principle of the expansion valve is described by an isenthalpic transformation, where the refrigerant undergoes a pressure drop with no enthalpy variation. Eq. 13 expresses this behavior:

$$h_4 = h_3 \qquad \textit{(eq. 13)}$$

The task of this component is to maintain a defined superheating of refrigerant vapor at the evaporator outlet to avoid liquid droplets transport inside the compressor. In this paper, a constant superheating of 5K is used.

3.4. Evaporator

This component, similarly to the condenser, is a plate heat exchanger, so it is modelled in a similar way. Evaporation and superheating zones are identified. Tough the superheating section is small in terms of heat transfer rate, it has to be included in order to have an accurate model. The governing equation is:

$$\dot{Q}_{evaporator} = \sum_{i=0}^{zones} U_i \cdot A_i \cdot LMTD_i \qquad \textit{(eq. 14)}$$

Thermal transmittance U is calculated using eq. 7 and the convective heat transfer coefficient h_{conv} is obtained from eq. 8 for single-phase fluids and from Han, Lee and Kim correlation (Han, et al., 2003) for the evaporating refrigerant fluid, as shown in eq. 15.

$$Nu = Ge_1 \cdot Re_{LS}^{Ge_2} \cdot Bo_{eq}^{0.3} \cdot Pr_{LS}^{0.4} \qquad \textit{(eq. 15)}$$

Ge_1 and Ge_2 are functions of the heat exchanger geometry and Bo_{eq} is the boiling number. They can be evaluated as follow:

$$Ge_1 = 2.81 \cdot \left(\frac{P_{COR}}{D_H}\right)^{-0.041} \cdot (\pi/2 - \beta)^{-2.83} \qquad \textit{(eq. 16)}$$

$$Ge_2 = 0.746 \cdot \left(\frac{P_{COR}}{D_H}\right)^{-0.082} \cdot (\pi/2 - \beta)^{0.61} \qquad \textit{(eq. 17)}$$

$$Bo_{eq} = \frac{q_{wall}}{G_{eq} \cdot \Delta h_{L-V}} \qquad \textit{(eq. 18)}$$

where P_{COR} is the corrugation pitch, $q_{wall} = G \cdot (h_{VS} - h_4)$ is the specific thermal power at the wall and $G_{eq} = G \cdot \left[1 - x_4 + x_4 \cdot \left(\frac{\rho_{LS}}{\rho_{VS}}\right)^{0.5}\right]$ is the equivalent specific flow rate of a single channel and x_4 is the fraction of vapor in the refrigerant flow rate at the inlet of the evaporator. In analogy with the condenser, also the evaporation and superheating areas are obtained by solving the analytical model and the total surface of the evaporator is determined at design condition.

To model pressure drop, as condenser the correlation of Martin is used for the superheated vapor. In the evaporation zone, the following correlation is chosen (Longo, et al., 2016).

$$\Delta p = \frac{5}{3} \cdot KEV \qquad \textit{(eq. 19)}$$

3.5. Refrigerant Fluid

The fluid used in the heat pump is R134a and is modelled using lookup tables created starting from the software REFPROP 9.1 (NIST, 2017), which implements equations of state of different compounds. The selected discretization step (1 °C for the temperature, 25 kPa for the pressure and 500 J/kg for the enthalpy) of the tables was selected to guarantee high accuracy while keeping a fast model convergence.

3.6. PV/T Modules

For solar panels, both thermal and electric modeling is needed. Thermal behavior is described by eq. 20, which takes into account optical losses of the glass and of the PV array and convective losses to the environment. Here, radiative losses are linearized with first order temperature differences which is a reasonable assumption considering the low operating temperature.

$$\eta_{th} = \eta_{opt} - a_1 \cdot \frac{(T_{pump,out} + T_{SC,in})/2 - T_{amb}}{G_T} = \frac{\dot{V}_{SC} \cdot \rho_{sc} \cdot c_{SC} \cdot (T_{pump,out} - T_{SC,in})}{G_T \cdot A_{panel} \cdot N_{panels}} \qquad \textit{(eq. 20)}$$

Coefficients η_{opt} and a_1 are obtained from an experimental campaign carried out at SolarTech^{Lab} at Politecnico di Milano between spring and summer of 2017. PV/T modules are roll-bond type, with poly-crystalline solar cells. Tab. 1 summarized the main characteristics of panels used.

Tab. 1: Characteristic of PV/T panels

A_{panel} [m²]	η_{opt}	a_1 [(W/m²)/K]	$\eta_{el,REF}$	$\dot{W}_{REF}$ [W$_p$]	γ [%/K]	$T_{cell,REF}$ [°C]
1.63	0.528	13.658	0.153	250	0.42	56

Electric behavior of PV cells is modelled using the power coefficient approach. The generated power is function of the solar irradiance G and the temperature of the cells (both considered uniform on the panel surface), as shown in eq. 21.

$$\eta_{el} = \eta_{el,REF} \cdot \left[1 + \gamma \cdot \left(T_{cell} - T_{cell,REF}\right)\right] = \frac{\dot{W}_{el}}{G_T \cdot A_{panel} \cdot N_{panels}} \quad \textit{(eq. 21)}$$

where $\eta_{el,REF}$ and $T_{cell,REF}$ are taken from the datasheet of the panel and T_{cell} is evaluated as the mean fluid temperature of the fluid circulating on the panel $\bar{T}_{fluid}$ plus a constant value, which is here assumed equal to 10K.

Pressure drops of PV/T panels are modelled using a polynomial curve of grade two extrapolated from a test done by the manufacturer, as shown in eq. 22.

$$\Delta p_{panel} = 980.9 \cdot \dot{V}_{SC}^2 + 4475 \cdot \dot{V}_{SC} \quad \textit{(eq. 22)}$$

where the volumetric flow rate is expressed in [l/min].

3.7. Hydraulic Loop

Secondary hydraulic loop is considered in the model including a volumetric pump, whose power consumption is modelled as follow:

$$\dot{W}_{pump} = \dot{V}_{SC} \cdot \frac{\Delta p_{sc}}{\eta_{pump}} \quad \textit{(eq. 23)}$$

Pump efficiency is assumed to be constant equal to 15%, a typical value for centrifugal pumps, and the pressure drop is calculated considering the hydraulic circuit, the evaporator and PV/T modules. Tab. 2 summarizes the characteristic of the hydraulic circuit, while eq. 24 shows the modelization of exchanger pressure drops.

Tab. 2: Characteristic of secondary hydraulic circuit

Tubes Length [m]	Losses [Pa/m*(l/min)²]	Volumetric Glycol Fraction (X_{SC})
7	9	0.3

$$\Delta p_{evaporator} = 51570 \cdot \dot{V}_{SC}^2 + 3.229 \cdot \dot{V}_{sc} - 0.2362 \quad \textit{(eq. 24)}$$

where the volumetric flow rate is expressed in [l/min]. However, a fraction of the pump power is dissipated as heat, which produces an increase of temperature of the fluid. This increase is considered by means of the eq. 25.

$$\dot{Q}_{diss,pump} = \dot{V}_{SC} \cdot \Delta p_{SC} \cdot \frac{1-\eta_{pump}}{\eta_{pump}} = \dot{V}_{SC} \cdot \rho_{SC} \cdot c_{SC} \cdot \left(T_{pump.out} - T_{SC,out}\right) \quad \textit{(eq. 25)}$$

4. Model Resolution and Optimization

Equations described in Section 3 are implemented in a MATLAB® code. To resolve the SAHP system, other equations are needed and a design condition must be defined. Firstly, energy balances of each zone of condenser and evaporator and surface balances of heat exchangers are introduced, as shown in the following equations.

$$\dot{m}_{refr} \cdot \left(h_{SV}(T_{cond}) - h_3\right) = U_{cond} \cdot A_{cond} \cdot \frac{\left(T_{cond} - T_{PR,in}\right) - \left(T_{cond} - T_x\right)}{log\frac{T_{cond} - T_{PR,in}}{T_{cond} - T_x}} = \dot{V}_{PR} \cdot \rho_{PR} \cdot c_{PR} \cdot \left(T_x - T_{PR,in}\right) \quad \textit{(eq. 26)}$$

$$\dot{m}_{refr} \cdot \left(h_2 - h_{SV}(T_{cond})\right) = U_{de-sh} \cdot A_{de-sh} \cdot \frac{\left(T_{cond} - T_x\right) - \left(T_2 - T_{PR,out}\right)}{log\frac{T_{cond} - T_x}{T_2 - T_{PR,out}}} = \dot{V}_{PR} \cdot \rho_{PR} \cdot c_{PR} \cdot \left(T_{PR,out} - T_x\right) \quad \textit{(eq. 27)}$$

$$\dot{m}_{refr} \cdot \left(h_{SV}\left(T_{evap}\right) - h_4\right) = U_{evap} \cdot A_{evap} \cdot \frac{\left(T_{SC,out} - T_{evap}\right) - \left(T_y - T_{evap}\right)}{log\frac{T_{SC,out} - T_{evap}}{T_y - T_{evap}}} = \dot{V}_{SC} \cdot \rho_{sc} \cdot c_{SC} \cdot \left(T_{SC,out} - T_y\right) \quad \textit{(eq. 28)}$$

$$\dot{m}_{refr} \cdot \left(h_1 - h_{SV}\left(T_{evap}\right)\right) = U_{sh} \cdot A_{sh} \cdot \frac{\left(T_y - T_{evap}\right) - \left(T_{SC,in} - T_1\right)}{log\frac{T_y - T_{evap}}{T_{SC,in} - T_1}} = \dot{V}_{SC} \cdot \rho_{sc} \cdot c_{SC} \cdot \left(T_y - T_{SC,in}\right) \quad \textit{(eq. 29)}$$

$$A_{condenser} = A_{cond} + A_{de-sh} \quad \textit{(eq. 30)}$$

$$A_{evaporator} = A_{evap} + A_{sh} \quad \textit{(eq. 31)}$$

T_x and T_y are the temperatures of the primary and secondary circuits at which the condensation and evaporation of the refrigerant fluid starts and stops respectively. The design condition determines the total area of the condenser and the evaporator together with the correct number of plates of the two heat exchangers which are determined with an empirical correlation (eq. 32):

$$N_{plates} = 2 \cdot \left\lceil \frac{\left(\frac{\dot{Q}_{HX}}{\dot{Q}_{plate}} + 2\right)}{2} \right\rceil \qquad \textit{(eq. 32)}$$

$\dot{Q}_{plate}$ is the heat exchanged by a single plate, set at 200 W/plate, after a preliminary analysis on different commercial softwares. Finally, $A_{condenser}$, $A_{evaporator}$, and the two $\dot{Q}_{HX}$ are obtained solving the complete model in a standard working condition that is common used to build the datasheet of a water-to-water heat pump. Tab. 3 shows the temperatures of this condition.

Tab. 3: Temperatures at the design condition

T_{evap} [°C]	ΔT_{sh} [K]	$T_{SC,in}$ [°C]	$T_{SC,out}$ [°C]	T_{cond} [°C]	ΔT_{sub} [K]	$T_{PR,in}$ [°C]	$T_{PR,out}$ [°C]
2	5	10	7	50	0	40	45

The model developed is a system of non-linear equations, that can be solved with the function *fsolve* available in the MATLAB® library. Fig. 4 describes the logical steps followed for all the simulations:

- In the first step, geometrical parameters of the evaporator and the condenser are calculated from the design condition. In this situation, T_{evap} and T_{cond} are set, as well as temperatures at the inlet and at the outlet of the heat exchangers and superheating in point 1 and subcooling in point 3 of the refrigerant cycle. All the unknown variables can be explicated and the solver is not required. Solar irradiance and ambient temperature for a fixed number of PV/T modules are a result in this case and their values can be used to do a preliminary evaluation of the energetic feasibility of the system;
- Secondly, *fsolve* function solves the system of equations (that with some passages can be reduced to a system of 5 non-linear equations in 5 variables, which are T_{evap}, T_{cond}, $T_{SC,out}$, A_{evap} and A_{cond}), using as input parameters the solar irradiance and the ambient temperature, which are exogenous variables, and the number of PV/T panels;
- If a solution is found by the solver, a series of physical boundaries are introduced to check the working point feasibility. The following equations explain this approach.

  $$img(solution) \neq 0 \quad \forall\, solution \qquad \textit{(eq. 33)}$$

  $$A_{evap}, A_{cond} > 0 \qquad \textit{(eq. 34)}$$

  $$envelope\left(T_{evap}, T_{cond}\right) = true \qquad \textit{(eq. 35)}$$

  $$T_{SC,out} > T_{freezing}(X_{SC}) \qquad \textit{(eq. 36)}$$

  Constrains are applied after the resolution of the system to avoid solver function failure when an intermediate unfeasible solution is found but the final solution is feasible.

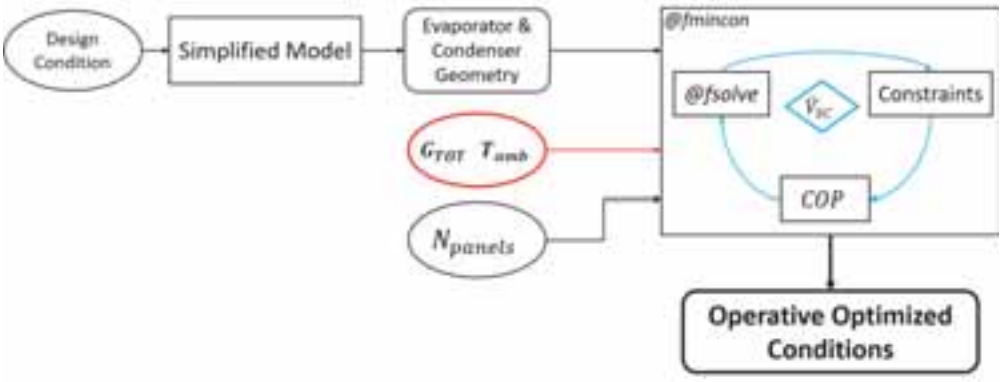

Fig. 4: Explanation of the logical steps followed for a simulation

In addition to the physical model of the SAHP, an optimization tool is used to maximize the performance parameter COP (Coefficient of Performance), which is expressed by eq. 37.

$$COP = \frac{\dot{Q}_{cond}}{\dot{W}_{comp}+\dot{W}_{pump}} \qquad (eq.\ 37)$$

The optimization is done with the function *fmincon* varying the volumetric flow rate $\dot{V}_{SC}$. Another constraint is introduced to implement the behavior of the PV/T panels: the flow rate must be between $0.008\overline{3}$ l/s (0.5 l/min) and $0.0\overline{3}$ l/s (2 l/min) for each line of PV/T panels in parallel to avoid low heat transfer coefficient and too high pressure drops. Fig. 5 is an example that shows the presence of a maximum of the COP in the range previously defined: thermal power at the condenser presents a limited grown, following the grown of the secondary loop flow rate, the electric consumption of the compressor is approximatively constant but the pump consumption increases strongly with a quadratic behavior. The opposite trends result in a maximum of the COP.

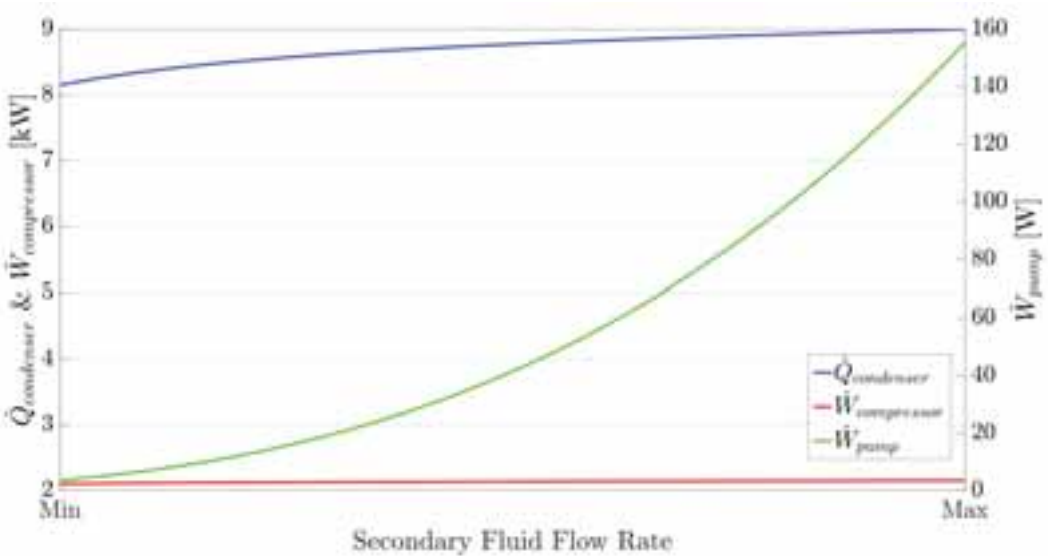

Fig. 5: Explanation of the presence of a maximum of COP as function of secondary fluid flow rate

In the end, Tab. 4 shows the results of the mathematical model obtained in the design condition, which are the same independently of the number of PV/T modules. Tab. 5 shows the solar irradiance needed to produce heat required in the evaporator in the design condition for 12, 16, 20 and 24 PV/T panels respectively.

Tab. 4: Results of the model in the design condition

COP	$\dot{Q}_{condenser}$ [kW]	$A_{PLATE,condenser}$ [m²]	$A_{PLATE,evaporator}$ [m²]	$N_{PLATE,condenser}$	$N_{PLATE,evaporator}$	T_{amb} [°C]
3.19	8.52	0.0258	0.0197	46	36	7

Tab. 5: Solar irradiance required in the design condition with different number of PV/T modules

	12 PV/T	**16 PV/T**	**20 PV/T**	**24 PV/T**
G_T [W/m²]	642.95	494.34	404.55	344.47

5. Results

Starting from the design conditions, the model is used to assess the performance of a SAHP system at different ambient conditions. In particular, solar irradiance was varied between 0 W/m² to 1000 W/m² with steps of 100 W/m², ambient temperature from -20°C to 20°C with steps of 5 °C.

Fig. 6 shows the behavior of the COP as a function of solar irradiance and ambient temperature for a layout with 12 and 24 panels, corresponding to a peak power of the installation of 3 kW_{el} and 6 kW_{el} respectively. As expected, COP increases with the ambient temperature and solar irradiance. The dependency is linear and the influence of solar irradiance is more pronounced than the one the ambient temperature. The case with more PV/T modules has better performance, even though differences are quite limited. In both cases, a non-operating zone is present (blue zone) representing the freezing conditions of the water plus glycol mixture points.

It is important to notice that the system can work also during the night with an acceptable COP (greater than 2). This is possible because of the high a_1 of the PV/T panels that permits to absorb enough energy from the environment (evaporation temperature is lower than the ambient one in these cases) and provide the heat required by the heat pump. This possibility increases the flexibility of the system extending the achievable working conditions to the all day.

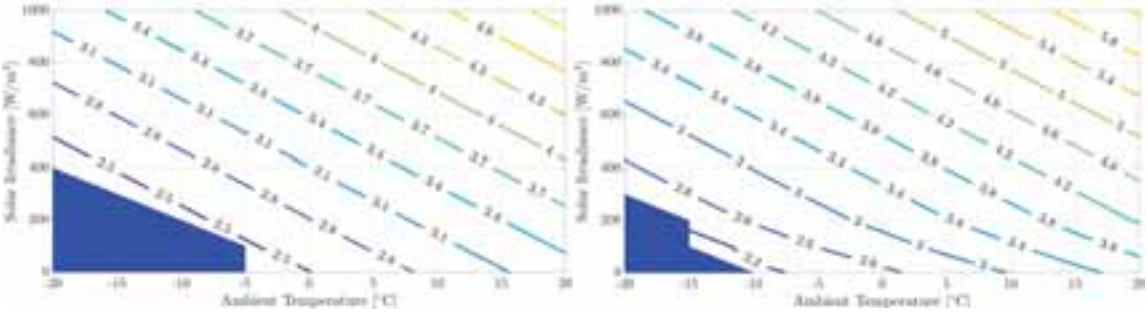

Fig. 6: Representation of COP for an indirect SAHP with 12 (left) and 24 (right) PV/T panels as a function of ambient temperature and solar irradiance

In Fig. 7, the ratio between the electric power produced by the PV/T modules and the power consumption of the HP and circulating pump for 12 (left) and 24 (right) PV/T is reported. When the ratio is greater than 1, the system is energetic self-sufficient, reducing the impact of heat pump consumption on the energetic costs and also the impact of the renewable power production on the national grid: the simultaneous production and consumption by the HP reduces the electricity import/export with respect to a more conventional solution with only PV modules and conventional heating system. In the case with 12 PV/T panels, the energetic self-sufficient condition is reached only with a high solar irradiance (between 600 and 800 W/m²), instead of the case with 24 panels that a lower value is needed, around 200-300 W/m².

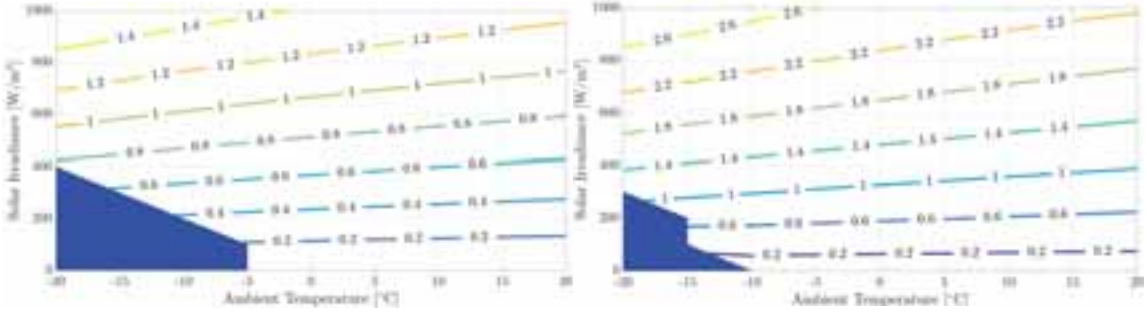

Fig. 7: Representation of the ratio between the electric power produced by PV/T modules and electric consumption of the SAHP with 12 (left) and 24 (right) PV/T panels as a function of ambient temperature and solar irradiance

Fig. 8 presents the advantages of this system with 12 PV/T panels respect of traditional technologies (air heat pump and PV modules). In the left graph, the difference between the inlet temperature of the evaporator and the ambient temperature is shown. It is possible to see that in most cases the temperature of the SAHP heat source is higher than the air temperature, which is the source of the standard air-to-water technology. Therefore, the proposed system improves the HP COP at constant thermal power produced, reducing the operational costs of the

machine. In addition, the typical performance decay of air-to-water heat pumps at ambient temperature below zero as consequence of the frost formation is not present here further increasing the SAHP performance gain.

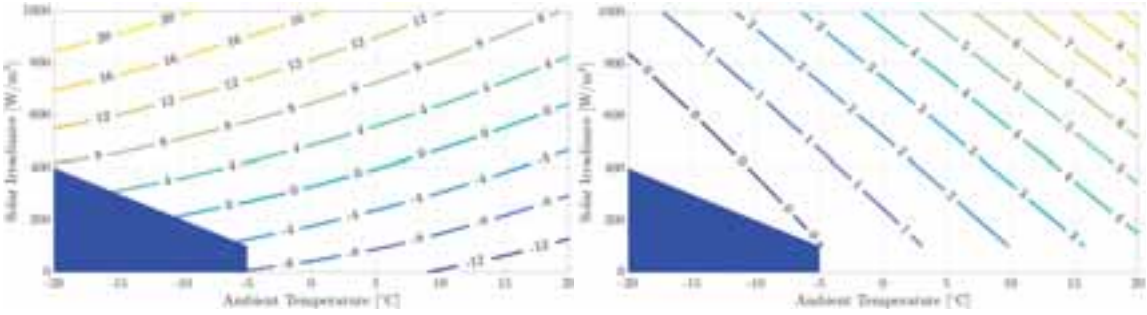

Fig. 8: Representation of the difference between the secondary fluid inlet temperature and the ambient temperature (left) and the increase of electric production of the PV/T modules (right) as functions of ambient temperature and solar irradiance

On the right of Fig. 8 the advantages in terms of electric power production are also reported, outlining the benefits of cooled cells with respect to conventional modules. As it is described in eq. 21, decreasing the temperature of the cell enhances the electric power production at the same solar irradiance. This effect is mainly visible with favorable ambient conditions and the increase reaches 8-9%. The standard PV module used for the comparison has the same peak power of the PV/T module and the power production is evaluated from the NOCT method.

6. Conclusions

In this paper, an analytical model of a solar-assisted heat pump combined with Photovoltaic Thermal modules is developed using the software MATLAB®. Governing equations for the heat pump and characteristic curve of the PV/T modules are identified. The compressor is modelled with polynomial expressions provided by manufacturer as function of the condensation and evaporation temperatures. Condenser and evaporator are discretized in two zones each (de-superheating and condensation the former, evaporation and superheating the latter) and physical behaviors are described by mean of the thermal transmittance U, evaluated using correlations from literature for mono-phase and two-phase heat transfer. The modeling considers also an isenthalpic expansion valve and R134a refrigerant fluid is used. Regarding PV/T modules, thermal and electric power are determined using the characteristic curve and the power method typical of PV technology. Two hydraulic circuits are considered to transfer the heat from the PV/T panels to the evaporator and from the condenser to the thermal load. A mixture of water and glycol is considered in the PV/T loop to prevent freezing phenomena.

MATLAB® *fsolve* function is used to resolve the system of equations related to the SAHP. The sizing of the heat exchangers is performed at design condition that is the same of a standard water-to-water heat pump. An optimization tool is also used to find the optimum operating condition of the whole system accounting for the circulating flow in the PV/T modules. This tool is the *fmincon* function of MATLAB® library. Solar irradiance and ambient temperature are varied to obtain the performance map of the system assuming different number of PV/T panels.

Results show that the COP of the SAHP varies between 2.5 and 4.9 in the case with 12 PV/T panels, and between 2.2 and 6.2 with 24 PV/T modules. The advantage of having more PV/T modules is quite limited in terms of thermal performance, but enlarges the operating conditions of the system (i.e. minimum ambient temperature) and increases the electric production. The study shows that the heat recovered by the PV/T modules is enough to permit the functioning of the heat pump also during the night with an acceptable COP (greater than 2), increasing the flexibility of the system. Other advantages are found regarding the temperature of the cold source respect of an air-to-water heat pump and the electric power production compared to a standard PV panel. For the first case, a higher temperature than the ambient temperature at the inlet of the evaporator is reached in most of the considered conditions. Advantages are even higher when the ambient temperature goes below zero, where a standard air source heat pump suffers of frost formation. Related to the electric production, the present paper shows that a cooled PV/T panel produces more power respect of a non-cooled PV panel, reaching values of 8-9% over referred to the standard production.

Future works will investigate all the advantages pointed out in this paper with experimental campaigns to confirm the results of the model.

Strategies, Policies, and Case Studies for Renewable Heat and Electricity

Huyro Smart Ecological Farm in Peru, an Approach to Sustainability

Miguel Hadzich[1], Sandra Vergara[1] and Juan Pablo Pérez[1]

[1] Pontificia Universidad Católica del Perú, Lima (Perú)

Abstract

The present work shows the results of the Huyro Ecological Farm project during its first 6 years of operation in Cusco, Peru. In an attempt to make it 100% sustainable and self-sufficient, many efforts were made to supply energy, water, communications and even food security within the 3 hectares of tropical wetland land.

This paper presents the evaluation of the sustainability of the project that includes the operation of renewable energy equipment and its validation in the field, in order to create a policy that allows the transfer and commercialization of the technologies used on farm to the community. With the use of the Star of Sustainability method we are able to see, visually and efficiently, the process of sustainability of technological projects.

Keywords: Sustainability, ecological farm, smart farm, evaluation, qualitative methods, solar energy

1. Introduction

The Rural Sector Support Group GRUPO PUCP is an operating unit of the Department of Engineering at the Pontificia Universidad Católica del Perú (PUCP) and has developed several designs and implemented equipment in various areas of Peru. This study considers the results of Huyro Ecological Farm conducted by GRUPO PUCP in Peruvian territory during the last six years.

The Huyro Ecological Farm is a training center dedicated to the development and diffusion of research and application of the appropriate eco technologies or appropriate technologies, complemented by rural tourism focused mainly on agro tourism that generates ecological awareness, change of habits and that drive the self-sufficiency of the population, as well as the preservation of the natural resources of the area. See Fig.1

The ecological farm offers the following benefits to the Peruvian community: It is an educational place to teach students of universities, institutes, schools and general public; a place for research in science and engineering; a reserve of Peruvian biodiversity as guardians of seeds; an example of a self-sufficient and sustainable project with ecological agro industry; Peru's first smart farm with state-of-the-art technology; a model for gastronomy, hotel and tourism projects and finally a model of Scientific Park of Appropriate Technologies that makes it the leader among Innovation Centers in provinces in Peru.

Fig. 1. Photos of the main house and hostel in Huyro Ecological Farm in Cusco.

doi:10.18086/swc.2017.34.01 Available at http://proceedings.ises.org

2. Methodology

Hypothesis

There is a place in the tropical zone of Cusco where you can live using only the kindness of nature, obtaining energy, water, communications with equipment that use renewable energy as a source of energy. Food security is obtained from the processing of fruits and products of the area based on solar energy, achieving a technological, economic, political, social and environmental sustainability of its operation.

Methodology used

The proposed method, Sustainability Star (Hadzich 2014, Ref 1), allows us to analyze the sustainability process of the technology projects that were implemented on the farm during the last 6 years of operation and provides us with a clear view to either decide the continuity of the projects or their cancelation. The Star has 5 tips that analyze the Technological (T), Economic (E), Political (P), Social (S) and Environmental (A) factors which from now own we will refer to as TEPSA (in Spanish). See Fig. 2

Each of these factors includes several aspects within themselves. In TECHNOLOGY we consider aspects such as utility, sustainability, operation, reliability and maintenance; in ECONOMY we consider the income, employment, savings, affordability and innovation; in POLITICS we consider the political interest, the acceptance, legal aspects, promotion and distribution; in SOCIAL we consider the compatibility, motivation, life improvement, participation and capacity; and in ENVIRONMENT we consider the friendliness, climate, pollution, awareness, and health.

We believe it is a good tool to be used in all projects with a technological and political base in their development processes. This method could also be used in other situations where projects have been completed technological base and gives us a good insight to decide the continuation or closure thereof.

SUSTAINABILITY DEVELOPMENT: TEPSA oR 5 E´s

T	Tecnología - Technology	**E**	Engineering
E	Economía - Economics	**E**	Economics
P	Politica - Political	**E**	Ethical
S	Social - Social	**E**	Equity
A	Ambiental - Environmental	**E**	Environment

Fig. 2: Factors of sustainable development in the Sustainability Star

To analyze the index that corresponds to each tip of the Star, a 25 question survey is made, defining the break percentage of the shape. These surveys refer to TECHNOLOGY (utility, sustainability, operation, reliability, maintenance), ECONOMY (income, employment, savings, affordability, innovation), POLITICS (political interest, acceptance, legal, promotion, and distribution), SOCIAL (compatibility, motivation, life improvement, participation and capacity) and ENVIRONMENTAL (friendly, climate, pollution, awareness, and health).

If all surveys questions have positive answers then the star will be perfect without any break, as shown in Fig. 2 and the project will be considered as 100% SUSTAINABLE .

In order to decide the percentage corresponding to each point of the star we use a survey of 25 questions which defines the percentage of the Star Broken. See Fig. 3. Negative responses from the survey will fall inside the star percentage values that indicate the failure of the project in each of TEPSA factors.

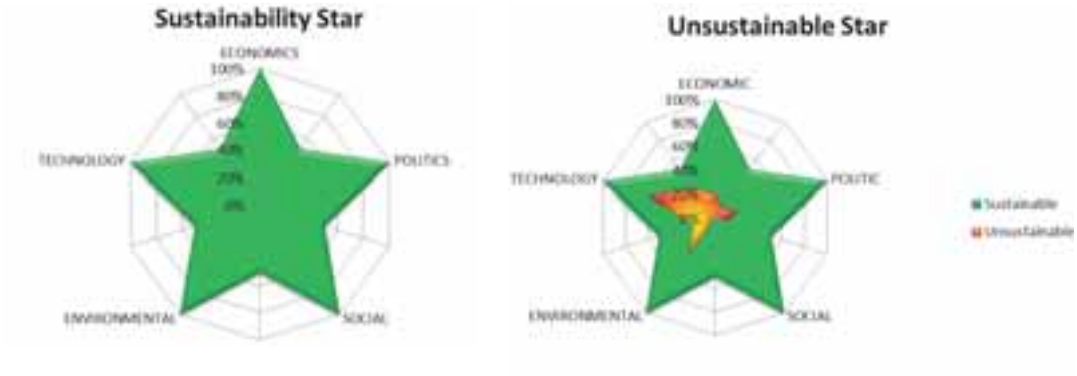

Fig 3: Example of Sustainability Stars – Perfect (left) and Broken (right).

3. Case Studied

The Huyro Ecological Farm is a training center dedicated to the development and diffusion of research and application of appropriate technologies or technologies that use renewable energies, complemented by rural scientific tourism focused mainly on agro tourism.The goal is to generate ecological awareness and change of habits that promote self-sufficiency and self-development of the population of the region, as well as the well care of natural resources.

This centre is a place that has the adequate infrastructure and equipment to be self-sufficient, provides its own electricity and the mechanical forces are obtained from the water, wind and sun sources. It provides its own food with eco farms. To avoid environmental pollution, water and solid waste are recycled and treated in treatment plants. It is a privileged place for demonstrating the operation of GRUPO PUCP technologies and to spread the achievements of the projects that have been developed.

The Huyro Ecological Farm has as its mission: To educate, train and promote awareness and to carry out actions that contribute to the development of sustainable communities. It provides on-site and distance classes, courses, workshops, internships and seminars on the subject of appropriate technologies, renewable energies and organic crops and provides national and international students with an opportunity to study and work voluntarily and learn about techniques for sustainable development.

It has an adequate infrastructure to provide the services required with architecture adapted and respectful to its surroundings; the design includes planned areas, flexible and dynamic spaces to meet educational needs, tourism and recreation in order to assure positive interaction with the environment and effective prevention of the ecological deterioration of the site.

Huyro Ecological Farm is located in Huayopata district, province of La Convención, department of Cusco, Perú, and 3 hours away from the historic Sanctuary of Machu Picchu. See Figs. 4 and 5.

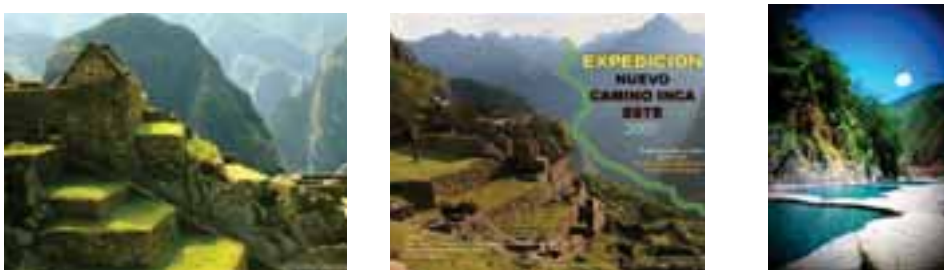

Fig. 4: Photos of Machu Picchu and Thermal Baths in Santa Teresa.

Fig.5: Satellite location of the project regarding Aguas Calientes - Machu Picchu. Google Map or Google Earth.

The technologies used on the farm are being disseminated to the community and the academic world of schools, technological institutes and universities that visit it continuously. See Fig. 6. This interaction of the farm with the visitors enables the products and technologies shown to reach the real world of the communities in need through their free distribution and marketing. GRUPO PUCP carries out the sale and demonstration of the technologies to visitors of the farm making it, both, an educational and commercial place.

Fig. 6: Catalog and Spanish Project of the Huyro Ecological Farm

See Catalog and Complete Project in Spanish in http://miguelhadzich.com/granja-ecologica-huyro/

4. Analysis of the farm's sustainability

The Huyro Ecological Farm obtains profits through training, research, development and transfer of appropriate technologies, volunteering and sustainable tourism. These activities generate economic benefits that can be reinvested to seek maximum profitability and generate the least negative impact. See Fig. 7

Fig. 7: General scheme of the Sustainability and Self-sufficiency of the Huyro Ecological Farm

4.1 TECHNOLOGICAL SUSTAINABILITY

The Farm generates its own energy thanks to the natural resources of the area; it provides its own electricity and its own mechanical forces of the sources of water, wind, sun and biomass using technologies already developed by the GRUPO PUCP in its 25 years of life. All agro-industrial technologies are operating within the farm as a model for visitors and finished products are available for sale.
Each technology is available to interested people through workshop courses that are taught throughout the year. See survey on Technology Sustainability in Fig. 8.

			TECHNOLOGY SUSTAINABILITY	
			Survey about machines or project operation	
	YES	NO		
1.-	x		**Do you tkink that the machine is going to be useful?**	
2.-		x	**Technology (or machine) is constantly being used during the last year?**	
3.-	x		**Do you think the machine can easily operate?**	
4.-		x	**Do you think is a reliable technology?**	
5.-	x		**Do you think that local technicians can repair, copy or modify -all or part- of this machine?**	

Fig. 8: Survey on the Technological Sustainability of the Huyro Ecological Farm

The supply of electric energy is through a hybrid system of photovoltaic panels, hydraulic wheel and connection to the grid. There are 6 photovoltaic panels of 300 Wp each, as well as a hydraulic wheel of 4m in diameter. Water consumption is supplied by 5 different sources: drinking water from the nearby town, water for technical irrigation, water from the springs or rainwater collection and water pumping from the Lucumayo River. Mobile and internet services were installed through a private company. All the waste is recycled and the organic matter is converted into compost and processed in biodigesters.

To generate electricity there are 6 photovoltaic panels of 300 Wp each, with atotal 1.8 kWp, which generate electrical energy with an average solar irradiation of 5.54 kWh / m2 day. There is also a (1) 2.4 m diameter hydraulic wheel that provides 2 kW of electric power at 12 V with an inverter at 220 V AC. In addition, there is (1) Pelton hydraulic turbine of 500 W to 220 V AC. For emergencies, there is an interconnected electrical grid which unfortunately has many fluctuations in voltage (180-230) and causes the machines to fail continuously.

To produce HEAT we have installed: Solar heat pipes and traditional hot water heaters. Hot boxes also provide hot water from firewood improved stoves. The wood used comes from controlled forest and only the surpluses of the largest trees are burned. There are two (2) Scheffler concentrators used for roasting products and cooking food. There are solar dryers both tunnel type (1) and domes (2) for the drying of products.

There are 5 WATER sources: Freshwater that comes from the city located 5 km away through the public network. This service costs US$ 3.00 a month to the board of irrigators. Technical irrigation supplies the farm with water through a 4-inch pipe from Huyro River specifically for sprinkler irrigation. In a future project, water from the Lucumayo River will be pumped to the house located 300 m away from it and at an altitude of 10 meters.. The farm can access water from the springs for flood irrigation. Finally, there is a traditional rainwater harvesting system using filters. For health reasons all water for human consumption has to be boiled.

Due to the good location of the land in relation to the transmission towers, there is a good telephone line service for cell phones and internet connection for which you pay $ 80 per month.

4.2 ECONOMICAL SUSTAINABILITY

Food security is achieved with the products of fruit trees and first need products to supply a family of 5 members. On the farm the following first need products produced are: Corn, sweet potato, cassava, beans, uncucha, potato, etc. Fruits such as oranges, mandarins, lemons, pineapples, avocados, bananas, medlars, raspberries, lucuma, cherimoya, passion fruit, cocoa and wild plants are produced. For controlled firewood trees we have pacae, walnut, tóroc, among others. There are medicinal and aromatic plants such as fennel, lavender, matic, chamomile, coca, tea, coffee, anise, etc. See Fig. 9 annual agricultural calendar of the farm.

The heat for cookers and ovens is obtained from wood from ecologically managed forest. To dry and roast products, solar thermal energy is used through Scheffler concentrators and linear parabolic plants that process coffee and cocoa in an agro-industrial and ecological way to produce solar coffee and chocolate.

Farm products are sold to villagers, such as tea, coffee, chocolate, sugar cane, jams, honey, etc .; souvenirs, books and videos regarding each of the technologies shown are also sold. The sale process is similar to that of the "Tiendecita Verde" of the GRUPO PUCP in Lima.

Internship programs are carried out for students from other countries; this project is carried out through the Field School program of PUCP. Refer to http://fieldschool.pucp.edu.pe/courses/engineering-ecological-technologies-cusco/general-information/#.U441K_l5OSp

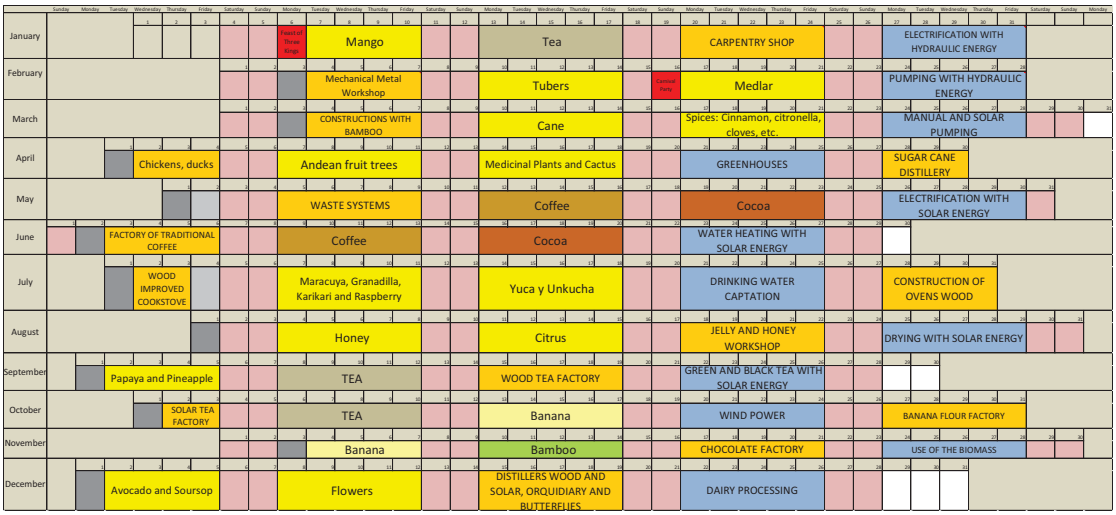

Fig. 9: Annual agricultural calendar of the Huyro Ecological Farm

Ecotourism and educational tourism are promoted for colleges, institutes and universities where GRUPO PUCP technologies installed on the farm are displayed and explained as well as the balanced coexistence between the natural environment and the dwellers. See Fig. 10. Rural ecotourism is promoted through guided tours, birdwatching activities and research projects designed for this type of climatic zones.

Fig. 10: Ecotourism and Training in the Huyro Ecological Farm

				ECONOMIC SUSTAINABILITY	
				Survey about machines and project cost	
	YES		NO		
6.-	x				**Do you see an economic improvement in your life or business when using this technology?**
7.-	x				**It has generated work for someone with the use of this technology in the community?**
8.-	x				**You think that you have saved on fuel or electricity when using this renewable technology?**
9.-			x		**Do you (or your neighbors) purchase or install a similar machine?**
10.-	x				**Do you think that this technology can be produced and sold in your community in the future?**

Fig. 11: Survey on the Economic Sustainability of Huyro Ecological Farm

In order for the farm to start generating more economic incomes that will make it profitable it is necessary to implement a tea factory that complements the existing coffee and chocolate factories. It is also necessary to increase the production of dried local fruits, especially citrus fruits such as orange, lime, grapefruit, mandarin as well as pineapple, mango and banana. See survey on Economical Sustainability in Fig. 11.

In addition, it is necessary to finish the preliminary research on the wild and native plants and implement the current nursery in a more modern and ecological way, using solar energy for thermal effects and laminar flow germinators for in vitro propagation of some endangered species.

For AGROINDUSTRY, there is a solar and coffee chocolate processing plant operating with 1.8 kWp photovoltaic panels that supply roasting machines (0.5 kW motor), a small 300 W refrigerator, (3) small electric motors for grinding - 0.25 kW each- as well as an electric motor of 0.5 kW for the de-pulping of coffee during production times. See Fig.12.

Fig. 12: Photo of the solar coffee and chocolate processing plant

The following figure 13 shows the financial evaluation of the farm project. The recovery time of the investment is calculated in around 9 years, but the farm can start generating incomes since its third year of operation.

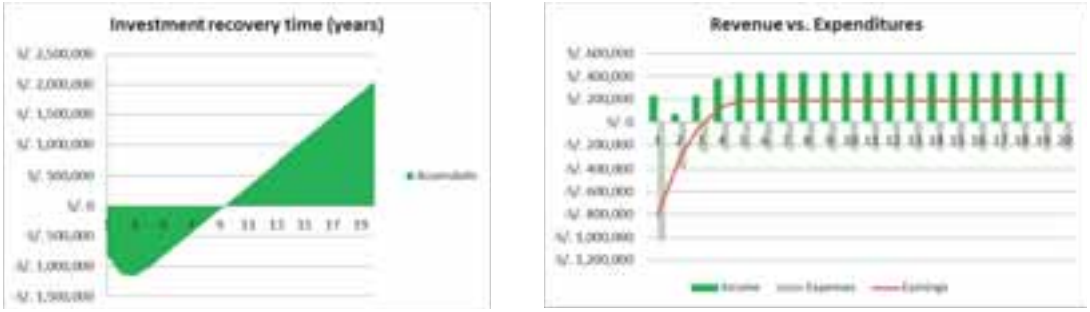

Fig. 13: Financial evaluation of the project

4.3 POLITICAL SUSTAINABILITY

We have a good social relationship with neighbours, as well as with the local and regional authorities. It has the recognition of the Huyro District Municipality and the Huayopata Governorship. See survey on Political Sustainability in Fig. 14.
It fosters an environment of solidary work amongst community residents and project staff.
Work is being carried out with the NGO “Projects Abroad” and with the “Colibrí Association” which also have offices in Huyro to encourage volunteering activities.

			SUSTAINABILITY POLICY	
			Survey on political and organizational project management	
	YES	NO		
11.-		x		**There has been interest in the project or the machine by any political authority?**
12.-	x			**The authorities of the community accept the project? There are requests from the community to some authority?**
13.-	x			**The project complies with the laws and regulations of the community and technical institutions ?**
14.-	x			**Do you believe that the government, person, or institution should promote this technology to other Peruvians?**
15.-	x			**The people of the town know the project?**

Fig. 14: Survey on the Political Sustainability of Huyro Ecological Farm

4.4 SOCIAL SUSTAINABILITY

The technologies developed are easily inserted into the sociocultural environment of the community, promoting development and revaluing local creativity. See survey on Social Sustainability in Fig. 15.

Community participation is sought through projects and activities that are carried out, especially with local schools and colleges. See Fig. 16. We have several projects with students from our own university supported by the Social Responsibility Direction focused on the construction of improved stoves in schools in the area.
We work with local people especially with builders, carpenters and metal mechanics.

			SOCIAL SUSTAINABILITY	
			Survey on the perception of the community about the project	
	YES	NO		
16.-	x			**The project is accepted "normal way" for the community?**
17.-	x			**There is interest in the community or their neighbors for the proposed technology?**
18.-		x		**The project has improved the standard of living of someone in the community ?.**
19.-	x			**The people have participated in some part of the project or activity?**
20.-	x			**There are people in your community with the necessary capabilities for operation and maintenance?**

Fig. 15: Survey on the Social Sustainability of Huyro Ecological Farm

Fig. 16: Visit of universities and colleges of the sector.

4.5 ENVIRONMENTAL SUSTAINABILITY

All systems, whether they are machines or processes, operate with technologies designed to maintain the ecological balance of the place. The use of renewable energy sources is mandatory and essential in all projects. Primarily local resources are responsibly used preserving the flora and fauna of the place making sure it is kept as a pleasant place where you can interact with nature.

All facilities have an environmentally friendly architecture to avoid negative influence in the management of its natural resources. See survey on Environmental Sustainability in Fig. 17.

				ENVIRONMENTAL SUSTAINABILITY	
				Survey on the impact of the project or the machine on the environment	
	YES		NO		
21.-	x				**The project is seen as a friendly environment technology ?**
22.-	x				**You do you think this machine is good for our Earth planet?**
23.-			x		**The project has created some kind of contamination in the environment?**
24.-	x				**Mind that this technology is clean rather than other similar package?**
25.-			x		**The use of this technology affects your health?**

Fig. 17: Survey on the Environmental Sustainability of the Huyro Ecological Farm

5. Conclusions

The Farm Sustainability Assessment shows us a great development in the fields of social, political and environmental components and the weaknesses in the economic and technological factors in which we are in the continuous process of improvement. In the case of the Huyro Ecological Farm, we are on the way to achieve 100% sustainability, but we still need to put a lot more effort to achieve this, especially in the field of food security.

We are aiming at attracting more tourists and environmental researchers so that their stay on the farm is pleasant and instructive. Thus, we plan to install more technologies such as a solar pool, a solar Jacuzzi, a solar tea factory, among others, that will become a model for the introduction of these technologies in the ecological hotels and rural communities of the surrounding areas and eventually be able to spread them throughout the world.

The Huyro Ecological Farm will be fully sustainable from the 9th year of operation. All constructions and technologies installed on the farm will be built by training/teaching local people, volunteers and participating students. We are trying to achieve sustainability through hard work and constancy.

Finally, the following Fig. 18 shows the evolution of sustainability in the Huyro Ecological Farm in the 5 years of existence and the positive advances in the different TEPSA aspects to try to achieve the necessary self-sufficiency and sustainability can be noticed.

Fig. 18: Evolution of the Sustainability of the Huyro Ecological Farm from 2012 to 2017

The proposed methodology for the evaluation of technological projects has proven to be a good tool for decision making, since it allows us to evaluate the results of a project by analyzing it's sustainability.

The evaluation of the sustainability of projects depends not only on technological and economic conditions of the equipment that works with renewable energy but also depends heavily on the social and political situations of the places where these projects are to be implemented.

SUSTAINABILITY ASSESSMENT OF SOLAR THERMAL COLLECTOR SYSTEMS FOR HOT WATER PREPARATION

Harald Kicker[1], Gernot M. Wallner[1] and Reinhold W. Lang[1]

[1] Institute of Polymeric Materials and Testing / Johannes Kepler University, Linz (Austria)

Abstract

Solar thermal collector systems are of high relevance and interest for the supply of low temperature heat for different purposes. Especially, hot water systems are dominating the solar-thermal market with non-pumped systems gaining more and more importance. The main objective of this paper is to assess various small and medium sized solar-thermal collector systems as to their sustainable development metrics. For the assessment a 5-step methodology developed by Ashby et al. (2016) was used. In ecological terms solar thermal hot water preparation significantly contributes to sustainability with energetic amortization times around 1 year. From an economic point of view systems in temperate climate zones for multi-family houses based on conventional metal/glass-collectors exhibit outstanding levelized costs of heat values. In hot climate zones small domestic hot water systems for single family houses fulfill both economic and ecological criteria. For such systems polymeric materials offer a better overall performance and mass production and ease of installation capability. The societal acceptance is high in less industrialized countries, but needs some improvement in industrialized countries, especially for most promising installations in multi-family houses.

Keywords: solar thermal collector; sustainable development; assessment

1. Introduction

Solar thermal collector systems are of high relevance and interest for the supply of low temperature heat for different purposes. Especially, hot water systems are dominating the solar-thermal market with non-pumped systems gaining more and more importance (Mauthner et al., 2016). Alternatives to the small hot water systems are medium-sized combi-systems allowing also for space heating or large systems for district heating and cooling or process heat. The main objective of this paper is to assess various solar-thermal collector systems as to their sustainable development metrics. Special focus is given to solar thermal collector systems for domestic hot water preparation.

2. Methodology and approach

The much-quoted definition of sustainable development by the Brundtland Commission tells: *'Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs'* (The Brundtland Report of the World Council on Economic Development, WCED 1987). But how is sustainable development to be achieved? The definition lacks of concrete guidance how to reach the goals.

Ashby et al. (2016) developed a 5-step analysis methodology for assessing sustainability of complex systems and multi-dimensional problems. The approach is to split the problem into layers and to follow a five-step strategy for assessing. The 5-step analysis includes:

- the definition of the prime objective as well as the size and time scale,
- the identification of the stakeholders,
- the fact-finding step to research both the factual background of the articulations and the validity of the concern expressed by the stakeholder,
- the synthesis of the facts for examination of how the facts influence human, natural and manufactured capital, and

doi:10.18086/swc.2017.34.02 Available at http://proceedings.ises.org

- the reflection step assessing the picture that has emerged and considering priority changes.

For the assessment of solar thermal collector systems for hot water preparation this 5-step methodology was used in this work.

3. Main results and conclusions

The layered approach to assess solar thermal collector systems as to their sustainable development metrics and the key findings are elucidated in the following. Due to the variety of solar thermal systems a special focus is on domestic hot water preparation, which is still the most important field of application. Further solar thermal technologies are currently evaluated.

Step 1: Background information, prime objective and scale

To meet carbon-reduction targets heat generation from renewable sources is of utmost importance. Direct conversion of sunlight via solar thermal collectors has many attractions. Mean solar irradiance varies between 150 and 250 W/m^2 dependent on the world region. In the use phase, solar thermal systems emit negligible CO_2 and they reduce dependence on imported energy. Historically solar thermal has grown at 15% per year for the last 15 years. Worldwide a capacity of 410 GW_{th} was installed corresponding to a total of 586 million m^2 of collector area. The annual collector yield of water-based systems in operation by end of 2014 was about 1.2 exajouls saving about 0.1 gigatonnes of CO_2 (Mauthner et al., 2016). While 2014 about 94% of the energy provided by solar thermal systems was used for domestic hot water, currently a trend to larger solar thermal systems coupled to district heating networks is discernible. Solar thermal at present contributes about 1% to total heat consumption. The potential contribution is much larger. Many national governments seek to realize this potential by offering subsidies and feed-in-tariffs.

In Europe targets for a 20% reduction in carbon emissions by 2020 and an 80% reduction by 2050 were defined. To which extent are these targets achievable by solar thermal? Is it a sustainable development?

Solar heat is intermittent. Most of the solar heat is generated in summer. However, the heating demand is significantly higher in winter. Hence, seasonal storage of heat is required. Economic storage is work-in-progress, yet just rather limited available. Large-scale investment is required. Furthermore, a significant drop in the growth rates of solar thermal are discernible, especially in Europe. Hence, efforts are put on significant cost reductions of solar thermal systems to regain market growth. In this study the focus is on systems for domestic hot water preparation.

Step 2: Stakeholders and their concerns

Contemporary news headlines suggest a range of stakeholders. Many current newslines are dealing with large systems. Only less can be found on the currently most important field of application which is domestic hot water preparation.

- “Drake Landing: A ray of sunshine for solar thermal energy”. Monty Kruger from CBC News posted that 2 or 3 sunny summer days are enough to heat homes throughout cold seasons in Alberta town`s solar community. (CBC News, February 14, 2016).
- “Gigantic Danish Solar Heating System Completed”. The world’s biggest solar heating system, completed in less than a year after signing the contract, consists of 156,694 m^2 of collectors and will provide 20% of the total heat consumption in Silkeborg. (Energy Supply, January 17, 2017).
- “Italy: new subsidy scheme for solar thermal up to 1000 m^2”. Large solar thermal plants will receive an incentive of 55 €/m^2 per year, over a period of 5 years. (solar district heating, February 6, 2013).
- “First Solar Civic Participation Project”. Crowdfunding participation model for solar thermal plants has reached €1.5 Mio. (EuroHeat&Power Industry News, November 2014).
- “Weltgrößter Solarspeicher soll Grazern einheizen”. Günter Pilch and Markus Zotter note that 20% of the district heating demand in Graz could be covered by solar thermal in 2019. (Kleine Zeitung, February 27, 2016).
- “ECREE begins move to exploit solar thermal energy potential in Ghana” The ECOWAS Center for Renewable Energy and Energy Efficiency (ECREE), has began processes to help Ghana exploit the

abundant solar thermal energy potential for domestic and industrial use. (ghanaweb.com, September 26, 2017).

- "The sleeping giant is waking up" Bhoo Thirumalai, the Chief Executive Officer of Aspiration Energy and a solar aficionado, is a busy man these days. For years, the man who co-founded the successful IT company had been trying to rev it up with limited success. But suddenly things seem to be falling in place. (thehindubusinessline.com, August 29, 2017)
- "Clean Energy Isn't Just the Future—It's the Present" Solar power geysers to heat hot water sit on the roofs of a residential shack in the Alexandra township outside Johannesburg, South Africa (Bloomberg, April 19, 2017)

Based on these quotes and the value creation chain of the solar thermal industry the following key stakeholders are suggested:

- Government: Solar thermal could provide a contribution to meeting renewable energy commitments. Government has the power to make it happen through subsidies and feed-in tariffs.
- Heat providers: Solar thermal and large-scale storages allow for the substitution of economically inefficient fossil fuel co-generation plants with the by-product electricity, which is hard to sell economically due to the low electricity market prices.
- Heat system industry: Solar thermal is an interesting alternative in their product portfolio. Some of them already invested in collector manufacturing facilities.
- Collector makers: Many small- or medium-sized collector makers are on the market. Their profit margins are diminishing due to large enterprises established in China offering cheap products mainly for hot water preparation.
- Installers: Current system technologies for hot water preparation or space heating are not easy-to-install. More reliable system designs are needed for small-sized installers. Large-scale systems offer interesting market opportunities for more specialized companies.
- Property owners: They are attracted by subsidies. In some regions solar thermal systems allow for independent hot water supply and improvement in comfort (especially in less industrialized countries).
- NGOs: are campaigning for decentralized, renewable energy to halt climate change.
- R&D: Solar thermal is an attractive research field with open issues (e.g., thermal energy storage; function-oriented design and simulation of systems). Funding for research on solar thermal systems is stimulating.
- Investors: Crowdfunding initiatives are attracting general public. Large-scale systems are of interest for investors. To meet carbon-reduction targets heat generation from renewable sources is of utmost importance.

The relationship between the stakeholders is displayed in Figure 1 reflecting also their specific influence / power and their interests.

Significant concerns for solar thermal heat is that this technology is in many cases to expensive. In contrast to photovoltaic power, there is still a lack of transparency and continuity regarding subsidies for solar thermal collector systems. Furthermore the intermittency of heat generation and the problem that heat storage is seen challenging, especially for domestic hot water systems with high performance collectors and poor performance storages. PV for hot water preparation (supplemented by heat pumps) is supposed by some as the smarter and cheaper solution.

Step 3: Fact-finding

To research the factual background of the articulations and the validity of the concerns expressed by stakeholders a comprehensive approach considering materials, environment, society, economics, legislation and energy issues was used.

In terms of sustainable development the overall question is, if solar collector systems can make a substantial contribution to carbon reduction targets in the next decades. Figure 2 summarizes the issues needing research.

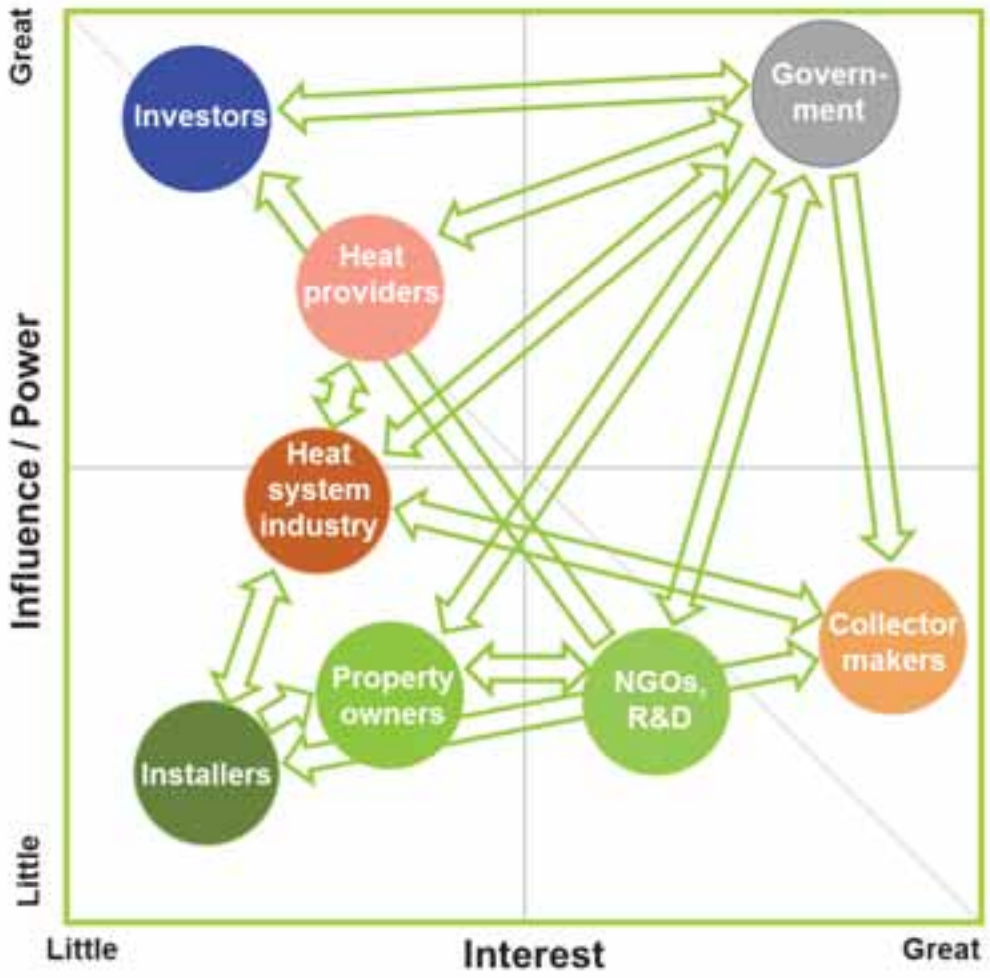

Fig. 1: Stakeholder matrix reflecting their influence and interest.

(a) Materials. State of the art solar thermal collector systems are mainly based on metals like copper, aluminum or steel and silicate glass for the collector, piping and storage. As evident in many other fields of application, a transformation to mass technologies and full market penetration is often associated with a material substitution towards polymeric materials. Interestingly, also for solar thermal systems major research efforts are put on the development of all polymeric collectors, piping and storages. Here, two different approaches are discernible. On the one hand, high performance plastics and related processing technologies are developed for space heating systems. On the other hand, affordable, overheating protected solar thermal collector systems made from commodity polymeric materials are developed. Research work focuses on failsafe overheating protection measures and novel material formulations with improved long term performance in the temperature range between 80 and 95 °C. For both issues adequate solutions have been developed, so that the main issue is now the industrial implementation and transformation (Bradler et al., 2017; Fischer et al., 2016; Grabmann et al., 2016a, 2016b; Geretschläger and Wallner, 2016; Kahlen et al., 2010a, 2010b, 2010c, 2010d; Köhl et al., 2012; Kurzböck et al., 2012; Olivares et al., 2010a, 2010b; Povacz et al., 2014, 2016; Wallner et al., 2016). Therefore, investors and venture capital is needed to successfully implement polymer based alternatives, especially for often poor.

(b) Energy. Mauthner et al. (2016) have shown that the annual collector yield of all water-based solar thermal systems in operation by the end of 2014 worldwide was 335 TWh (= 1,208 PJ) corresponding to a final energy savings equivalent of 36.1million tons of oil and 116.4 million tons of CO_2. 94% of the provided energy by solar thermal collector systems was used for domestic hot water heating. This is dominated by small-scale systems in single-family houses (68%) and larger applications (27%) for multi-family houses, schools, hotels etc. Swimming pool heating adds 4% and 2% of the energy supply and CO_2 reduction is contributed by solar combi systems for

hot water preparation and heating. Regarding hot water preparation the most important issue is to replace electric hot water power systems in less-industrialized countries in sub-tropical and tropical climate zones. So far, no comprehensive investigation has been carried out to which extent this measure could contribute to fossil-based energy savings.

(c) The Environment. It is a well-known fact, that the use of metals, especially aluminum, for solar thermal collector systems has a significantly higher environmental impact than the use of polymeric materials (Arnaoutakis et al., 2017; Battisti and Corrado, 2005; Carlsson et al., 2014; Kicker, 2009; Koroneos and Nanaki, 2012; Singh et al., 2016; Weiss et al., 2015; Zambrana-Vasquez et al., 2015). In case of polymers a worse environmental effect was deduced for high performance polymers compared to commodity plastics such as polyolefins. Nevertheless, solar thermal systems reveal energetic and environmental amortization times ranging from 0.5 to 1.5 years depending on the system type and the location (Buchinger, 2017; Carlsson et al., 2014; Kicker, 2009; Weiß et al., 2015).

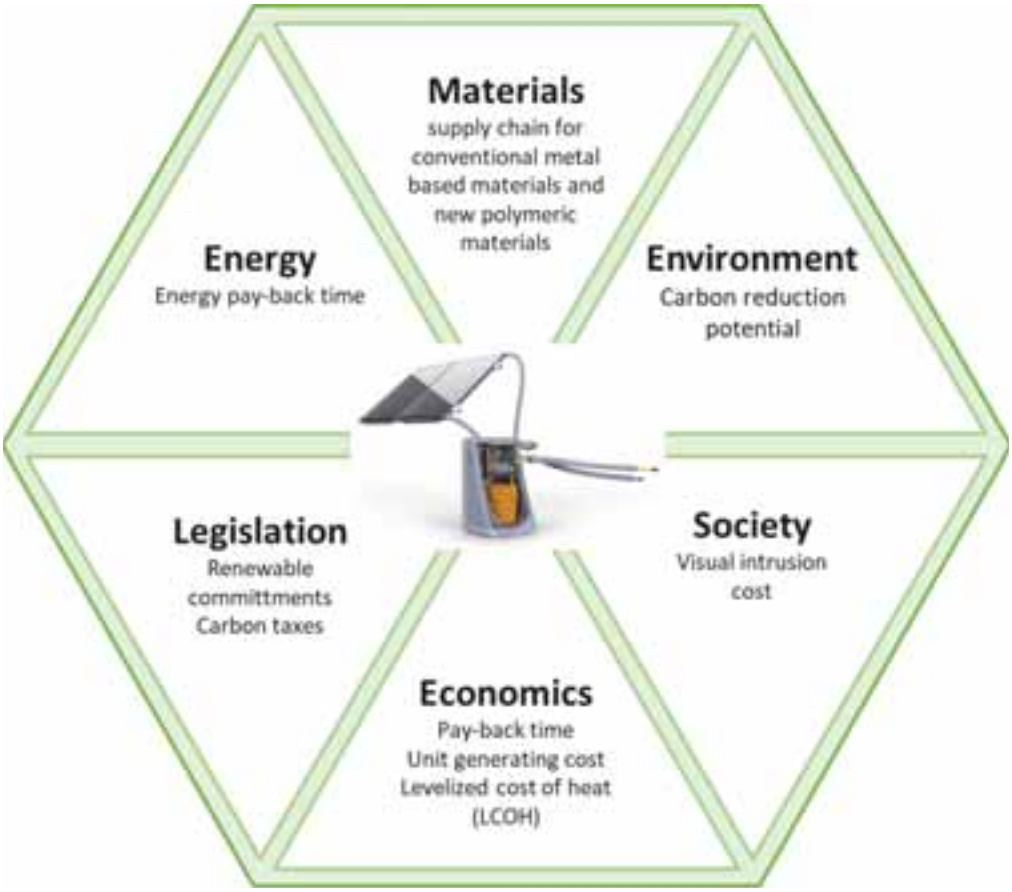

Fig. 2: Fact-finding summary.

(d) Legislation. The production of heat accounts for more than 50% of global final energy consumption. At present 75% of global energy use for heat (129 exajouls) is met with fossil fuels. About 1/3 of global energy-related carbon dioxide emissions (10 gigatonnes of CO_2) is related to the production of heat (Eisentraut and Brown, 2014). In 2015 many nations have agreed to hold global temperatures well below 2°C above pre-industrial levels and to pursue efforts to limit the temperature increase to 1.5°C. This implies that global CO_2 emissions have to peak as soon as possible and that rapid emission reductions must follow (Streck, 2015). This agreement is a clear commitment to a sustainable development. However, this commitment still lacks a regulatory framework and is often not subject to public law. Moreover, current standardization procedures for solar thermal systems are dominated by individual countries and by the copper and glass industry.

(e) Economics. To assess the costs of the heat generated by solar thermal collector systems recently the levelized cost of heat (LCOH) evaluation procedure has been implemented. Important parameters affecting the LCOH are depicted in equation 1. Of significant importance are investment costs, the saved final energy and the lifetime (Fischer, 2017; Louvet et.al, 2017; Mauthner et al., 2016).

$$LCOH = \frac{I_0 - S_0 + \sum_{t=1}^{T} \frac{C_t(1-TR) - DEP_t * TR}{(1+r)^t} - \frac{RV}{(1+r)^T}}{\sum_{t=1}^{T} \frac{E_t}{(1+r)^t}} \qquad \text{(eq. 1)}$$

Where:

$LCOH$: levelized cost of heat in €/kWh
I_0: initial investment in €
S_0: subsidies and incentives in €
C_t: operation and maintenance costs (year t)
TR: corporate tax rate in %
DEP_t: asset depreciation (year t) in €
RV: residual value in €
E_t: saved final energy (year t) in kWh
r: discount rate in %
T: period of analysis in year

Fischer (2017) has shown that the LCOH for conventional, fossil oil based hot water preparation for a single family house (SFH) in Austria amounts to 10 €ct/kWh$_{th}$. The LCOH for conventional, metal based, pumped flat plate collector systems for a single family house are ranging from 12 to 15 €ct/kWh$_{th}$. It is a clear fact that the costs for solar hot water preparation with conventional flat plate collectors in SFH is too high and needs significant reduction. On the other hand, Buchinger (2017) shows that LCOH for an all polymeric pumped flat plate collector system can go down to 2 €ct/kWh$_{th}$, if the performance and the degree of utilization is high, which is especially achieved for small systems in hot climate regions. For thermosiphon systems with evacuated tubes no LCOH figures are currently available. Data are evaluated and established in IEA SHC Task 54.

(f) Society. The news-quotes show that present solar thermal collector systems are widely seen as large-scale installations for district heating. Although the market is dominated by systems for hot water preparation the stakeholders do not recognize this fact. Presumably, the situation is different for China.

For domestic hot water preparation in Europe solar thermal collector systems for single family houses are widely accepted by the public, but seen as much too expensive for an auxiliary source of heat for summer season. In this region solar thermal collectors are commonly replaced by photovoltaic modules and electric heaters. Interestingly, solar thermal hot water preparation for multi-family houses, which is already more economic than fossil based technologies or much more efficient than PV based systems, is of limited acceptance in society. Most likely, the outstanding advantages of this system type have not been communicated to the people, the building developers and the investors.

Due to limited data availability, the fact-finding procedure cannot be concluded at this stage. More comprehensive data sets have to be established especially regarding the overall energy needs for hot water preparation and the fossil fuel and non-renewable electricity substitution potential as well as the levelized costs of heat for the different solarthermal system types and technologies. Hence, the steps 4 and 5 of the sustainability assessment dealing with the “Synthesis of the facts” and the “Reflection step” are carried out and described in a follow-up paper. Further research work is focused on these steps and will also consider other solar thermal system types such as the integration of large collector fields in district heating systems with seasonal storage tanks.

4. Acknowledgements

This research work was performed in the platform project IEA SHC Task 54 “Cost Reduction of Solar Thermal Systems” (www.iea-shc.org). The Austrian participation in the project is funded by the Austrian ministry of traffic, innovation and technology (bmvit).

SOLAR HEATING AND COOLING IN AUSTRALIA'S BUILT ENVIRONMENT – AN INDUSTRY ROADMAP

Marc R. Sheldon[1] and Dr. Subbu Sethuvenkatramam[2]

[1] Coolgaia Pty Ltd, Brisbane, QLD (Australia)

[2] CSIRO Energy Centre, Newcastle, NSW (Australia)

Abstract

The Australian market is simultaneously small and large – 24 million residents live in a country the size of the USA. It has the highest average solar radiation per square metre of any continent in the world. Despite this, solar energy use in 2014-15 represented 0.6 per cent of Australia's total primary energy consumption and 2.4% of electricity production. The energy used by buildings represents about 20% of total energy consumption in Australia, contributing about 26% of national (anthropogenic) greenhouse emissions. Of that energy, on average 40% are used for space conditioning and domestic hot water. This paper will discuss Australia's market for heating and cooling, and how solar heating and cooling (SHC) can be used in Australia's built environment to augment, replace or improve existing heating and cooling technology solutions. Specific opportunities for improving the market uptake of SHC technologies have been identified in the context of declining political appetite for subsidies.

Keywords: solar heating, solar cooling, regulatory, roadmap

1. Introduction

Australia is in a globally unique position. Most of its landmass boasts an annual average solar radiation of more than 19 MJ/m2 per day, overall 58 million petajoules (PJ) per year, nearly 10,000 times the national annual energy consumption. High energy prices, low PV module and inverter costs over recent years in conjunction with a highly competitive market resulted in the highest penetration of household scale distributed solar PV in the world (Australian Energy Council, 2016) with 23.2% of all households owning home solar electric panels (Roy Morgan, 2017). This contrasts with the weakening growth of rooftop solar thermal domestic hot water systems, installed in 10.29% of Australian households (Australian Bureau of Statistics, 2017; Clean Energy Council, 2017).

Despite local R&D and commercialisation of solar thermal hot water systems dating back to 1950s, installations of larger-scale solar thermal systems, both for heating and cooling, continue to be elusive. Unique national market conditions, a changed legislative situation as well as an uncertain political climate has stunted possible market growth in the recent past. This situation is further exacerbated by Australia's range of local conditions - climate zones ranging from temperate to equatorial and arid to tropically humid provide for special challenges. No single solution fits all requirements.

Rising gas and electricity prices have caused stress on the operating budget of various built environment sectors. Solar generated thermal energy is well suited to replace a large extent of fossil fuel based thermal energy used in various built environment applications. Technically mature solar energy solutions are available for delivering thermal energy in the built environment These solutions provide a viable path forward to minimise both energy use and related cost in the built environment.

In this context, we analyse the current SHC market situation in Australia, discuss market barriers for growth and provide suggestions for market-suitable SHC installation types in the built environment. We then advance recommendations for regulatory support measures, financial market stimulation, research and development activities, pilot projects, skills training for trade and consultants and market education. The motivation for this work is to outline a roadmap for the SHC industry to grow and deliver on positive energy and greenhouse gas emissions outcomes for Australia.

2. The Australian Market

The built environment is one of the largest consumers of energy in Australia. While energy use per household has been steadily decreasing since the early 2000s (Coleman, 2017), the overall residential sector energy consumption increased from 402 PJ in 2008 to 441.1 PJ in 2017 (DEWHA, 2008). A key driver is the growth of occupied

doi:10.18086/swc.2017.34.03 Available at http://proceedings.ises.org

residential households and the increasing size of these households. Household numbers increased 6.06 million in 1990 to 9.4 million in 2017, an increase of 55% (DEWHA, 2008). Over the same period, total residential floor area rose from 685 million square metres to 1,564 million square metres, an increase of 128% (DEWHA, 2008).

In comparison, total commercial building energy consumption in Australia grew from 134.6 PJ in 2009 to 159.4 PJ in 2017, a growth of 18.4% principally due to 16% growth in commercial building stock from 135,726,000 m^2 in 2009 to 157,376,000 m^2 in 2020 (Pitt&Sherry, 2012).

In Australia, space conditioning represents the single largest energy user in both the residential and commercial building environment, closely followed by domestic hot water generation (Lecamwasam et al, 2012). In some building types, thermal end use of energy can be even more significant. For example, in hospitals natural gas usage is nearly 50% of total annual energy use, predominantly used for space heating and water heating requirements (Pitt&Sherry, 2012).

Still, the trend of energy use in Australia was more differentiated in the recent past. While overall energy consumption rose, per building energy use in the residential sector declined. Nevertheless, for all buildings the cost of energy increased disproportionally to its use. In the residential sector, per-household consumption of gas grew by only 5.7% from 2008 to 2013, but its expenditure grew by 64% (Coleman, 2017). Similarly, per-household electricity consumption declined by 4.7% and its expenditure grew by 69.3% from 2008 to 2013 (Coleman, 2017). The cost development in the commercial building sector was comparable (Pitt&Sherry, 2012).

From the generation perspective, solar thermal and PV installers have been adding capacities targeting applications in the built environment. The solar PV market grew by 7% in 2016, with small-scale (< 10 kWe) solar PV rooftop systems making up more than 90% of the national installed solar PV generation capacity (Clean Energy Regulator, 2017; Australian PV Institute, 2017). In 2016 the average size of new installed small-scale solar PV rooftop generation surpassed 6 kWe (Australian Energy Council, 2017). Overall, there is more than 5 GW installed Solar PV capacity under the 10 kWe range and 800 MW in the 10 to 100 kWe range.

The domestic Australian solar thermal market also predominantly consists of rooftop solar hot water systems. Spurred by federal and some state subsidies for the installation of solar hot water systems and the national phase-out of electric resistance hot water systems, growth in the solar thermal market was strong through 2010. Despite the marginal growth in installed base, new installations for the domestic solar thermal market declined by more than 60% and continue to shrink (Clean Energy Council, 2017). With an average installed market price of A$4,500, the Australian 2016 rooftop solar hot water market was just under A$223 million p.a. (Table 1 provides annual market figures from Clean Energy Council, 2017).

Table 1: Annual Installations of Solar Hot Water Heaters (Clean Energy Council, 2017)

Year	ACT	NSW	NT	QLD	SA	TAS	VIC	WA	Nat'l	Installed Base
2006										**161,446**
2007	453	8,765	1,414	16,830	2,869	350	9,157	11,139	50,977	**212,423**

Commercial scale solar hot water systems data (available through clean energy regulator) presents a grim picture. Studies commissioned by the Clean Energy Regulator (CER) indicate the number of Small Scale Technology certificates (STC) created for commercial hot water systems is expected to drop from 131,000 in 2016 to 34,000 in 2019 (Parisot, 2017).

Solar thermal cooling is still a niche in Australian built environment, counting less than 20 active installations. With very few exceptions, these installations are demonstration plants, research and development systems or proof-of-concept installations. Despite the more common use of solar thermal air heating in colder climatic conditions (e.g. North America), space heating with solar thermal collectors has not taken off in Australia, likely due to moderate day time temperature in many parts of the country and lack of market awareness of its benefits.

Large-scale solar thermal systems servicing hot water, heating and cooling needs of a commercial built environment application are very few. Discounting the demonstration projects in this space, Table 2 shows typical examples of operational solar assisted heating, cooling and hot water delivery systems operational in Australia.

Table 2: Representative Solar Heating and Cooling projects

Type of installation	Location	Typical system details	Operational since
Hot water / space heating	University building, Australian National University, Canberra, ACT	392 m2 collector area (140 evacuated tube collectors)	2012
Hot water / space heating / boiler preheat	Monash University, Clayton, VIC	1 MWth collector area (evacuated tube collectors)	2017
Space cooling / hot water	Hospital building – Echuca Regional Hospital, VIC	406 m2 collector area (evacuated tube collectors), 500 kWth single stage absorption chiller	2011
Space heating & cooling / hot water	Educational building – Hamilton, NSW	400 m2 collector area (flat plate collectors)	2013

Use of solar electricity for partially meeting the heating, cooling and hot water needs of residential and commercial buildings is achieved through grid connected solar PV installations. However, these systems are not directly coupled to thermal energy use in the buildings. Theoretical studies of using PV integrated air conditioning systems for Australian climates have been explored, but there are no known demonstration systems that are designed specifically to meet the thermal energy needs of a building.

Market Development

The key drivers for continued heating and cooling demand in Australia are overall population and economic growth. Since 2000, Australia's population grew between 1% and 2% annually (Australian Bureau of Statistics, 2017a). Similarly, national GDP growth was always positive and mostly above 2% p.a. in the same timeframe (Reserve Bank of Australia, 2017). With positive economic outlook, this growth is expected to continue. As a result, the overall residential sector energy consumption is forecast to increase to 467 PJ in 2020, the number of occupied households is expected to increase to almost 10 million and aggregate residential floor space to rise to 1,682 million square metres by 2020 (DEWHA 2008). Total commercial building energy consumption is forecast to grow to 169.6 PJ, a growth principally due to an increase in commercial building stock to 165,970,000 square metres in 2020 (Pitt&Sherry, 2012). In both residential and commercial sectors, energy cost is expected to continue to rise disproportionally, outpacing energy use growth significantly (Letts, 2017; Potter and Tillett, 2017; Mountain and Gassem, 2017).

Escalating energy costs will likely continue to be the main driver for end users adopting onsite energy generation options. Declining solar PV system costs will further drive growth in the solar rooftop PV market in Australia. Solar thermal rooftop hot water will face growing competition from alternative technologies.

Heating and Cooling Requirements

Heating and Cooling requirements are substantially different based on building use and the local climate zone of the building. In general, Australian building occupants have a high tolerance for cool buildings in winter and little tolerance for warm buildings in summer. Historically, Australian residential buildings have little insulation and building envelopes that are not air-tight. Minimum energy efficiency standards have been part of the NCC since 2006 and are mandatory for new buildings. Nevertheless, a large proportion of residential and mid-tier commercial building stock uses significant energy for active heating and cooling to reach appropriate occupancy comfort levels. Even new buildings on average have only minimum legally required energy efficiency features, making a functional active heating and cooling system essential for some level of thermal comfort.

The Australian Standard AS5389-2016 *Solar heating and cooling systems— Calculation of energy consumption* nominates 6 climate zones with locations of similar climatic characteristics for the purposes of evaluating the annual energy performance of solar water heaters. Using the modelling from DEWHA, 2008, we derived a representative heating and cooling load range for each zone; the definitions are shown in Table 3.

Table 3: Australian Climate Zones, comfort space conditioning requirements and representative annual residential heating/cooling loads (for NatHERS 3 to 5 star buildings estimated per DEWHA, 2008)

Climate Zone	Space Conditioning Requirements	Representative Heating Load (MJ/m2)	Representative Cooling Load (MJ/m2)
SC1: Warm humid summer, mild winter	Little heating requirements, cooling requirements for 3 to 6 months per year.	20 - 40	150 - 300
SC2: Hot dry summer, warm winter	Heating requirements for 1 to 2 months, cooling requirements for 3 to 6 months per year.	50 - 150	150 - 300

SC3:	**Warm temperate**	Heating requirements for 1 to 2 months, cooling requirements for 1 to 2 months per year.	50 - 180	45 - 150
SC4:	**Mild temperate**	Heating requirements for 3 to 5 months, cooling requirements for 1 to 2 months per year.	280 - 360	30 - 50
SC5:	**Cool temperate to Alpine climate**	Predominant heating requirements, with heating needs for 8+ months per year.	450 - 570	15 - 40
SC6:	**High humidity summer, warm winter**	Predominant cooling requirements for most of the year.	0	400 - 570

Note that climate zone SC6 and SC1 have monsoonal weather patterns, with notable overcast and precipitation during the summer months. For climate zones SC1, SC3 and SC6 the average annual latent load is significantly higher than in the other climate zones. Figure 1 depicts the distribution of the climate zones in Australia.

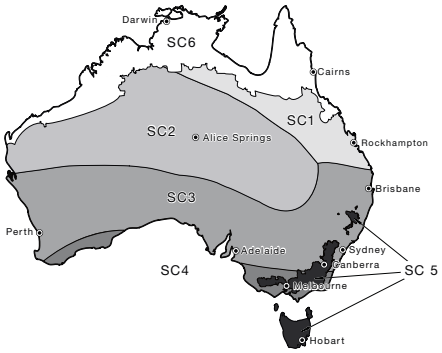

Figure 1: Climate Zones in Australia as per AS5389-2016

Regulatory and other support measures

In line with other countries, Australia introduced several measures to make renewable energy use more affordable. These include state-by-state feed-in tariffs with a subsidised fixed rate for all small-scale renewable energy producers based on the energy fed back to the grid from sources such as solar or wind. All attractive state feed-in tariffs for new installations have been discontinued between 2011 and 2015. There is no current nationalised feed-in tariff, prompting consumers to self-consume onsite generated power.

The federal government also introduced a solar rebate scheme to encourage installation of these systems. The **Renewable Energy Target (RET)** is national government scheme designed to reduce emissions of greenhouse gases in the electricity sector and encourage additional generation of electricity from sustainable and renewable sources. It provides both large-scale generation certificates (LGC) for large-scale power stations and **small-scale technology certificates (STC)** for owners of small-scale systems. Certificates are then purchased by electricity retailers and submitted to the CER to meet the retailers' legal obligations under the Renewable Energy Target. Small-scale technology certificates are created based on the estimated amount of electricity a system produces or replaces (that is, electricity from non-renewable sources) over the life of the renewable energy system.

The **Clean Energy Finance Corporation (CEFC)** is a statutory authority established by the Australian Government under the Clean Energy Finance Corporation Act 2012. It acts as a specialist clean energy financier, investing with commercial rigour to increase the flow of finance into renewable energy, energy efficiency and low emissions technologies. Its investment portfolio ranges from large-scale solar and wind farms to technology-specific research and development activities.

Additionally, there are several national and state programs that encourage energy efficiency in buildings. None of them explicitly nominate the use of renewable energy solutions, but onsite renewable energy generation is an accepted tool to help in improving energy efficiency as per these programs.

On a federal level, the **National Construction Code (NCC) Volume 1, Section J** defines energy efficiency requirements for commercial buildings (class 3 to 9). While it is a national code, it is individually modified and enforced by state law. Section J and the remainder of the NCC mention solar and other renewable energy generation systems only in passing and do not mandate their use. The **National House Energy Ratings Scheme (NatHERS)** is aimed at promoting energy efficiency in residential buildings. A software tool uses defined building characteristics (i.e. climate zone, orientation, building materials etc.) to estimate its annual energy use. Under NCC energy efficiency provisions, every new home or renovation needs to have at least a 6-star NatHERS rating.

The **National Australian Built Environment Rating System (NABERS)** is a national rating system that

measures the environmental performance of Australian commercial buildings and tenancies. It rates buildings according to their measured operational performance over the preceding year pertaining to energy and water use, waste handling and indoor environment. Research suggests that offices with high NABERS Energy ratings tend to offer higher investment returns, whilst offices with low NABERS Energy ratings tend to offer lower investment returns (Slow, 2013).

Relying very much on NABERS is the 2010 **Building Energy Efficiency Disclosure (BEED)** Act, which requires anyone selling or leasing office buildings or space greater than 1,000 m2 to obtain a Building Energy Efficiency Certificate (BEEC). BEECs are only valid for 12 months and include a NABERS Energy for offices star rating. The program, called **Commercial Building Disclosure (CBD)**, aims to improve the energy efficiency of Australia's large office buildings and to ensure prospective buyers and tenants are informed. Since inception, more than 72% of the Australian national office market has received an energy rating (McMahon, 2016). Buildings with at least two consecutive NABERS Energy ratings, demonstrated an average reduction in energy use of 8.7% and a reduction in greenhouse gas emissions of 11.5% (Ernst & Young, 2015). A similar program for the federal government is the **Energy Efficiency in Government Operations (EEGO)** Policy, which aims to reduce the energy consumption of government operations with emphasis on building energy efficiency. EEGO mandates the use of Green Lease Schedules (GLS) to form part of lease documentation (or MOUs where the Government owns the building). GLS are designed to ensure that buildings are operated at the required level of energy efficiency, including a required minimum 4.5 stars NABERS Energy for Based Building rating. Contractual language in the GLS is usually coached in “best effort” terms, with little recourse for the tenant in case of a breach of the energy efficiency terms. All state governments in Australia except for Tasmania have similar requirements, at minimum 4.5 stars NABERS Energy for offices rating for all new buildings and fitouts and at minimum 3.5 stars for existing buildings and fitouts.

In addition, some states and municipal governments provide local incentives and funding schemes to drive building energy efficiency and the use of renewable energies. Amongst these are Environmental Upgrade Agreements (EUAs) in New South Wales and in Melbourne – called 1,200 Buildings in Victoria, the Energy Savings Scheme in New South Wales, Victorian Energy Upgrade, ACTSmart Business Energy and Water Program in Canberra, Energy Savers in Queensland and the South Australian Energy Productivity Program. Furthermore, most state electricity utilities have programs with funding for provable peak demand reduction projects, demand management projects and renewable energy buyback schemes. The extent and funding depth varies with each project; Energex offers up to $185 per kW peak demand savings in select supply areas (Energex, 2017).

Outside of government measures, the Green Building Council of Australia (GBCA) manages the **Green Star** rating system, a voluntary sustainability rating system for buildings in Australia. It assesses the sustainability of building projects at all stages of the life cycle. Ratings can be achieved in the planning phase for communities, during design, construction or fit out of buildings, or during the ongoing operational phase and range from one star (minimum practice) to three star (good practice) and six star (world leadership). Energy-efficiency outcomes for Green Star rated buildings are good with 66% less electricity use and 62% fewer greenhouse gas emissions than average Australian buildings (Green Building Council of Australia, 2013), the rated buildings tend to be Premium and Grade A buildings (Ernst & Young, 2015), with limited investment going to the mid-tier market. This market makes up more 50% of the Australian commercial office stock (Ernst & Young, 2015) and is typically comprised predominantly of smaller buildings, often better suited for solar energy use due to a larger proportion of roof space to lettable floor space.

AS5389-2016 (draft) is another initiative to encourage adoption of solar heating and cooling systems in buildings. This draft standard provides an approach for estimating energy consumption of solar heating and cooling systems for receiving government support such as STCs.

Australia ratified the Paris climate agreement committing to achieve 26–28% reduction in greenhouse gas emissions below 2005 levels by 2030. CSIRO’s low emissions technology roadmap advocates fuel switching as one of the options to achieve deep cuts in emissions from the built environment that can help in achieving the 2030 emission reduction targets. In the context of the RET being phased out by 2030, an alternate policy landscape to specifically encourage renewable energy use in the built environment is unclear.

3. Market Barriers / Challenges

The authors of this paper interviewed various stakeholders related to the use of solar heating and cooling technologies in the built environment. This included representatives from the building industry, solar equipment

manufacturers, HVAC contractors, consultants and entities dealing with regulatory bodies. A summary of findings from these discussions are provided below.

Initial Cost

Due to Australia's small market size, local production of complex solar heating and cooling components is limited. Importing such equipment results in a relatively large logistics costs due to the distance from the manufacturing countries. This is further exacerbated by limited experience of consulting engineers, contractors and installers with new, custom designed SHC installations. To mitigate potential risks, these projects are often quoted with high risk margins that make them financially nonviable.

A necessary optimisation or retrofit of a heating or cooling delivery system is often fruitful ground for the introduction of renewable energy systems. While a suitable SHC application with attractive payback periods might be a good fit, consultants and system designers often lack the required knowledge and resources (e.g. a design and optimisation tool) to help them identify such introduction opportunities.

Stakeholders are often not aware of appropriate local, regional or federal energy efficiency programs as outlined above. Bureaucratic hurdles to participate in these programs can also be too onerous for the program to be useful, resulting in unused funds which could offset some of the high initial costs.

Lack of awareness of benefits & unrealistic expectations

While there is strong general interest in renewable energy technologies, most of the stakeholders including architects, engineers and building owners do not have sufficient information on capabilities and benefits of solar generated thermal energy and its use in the built environment. Consequently, SHC solutions are either not considered for a project, or poorly planned and designed. These badly designed and commissioned systems bring a negative reputation to the technology, further limiting market growth.

Unrealistic expectations also bring negative reputation to the technology. These expectations range from an expected payback of less than two years, delivery of complete comfort during all periods of the day to maintenance free operation and more. Oftentimes the end-users would not have had similar expectations on the incumbent technology and may be more forgiving for any performance deficiencies of the incumbent technology.

Inexperienced and untrained consultants and trade

SHC systems are not covered in the standard training repertoire of architects, engineers and installers. As a result, a commercial building may be designed such that any inclusion of SHC technologies may result in expensive variations or site preparation costs. This is compounded by the limited number of component suppliers and installers.

Consultant fee models are often predicated on providing standard systems design with only small variations. The business model does not allow for providing a bespoke solution capable of leveraging SHC technology for the best outcome. In addition, most engineers and installers are unsure of the correct use of the technology and inflate the costing of the project to tackle "unknown" risks.

Technical and financial risks

Project owners are often worried about the risks associated with SHC technology installations. These risks can be related to performance, maintenance or the commercial benefits. Negative risk perception is fueled by the lack of suitable local reference installations and access to historical data. Badly designed and underperforming SHC deployments add to this perception. Finally, specialized international SHC vendors often approach the Australian market with insufficient focus and funds, partnering with small, local companies for commercial representation. These small companies do not have the reliability of major vendors, resulting in real execution risk with the associated risk of losing warranty and maintenance options if such a small company were to change direction or enter liquidation.

Split Incentives

Not unique to solar generated thermal energy systems, split incentives are a barrier to the high initial deployment cost of any energy efficiency measures in buildings. So far, the additional capital cost of an SHC installation is not always offset by a commensurate increase in sales or lease price. The tenant or final building operator would reap the rewards of the efficiency measure and the entity making the capital investment would have foregone possible higher profits. Given the higher initial cost of SHC systems, split incentives result in landlords often not not motivated to install such systems in their buildings.

Alternative Technology advancements

New technology innovations disrupt the current technology development and diminish the unique benefits provided by solar thermal heating and cooling solutions. An example is the slowdown in the rooftop solar thermal market due to the decline of PV prices. In residential applications, home owners often prefer a single solar energy collection technology meeting their energy needs rather than dealing with two sets of system installers and technologies. The potentially higher installation cost (labour) of a solar thermal system could be the further differentiator between the installed cost of a solar PV system and a solar thermal system. More disruption potential can be expected from the maturing of electrical storage (so that it becomes competitive with thermal storage) and a potential reduction in price of high efficiency heat pump systems.

4. Opportunities

Solar thermal generated energy for active use in the built environment is available in several forms:

- Solar Thermal driven Absorption/Adsorption Chillers – using heat from solar thermal collectors (flat plate, evacuated tube, concentrating) to drive absorption chillers (LiBr/Water, NH_3/Water, Zeolite/Water, Silica Gel/Water etc.)
- Solar Thermal driven Desiccant Chillers – using heat from solar thermal collectors (flat plate, evacuated tube, concentrating) to drive desiccant chillers (solid or liquid)
- Solar Thermal Heating Hot Water and/or Domestic Hot Water – using heat from solar thermal collectors (flat plate, evacuated tube, concentrating) to generate hot water, either for heating hot water (HHW) or for domestic hot water (DHW)
- Solar PV assisted high-efficiency chillers – using electricity generated from solar PV to drive high-efficiency chillers
- Solar PV assisted high-efficiency heat pump – using electricity generated from solar PV to drive high-efficiency heat pumps to generate HHW or DHW

Ongoing research has been conducted into the cost comparison of solar thermal, solar PV assisted thermal energy generation and conventional heating and cooling. The more rapid change in PV pricing as compared to the components of solar thermal cooling systems make PV-assisted cooling systems increasingly viable alternatives to solar thermal cooling and substantially improve the financials of a deployed system (Otanicar et al, 2012; Kohlenbach and Dennis, 2010; Greenaway and Kohlenbach, 2016). As current representative residential electricity prices continue increasing, the financial performance and ROI of both solar thermal and solar PV-assisted cooling systems will also become more attractive.

Small-scale solar thermal HHW and DHW systems compare well financially to gas or standard heat-pump systems. Solar PV-assisted high-efficiency heat pumps (Mayekawa, 2017; Sanden, 2017) provide a very competitive alternative for HHW and DHW systems, even for medium-sized HHW and DHW requirements. In medium-sized and larger deployments, solar thermal HHW and DHW systems are also financially attractive (Witts, 2017).

Not all situations provide a good fit for solar thermal generated energy. Smaller-scale deployments result in a disproportionately expensive solar thermal driven cooling system. For cooling needs of 20 kWth or less and standard residential or commercial office requirements, there are few criteria to make such a system cost-competitive with a small-scale split system air conditioner or a solar PV-assisted split system air conditioner.

Beyond the need for sufficient annual solar radiation, the essential criteria for the fit of solar generated thermal energy to a buildings heating and cooling needs are:

- Appropriately located available roof space
- Diurnal load match (more than 50% of thermal energy used should be during average daytime hours)
- Annual combined thermal needs (heating in winter, cooling in summer) or significant all-year heating or cooling needs, overall more than 200 $MJ/m^2/a$
- Combined domestic hot water and heating/cooling loads to maximise utilisation

For the purposes of this analysis, we used building classifications following those of the Australian National Construction Code (NCC).

Table 4 summarises the findings, highlighting cost-efficient suitability for solar thermal energy use for providing heating, cooling and domestic hot water by colour; comfort tolerance was classified as the willingness of the building occupants to tolerate building temperatures marginally outside the generally accepted temperature set points of 21°C to 24°C. Green symbolises a good fit, orange an average fit and red highlights a likely bad fit.

Table 4: Australian Built Environment, space conditioning, hot water requirements and market information (estimated as per DEWHA, 2008; Pitt&Sherry, 2012; Goldsworthy and Sethuvenkatraman, 2016)

Application	Residential	School	Universities & VET	Office	Public buildings	Hotel	Restaurant	Retail			Hospital

In a country the size of Australia, climate Zones are a vital decision criteria to deploy a system using solar generated thermal energy, i.e. monsoonal high cloud cover during summer months in SC1 (and parts of SC6) is likely to result in low solar yield. Similarly, solar heat driven desiccant chillers will have limited value in SC2 because of predominantly arid summers.

Every project is different and requires specific adjustment. Nevertheless, in addition to the above essential criteria for deploying solar generated thermal energy systems in Australia we believe sizeable opportunities exist with deployments outlined in Table 5[1].

Table 5: Opportunities for deployment of solar generated thermal energy systems in the built environment in Australia

Climate Zone		Residential	School	Universities & VET	Office	Public buildings	Hotel	Restaurant	Retail	Hospital
SC1	Heat	◆◆ / ■■/ ▲▲	◆ / ▲				▲▲▲ / ◆◆◆	(▲ / ◆)[2]		◆◆◆ / ▲▲▲
	Cool	△△	△ / (◇)[3]	◇◇◇ / (△△)[4]	□□ / (△△)[4]	□□ / ◇◇ / (△△)[4]	□ / ◇ / (△△)[4]	(△)[2]	□□ / (△△)[4]	◇◇◇
SC2	Heat	◆◆ / ■■/ ▲▲	◆ / ■/ ▲	■■	■■	■■	▲▲▲ / ◆◆◆	(▲ / ◆)[2]		◆◆◆ / ▲▲▲
	Cool	△△	△	(△△)[4]	□□ / (△△)[4]	□□ / ◇◇ / (△△)[4]	□ / ◇ / (△△)[4]	(△)[2]		

[1] Solar generated thermal energy use in SC6 will need to be evaluated on a case-by-case basis and will likely represent marginal cases
[2] Not a good diurnal load match; for worthwhile deployments, requires daytime usage.
[3] Dependent on fresh air requirements and latent load
[4] For smaller deployments

SC3	Heat	◆◆ / ■■/ ▲▲	◆ / ■/ ▲	(■■)	(■■)	(■■)	▲▲▲ / ◆◆◆ / (■■)[1]	(▲ / ◆ / ■)[2]	(■■)[1]	◆◆◆ / ▲▲▲ / (■■■)[1]
	Cool	△△	△ / (◇)[3]	(◇◇◇)[1] / (△△)[4]	□□ / (△△)[4]	□□ / ◇◇ / (△△)[4]	□ / ◇ / (△△)[4]	(△)[2]	(□□) / (△△)[4]	(◇◇◇)[1]
SC4	Heat	◆◆ / ■■/ ▲▲	◆ / ■/ ▲	■■■	(■■■)	■■■	▲▲▲ / ◆◆◆ / ■■■	(▲ / ◆ / ■)[2]	■■	◆◆◆ / ▲▲▲ / ■■■
	Cool	△△	△	(△△)[4]	(△△)[4]	(△△)[4]	(△△)[4]	(△)[2, 4]		
SC5	Heat	◆◆ / ■■	◆ / ■■	■■	(■■)	■■	◆◆ / ■■	(◆ / ■)[2]	■■	◆◆ / ■■
	Cool			□ / △						□
SC6	Heat	◆◆ / ■■/ ▲▲	◆ / ■/ ▲				▲▲▲ / ◆◆◆	(▲ / ◆)[2]		◆◆◆ / ▲▲▲
	Cool	△△	△ / (◇)[3]	◇◇◇ / (△△)[4]	(△△)[4]	(△△)[4]	(△△)[4]	(△)[2,4]	□□ / (△△)[4]	◇◇

▲: Solar Domestic Hot Water - solar PV, high efficiency heat pump, tank, optionally with reverse cycle air conditioner for space heating

◆: Solar Domestic Hot Water - solar thermal collectors, tank

■: Solar Heating and Domestic Hot Water - solar thermal collectors, tank

□: Solar Thermal Cooling AB - solar thermal collectors, tank, thermal (absorption, adsorption) chiller

◇: Solar Thermal Cooling DES - solar thermal collectors, tank, desiccant systems

△: Solar PV Cooling - solar PV, high efficiency vapour compression chiller

As solar energy is an intermittent energy source, backup and possibly storage will be needed to guarantee the intended service during all periods of the day in a year.

5. Recommendations

To address the market barriers and enable local and international heating and cooling industry to better address the Australian market, we recommend a three-pronged approach:

Regulate	Support	Inform
Standardisation / Best Practice design – extend AS5389	Environment Upgrade Agreements (EUA)	Training/Knowledge dissemination
	On-Bill Finance	Pilot projects
	Energy Performance Contracts (EPCs) / Energy Services Companies (ESCOs)	

Regulate - Standardisation / Best Practice design

We recommend a project for documenting global best practice for a modular design of a solar thermal heating/cooling system for use in Australia. It needs to provide for options for different collector technologies (flat plate, evacuated tube, concentrating), optional different chiller technologies (absorption / adsorption / desiccant / none), optional HHW and optional DHW systems. Integration into existing systems also needs to be addressed (i.e. utilising existing air handling units, providing boiler pre-heat etc.). Standardisation of solar thermal system design for a given application has the potential to address many of the barriers discussed above:

- Has the potential to lower the initial cost of the system by reducing the design and installation time.
- Increases confidence of various stakeholders in the value chain to move ahead with implementing solar thermal projects.
- Supports the development of components and equipment associated with the technology and helps in improving the availability of local components rather than importing.

This activity must be firmly supported by regulatory means that help in estimation of energy savings from the standardized designs. Extension of AS5389 to incorporate various solar heating and cooling technologies is one typical example. Additionally, efforts should be directed towards developing best practice design documents that can be used by installers (e.g. Master Plumbers' and Mechanical Services Association of Australia and Sustainability Victoria, 2009)

Support

We believe there are various renewable energy support mechanisms already available for large scale utilisation. However, some of the following approaches have been largely overlooked or not yet deployed consistently across Australia. We suggest a reinvigorated approach towards these policies.

[1] For parts of climate zone as per requirements

Environmental Upgrade Agreement (EUA)

An Environmental Upgrade Agreements (EUA) is a contractual agreement between a building owner, a finance provider and a local council. The building owner agrees to undertake environmental upgrades to their building and the finance provider agrees to advance capital to the building owner to fund the works. The money is repaid to the lender through council rates. This environmental upgrade charge is collected quarterly as a line item on top of the normal council rates. Once payments are completed, the building owner owns all capital equipment covered by the agreement, i.e. it is a balance sheet item.

As such it allows a building owner to access capital at a better rate over a longer term than a conventional bank loan. EUAs also allow some of the costs of the upgrade to be shared with tenants, where the tenant also benefits from the cost saving delivered by the upgrade. Furthermore, it minimizes financial risk to the lender, as the loan is attached to the land/property.

EUAs are currently only available in Victoria (Department of Energy, Land, Water and Planning, 2015) and New South Wales (Office of Environment & Heritage, 2016). Extending these agreements and consolidating their contractual structure, commercial and technical prerequisites based on the above best practice design would remove financial risk and at least partially address the problem of split incentives for retrofits of buildings.

Support - On-Bill Finance

On-bill financing is an alternative way of obtaining access to capital to fund building energy efficiency upgrades, where repayments are made through an electricity utility as part of the energy bill. The energy utility will typically aim to make the monthly payments equal to or less than the energy savings achieved through the upgrade works. Here as well, building owners can access capital at a better rate over a longer term than a conventional bank loan and costs can be shared with tenants, lowering financial risk and mitigating split incentives. In Australia, On-bill financing is currently offered by AGL and Origin Energy for medium to large customers only (Office of Environment & Heritage, 2016a). On completion of payments, the building owner owns all capital equipment covered by the contract, i.e. it is a balance sheet item. We recommend extending standard demand-management practices of all electricity utilities to include on-bill financing for solar generated thermal energy projects, adhering to the above standards and leveraging the best practice design to mitigate technical risk.

Support - Energy Performance Contracts (EPCs) / Energy Services Companies (ESCOs)

Already established in Australia, Energy Performance Contracting (EPC) is when an Energy Service Company (ESCO) is engaged to improve the energy efficiency of a facility, with the guaranteed energy savings paying for the capital investment required to implement improvements. Under a performance contract for energy saving, the ESCO implements and operates the project and guarantees cost savings over an agreed term, lowering financial and technical risk. We recommend working with reputable national and international ESCOs to extend their offering to include solar generated thermal energy projects in Australia, leveraging EUAs, On-bill Financing and the best practice design. Quick wins could be had by integrating an ESCO-operated solar thermal component into a district cooling system such as the CitySmart Brisbane project.

Inform - Training/Knowledge dissemination

Solar generated thermal heating and cooling technology and the relevant design and installation criteria need to be integrated into the standard University and Vocational Education and Training (VET) curriculum for architects, engineers and trades. To this end, the best practice design document needs to become part of the respective curricula and a continued professional development training program needs to be instituted in close cooperation with the relevant industry bodies (Australian Institute of Architects, Australian Institute of Refrigeration, Air Conditioning and Heating). Once implemented, it will reduce technical risk and facilitate that solar generated thermal heating and cooling systems can be designed, built, commissioned and operated by anyone in the industry.

Inform – Pilot Projects

Australia is not home to any commercial large-scale solar thermal cooling projects. We recommend using the outlined Regulate, Support and Inform recommendations to initiate showcase commercial solar generated thermal energy projects with the CEFC acting as a cornerstone investor working with proven national or international industry operators with appropriate and demonstrated experience. This includes adding solar thermal generated thermal energy options to district level heating/cooling infrastructure in early or late planning stages, such as the district cooling system to service downtown Brisbane (Citysmart, 2016).

We believe that if acted upon soon, these recommendations will enable Australia to build a thriving local market

for solar generated thermal energy systems, saving energy, greenhouse gases and money for all stakeholders in its built environment.

6. Acknowledgments

The authors wish to acknowledge the Australian Renewable Energy Agency (ARENA) for funds received through the Promoting Use of Solar Cooling and Heating in Australia (PUSCH) project.

On the Economics of Solar Chemical Processes – Case Study for Solar-Co-Production of Methanol and Power

Henrik von Storch[1], Martin Roeb[2], Hannes Stadler[1], Christian Sattler[2], Bernhard Hoffschmidt[2]

[1] German Aerospace Center (DLR), Jülich (Germany)

[2] German Aerospace Center (DLR), Cologne (Germany)

Abstract

In several studies, the efficiency of solarized industrial processes was assessed and showed promising results. However, the economic competitiveness of such processes is a mainly unanswered question. In this work, the economic performance of a solar aided methanol production process is determined. The assessment yields promising results for the considered co-production process. The presented results also show that for a penetration of renewable energies beyond electricity production, the common support model of fixed feed-in-tariffs is not suitable. A reasonable cost for CO_2 emissions or reward for their reduction will allow finding the most economic application for renewable energies independent of the end product of the process. When reasonable rewards of 75 $/t_{CO2}$ for the reduction of CO_2 emissions compared to fossil reference processes are considered, the process can produce methanol and electricity at competitive prices.

Keywords: Solar thermochemistry, CSP, solar fuels, reforming, economics

1. Introduction

The necessity to reduce greenhouse gas emissions by substituting fossil energy carriers by renewable energy sources such as solar- and wind energy is widely accepted and ongoing today. Regarding the production of electricity, this process has already well advanced in several countries. For instance, in Germany more than 30 % of the electricity was produced from renewable energies in 2015 [1]. However, as also increasingly discussed, the implementation of renewable energies has to advance towards industrial processes to achieve a complete energy transition. von Storch et al. [2] as well as Bai et al. [3] proposed processes for production of methanol with the aid of solar energy that also include further energy streams into and out of the process. In both publications, solar energy is concentrated (i.e. concentrated solar power (CSP)) to provide high temperature heat. Furthermore, both give promising results for the processes regarding the efficiency of solar energy utilization. However, for new renewable energy applications to be commercialized, favorable economics are necessary. Bai et al. [3] give an estimation on economic performance and show methanol prices between 440 and 516 $/t, but they are not put into context with market prices and common costs for renewable energy utilization. In von Storch et al. [2], economic aspects of the proposed process are not assessed at all. On the one hand, it is necessary to determine product costs for such processes to assess their potential to become commercially viable. On the other hand it is also necessary to carry out an economic assessment in order to carry out process optimization. For instance, as stated by von Storch et al. [2], the possibility of implementing thermal energy storage to increase operating hours of the investigated process is a central advantage of the considered technology. However, implementation of thermal energy storage can only enhance the economic performance, and not the efficiency. Hence, the suitable storage size can only be determined through economic optimization of a process. The same applies for the solar multiple, which represents the energy provided by the solar part at nominal operation in relation to the nominal energy input into the reforming process. The larger the solar multiple, the higher the capacity factor for the reforming process, but the larger and more expensive the solar receiver and heliostat field. Therefore, the optimal solar multiple can only be found through economic considerations.

In order to close the gap regarding information on the performance of these processes, the process presented by von Storch et al. [2], which is based on solar aided reforming of natural gas for methanol production (SOLME process), is assessed regarding its economic performance in this work.

2. The SOLME Process

The SOLME process presented by von Storch et al. [2] is a process that produces methanol and electric power form

doi:10.18086/swc.2017.34.04 Available at http://proceedings.ises.org

concentrated solar radiation and natural gas. A simplified flowchart of the process is presented in Figure 1. To provide the concentrated solar irradiation, a solar power tower is used: A heliostat field concentrates solar irradiation onto a central receiver where the irradiation is absorbed and converted into heat. As central receiver, an open volumetric receiver, as thermal storage a ceramic brick storage, both similar to the system installed at the solar tower Jülich (cf. Alexopoulos and Hoffschmidt [4]) are considered. Air is used as heat transfer fluid and transports the heat from the receiver or thermal storage to the reforming reactor. In the reforming reactor natural gas is converted into syngas via the reforming reaction. The syngas is cooled, compressed and given into a methanol synthesis reactor, where it is converted into methanol. Due to a large recycle stream in the methanol synthesis, it is necessary to purge an off-gas. This off-gas consists of inert species as well as unreacted methane, hydrogen and carbon monoxide. Hence it has a significant heating value. It can be combusted to provide heat to the reforming reactor or co-combusted in a power plant, for instance a combined cycle gas turbine power plant (CCGT). The off heat that is available from syngas cooling and as heat of reaction from methanol synthesis cannot be completely integrated into the process. It is considered, that the heat is used in a water-steam cycle to generate additional electricity. A more detailed description of the SOLME process can be found in refs [2, 5].

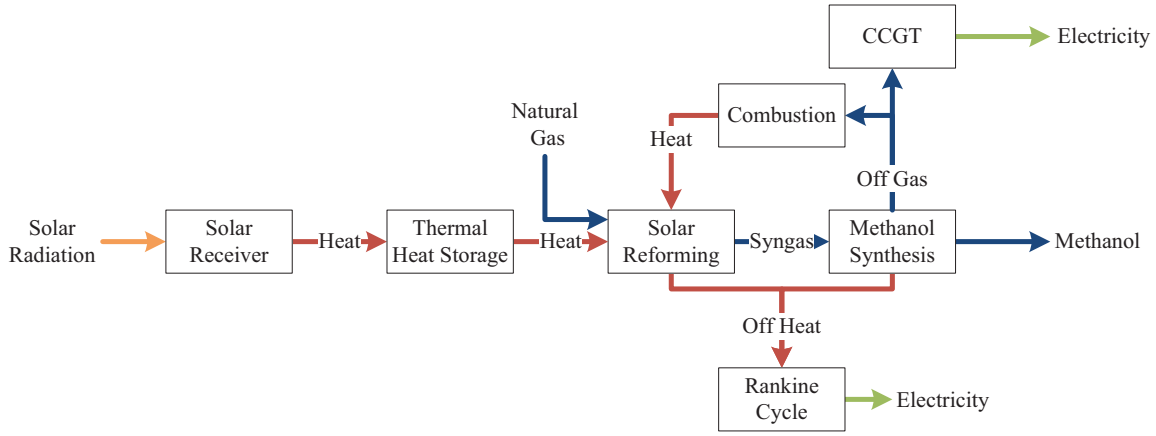

Figure 1 – Schematic of the SOLME process

As can be seen in Figure 1, the process consumes solar energy, natural gas and water to produce electricity and methanol. The production of two products from a renewable and a fossil energy resource complicates the economic assessment. Usually the utilization of renewable energies makes the product more expensive. In the case of facilities for the production of electricity, this is taken care of by increased feed-in-tariffs; which act as subsidy. For methanol production facilities, this procedure is not known.

Regarding the energetic performance of the process, von Storch et al. [2] report that the SOLME process can produce a given amount of electricity and methanol from the same amount of solar energy but approx. 5 % less natural gas than a system of conventional methanol synthesis and solar power plant. This indicates that the hybrid process for methanol and power production is more efficient regarding natural gas consumption than a separate production of solar power and conventional methanol would be. They state that the SOLME plant, that is scaled by the solar receiver with a capacity of 50 MW produces 127.5 GWh of Methanol and 21.41 GWh of electricity per year from 176.1 GWh of solar energy (onto heliostat field) and 148.4 GWh natural gas. The same size SOLME plant is assessed in this work. However due to the parameter variations, which are mentioned in the following chapter, the amounts of methanol and electricity produced will vary.

3. Methodology and procedure

Several options exist for the economic assessment of a process such as the SOLME that produces two products. Firstly, realistic market price for the products can be retrieved from a suitable source and the achievable profit can be determined based on capital cost and operational cost. However, as this would lead to negative profits for most processes that use renewable energy resources, for processes using renewable energy resources the concept of *levelised cost of electricity* (LCOE) is commonly used [6]. In this concept, the capital cost and operational cost (C_{OPEX}) of the process are determined. The capital cost is usually taken into account as the annuity of the initial investment ($C_{Annuity}$), considering a certain weighted average cost for capital (WACC). By division of the total cost with the amount of produced electricity, the LCOE is determined, as shown in equation (1). The resulting value indicates the minimum electricity price, to achieve the required interest rate/profit. This concept can also be applied

to other products than electricity, for instance to methanol. However, it cannot be applied in the same way to processes, which produces two products such as the SOLME process. Therefore, for this process, a realistic price for methanol (c_{Methanol}) is considered and the revenues subtracted from the annual costs in determining the LCOE. The resulting equation is shown in (2), where $m_{\mathrm{Methanol,SOLME}}$ is the annual amount of methanol produced in the process. The LCOE determined through this procedure can subsequently be compared with other processes. Then the LCOE is also the objective criterion to be minimized.

$$LCOE = \frac{C_{Annuity} + C_{OPEX}}{E_{El}} \tag{1}$$

$$LCOE_{\mathrm{SOLME}} = \frac{C_{\mathrm{Annuity,SOLME}} + C_{\mathrm{OPEX,SOLME}} - m_{\mathrm{Methanol,SOLME}} \cdot c_{\mathrm{Methanol}}}{E_{\mathrm{El,SOLME}}} \tag{2}$$

It is aimed to minimize the LCOE by variation of two central parameters: Solar multiple and thermal storage size. The solar multiple is defined as the nominal thermal capacity of a receiver in relation to the nominal thermal input of the reforming process. The heliostat field is size is fixed to provide sufficient concentrated solar irradiation to the receiver for nominal operation at noon of the 21st of March, which is a flux of 50 MW. The procedure is presented in detail by von Storch et al. [2]. The resulting heliostat field has a size 62,854 m² at the location in In Amenas in Algeria. The solar multiple is varied by scaling the non-solar part of the SOLME process. This means that the solar energy collected by the heliostat field and transformed into thermal energy in the solar receiver is fixed, the time period over which the process consumes and the amount that has to be dumped because the storage is full are varied. Energy consumption for operation of the heliostat field are taken into account as parasitic losses based on data published in the ECOSTAR report [7], where 6.5 W_{el} per square meter of heliostat field are stated. This results in a total consumption of 408.6 kW during solar operation. Based on heliostat field layout, the solar operating time is 4383 hours per year. Other major parasitic losses, such as blower for the air system are taken into account in the process model directly.

Despite a rapid reduction in costs for renewable energy technologies, processes that use renewable energy resources usually still have a higher cost of product than processes that use fossil fuels. This can be well observed at recent solar power projects, such as the recently inaugurated solar power plant *crescent dunes.* Besides subsidized loans, this kind of solar power plant is mainly supported through an increased feed-in-tariff, in this case 135 $/MWh [8] (the market price of electricity in that region is approx. 80 $/MWh [9]). The total subsidy for the project through increased feed-in-tariff can be estimated by multiplication of the difference in electricity price (in this case approximately 55 $/MWh) with the total amount of electricity produced. In the case of the SOLME plant, compared to a conventional solar power plant of identical scale, less electricity is produced because a fraction of the solar energy input is used in the methanol production. However, as the methanol is sold at a conventional market price (cf. paragraph above), the additional cost due to the solar field, receiver, etc. is spread over a lower amount of electricity. Hence, the resulting LCOE will be higher than for a conventional solar power plant even if the economic performance of the SOLME plant may be better. Therefore, comparison of the LCOE of the SOLME plant with published LOCEs of real solar power plants will lead deceptive conclusions.

To compare the economic performance of the SOLME process and conventional solar plants realistically, the total necessary subsidy to achieve marketable product prices should be determined. This can be done in several ways, for instance by considering a fixed annual sum or by considering a *reward* for the reduction of CO_2-emissions compared to the state of the art. In this work, both is done. Considering rewards for the reduction of CO_2-emissions is especially interesting, as it could be an effective measure to help achieving the superordinate goal in renewable energies utilization: The reduction of greenhouse gas emissions. Through this procedure, the more economic route for reduction of greenhouse gas emissions through solar energy utilization can be determined; in this case between a conventional solar power plant and the SOLME plant. Therefore in a parameter variation, the results for LCOE are determined in dependence of reward for reduction of carbon dioxide emission. The reward is varied between 0 and 200 $/$t_{CO2.}$ This reward can be considered as a potential income from excess CO_2 certificates as they exist in the EU. Currently the prices of the certificates are below 10 €/t (cf. https://www.eex.com/de/). However, they are expected to rise in the future and achieve values up to 76 €/t (100 $/t) according to Schlesinger et al. [10].

In order to obtain a comparable and realistic price for methanol, the price is determined based on own simulations rather than obtaining data from literature or real market prices. This ensures that comparable assumptions and boundary conditions are used for the SOLME process and the reference methanol price. The determination of reference methanol price is based on the process used as reference methanol process for energetic performance

assessment by von Storch et al. [2]. The resulting value is 180\$/$t_{Methanol}$. However, the value is varied to determine if it will affect the optimum values for storage size and solar multiple. In the case of the reference solar power plant, the receiver and storage size as well as solar multiple are set to the same values as in the SOLME process to ensure comparability of the results. This is done to obtain a comparable plant regarding the duration of which it can provide electricity to the grid throughout the year.

Determining the capital cost of SOLME process

The capital cost of the processes can roughly be categorized as conventional process units and CSP components. The cost of conventional process units is determined according to data by Ulrich and Vasudevan [11] and the prices converted from 2004 to prices of 2014 with the chemical engineering cost index (CEPCI) [12, 13]. The calculation is done in US-\$. If prices are retrieved in other currency, it is converted to US-\$ with the average exchange rate applicable for the year of publication from [14]. In accordance with Ulrich and Vasudevan [11], the bare module component costs (C_{BM}) are multiplied by a factor of 1,534 to yield the grass roots cost (C_{GR}), which includes fees and contingencies as well as auxiliary facilities, i.e. represents the total investment.

The prices for CSP-related components are retrieved from the ECOSTAR Report [7] and Vogel and Kalb [15]. The values used for the components are given in Table 1. Some of the data used to determine the prices of CSP components is several years old already. It is well known that significant cost reductions were achieved in the meantime. However, no reliable, detailed data is publicly available. Therefore, based on the predictions by Trieb [16], a reduction in CSP-Component cost by 30 % are assumed to take into account current developments.

Table 1 – Cost data for CSP components

Component	Source	Value and basis in source	In 2014-\$	30 % reduced value
Tower	ECOSTAR Report [7]	2 mio. €$_{2003}$	3.55 Mio. \$	2.73 mio. \$
Heliostat Field	Vogel and Kalb [15]	100 \$$_{2002}$/m²	146.64 \$/m²	102.65 \$/m²
			9.22 Mio. \$ (total)	6.45 mio. \$
Receiver	ECOSTAR Report [7]	115 €$_{2003}$/kW$_{th}$	204 \$/kW$_{th}$	142.8 \$/kW$_{th}$
Storage	ECOSTAR Report [7]	60 €$_{2003}$/kWh$_{th}$	106 \$/kWh$_{th}$	74.2 \$/kWh$_{th}$

The price of the Rankine cycle (RC) of the reference solar power plant is based on information from the ECOSTAR Report [7] according to equation (1) in dependence of the of its nominal electric output, assuming a value of 0.6 as scaling factor as recommended by Ulrich and Vasudevan [11].

$$C_{\mathrm{BM,PB}} = 1{,}064{,}400\,\frac{\$}{\mathrm{kW}} \cdot \left(\frac{P_{\mathrm{RC,el,nom}}}{10\ \mathrm{MW}}\right)^{0.6} \qquad \text{(eq. 1)}$$

For the combustion of the off-gas in a CCGT, it is assumed that it is co-combusted in an industrial scale CCGT rather than building a small scale CCGT for this purpose only. Therefore, the specific cost for a 200 MW CCGT plant are determined based on information from Ulrich and Vasudevan [11] and the fraction of capacity that can be attributed to the SOLME plant is considered in the investment cost. The specific cost (grass roots) is 3250 \$/kW$_{el}$.

Further relevant parameters for calculation of annuity and operating costs of the plant are given in Table 2. The WACC and expected lifetime are based on values proposed by Dieckmann et al. [17] for the near term future. The operation and maintenance cost (O&M) of CSP related components are set to 2% of the investment per year in accordance with Hernández-Moro and Martínez-Duart [18]. The O&M cost factor is set to 0.5% for all other components. The cost for demineralized water is determined with information provided by Ulrich and Vasudevan [11]. As cost for natural gas, based on the average values published for Henry Hub spot price between 2010 and 2016 [19], a value 0.012\$/kWh (3.5 \$/MBtu) is assumed.

Table 2 – Annuity input data for SOLME plant

Parameter	Value
WACC	6.5%
Payback time	25 years
O&M	
CSP – related components	2 % of investment/year
Other components	0.5 % of investment/year
Cost for demineralized water	0.35 Mio. $/year
Natural gas price	0.012 $/kWh

Determining CO_2-emissions reduction

The CO_2-emissions reduction is estimated by the difference in natural gas consumption compared to a benchmark value. In the case of methanol production, benchmark is based on a conventional methanol production plant based on the information by von Storch et al. [2]. In the case of electricity production, the benchmark is based on a CCGT plant. Indirect CO_2-emissions are not taken into account in this case, as it is assumed that they are similar for all processes.

Based on the composition of the natural gas and the molar weight of CO_2, 42.6 $t_{CO2}/Mmol_{Natural\ Gas}$ are considered. This leads to specific emissions of 1.865 $t_{CO2}/t_{Methanol}$ as benchmark value. For electricity production, a CCGT with 60 % efficiency is assumed for the benchmark. Based on the same natural gas composition, this leads to specific emissions of 416 t_{CO2}/GWh_{el}. The reference solar power plant does not consume natural gas. Therefore, no CO_2-emissions are considered.

4. Results & Discussion

LCOE of SOLME process

At first, it was assessed, if the assumed methanol price has an influence on the optimum values for solar multiple and storage size. The results for LCOE of the SOLME process for different methanol prices are shown in Figure 2 in dependence of solar multiple and Figure 3 in dependence of storage size. In both figures, it can be seen that the assumed methanol price has a relevant influence on the LCOE, which was to be expected because the methanol revenues are higher when methanol prices are higher. Thus the remaining costs on which the LCOE is based are lower. Furthermore, it can be seen, that an optimum evolves for both solar multiple (approx. 3.4) and storage size (approx. 150), which is not dependent on methanol price in the considered range.

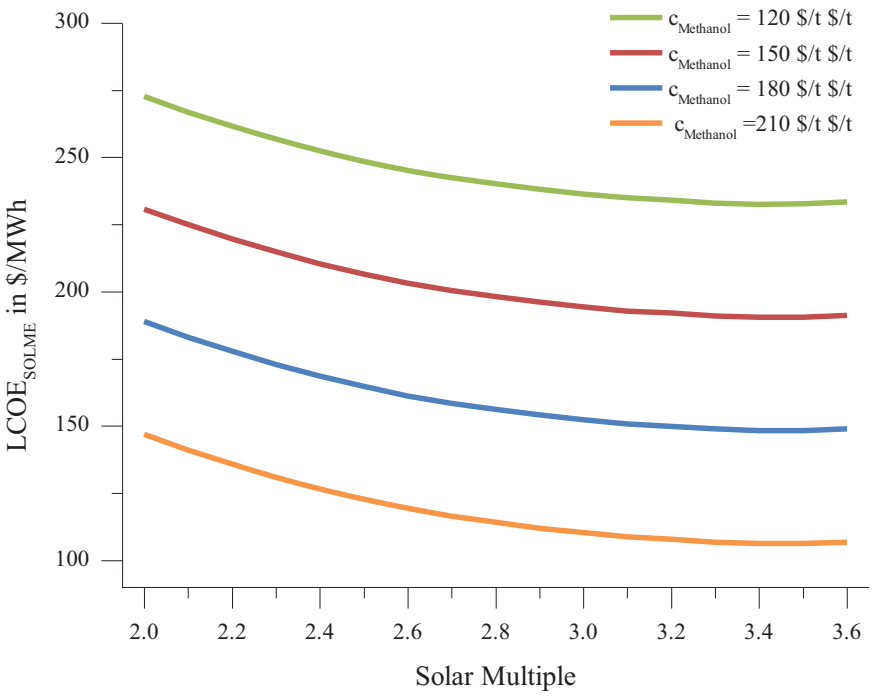

Figure 2 – LCOE for SOLME in dependence of Solar Multiple for different assumed methanol prices, assuming a storage size of 150 MWh

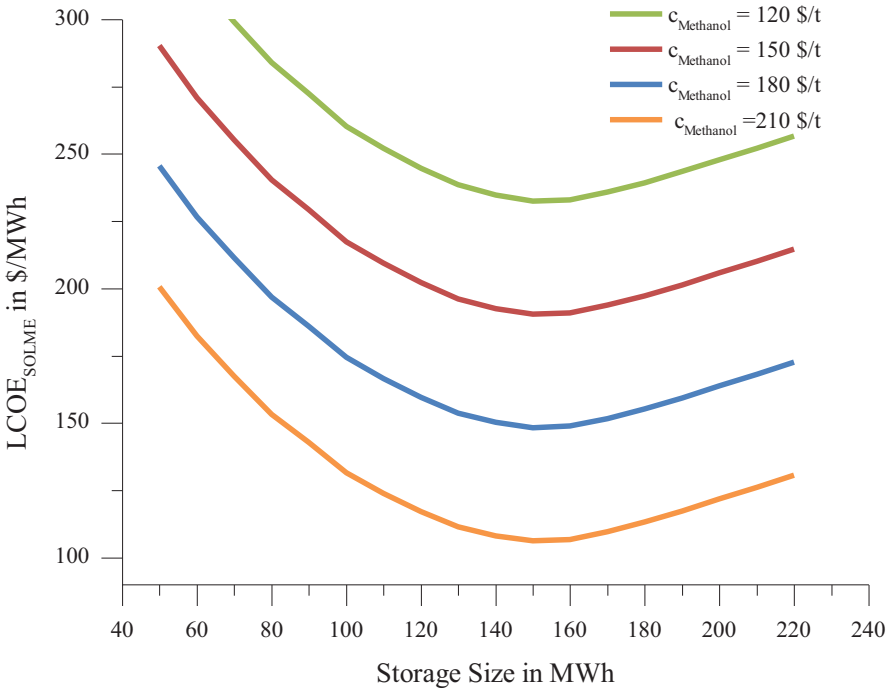

Figure 3 – LCOE for SOLME in dependence of thermal storage size for different assumed methanol prices, assuming a SM of 3.4

The results shown in Figure 2 and Figure 3 show that the optimum for the two considered optimization parameters can be found independently of the assumed methanol price. Hence it is justified to set the methanol price to a realistic value, which is 180 $/t in this work.

In Figure 4, the results of the optimization of the LCOE by variation of solar multiple and storage size is shown. It can be seen that the lowest value for LCOE is achieved at a solar multiple of 3.4 and storage size of 150 MWh. The resulting value of LCOE is 148.3 $/MWh. For the same storage size and solar multiple, the LCOE of the reference solar power plant is 124.4 $/MWh.

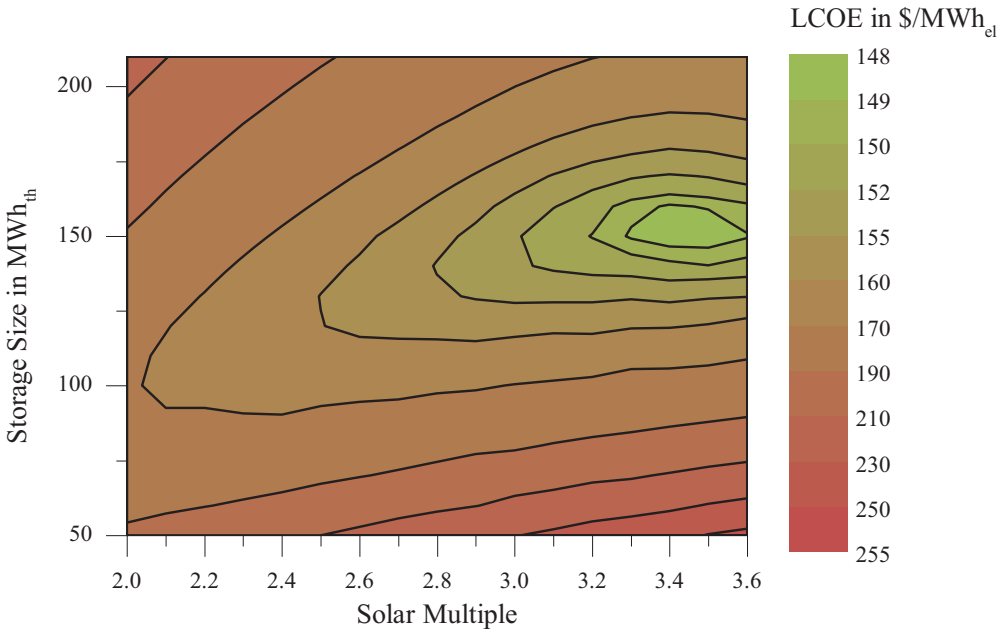

Figure 4 – Optimization of LCOE by variation of storage size and solar multiple

In the optimum configuration, the process achieves 7395 operating hours per year, which corresponds to a capacity factor of 86 %. This means that nearly continuous operation is possible, except for periods of continuously low solar irradiance during winter. Some further key results on the operation of the process at this configuration are given in Table 3. It can be seen that the nominal thermal input into the process is 10.74 MW. Consequently, with a 150 MWh thermal storage, a storage-only operation of 14 hours is possible. The results on process costs are summarized in Table 4.

Table 3 – Key parameters on the operation of SOLME with solar multiple of 3.4 and 150 MWh storage size

Parameter	Result
Nominal thermal input	10.74 MW
Dumped energy	3.61 %
Produced methanol	22,361 t/year
Produced electricity (net)	15.9 GWh/year

Table 4 – Key results on economic aspects of SOLME process for solar multiple of 3.4 and 150 MWh storage size

Parameter		Result
Total investment cost (grass roots price)		45.7 Mio. $
	Heliostat Field	6.5 Mio. $
	Solar Receiver	5.2 Mio. $
	Thermal Energy Storage	11.1 Mio $
	Non-Solar part	20.5 Mio. $
	Power block (1.40 MW)	5.93 Mio. $
	CCGT (2.27 MW)	4.63 Mio. $
	Air heated reforming reactor	2.36 Mio. $
Annual costs		6.39 Mio $
Annuity of investment		3.75 Mio. $
Operation & Maintenance (annually)		0.6 Mio. $
Natural gas consumption(annually)		1.68 Mio. $
Cost for demineralized water		0.35 Mio. $
Revenue methanol		4.03 Mio. $
LCOE		148.3 $/MWh

The reference solar power plant has an annual net production of electricity of 31.0 GWh with the same heliostat field as the SOLME plant at total investment costs of 37.9 Mio. $. The resulting annuity is 3.1 Mio. $, the operation and maintenance costs are 0.76 Mio. $, resulting in an LCOE of 124.4 $/MWh.

The necessary subsidy for each of the plants can be determined by multiplying the produced electricity with the difference between the LCOE and the market price. As proposed above, 80 $/MWh can be assumed as market price. For the SOLME plant, this yields a required annual funding of 1.086 Mio. $. For the reference solar power plant the required annual funding is 1.379 Mio. $. Hence, the SOLME process can be commercially viable with a lower funding than the conventional solar power plant.

Influence of reward for CO_2 emissions reduction on LCOE

The key results that are relevant to determine the influence of a reward for the reduction in CO_2-emissions are summarized in Table 5. The CO_2-emissions of the SOLME plant are compared with the previously defined benchmark values. No CO_2-emissions are considered for reference solar power plant. Therefore, it achieves a reduction in CO_2-emissions compared to the benchmark by 100 %. As can be seen in Table 5, the SOLME plant achieves a yearly reduction in CO_2-emissions by 13,197 t, the reference solar power plant by 12,909 t

Table 5 – Data on CO_2 Emissions of SOLME process, reference solar power tower and reference methanol plant and CCGT

Parameter	Result
Natural gas consumption (SOLME)	824 Mmol
CO_2-emissions	
SOLME	35,132 t
Benchmark Methanol (22.361 $t_{Methanol}$)	41,703 t
Benchmark electricity SOLME (15.9 GWh_{el})	6,614 t
Benchmark electricity SPT (31.0 GWh_{el})	12,909 t
Reduction of CO_2 Emissions by SOLME plant	13,197 t
Reduction by reference solar power plant (31.0 GWh)	12,909 t

The influence of a reward for the reduction of CO_2 emissions on the LCOE of the SOLME process as well as the reference solar power plant is shown in Figure 5. It can be seen that the LCOE is reduced with increasing reward. It can also be seen that the reduction is faster for the LCOE of the SOLME plant than for the reference solar power plant. This is caused by the higher reduction in CO_2-emissions of the SOLME process as indicated in Table 5. Without, or with low rewards, the LCOE of the SOLME plant is higher than the LCOE of the reference solar power plant. However, for a reward of 50 $/t$_{CO2}$ or higher, the LCOE of the SOLME is lower than for the reference solar power plant. The SOLME plant achieves a competitive LCOE of 80 $/MWh at a reward of 80 $/t$_{CO2}$, while the conventional solar power plant only achieves this value at 110 $/t$_{CO2}$. This shows that even without further CSP-component cost reduction, the SOLME process has the capacity to achieve competitiveness, if suitable funding mechanism, such as reasonably priced CO_2-emissions certificates exist.

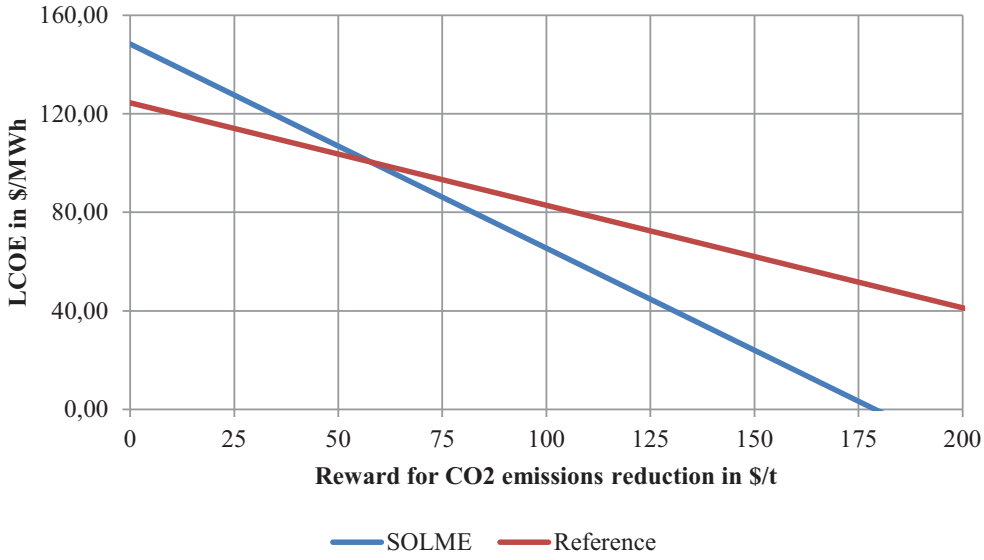

Figure 5 – Influence of reward for reduction of CO_2-emissions on LCOE

5. Summary and Conclusions

The economic performance of a process for hybrid solar-fossil co-production of methanol and electric power (SOLME process) is assessed. A reasonable price for methanol is fixed and the resulting levelized cost of electricity (LCOE) is determined. The solar multiple and thermal storage size are varied to optimize the economic performance and find the minimum LCOE. A value of 148.3 $/MWh is achieved for a solar multiple of 3.4 and a thermal storage size of 150 MWh, which allows up to 14 hours of off-sun / storage-only operation.

The resulting LCOE is higher than for a comparable solar power plant that produces only electricity, which would achieve 124.4 $/MWh. This is the case, because the additional cost of the CSP-components is spread over a lower amount of electricity, when the methanol is sold at market price. By determining the required subsidy to achieve competitive operation independent of product, it is shown that the SOLME process is closer to commercial viability. For electricity from renewable resources, power purchase agreements are commonly concluded with electricity prices higher than the market price. This is caused by the requirement of many utility services to reduce their overall CO_2 emissions. This practice does not exist for commodities such as methanol. A suitable mechanism to support the utilization of renewable energies in commodities production could be reasonably priced certificates for CO_2-emissions. When considering a possible reward for the reduction of CO_2-emissions, favorable results for the SOLME process are obtained. Because it causes a higher reduction in CO_2-emissions than a conventional solar power plant, it achieves a competitive LCOE of 80$/MWh$_{el}$ at a reward of 80 $/t$_{CO2}$. The conventional solar power plant would require a reward of 110 $/t$_{CO2}$ to achieve the same LCOE. This also shows that the SOLME process requires lower subsidy to become commercially competitive than a conventional solar power plant.

In conclusion it can be stated that the SOLME process achieves a very promising economic performance, even at current CSP component prices. However, currently no effective funding mechanisms exist to support the production of less carbon intensive commodities.

Sustainable Building Materials and Components

Thermoelectric Modules Testing for Sustainable Buildings Applications

Mohamed Al Musleh[1], Evangelia Topriska[1] and David Jenkins[2]

[1] Heriot Watt university, Dubai (United Arab Emirates)

[2] Heriot Watt University, Edinburgh (United Kingdom)

Abstract

In order for buildings to be sustainable from an operational point of view, the basics are to save energy and maximize efficiency. This is only possible with the availability and around the clock collection of real-time data for energy use. These data can be collected via sensors installed all around the building which then feed back to the building management system or to the occupants. Transmitting data and powering those sensors remains a challenge. With today's wireless technologies and microcontrollers, transmitting is well developed, however, sensor power sources are still in the developing stage. This work describes the testing of Thermoelectric Generators (TEG) at the ultra-low temperature difference level (5ºC and below). TEGs are used as energy harvesters that make use of the temperature difference within the building energy systems, to power wireless sensors, thus eliminating the need of a battery and the maintenance/operation costs that come with it.

Keywords: Smart Buildings, Sustainable Buildings, Thermoelectric, Wireless Sensing, Energy-Harvesting.

1. Introduction

Thermoelectricity is the direct conversion of a temperature gradient to electricity and vice versa. TEG modules are made of multiple Thermoelectric (TE) blocks connected electrically in series and thermally in parallel, to maximize power generation. This effect is known as Seebeck effect, where the generated electricity depends on the temperature difference between the two sides of the TEG module. The Seebeck coefficient of the blocks is used, as shown in the relationship of Equation 1:

$$E_{emf} = S\,\Delta T \qquad \text{(eq. 1)}$$

Where E_{emf} represents the generated electromotive force, S is the Seebeck coefficient which is material dependent, and ΔT is the temperature gradient difference (Ahıska and Mamur 2014). Figure 1 shows a schematic diagram of a typical TEG.

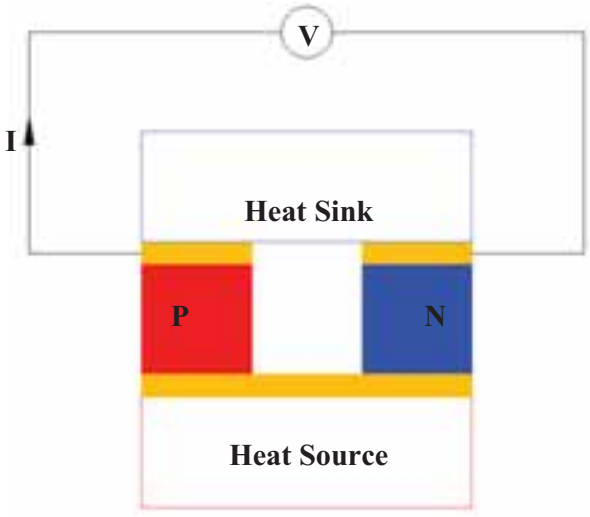

Figure 1 schematic diagram of a typical TEG.

doi:10.18086/swc.2017.35.01 Available at http://proceedings.ises.org

To run building resources and energy systems at a more sustainable level, systems feedback is required. This feedback is achieved using a network of sensors distributed around the building. Such sensors can measure building temperature, indoor light intensity, air quality, etc. and are either wired or wireless. Wireless sensors are often referred to as wireless sensor network (WSN). WSN could use batteries as a power source but the maintenance stays as a challenge from an operational point of view. Using ambient energy harvesters to power such sensors is a feasible option and TEGs are one of the techniques used for energy harvesting to power sensors. However, most of the commercially available TEG based energy harvesters require high-temperature difference, which is targeting industrial applications. Within the built environment low-temperature difference applications are common, if heating and hot-water systems are excluded. Typical examples of built environment applications are the temperature difference of an exterior wall surface, of a cold air duct with respect to the surroundings temperature, the heat emitted from a light fixture, the heat emitted from information technology (IT) equipment such as wireless routers, or security equipment such as surveillance cameras. Figure 2a shows a thermal image highlighting the heat emission from lighting fixture, where measured temperature difference is about 10°C. Figure 2b shows a thermal image of two different IT and security equipment, a wireless communication router and surveillance camera. The wireless router temperature is measured to be about 5°C above surroundings, while the surveillance camera measured at 9.6°C above surroundings. TEG used as power source for WSN has an increasing research interest but researchers in the field often face difficulties of the availability of TEG performance test data at very low-temperature difference. Therefore, the aim of this study is to provide such performance data and ultimately develop a universal test setup for TEG at this temperature range. (Salerno 2010) (Snyder 2008) (Moczygemba 2015) (Huang et al. 2011) (He et al. 2015) (Wang et al. 2013) (Wellington City Council 2017).

2. Experimental Setup

A TG12-4 TEG module was acquired for this test, which is a Marlow Industries Inc. product. This is designed as a universal TEG, rated at 4 watts at a temperature difference of 180°C (Marlow Industries). The experimental setup consisted of a high precision temperature controlled hotplate, which acted as a heat source. The hot side of the TEG was placed on top of the hot plate using thermal paste to maximize heat transfer and a K-type thermocouple was placed between the TEG and the hotplate to measure the hot side temperature. On the other side of the TEG a heat sink was used to dissipate the heat and an electric fan was attached to the heat sink to ensure cooling via forced convection. Another K-type thermocouple was placed between the TEG and the heat sink to measure the cold side temperature. Schematic diagram of the test setup is shown in Figure 3. Both thermocouples were connected to a temperature data logger shown at the left of the test setup photo in Figure 4. A digital multimeter was used to measure the generated open-circuit voltage (V_{OC}) and short-circuit current (I_{SC}) of the TEG. The complete experimental setup is shown in Figure 3 below.

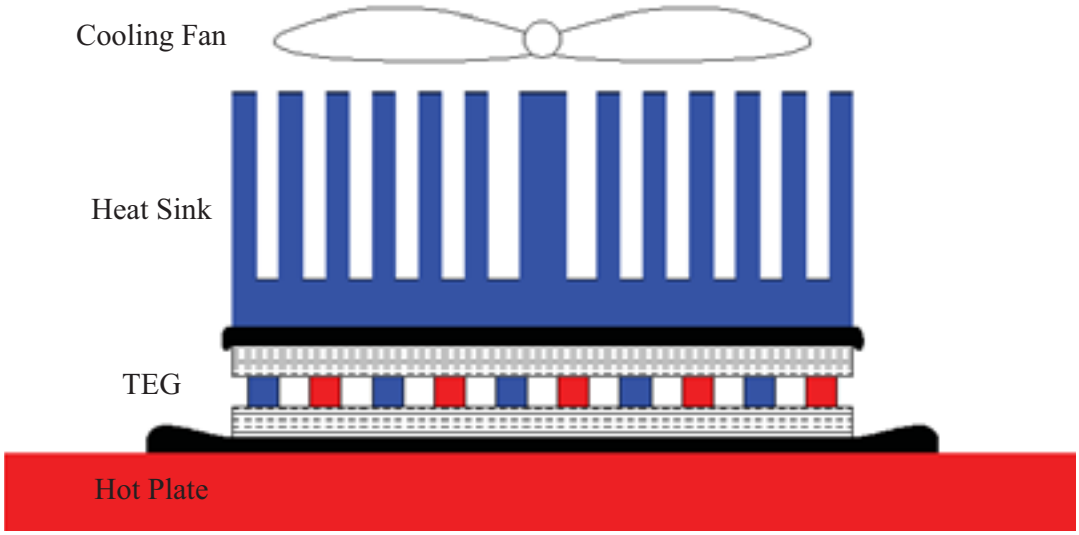

Figure 3 schematic diagram of the experimental setup.

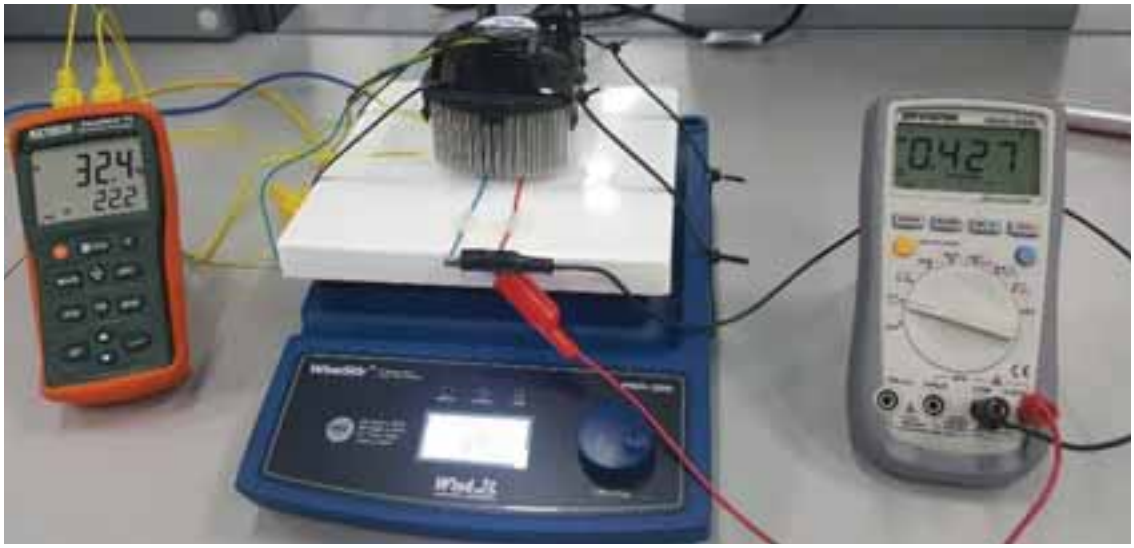

Figure 4 The complete setup of the experiment showing the temperature data logger at left, the hotplate with the TEG mounted on it below the heat sink, and the multimeter at the right.

As cooling was performed using an air-cooled heat sink, it was rather complicated to estimate the heat dissipation from the TEG. To further investigate the heat flux through the TEG and device efficiency it was found appropriate

to use water blocks on both sides of the TEG. The all copper water block is shown in Figure 5 were sourced out for this test.

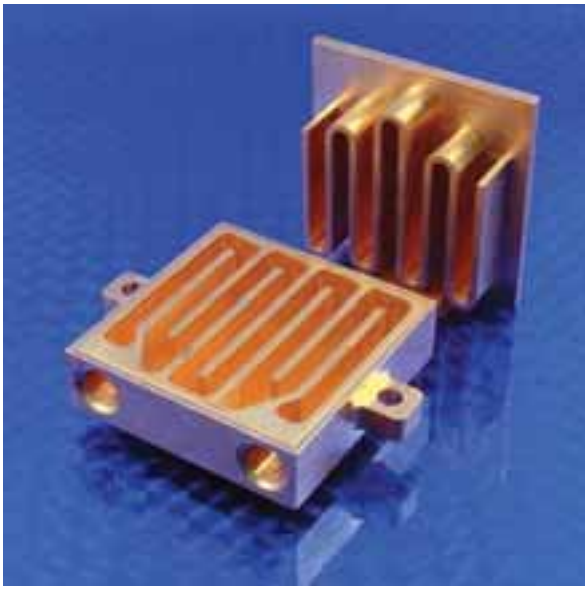

Figure 5 The all copper water block which was sourced out for the test.
(Image source: customthermoelectric.com)

One block for the hot water cycle attached to the TEG hot side and the other for the cooling water cycle on the cold side. 3D designed and printed holders were used for holding the water block in place and to make sure that TEG is always in the center. The complete setup of the TEG installed on the water block is shown in Figure 6.

Figure 6 the TEG installed on one side of the water blocks.

The test setup is planned to be attached to a heat exchanger supply unit. The unit will supply to two separate water cycles, one is hot and the other is cold. Both cycles have inlet and outlet temperature recorders along with recording the water flow rate.

3. Experimental Results

The temperature of the hotplate was increased in steps of 0.5°C above the room temperature, allowing enough time for both sides of the TEG to reach a steady state temperature. Both V_{OC} and I_{SC} were measured at each step and the recorded values are shown in Figure 7 below.

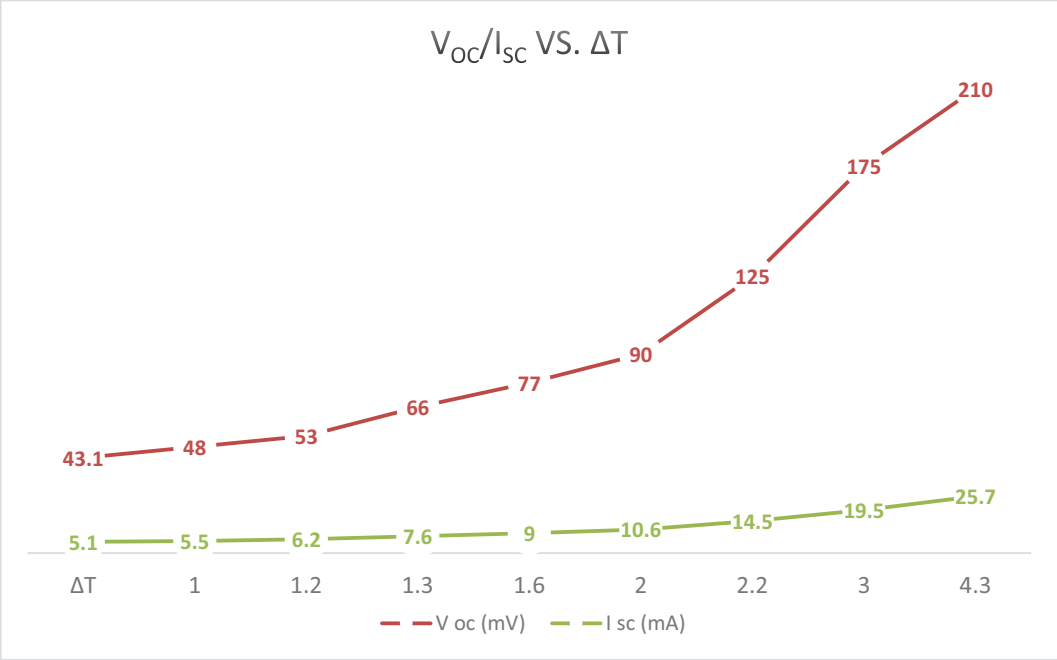

Figure 7 Open-circuit voltage (V_{OC}) and short-circuit current (I_{SC}) vs. temperature difference (ΔT) Using hot plate and air cooled heat sink.

The temperature deference covered a small range of 1-5 C°, which is considered as very low-temperature difference in TEG applications. This range was investigated being the most commonly available range within buildings. The open-circuit voltage and short-circuit current were observed to be directly proportional to the temperature difference, and closely following the increase in the TEG hot side temperature as shown in Figure 7. Using the measured values and using Equation 1, the Seebeck coefficient was calculated, to an average of 40.72 mV/C° over the test range.

A similar test was performed using the heat exchanger unit and the water blocks. Both cycles were set to a water flow of 2 liters per minute. An important observation using this setup is that precise control can be applied to the temperature difference (ΔT). ΔT across the TEG was increased from 0°C up to 7°C. V_{OC} and I_{SC} were measured at various temperature differences as shown in Figure 8.

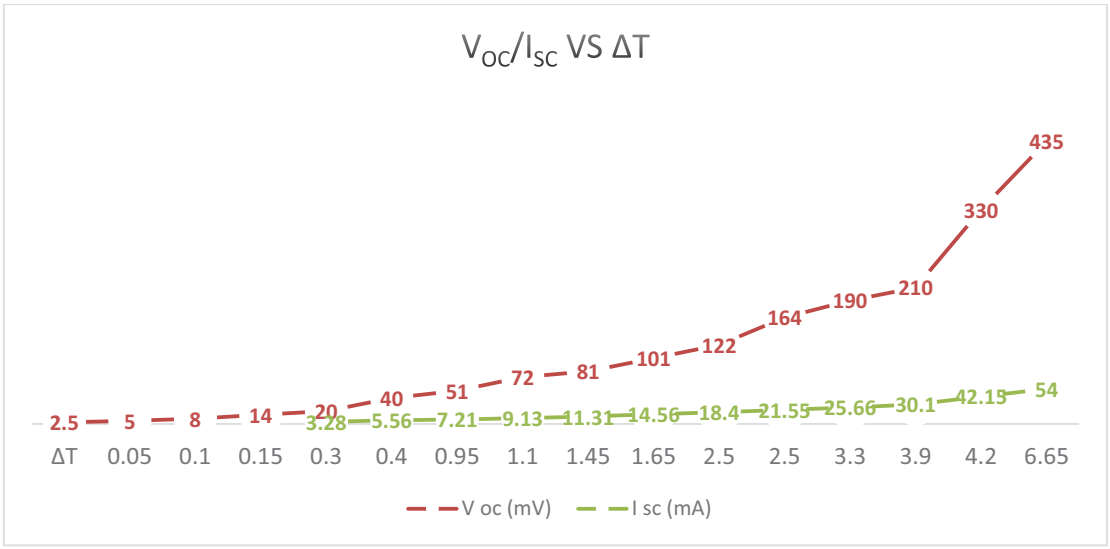

Figure 8 Open-circuit voltage (V_{OC}) and short-circuit current (I_{SC}) vs. temperature difference (ΔT) Using heat exchanger unit and water blocks.

Comparing the two sets of results highlighted much higher power generation with the water blocks setup at similar

ΔT. This variation requires further investigation, but could be due to one or more of the following:

- Nonuniform cooling of the heat sink in the air-cooled experiment.
- Nonuniform heating by the hot plate.
- The better thermal conductivity of the all copper water blocks.
- Improved heat dissipation from the TEG cold side with water blocks.
- The elimination of thermocouples between the TEG and hot/cool sides in the water blocks experiment.

4. Conclusions and Future Recommendations

The experimental results highlight a good indication of the TEG energy harvesting capabilities at the very low-temperature difference. It was difficult to estimate the overall device efficiency due to the fact that the first setup used an air cooled heat sink. Closed water cycle setup to cool the TEG was developed and tested. The continuous monitoring of the inlet temperature, the outlet temperature, and the flow rate will allow more accurate estimation of the heat dissipation and overall efficiency. The V_{OC} and I_{SC} are used as an indication for power output data. For more accurate electrical generation characterization connecting a load or I-V tracer is essential. Testing of TEG electrical output using I-V tracer is planned for future research and publication. I-V tracer will provide under load test for accurate load current and voltage. In addition to that programable I-V tracer simulate dynamic load setup which continuously adjust the virtual load impedance to match TEG internal impedance. Impedance matching is essential to track the maximum power point of generated power. It was clearly noted that the TEG performance was much better using the water blocks setup. Further investigation is required to identify the reasons. Possible reasons are that the pure copper water blocks offer enhanced uniform heat transfer on both sides and the continuous water flow continuously removing large amounts of heat from the cold side compared to the air-cooled heat sink of the first test. Current tests were run using 30mmx30mm TEG, while the second test used 40mmx40mm water block, a future test is planned using a purpose made 40mmx40mm TEG designed for extra low temperature applications. The matching size of 40mmx40mm will minimize error sources when it comes to accurately measure thermal energy or input power to the TEG for accurate efficiency evaluation. A computer model is under development using COMSOL Multiphysics, the model will use the experimental data as a basis of calibration in order to develop accurate model to be used for virtual testing if TEGs.

TOWARDS NOVEL GLAZING WITH SEASONAL DYNAMICS BASED ON MICRO COMPOUND PARABOLIC CONCENTRATORS

Jing Gong[1], André Kostro[2], Andreas Schüler[1]

1 Solar Energy and Building Physics Laboratory, Ecole Polytechnique Fédérale de Lausanne (EPFL), CH-1015 Lausanne, Switzerland

2 BASF Schweiz AG, Klybeckstrasse 141, CH-4057 Basel, Switzerland

Abstract

Thermal loss and overheating caused by glazing is a key issue in reducing CO2 emission and energy consumption of buildings. A novel glazing based on micro compound parabolic concentrators (CPCs) is proposed. The glazing consists of a polymer layer with embedded micro CPCs, which is attached to a glass pane of glazing. Thanks to the geometry and the micrometric size of the embedded CPCs, the proposed novel glazing can reduce energy consumption in cooling, improve visual comfort and maintain clear view through glazing. In the present work, the potential benefits of such glazing are preliminary estimated for Dubai. The seasonal dynamics are investigated by analyzing the direct solar transmittance for the working hours on the spring equinox and the winter solstice. The improvement of visual comfort is studied based on the assessment of glare. First samples with micro CPCs are fabricated, and the high transparency is achieved. The optical characterization using goniophotometer confirms the seasonal dynamics of the novel glazing.

Keywords: Advanced glazing, Microstructures, Compound parabolic concentrators, Seasonal dynamics, Visual comfort.

1. Introduction

The design of highly glazed building has become a worldwide trend in modern architecture. However, glazing may induce large thermal loss in winter while increase cooling load in summer, and it may also cause glare [1, 2, 3]. In the past decades, various glazing systems and daylighting systems have been developed to provide thermal and visual comfort. The "smart windows" coated with electrochromic or thermochromics materials are able to regulate the thermal radiation leading to lower solar gains in summer and higher solar gains in winter [4]. However, different color rendering from the normal spectrum of those windows can reduce the interest to users. A venetian blind should be combined with the electrochromic windows to block direct sunlight in order to avoid glare [5]. Anidolic systems consist of light-redirecting device can be alternatives. However, the installation of an anidolic system which varies in size going from 0.5 to 1 m long can be an architectural challenge [6]. The usage of blinds by occupants is not always made according to the solar availability, and therefore large performance gaps may appear between theoretical prediction and reality. With the use of blinds, the view through glazing will be obstructed.

In order to solve the problems, a multifunctional glazing based on micro compound parabolic concentrators (CPCs) is proposed. An important property of CPCs [7] is acceptance angle. Light arriving within the acceptance angle is concentrated and leaves the concentrator through the exit aperture of the structure, while the light out of acceptance angle will be reflected back to exterior through the input aperture. The glazing consists of a polymer layer with embedded micro CPCs, which is attached to a glass pane of glazing. Thanks to the geometry and the micrometric size of the CPCs, the proposed novel glazing can have the potential advantages with respect to three aspects: reducing energy consumption in cooling, improving visual comfort and clear view through glazing.

In the present work, we focus on the preliminary investigation of the potential advantages of the proposed glazing. The glazing is modelled for ray-tracing simulation, and the angular-dependent transmittance at the azimuth angle of 0˚ is calculated. The potential benefits of such glazing for Dubai are estimated by simlations. Seasonal thermal dynamics is investigated by calculating the direct solar transmittance for the working hours on the winter solstice

doi:10.18086/swc.2017.35.02 Available at http://proceedings.ises.org

and on the spring equinox. The improvement of visual comfort is studied based on the assessment of glare. First samples with micro CPCs are fabricated. Structural characterization by optical microscope is carried out. The redirection performance and the light-blocking ability are qualitatively demonstrated. The optical characterization by goniophotometer is conducted.

2. Methods

The CPC [8] was initially the essential component of a solar concentrator, and generally consist of two symmetric parabolas (named parabola L and parabola R respectively in our case), as shown in Figure 1 (a). The focal point for parabola L (F_L) lies on parabola R, likewise the focal point of parabola R (F_R) lies on parabola L. By definition, the axis of parabola L passes through the focal point of parabola L and the axis of parabola R likewise passes through the focal point of parabola R. The angle that the axes of the parabola L and R make with axis of the CPC defines the acceptance angle of the CPC [9]. All radiations arriving within the acceptance angle is concentrated and leaves the concentrator via the lower exit of the structure, while the radiations out of acceptance angle will be reflected back out through the input aperture.

The program CFSPro [10] which is developed especially for the study of complex fenestration system, is used to obtain the angular-dependent transmittance by ray-tracing simulation. The design of the geometry of the CPC is based on the calculation developed by Rabl [11]. In order to understand the potential benefit of the angular-selective transmittance for the reduction of energy consumption in heating and cooling, simulation referring to the double glazings with CPC30-30 and with CPC40-40 on south-facing facades is conducted for Dubai. In the case study, the transmittance of direct solar light in the visible range is calculated for the working hours (from 8:00 to 17:00) on the winter solstice and on the spring equinox. Monthly average high temperature and average low temperatures are show in Figure 1[12].

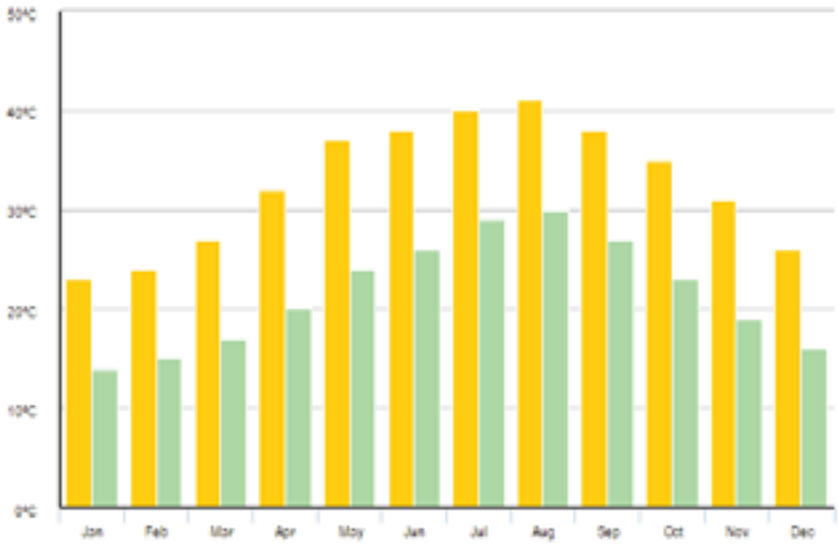

Figure 1 monthly average high and average low temperatures in Dubai.

Comfortable daylight environment in schools and offices can improve the occupants' productivity and tend to reduce the absenteeism [13, 14]. The improvement of daylight environment is investigated with the assessement of the risk of glare by Daylight Glare Index (DGI). A DGI is calculated by

$$DGI = 10log0.478\sum_{i=1}^{n}\frac{L_{s,i}^{1.6}\cdot\Omega_{s,i}^{0.8}}{L_b + 0.07\omega_{s,i}^{0.5}L_{s.i}}$$

where $L_{s,i}$ (cd/m^2) is the luminance of a glare source (i) in the field of view, $\Omega_{s,i}$ (sr) is the solid angle subtended by the source, modified for the effect of the position of the observer in relation to the source, L_b (cd/m^2) is the average luminance of the visual field excluding the glare sources, and $\omega_{s,i}$ (sr) is the solid angle subtended by the glare source.In the present paper, a viewpoints were chosen in the standard Reinhart-defined room [15] with the

dimension of 8.2-m long × 3.6-m wide × 2.8-m high. The view point was set at 1-m distance from the window, with a height of 1.25 m and the line of sight points towards the wall, in order to simulate a working position in a realistic state, referred to as employee position. This viewpoint is in the area where direct sunlight was generally received during most of the year with a conventional glazing, and is considered as an uncomfortable position.

The preparation of embedded micro CPCs requires the fabrication and the replication of microstructures, as well as the coating with reflective materials on the selective surfaces of microstructures [16, 17]. The master mold with the desired microstructures for the sample in the present manuscript is produced by laser ablation. In the present work, a PDMS stamp of the negative microstructure with respect to the master mold is prepared. Then another PDMS stamp with the positive microstructure is replicated from the first PDMS stamp. After that, the negative microstructures are replicated from the PDMS positive template by UV-cured acrylated hyperbranched polymer (HBP) on a glass substrate. The selected surfaces of the HBP microstructures on the glass substrate are coated with aluminum by physical vapor deposition. Then the grooves of microstructures are filled with the identical HBP to encapsulate the micro-CPCs, and a sample with clear view is achieved.

3. Results and Discussions

Double glazing with the embedded micro CPCs in a polymer layer, which is attached to the inner side of the outer glass pane, is modeled, as shown in Fig. 1 (a). The refractive indexes of glass and the used polymer are the same (refractive index n = 1.5). The thickness of the glass panes and the thickness of the polymer layer for modelling are bigger by factors of 10-100 than that of reality, for the convenience of viewing. In winter where solar elevation angles are low, the solar radiation is partially redirected by the reflective parabolic surface and then enters in the interior space. In contrast, in summer where the elevation angle is high, the direct solar radiation is reflected outside after two or more reflections. The transmittance of the visible light as the function of elevation angles at the azimuth angle of 0˚ is calculated, for the conventional double glazing and the double glazing integrated with two different geometries of CPCs (Fig. 1 (b)). Symmetric CPC of a half acceptance angle of 30˚ is labelled as CPC30-30 and with a half acceptance angle of 40˚ it is labelled as CPC40-40. Due to the refractive index of 1.5 of the polymer, the incident angles corresponding to the acceptance angles for the two CPCs embedded in the polymer layer are 48.6˚ (CPC30-30) and 74.6˚ (CPC40-40). For CPC30-30, the transmittance is at about 0.64 which is approximately the same as that of the low-e double glazing in the angular range between 0˚ and 25˚. Beyond 25˚, a fraction incident light is redirected by two or more times and then leave the system through the input aperture. Therefore the transmittance significantly reduces beyond 25˚ and reach 0 at about 50˚. Likewise, for CPC40-40, the transmittance stay at 0.72 in the angular range between 0˚ and 12˚. After 12˚ the transmittance gradually reduce, and this trend is unlike that of CPC30˚, as the curvature of the parabolic mirrors is smoother than that of CPC30-30. The transmittance stays at 0 beyond 80˚.

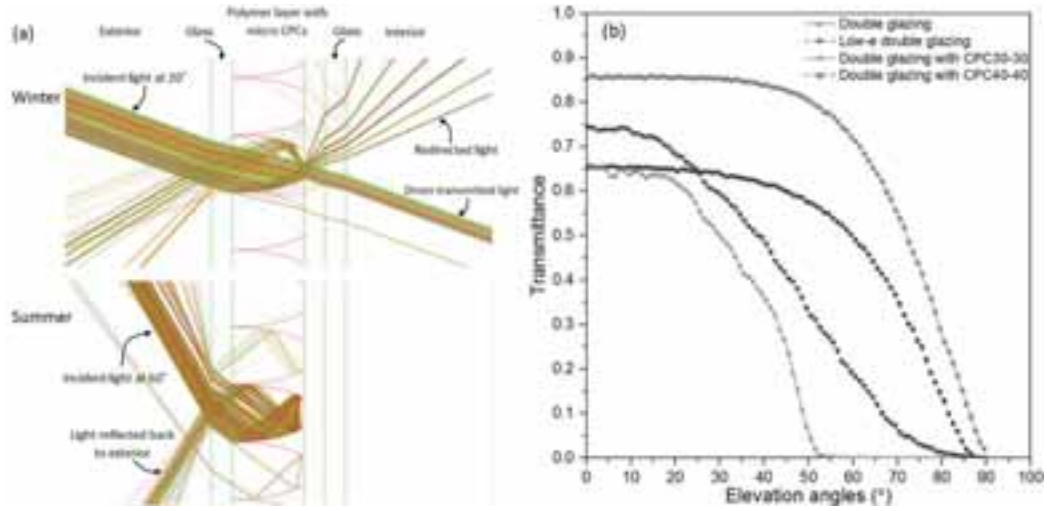

Figure 2: (a) Model of embedded micro CPCs in a polymer layer attached to the inner surface of the outer glass pane of a double glazing for ray-tracing simulation; (b) simulated transmittance as the function of elevation angles of the sun at the azimuth angle of 0˚

In order to understand the potential benefit of the angular-selected transmittance for the reduction of energy

consumption in cooling, calculation of direct solar transmittance of visible light is conducted for the working hours (8:00-17:00) on the spring equinox and (b) on the winter solstice for the CPCs applied to a vertical double glazing in Dubai.

For CPC30-30 on the spring equinox, the direct solar transmittance remains at 0 between 10:00 to 15:00, suggesting the potential strong reduction in cooling. The transmittance between 8:00 to 10:00 and 15:00 to 17 is also reduced to the average transmittance of 0.09. On winter solstice, the transmittance from 8:00 to 9:00 and from 16:00-17:00 is similar to that of low-e double glazing. A reduction with the average amplitude of 0.2 is observed between 9:00 and 16:00, and at noon the direct transmittance is reduced from 0.61 to 0.35. Compared with the case on spring equinox, the reduction of the transmittance on winter solstice is moderate. However, a moderate reduction may be preferred, as the average high temperature in Dubai is above 20℃ but not as harsh as that in spring and summer.

For CPC40-40 on the spring equinox, the transmittance from 8:00 to 17:00 remains rather constant at about 0.15. On the winter solstice, the transmittance is modestly reduced. The transmittance is reduced from 0.61 to 0.47 at noon on the winter solstice. Interestingly, the transmittance from 8:00 to 9:00 and from 16:00 to 17:00 is about 0.1 higher than that of low-e double glazing. The increase might contribute to the improvement of thermal comfort in the early morning and in the late afternoon, considering that the average low temperature in December in Dubai is in the order of 15℃.

The conventional double glazing with micro CPCs might not be the best configuration for the application in Dubai. Nonetheless, it shows the working principle of glazing with micro CPCs to achieve the seasonal dynamics. Moreover, the polymer film with embedded micro-CPCs can be attached to large variety of glass panes. In the future, optimization of the configurations will be conducted.

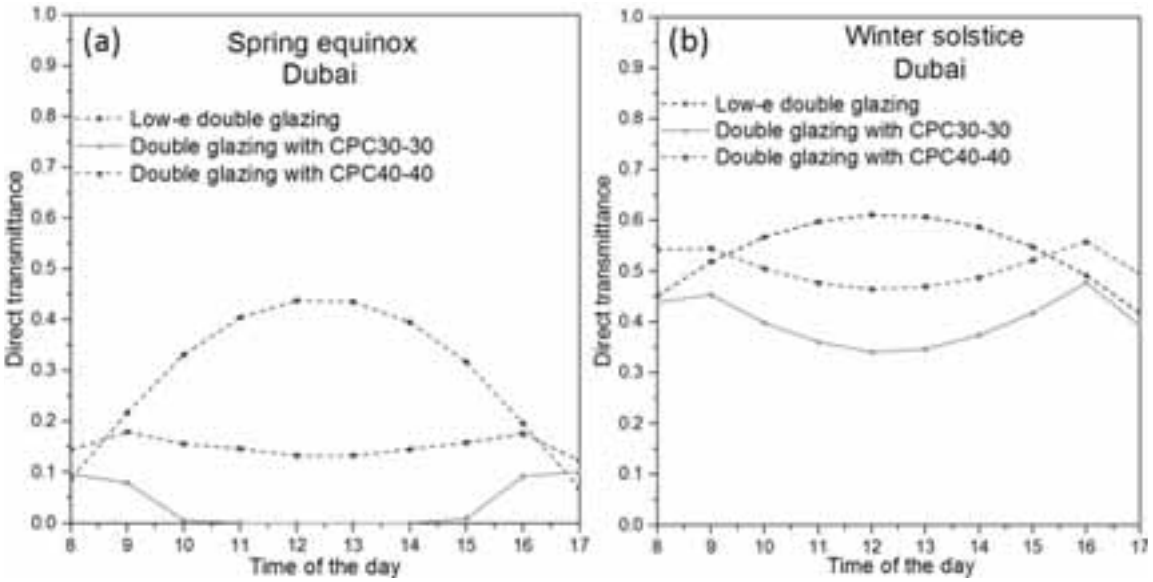

Figure 3: Plots of direct visible solar transmittance of visible light during working hours (8:00-17:00) (a) on the winter Solstice and (b) on the spring equinox for the CPCs applied to a vertical double glazing in Dubai.

Figure 4: The plots of hourly Daylight Glare Index (DGI) values: a) on the spring equinox, and b) on the winter solstice at the employee's position. Intuitively speaking, glare is likely to happen when the direct light source in the field of view. For the case with low-edouble glazing, the direct sunlight of incident angle larger than 53.5˚ will not reach the eye of the employee. Therefore, on the spring equinox, the DGI falls in the acceptable level for the three types of glazings during the working hours (from 8:00 to 17:00). On the winter solstice, the improvement of thermal comfort is evident using micro CPCs. The case with low-e double glazing suffers from glare for 60% of the daytime on the spring equinox. The glazing with CPC30-30 and CPC40-40 suppress the risk of glare to only 20% and 30% of the daytime.

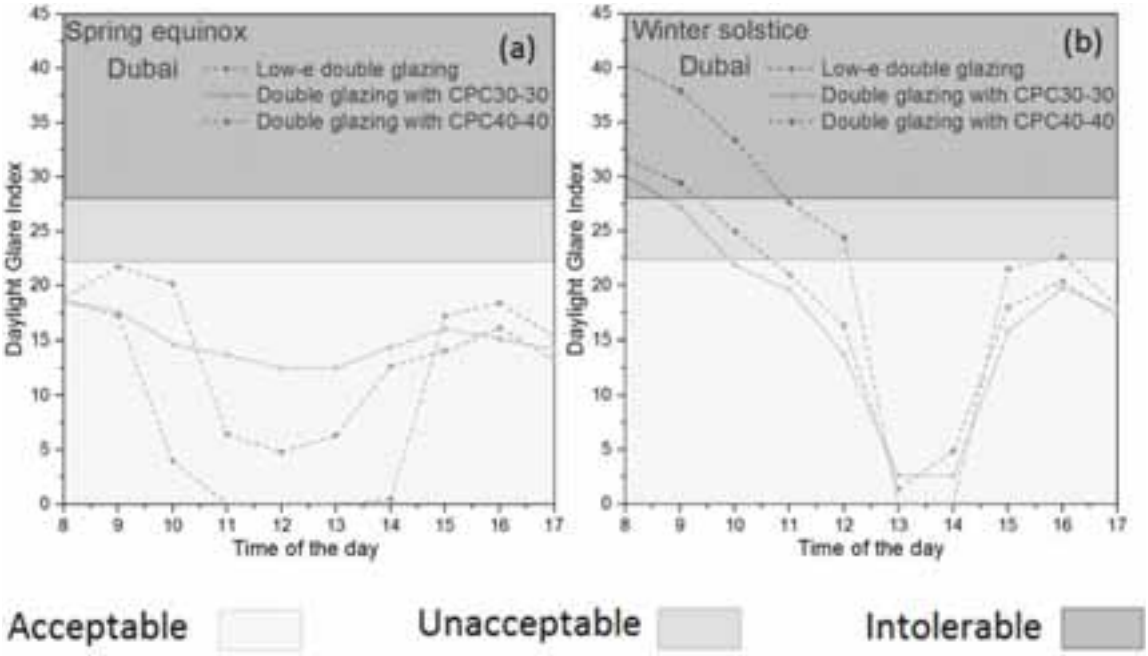

Figure 4: The plots of hourly Daylight Glare Index (DGI) values: a) on the spring equinox, and b) on the winter solstice at the employee's position.

The preparation of embedded micro CPCs requires the fabrication and the replication of microstructures, as well as the deposition with reflective materials on the microstructures [18,19]. An example of the HBP microstructures based on the theoretical design of micro CPC30-30 is shown in Figure 5 (a). The width of the outgoing aperture is 34 μm, and the height of the microstructure is around 80 μm. The dash arrow shows the surface where the highly reflective materials are deposited. In the present work, the thickness of the deposited materials is in the order of 50 nm. Due to the micrometric size of the microstructures, a clear view seen through the glazing with embedded micro-mirrors is achieved, as indicated in Fig. 2 (b). The present sample consists of a single glass pane with an attached polymer layer in which micro CPC30-30 are embedded. The area with micro CPC30-30 is 5 cm x 4 cm. The redirection performance and the blocking ability of the sample are studied with a collimated beam, as indicated in Figure 6 (a). At a low incident angle, the incident light splits into redirected part and direct-transmitted part after going through the CPCs. At a high incident angle, the majority of light is reflected outside after two or more reflections, that explains why the sample looks bright when it is observed from the side of the light source, as shown in Figure 6 (b).

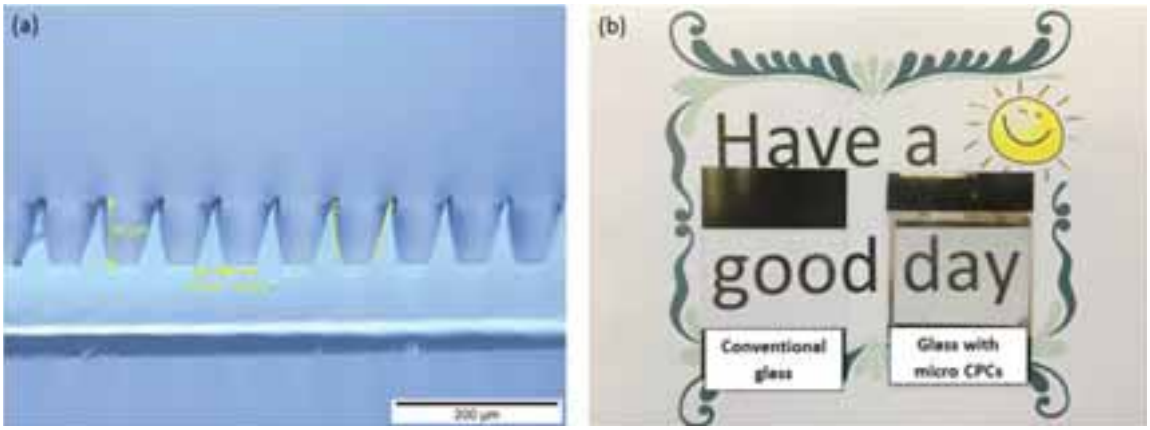

Figure 5: (a) An example of HBP microstructure; (b) the views seen through the conventional glass and the glass with the polymer layer which consists of embedded micro CPCs. The viewing direction is perpendicular to the surface.

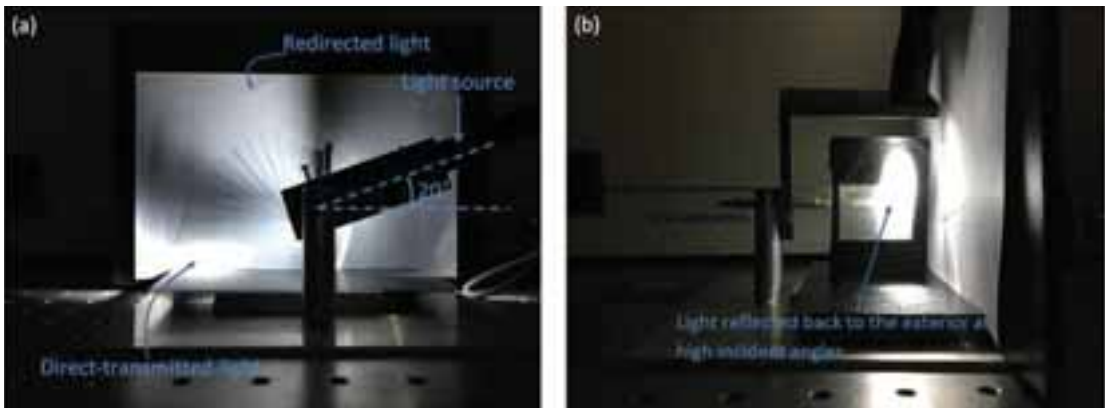

Figure 6: The redirection performance and the blocking ability of the sample are studied with a collimated beam at the incident angle of (a) 20˚ from the front side and (b) 60˚ viewing from the side of the light source.

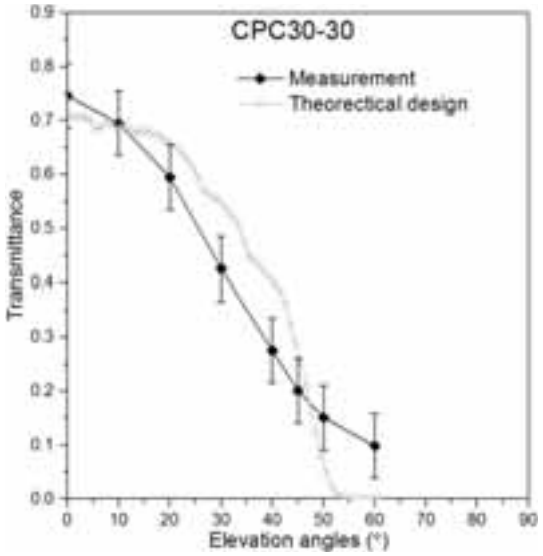

Figure 7: Comparison between the measurement result from goniophotometer and the simulated transmittance.

The angular dependent transmittance is further observed Measurement of transmittance as the function of elevation angles at the azimuth angle of 0˚ is carried out using goniophotometer. As shown in Figure 7, the transmittance reduces with the increase of elevation angle. The transmittance at the elevation angle of 0˚ is about 0.75 while at the elevation angle of 60˚ it is only about 0.1. The optical properties of the sample suggest that the seasonal thermal regulation may be realized. The microstructure is fabricated following the geometry of the CPC 30-30. The deviation of the measurement from the simulation can be due to the three reasons: i) the height of the fabricated microstructure is about 80 μm while the theoretical design is about 90 μm; ii) shrinkages change the shape of the microstructure during polymerization for replication; and iii) the thickness of the deposited reflective material is insufficient and the light may directly transmitted through the reflective parabolic surface. In the future, rigorous parameters concerning the fabrication of microstructures, replication and deposition will be carried out, in order to minimize the deviation.

4. Conclusions

A novel glazing with embedded micro CPCs in a polymer layer which is attached to a glass pane is developped. A case study by simulation referring to seasonal thermal regulation due to the transmittance of direct solar light for Dubai shows that the novel glazing may reduce energy consumption in cooling and improve thermal comfort. The assessment of glare indicates that the novel glazing can reduce the risk of glare from 60% to only 20%. First samples with micro CPCs are fabricated, and the high transparency is achieved. The optical characterization using goniophotometer shows that the desired angular-dependent transmittance is obtained.

5. Acknowledgement

The authors would like to thank the Swiss Competence Center for Energy Research (SCCER) for funding of this project. The authors would like to show our gratitude to BASF Switzerland regarding the assistance for the preparation of samples.

Abstract

The aim of this work is to assess building energy performance optimization potential of cool roof solutions in different climate conditions worldwide through dynamic thermal-energy simulation and optimization analysis. Moreover, given the dependence of roof performance on insulation level, the influence of roof insulation variation on optimum roof solar reflectance is evaluated. Therefore, the multi-dimensional optimization of combined building roof solar reflectance capability and thermal insulation level is carried out to minimize annual energy consumption for air-conditioning of standard ASHRAE building model for small offices, in each considered climate zone. Findings of this research highlight how the classic approach of super-insulated buildings for energy saving needs to be reframed for the office case, by integrating other passive solutions for truly environmentally friendly and comfortable buildings.

Keywords: Cool Roof, Solar Reflectance, Thermal Insulation, Building energy saving, Optimization

1. Introduction

Cool roofs are a widely acknowledged strategy for building thermal-energy performance improvement, by acting mainly on energy requirement for cooling (Levinson and Akbari, 2010; Pisello, 2017) and Urban Heat Island (UHI) phenomenon mitigation (Akbari and Kolokotsa, 2016; Santamouris et al., 2017). In fact, given their high solar reflectance and thermal emissivity properties, compared to conventional construction materials, cool materials are able to decrease heat release to the outdoor urban environment and to the indoor ambient air Santamouris, 2015).

However, the effectiveness of cool roofs along the whole year is affected by building boundary conditions, including envelope characteristics, building end-use, and climate conditions. For instance, the use of such materials in heating-dominated regions may generate penalties in terms of heating energy use in winter (Hosseini and Akbari, 2014; Kolokotroni et al., 2013). With the aim of estimating the impact of using cool roofs under different climatic conditions, Synnefa et al. (2007) simulated the heating and cooling load of residential building in 27 cities around the world. For the case study locations, the heating penalty was shown to be lower than the cooling load reduction. Hosseini and Akbari (2016), instead, focused on cold climates and demonstrated that cool roofs provided annual energy savings in all considered climates for the simulated prototype office and retail buildings. Considering researches focused cool roofs performance in Italian climate context, Costanzo et al. (2013) showed the suitability of cool roofs for the reduction of building annual energy consumption in three Italian cities and with different insulation levels. They stated that the use of such materials in heating-dominated regions should be preliminarily evaluated in association with high insulation levels and very efficient heating systems. Instead, Zinzi et al. (2014) defined an energy-rating scheme for cool roofs application in residential buildings in different Italian climate zones based on numerical calculation results.

doi:10.18086/swc.2017.35.03 Available at http://proceedings.ises.org

As regards building envelope characteristics, a key parameter influencing benefits achievable through cool roofs is the level of roof insulation (Daouas, 2016). The effect of cool roofs in improving building indoor thermal comfort conditions was found less important with low thermal transmittance roofing systems (Synnefa et al., 2007; Di Giuseppe and D'Orazio, 2015). On the other hand, Smith et al. (2012) stressed that in temperate climates standard energy saving approaches, e.g. lowering thermal transmittance, while useful may be unnecessary, unless other parameters are poorly designed. A further study carried out in a hot-arid climate (Radhi et al., 2017), demonstrated that the difference in heat gains through the roof with and without thermal insulation is lower when a cool roof is implemented that with other roof systems.

Given the significant interaction between roof coating optical properties and sub-roof insulation level in affecting building energy efficiency, different optimization studies involving these two envelope characteristics were carried out. For instance, Gentle et al. (2011) performed a systematic analysis of the combined effect of three roof parameters, i.e. solar albedo, thermal emittance, and sub-roof R-value. Cool roofs were shown to optimize cost and environmental benefits when the sub-roof R-value is tailored to the spectral properties of the roof. Moreover, the impact on energy saving of an additional PCMs layer in the roof was assessed (Aguilar et al., 2013). Farhan et al. (2016), instead, developed a BIM-based approach to decide the most effective technology to be implemented to reduce CO_2 emission and improve the thermal comfort level of residential buildings. Through a two-step experimental and numerical analysis, Ramamurthy et al. (2015a, 2015b) studied the joint influence of roof albedo and insulation on its energy performance. They highlighted that both albedo and insulation thickness play a significant role in reducing the combined heating and cooling load attributable to the roof, and that wintertime penalties of cool roofs are negligible compared to summertime benefits. Similarly, Arumugam et al. (2015) optimized the interaction of this two roof characteristics in different Indian climate zones via energy simulation and parametric analysis. The insulation thickness increase was demonstrated to provide incremental benefits in energy savings which were reduced after a limit.

2. Motivation

Building upon the previous literature, the purpose of this work is to contribute in defining a method for assessing the effectiveness of implementing cool roofs in different climate zones in terms of annual energy saving of the HVAC system, with varying different boundary conditions. Given the consolidated research about cool roofs performance as passive cooling technique and the awareness of the influence of roof R-value on their effectiveness, acknowledged by a variety of scientific contributions worldwide, this study proposes a replicable method for enhancing building thermal-energy performance by optimizing roof configuration. In particular, roof solar reflectance capability and thermal insulation level are considered as key drivers influencing roof performance. Therefore, the optimum combination of solar reflectance value and insulation layer thickness for minimizing building annual energy consumption for air-conditioning is evaluated in different international climate zones. The procedure consists of an integrated and timesaving approach based on the coupling of dynamic simulation and optimization analysis.

Finally, this work is aimed at filling the gap between theory and practice by providing indications for the effective use of roof coatings in buildings, by taking into account mainly their energy efficiency. Therefore, findings on cool roofs effectiveness, which are usually referred to case specific experimental campaigns, can be generalized with varying boundary conditions. In fact, the general proposed procedure can be replicated in a variety of climate contexts in the world. Therefore, guidelines for the efficient implementation of cool roofs in different climate conditions can be developed based on findings of this work.

3. Methodology

The methodology presented in this work is based on numerical analysis via dynamic energy simulation and optimization. In particular, the optimum roof configuration is investigated with the aim of minimizing building annual energy consumption for heating and cooling with varying climate zone conditions. The two roof characteristics selected as variables affecting building energy performance are the coating solar reflectance and the thermal insulation layer thickness. The range of considered roof solar reflectance (ρ_{solar}) values for the study varies from 0.1, i.e. dark roof, to 0.8, i.e. cool roof. Regarding roof thermal insulation, standard expanded polystyrene (EPS), i.e. characterized by thermal conductivity equal to 0.04 W/m K, is used considering a

thickness range ($I_{thermal}$) from 0.01 m to 0.25 m. The minimum thickness value is not 0, but very close to, because this value is not allowed by the simulation software.

For the purpose of this study, different climate zones worldwide are considered as case study weather conditions and the ASHRAE standard building model for small office building (ASHRAE,2016) is used as case study building, when modifying only the envelope components thermal transmittance (U-value) with varying the climate zone. Firstly, one-dimensional optimization analysis is carried out when varying the sole roof solar reflectance or thermal insulation thickness. When varying the thermal insulation level, two different roof solar reflectance scenarios are defined: "standard roof", where ρ_{solar} value is left equal the value of the ASHRAE prototype model (ASHRAE,2016) , i.e. 0.3, and "cool roof", where ρ_{solar} value is set equal to 0.8. Therefore, the sensitivity of building annual energy consumption to each parameter variation is evaluated to assess their separate contribution in different climate zones. One-dimensional optimization analysis is carried out only for six cities that representative of six defined heating degree days (HDD) ranges. Such ranges are reported in detail in the following section 4 (Fig. 2). Secondly, multi-dimensional optimization analysis is performed to define the optimum roof configuration by coupling solar reflectance capability and thermal insulation level in each considered climate condition. The methodology procedure is summarized in Fig. 1.

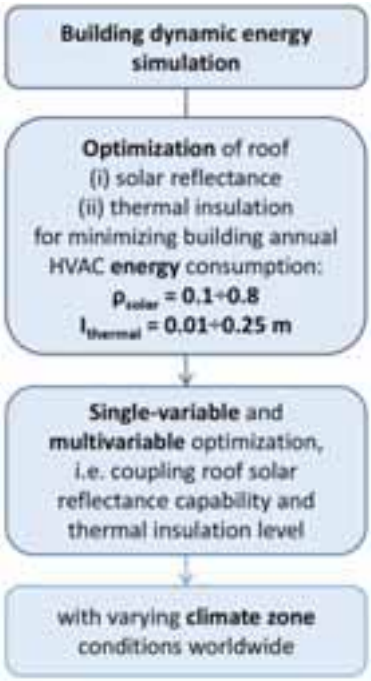

Fig. 1: Methodology implemented in the work

3.1. Numerical modeling

To perform the numerical analysis, the acknowledged simulation engine EnergyPlus v8.4 (Crawley et al., 2000) is used to develop the dynamic energy simulations. EnergyPlus is a whole-building thermal-energy simulation program (Crawley et al., 2001), based on previous validated BLAST and DOE-2 programs. EnergyPlus includes many advanced modeling tools, such as heat balance load calculations, integrated loads, user-configurable HVAC system description, system and plant calculations in same time step, simple input and output data formats, simulation of materials with variable thermal properties, etc. Further capabilities that give power to this calculation engine are advanced fenestration analysis as well as general envelope calculations (outside and inside surface convection algorithms), advanced infiltration, ventilation, room air and multi-zone airflow calculations, environmental emissions and developed economic evaluation including energy costs, and life cycle costs. Additionally, it includes several developed human thermal comfort algorithms for analyzing occupants' thermal well-being and indoor air quality.

In this study, the conduction transfer function (CTF) algorithm is selected among the available calculation algorithms to calculate transient heat conduction transfer (U.S. DOE, 2016).

3.2. Optimization

For the additional optimization analysis, the generic optimization program GenOpt v3.1.1 (Wetter, 2000) is selected. This tool is capable of solving building energy performance related optimization problems developed with dynamic simulation software. It can be coupled with several simulation engines, including EnergyPlus. GenOpt performs optimization of a user-defined objective function, such as, for instance, annual energy consumption, which depends on selected independent variables. The objective function is expressed as a target quantity or a relation that has to be minimized or maximized. Generally, GenOpt optimization problems are described as shown in eq. 1:

$$min_{x \in X} f(x) \qquad \text{(eq. 1)}$$

where $f: X \rightarrow \mathbf{R}$ is the user-specified objective function that measures the system performance and $x_1, x_2 \in X \subset \boldsymbol{R}^n$ is the set of user-specified design parameters set for the independent variables. In this study, the optimization design parameters are roof solar reflectance and thermal insulation thickness, which are considered as independent continuous variables. Therefore, any value on the real line between lower and upper bounds can be used, as shown in eq. 2:

$$X = \left\{ x \in \boldsymbol{R}^n \middle| l^i \leq x^i \leq u^i, i \in \{1, \dots, n\} \right\} \qquad \text{(eq. 2)}$$

where $l \in \mathbf{R}^n$ and $u \in \mathbf{R}^n$ are the lower and upper bound, respectively, for design options and $-\infty \leq l^i < u^i \leq \infty$ for $i \in \{1, \dots, n\}$.

The objective function is defined to minimize building annual energy consumption for air-conditioning by finding out the optimum values for roof solar reflectance or thermal insulation level, in one-dimensional optimization analysis, and the optimum combination of roof solar reflectance capability and thermal insulation, in multi-dimensional optimization procedure (eq. 3).

$$f(x) = E_{total}(x_1, x_2) \qquad \text{(eq. 3)}$$

Various integrated mathematical optimization algorithms are available to be chosen in GenOpt. In the present work, the Generalized Pattern Search (GPS) implementation of the Hooke-Jeeves algorithm is used for both one- and multi-dimensional optimization analysis. Multiple starting points are selected to avoid falling in local optima (Evins, 2013).

4. Case study

4.1. Climate zones

To perform the study for a variety of climate conditions worldwide, 28 cities representing different climate zones according to the international Köppen-Geiger classification (Kottek et al., 2006), including temperate, tropical, continental, and arid conditions, are simulated. The cities, selected based on (Synnefa et al., 2007), are listed in Tab. 1, which indicates the climate zone and the heating degree days (HDD) for each city.

4.2. Case study building

For the purpose of the application of the above-defined methodology, the ASHRAE validated standard building model for small office building (ASHRAE, 2016), characterized by high internal heat gains, is selected. The standard case study office building model presents a single-floor rectangular prism shape. A single-floor building model is selected because of the major influence of roof properties on the floor just below it. Moreover, office buildings are suitable for the installation of cool roofs (Hosseini and Akbari, 2016).The external walls are wood-framed with intermediate insulating layer, while the roof presents wood joints, EPS insulation, added to achieve acceptable roof U-value in the different climates, and coating asphalt shingles. The main building envelope features (Winiarski et al., 2007) are summarized in Fig. 2. The building is equipped with air-source heat pump and gas furnace as back up. The air distribution is constant air volume, with one unit per occupied thermal zone (Winiarski et al., 2006). Heating and cooling set-point temperatures are set equal to 20°C and 26°C, respectively, according to EN 15251:2007 (2007). Internal heat gains, due to lighting and equipment, are equal to about 15.6 W/m^2 in the whole building (ASHRAE, 2016).

The main envelope components, i.e. external wall, roof, and window, of the standard ASHRAE model are

modified in terms of their thermal properties, to achieve suitable thermal transmittances in each climate zone. Values are set in each climate zone according to the indications of the Italian current building regulation (Repubblica Italiana, 2015). The Italian regulation defines the maximum acceptable U-values for the external envelope components in a zone with varying the HDD. According to these general indications, U-values are set based on the HDD of each selected city. The thermal transmittance values of the different envelope components are adjusted by modifying the thickness of the thermal insulation in the opaque components and the window layers of the standard models (when necessary), in order to be as close as possible to the limit value. The final U-values defined in each climate zone are summarized in Fig. 2. Furthermore, the specific model inputs in terms of site location and design days for each climate scenario are implemented according to the EnergyPlus weather files (U.S. DOE's BTO, 2016).

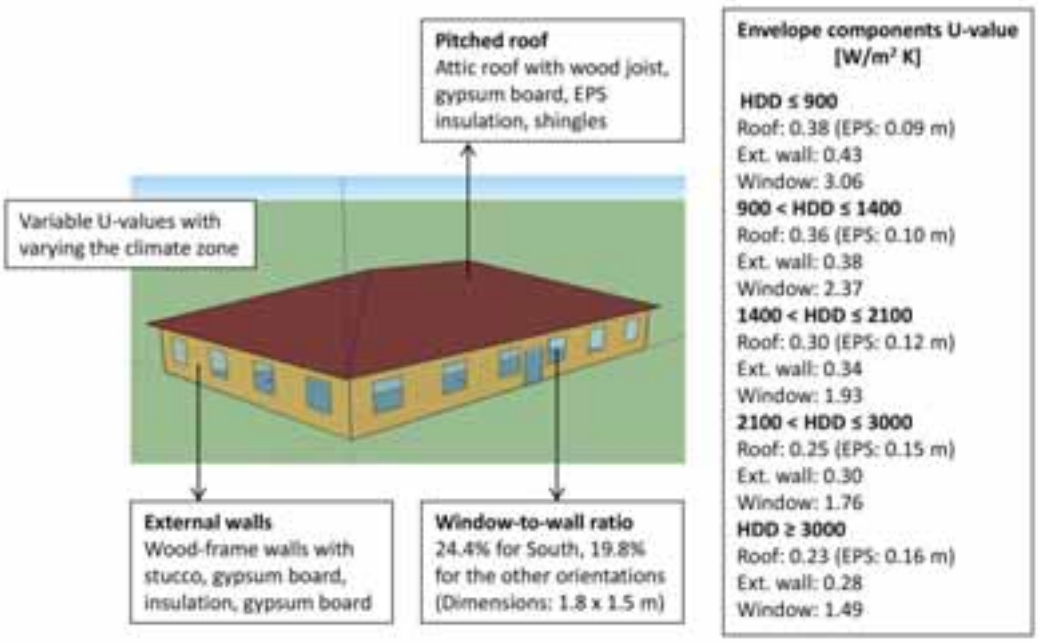

Fig. 2: Case study small office building model and envelope characteristics

5. Results

5.1. Sensitivity to roof solar reflectance variation

Firstly, the one-dimensional optimization of roof solar reflectance in the climate conditions of six selected cities representative of the HDD ranges defined in Fig. 2, i.e. Abu Dhabi, Palermo, Buenos Aires, Rome, Paris, and Tampere, is carried out. Results show that in a standard small office building the optimum roof solar reflectance corresponds to the maximum available cool capability, namely 0.8, in almost all climates except that in the almost totally heating dominated subarctic zone of Tampere (Finland). Accordingly, the configuration characterized by the lowest performance is the dark roof, i.e. ρ_{solar} equal to 0.1, in all climate zones except Tampere, where the situation is inverted and $\rho_{solar} = 0.1$ results to be the optimum value.

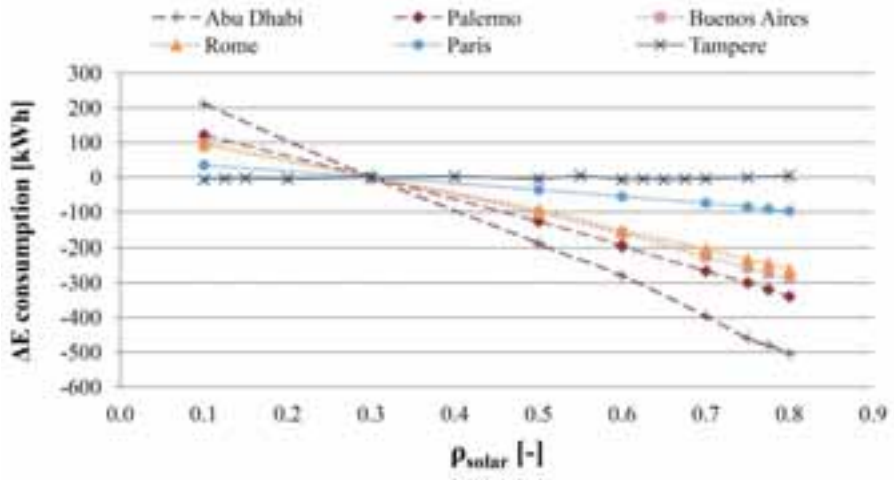

Fig. 3: Total building HVAC energy consumption difference variation with varying only roof solar reflectance in the selected climate zones

Moreover, the sensitivity of annual building energy performance to roof solar reflectance variation in the different climate zones is assessed. Fig. 3 depicts the trend of total HVAC energy consumption difference (ΔE) between roof ρ_{solar} scenarios in the considered range (0.1 ÷ 0.8) and the "standard roof" ($\rho_{solar} = 0.3$) for each selected case study city. Trend lines demonstrate how the influence of roof solar reflectance is mostly perceived

in hot and warm climate conditions, which are totally or mainly cooling dominated. The difference in terms of annual HVAC energy need of the office building is equal to 3.7%, corresponding to about 716 kWh, 5.2% (461 kWh), 5.9% (384 kWh), and 4.3% (357 kWh) in Abu Dhabi, Palermo, Buenos Aires, and Rome, respectively, between ρ_{solar} equal to 0.8 (optimum) and 0.1 (worst). Whereas, in Paris and Tampere, the building annual HVAC ΔE consumption variation trend is flatter (in particular in the subarctic city) with energy savings equal to about 132 kWh (3.7%) and 12 kWh (0.1%), respectively, between the optimum and worst ρ_{solar}.

5.2. Sensitivity to roof thermal insulation level variation

To analyze the impact of roof thermal insulation on the energy performance of the office building, the same one-dimensional optimization method is applied in the six selected representative cities by varying only the roof thermal insulation level. As previously mentioned, two different scenarios are considered for the roof solar reflectance, i.e. (i) "standard roof" and (ii) "cool roof".

As regards models with "standard roof", i.e. ρ_{solar} equal to 0.3, the maximum available roof thermal insulation thickness of 0.25 m is found to be the optimum value in all considered climates. However, the thermal insulation level variation is mainly perceived in extreme climate conditions, namely in Abu Dhabi and Tampere, as depicted in Fig. 4, which reports the trend of total HVAC ΔE consumption between roof $I_{thermal}$ scenarios in the considered range (0.01 ÷ 0.25) and the "standard roof" ($I_{thermal}$ according to HDD) for each case study city. In Abu Dhabi and Tampere the annual HVAC energy savings in the case study building are equal to 3.2% (about 615 kWh) and 5.6% (526 kWh), respectively, between $I_{thermal}$ equal to 0.25 (optimum) and 0.01 (worst). On the contrary, in temperate and milder climates, especially in those cooling dominated, the building annual HVAC energy need is only reduced by 2.7% (about 242 kWh), 3.0% (195 kWh), 1.7% (142 kWh), and 5.3% (194 kWh) in zone Palermo, Buenos Aires, Rome, and Paris, respectively, with the optimum and worst $I_{thermal}$.

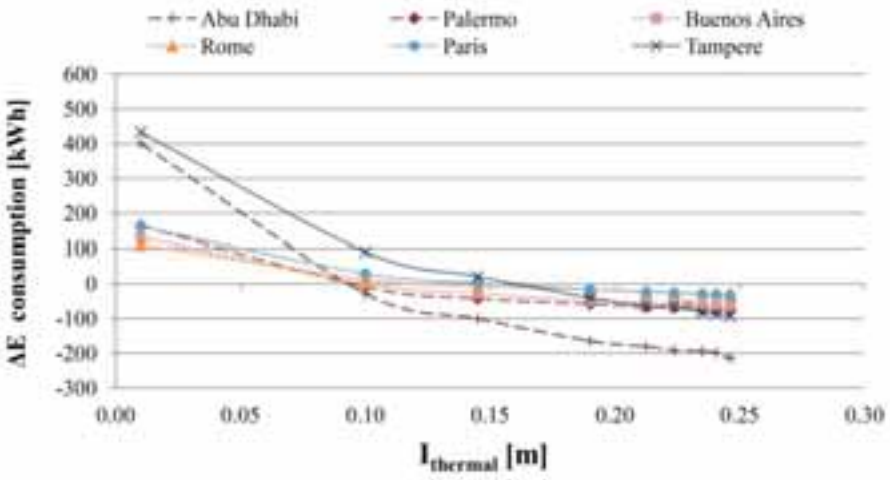

Fig. 4: Total building HVAC energy consumption difference variation with varying only roof thermal insulation thickness in the selected climate zones with "standard roof"

On the contrary, in the models with "cool roof", i.e. ρ_{solar} equal to 0.8, the annual HVAC energy consumption is minimized by applying the thinnest thermal insulation (0.01 m) as roof layer in milder climates, i.e. Palermo, Buenos Aires, Rome. Instead, in extremely hot conditions, i.e. Abu Dhabi, the optimum is increased up to 0.04 m. Finally, in heating dominated climates, namely Paris and Tampere, the optimum corresponds to the maximum available value, i.e. 0.25 m. Nevertheless, the trend of annual HVAC energy need variation is flatter (Fig. 5) and the roof thermal insulation optimization is less significant, except that in extreme cold conditions, i.e. Tampere. In fact, the cooling load is predominant in all other case study climate contexts. Accordingly, in Palermo, Buenos Aires, Rome, and Paris about 2% benefit (138 kWh, 118 kWh, 171 kWh, and 62 kWh, respectively) is observed in terms of total energy saving, while in Abu Dhabi only 0.2% (42 kWh), between the optimum and worst $I_{thermal}$. Conversely, in Tampere the HVAC energy consumption reduction increases up to 5.9%, corresponding to about 556 kWh, between $I_{thermal}$ equal to 0.25 (optimum) and 0.01 (worst).

It has to be noticed that the annual HVAC energy consumption of the case study building is more affected by roof solar reflectance variation than thermal insulation level variation, in the considered cities, except that in the

coldest climate conditions.

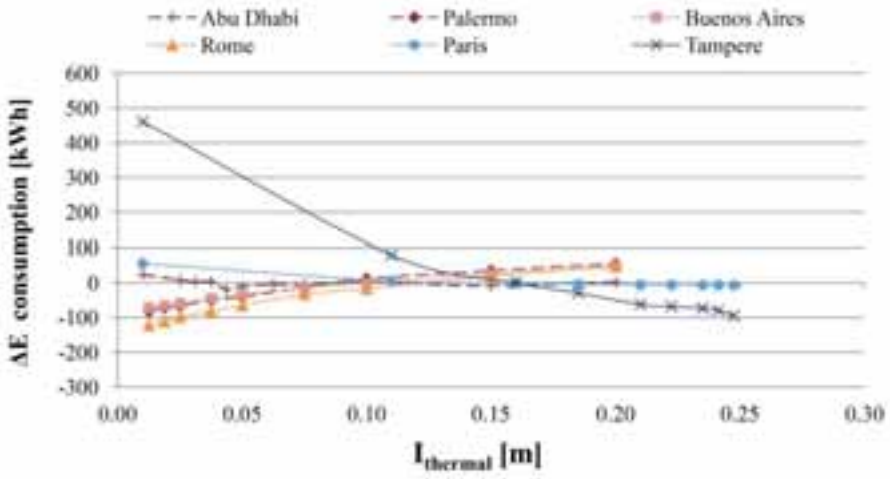

Fig. 5: Total building HVAC energy consumption difference variation with varying only roof thermal insulation thickness in the selected climate zones with "cool roof"

5.3. Optimum roof configuration with varying climate zone

Results of the multi-dimensional optimization analysis are reported in Fig. 6 and Tab. 2 for all the simulated case study climate conditions. In particular, Tab. 2 shows the optimum roof configuration (i.e. combination of ρ_{solar} and $I_{thermal}$) in each city and the corresponding total, heating, and cooling energy consumption. The roof configuration which minimizes building annual HVAC energy consumption is mostly characterized by high solar reflectance (ρ_{solar} equal to 0.8), except in the three coldest cities, while the optimum insulation level is more variable with varying the climate context. In temperate and Mediterranean zones, $I_{thermal}$ is almost negligible, since values between 0.01 and 0.04 m are found to optimize the roof energy performance (Tab. 2). On the contrary, in the extremely hot zones a suitable thermal insulation level is required to minimize heat gains. On the other hand, in the colder zones, the maximum available $I_{thermal}$ equal to 0.25 m is required to reduce heating energy losses through the roof. Therefore, Tab. 2 shows how in the majority of considered climate zones, i.e. milder, the optimum roof configuration in order to minimize annual HVAC energy consumption involves the combination of high solar reflectance capability and low insulation level (blue rectangle).

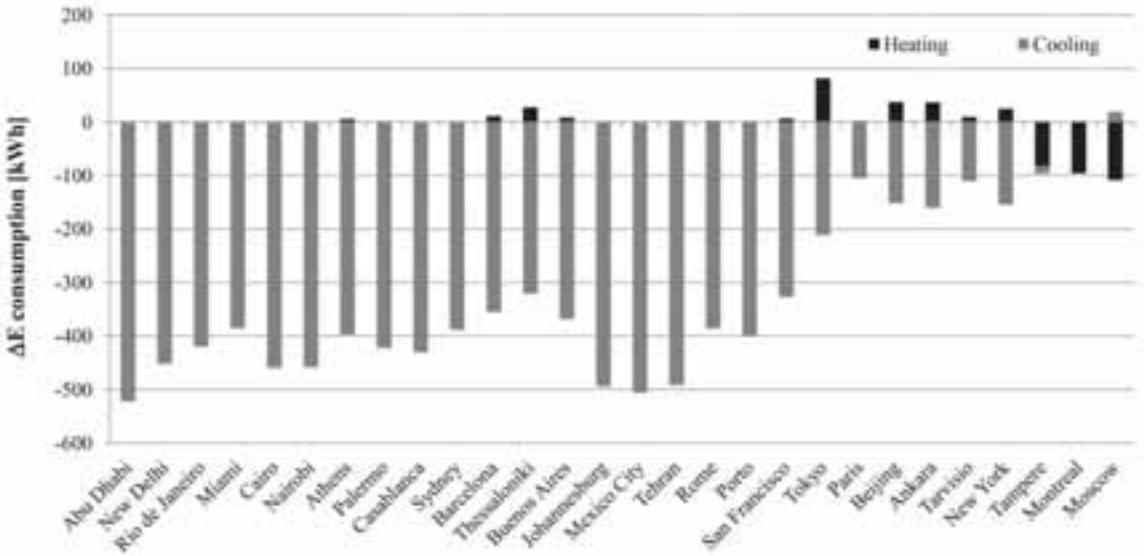

Fig. 6: Building HVAC energy consumption difference between the optimum and the "standard roof" configuration in each climate zone, reporting the separate contributions for heating and cooling

Moreover, Fig. 6 depicts the ΔE in terms of heating and cooling energy need between the "standard", i.e.

characterized by ρ_{solar} = 0.3 and $I_{thermal}$ according to the regulation (Repubblica Italiana, 2015) depending on HDD, and the optimum roof configuration in each climate. The comparison of annual HVAC energy saving with the optimum roof configuration, with respect to the "standard", demonstrates how the optimization of combination of roof solar reflectance and thermal insulation generates non-negligible annual energy saving in all considered climate conditions. However, benefits are mainly perceived in cooling dominated climates. Office building annual energy consumption for air-conditioning is reduced by about 1% to 11%. The maximum achievable actual energy saving is equal to 522 kWh, 507 kWh, 493 kWh, and 490 kWh, in Abu Dhabi, Mexico City, Johannesburg, and Tehran, respectively, always in terms of cooling energy consumption. On the contrary, the energy need reduction decreases up to 90 kWh, 95 kWh, and 97 kWh in the coldest Moscow, Montreal, and Tampere, respectively, in terms of heating energy saving. In general, the cooling load is predominant in almost all considered climate conditions, due to building end-use and associated high internal gains too.

6. Discussion

Findings of the above mentioned analyses show that, in order to minimize the annual energy consumption for air-conditioning in a standard small office building worldwide, roof solar reflectance plays a significant role.

Roof thermal insulation level is also important, yet mainly in heating dominated climates or extreme climate conditions. However, in accordance with existing works in literature (Radhi et al., 2017), when coupling cool roof and thermal insulation capability, the role of roof insulation in improving building energy performance becomes negligible, for the case study building in the majority of considered climate zones. In fact, office buildings are characterized by high internal gains, and, therefore, heating load is dampened down by such heat gains, while cooling load becomes predominant also in heating dominated climate contexts. However, in the coldest zones, a consistent insulating layer is required to limit the significant heating energy need.

Thermal insulation level increase provides benefits mainly in terms of heating load reduction. Therefore, when implementing a "standard roof", characterized by higher external heat gains with respect to the "cool roof", high thermal insulation provides significant benefits in terms of both cooling and heating energy saving. On the other hand, in the "cool roof" scenario, the cooling load is already minimized by the positive passive cooling effect due to the low roof coating solar absorptance. In this scenario, although high thermal insulation level provides positive effect in the cold season (heating load reduction), the cooling load is even increased when thick insulating layers are implemented. Since, in the case study building typology, i.e. office building, the cooling load is predominant, the annual HVAC energy consumption is generally minimized with low thermal insulation thickness, with the exception of the coldest climates. Accordingly, building annual HVAC energy consumption is more sensitive to roof solar reflectance variation, with respect to roof thermal insulation variation. Moreover, when "cool roof" is applied over the building, the effect of thermal insulation variation is less significant, except that in extremely cold conditions, because in the case study building the heating need is generally a small percentage of the annual HVAC energy requirement.

In milder climate contexts, characterized by hot summer and mild/cold winter, the expected optimum roof configuration, i.e. combination of roof solar reflectance and thermal insulation, would be with high solar reflectance, which minimizes the cooling energy consumption, and maximum available thermal insulating layer thickness, which minimizes the heating energy consumption. Nevertheless, due to the predominance of cooling load in the case study building typology (characterized by high internal gains) and to the penalties in terms of cooling need associated to high insulation levels, the optimum configuration is characterized by maximum solar reflectance and minimum thermal insulation.

7. Conclusions and future developments

In this work, a replicable method for optimizing the combination of cool roof and roof thermal insulation as passive strategies for building energy efficiency in different climate contexts is proposed. To this aim, optimization analysis based on dynamic thermal-energy simulation is carried out with the final purpose of minimizing annual energy requirement for air-conditioning by optimizing the roof configuration of a small office building in different climate contexts worldwide. In particular the combination of two key parameters affecting roof energy performance is taken into account, i.e. solar reflectance and thermal insulation thickness.

Results show that between the two considered roof characteristics, solar reflectance capability mostly affects building energy performance. Moreover, "cool roof" optimizes the annual HVAC energy consumption of the case study building in the majority of climate conditions. On the other hand, building energy performance is more sensitive to roof thermal insulation variation when a low reflectance "standard roof" is implemented. Nevertheless, when considering the combination of roof solar reflectance capability and thermal insulation level, the optimum configuration is characterized by high cool capability, i.e. R_{solar} equal to 0.8, and low insulating layer thickness, i.e. $I_{thermal}$ between 0.01 and 0.04 m, in the majority of climate zones (milder zones). The exception is represented by the extremely hot and the coldest considered climate zones, where an insulating layer up to 0.11 m and 0.25 m is required, in the hottest and the coldest zones, respectively, to limit the significant thermal energy gains or losses through the roof. All in all, the optimum combination of roof solar reflectance capability and thermal insulation level provides the maximum annual energy saving.

Although the present study refers to selected climate zones, reliable indications are provided also for other regions in the world with similar climate classifications. Moreover, the same analysis procedure is reproducible for other climate conditions. In addition, findings of this work highlight how both climate conditions and further boundary conditions affecting building energy performance, namely end-use and envelope characteristics, e.g. coating optic-energy properties, have to be taken into account simultaneously when targeting building envelope

thermal requirements. Given the promising multivariable optimization results of this paper, future developments of this work can be the investigation of economic and life-cycle benefits associated to coupling cool roof and thermal insulation design of building envelopes. Furthermore, this optimization methodology can be implemented to study the influence of further building boundary conditions in the optimum roof configuration, e.g. end-use, type of HVAC system, occupancy, internal gains. The final goal is to develop guidelines for the efficient implementation of cool roofs in different climate conditions.

Testing, Standards, and Certification for Solar Thermal Technologies

ACCELERATED AGING TESTS OF ABSORBER COATINGS FOR UNGLAZED METALLIC SOLAR COLLECTORS

Summary

During the expected minimum life-span of 20 years, the absorber coating of unglazed thermal solar collectors is directly exposed to different stresses like heat, rain and ice. With increasing application possibilities for this type of collectors (e.g. for borehole regeneration), there is a need for the quality certification of absorber coatings. However, there is no standard procedure available to assess the durability of spectrally selective coatings for unglazed collectors. Existing aging tests (ISO 22975-3) are designed for absorber coatings used in glazed solar collectors, where the degradation loads (e.g. for humidity and condensation) are very different. Preliminary steps for developing an accelerated lifetime testing procedure are presented. First results showing the optical performance after aging of two spectrally selective absorber coatings on stainless steel are reported.

Keywords: unglazed solar thermal collectors, spectrally selective absorber coatings, time of wetness, accelerated aging, optical performance.

1. Introduction

For certifying new absorber coatings, the expected service life must be predicted. Accelerated aging tests considering the relevant degradation factors are required. The in-service conditions and environmental stresses must be measured. High temperature, high humidity and moisture, and airborne pollutants were identified by the IEA Working Group MSTC (Materials in Solar Thermal Collectors) as the most relevant degradation factors for glazed flat plate collectors, used for domestic hot water production (Brunold et al., 2000). However, the loads in terms of humidity, condensation, snow/icing and hail largely differ in the case of unglazed collectors, because their absorber coating is directly exposed to the environmental stresses (Dudita et al., 2016).

Several degradation mechanisms are influencing the performance and lifetime of absorber coatings, including metal oxidation, elements diffusion and modification of the antireflective layer (Carlsson et al., 2000; Dudita et al., 2015a). This might influence the optical performance expressed by the solar absorptance (α_s) and thermal emittance (ε_t), and the long term durability of the absorber coating. High temperature increases the metal oxidation rate leading to a decrease in α_s and an increase of ε_t. Humid air and condensation occurring on the absorber surface can lead to hydration reactions of inorganic oxides and electrochemical corrosion. The corrosion can be accelerated by airborne pollutants.

Accelerated lifetime testing of materials is thus highly important for the service life estimation, especially for certification of new products prior to their market introduction. However, there is currently no standard procedure to assess the durability of unglazed metallic absorbers. Existing tests (ISO 22975-3) are specially designed for glazed solar collectors (Brunold et al., 2000).

For developing an accelerated lifetime testing (ALT) procedure, realistic loads for the absorber surface are needed. For unglazed solar thermal collectors, the degradation due to temperature and high humidity and condensation might be predominant. We have performed, as a first step, simulations to determine the temperature frequency distribution (TFD) and time of wetness (TOW) frequency distribution for the absorber surface. A representative TOW diagram which is needed to quantify the humidity induced stress, is presented in this paper. Wetting due to rain or due to environmental humidity condensing on the absorber surface was considered. Moreover, we have performed preliminary tests to assess the durability of new selective coatings on stainless steel substrate that can potentially be used in unglazed collectors. Our tests are based on the procedure mentioned in ISO 22975-3, nonetheless higher testing temperature were also included. Two samples from under development selective coatings were exposed to high humidity and condensation, at

doi:10.18086/swc.2017.36.01 Available at http://proceedings.ises.org

constant temperature (sample temperature between 40 °C and 70 °C) and constant humidity (95% RH). The optical degradation of the coatings was monitored with the help of a Bruker IFS 66/S spectrometer with a custom made configuration. A detailed description of the experimental procedure is described elsewhere (Dudita et al., 2015b).

2. Durability assessment of spectrally selective absorber coatings for unglazed solar thermal collectors

The temperature frequency distribution and the time of wetness (TOW) expected for absorber plates of unglazed collectors in different system configurations were determined by means of transient system simulations (TRNSYS v.17). In particular, a heat pump heating system with a small ice storage tank, where the collectors are operated in very harsh conditions, was selected (Mojic et al., 2015). The simulation model of the collector (TRNSYS Type 832 v5.10) includes condensation, frost and rain heat gains. As boundary conditions for the simulations, weather data for different climatic regions were considered.

An example of a yearly time of wetness (TOW) frequency distribution (humidity or condensation) for an unglazed collector is represented in Fig. 1 together with the one specific for the glazed collectors from IEA SHC Task X. The climate data represent a typical year for Zürich (Switzerland), with a time resolution of 6 minutes. Since unglazed collectors are operated at lower temperatures and in the simulated system frequently below dew point, their TOW distribution shows much larger frequencies at low temperatures. Ultimately, the established load profiles, together with the experimentally determined activation energies for the different degradation modes, will be used to define the parameters of the accelerated aging tests.

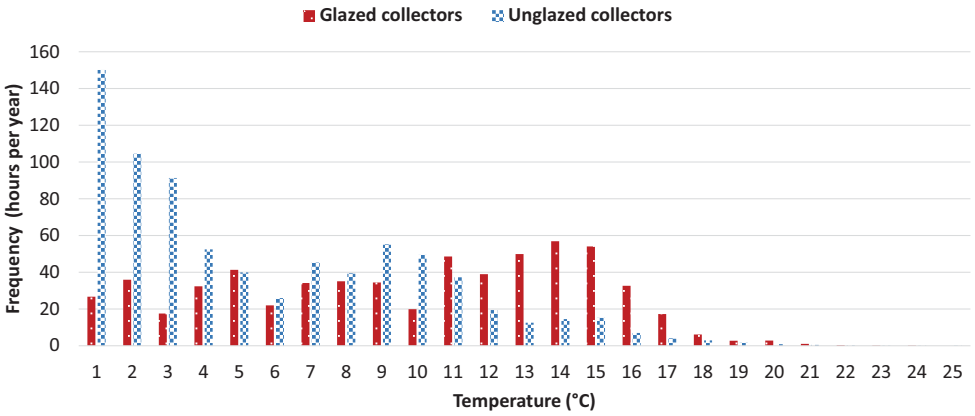

Fig. 1 Yearly time of wetness frequency distributions for absorber surfaces of glazed and unglazed collectors (criteria for the TOW were a relative humidity at the absorber surface of RH ≥ 99 % or a rain rate >= 3mm/h)

The resistance of absorber coatings to high humidity and condensation conditions was investigated for two different absorber coatings. An adapted procedure based on ISO 22975-3 for the qualification of solar absorber coatings used in glazed collectors was followed. Different testing sample temperatures (40°C to 70°C), high humidity and condensation conditions were applied for the two spectrally selective coatings (Type A and Type B) deposited via physical vapor deposition on stainless steel substrate. The optical performance expressed as the variation of solar absorptance and thermal emittance remained constant in the 40°C test (see Fig. 2 and Fig. 3). Higher testing temperatures (60°C and 70°C) were used to estimate the activation energy and the coatings lifetime.

3. Concluding remarks

The market of unglazed solar thermal collectors with spectrally selective coatings on metal substrate is continuously increasing as new applications like boreholes regeneration or combination with ice storages are emerging. There is currently no standard procedure to assess the durability of unglazed metal-based absorbers used for unglazed solar thermal collectors. However, accelerated lifetime testing of materials is highly important for the development and certification of (new) products prior to their market introduction. Introduction of new materials for the absorber coating is hindered by insecurities regarding lifetime.

First results of a project aiming at the development of an accelerated aging procedure for spectrally selective coatings on metal substrate for unglazed collectors are presented. Realistic load profiles, e.g. the yearly time of wetness (TOW) frequency distribution due to humidity or condensation generated by simulations are shown.

In order to propose an accelerating aging procedure, further studies are necessary. In particular, an appropriate Performance Criterion (PC) must be established to set limits on the acceptable change of the optical properties of the absorber coating, corresponding to an acceptable decrease of the performance of a typical energy system with uncovered solar collectors.

Analysis of Test Methods for Durability and Performance of Heat-pipes for Solar Thermal Application

HE Zinian

Beijing Solar Energy Research Institute Group Co., Ltd, Beijing (China)

Abstract

After introducing the configuration of a heat-pipe for solar thermal application, this paper analyses test methods for two main aspects which affect the durability of heat-pipes, i.e. high temperature resistance and freeze resistance, and also analyses test methods for three important parameters which indicate the performance of heat-pipes, i.e. starting temperature, temperature uniformity and heat transfer power. For each durability test and performance test of heat-pipes, their significance and necessity, as well as their test objective, test principle, test conditions, test apparatus, test procedure, test results, etc. are respectively introduced in this paper. These test methods have been newly developed as the International Standard ISO 22975-2: 2016, which will play an important role in enhancing product quality and reducing test cost of heat-pipes.

Keywords: Heat-pipe, test methods, durability test, performance test, International Standard

1. Introduction

Heat-pipe is a highly efficient heat transfer element and has been widely used for solar thermal application. For this reason, ISO/TC 180 has recently developed the International Standard ISO 22975-2: 2016 titled as Solar Energy – Collector components and materials, Part 2: Heat-pipe for solar thermal application – Durability and performance.

ISO 22975-2: 2016 specifies test methods for durability and performance of heat-pipes, and is applicable to all heat-pipes for use with evacuated tubes, including glass-metal sealed evacuated tubes and double-glass evacuated tubes, as well as for use with flat-plate collectors.

For each durability test and performance test of heat-pipes, their significance as well as test objective, test principle, test condition, test apparatus, test procedure, test results, etc. will be introduced in the paper.

2. Configuration of the heat-pipe

Heat-pipes operate only by utilizing latent heat of phase-change of the working fluid for heat transfer. Heat-pipes can be basically classified into two categories according to backflow manner of the working fluid. One is the heat-pipe with a capillary wick, and the other one is the heat-pipe without a capillary wick. For the former, backflow of the liquefied working fluid relies on the capillary action; whereas for the later, backflow of the liquefied working fluid relies on its gravity. Therefore, the later is also called as the gravity heat-pipe.

Since this international standard is only applicable to gravity heat-pipes, so the gravity heat-pipe essentially consists of evaporator, condenser, adiabatic section and working fluid, as shown in Fig. 1, and there is a highly evacuated space inside the heat-pipe. For the gravity heat-pipe, the liquefied working fluid returns from the condenser to the evaporator due to its own weight.

3. Durability of heat-pipes

3.1. High temperature resistance test

As heat-pipes used for solar thermal application may probably undergo an exposure state under the sun to reach a quite high temperature, for example, in the range of 180 °C to 280 °C for different applications, so it is necessary to perform a high temperature resistance test.

This test is intended to assess the capability of the heat-pipe to withstand quite high temperature without failure.

The test needs indoor environment. The test shall be carried out using a set of test apparatus which consists of a heating chamber and a thermometric system, of which the test temperature shall be at 180 °C ± 5 °C or 230 °C ± 5 °C or 280 °C ± 5 °C, depending on specific application and manufacturer's declaration.

In the test, place all sample heat-pipes with a tilt angle 90° ± 1° into the heating chamber; increase the temperature slowly (maximum 20 K/min) up to the selected test temperature; maintain the test temperature for 30 h; then let heat-pipes naturally cool down; after the heat-pipes have cooled to room temperature, visually inspect for damage such as leakage, breakage, distortion or deformation.

The heat-pipes will be qualified if there is no visual evidence of damage.

3.2. Freeze resistance test

As heat-pipes used for solar thermal application may undergo a freeze weather condition in winter season in many areas to reach a rather low temperature, such as below 0 °C, so it is very important to perform a freeze resistance test.

This test is intended to assess the extent to which the heat-pipe which is claimed to be freeze resistant, can withstand freezing without failure.

The test needs indoor environment. The test shall be carried out using a set of test apparatus which consists of an appropriate freezing device and a thawing device. The freezing temperature shall be at −20 °C ± 1 °C and the thawing temperature shall be at 20 °C ± 1 °C.

In the test, place all sample heat-pipes with a tilt angle 90° ± 1° into the freezing device for 60 min; remove the heat-pipes from the freezing device and insert them into the thawing device, keeping the evaporator in lower position; measure the temperature on the condenser surface; wait for 5 min after the temperature

difference between the thawing device and the condenser surface is less than 9 K, which indicates that heat-pipes have started to operate again; repeat above-mentioned steps 20 times; then visually inspect for damage such as leakage, breakage, distortion or deformation.

The heat-pipes will be qualified if there is no visual evidence of damage.

4. Performance of heat-pipes

4.1. Starting temperature of heat-pipes

Heat-pipes used for solar thermal application always face such a problem, whether and when the heat-pipe can start operating. From the evaporation point of view, as there is a negative pressure inside the heat-pipe, the evaporation temperature of the liquefied working fluid should be lower than that at atmospheric temperature, so as to easily start operating of the heat-pipe, and undoubtedly the lower starting temperature the better for solar thermal application. Therefore, starting temperature is one of the important parameters of heat-pipes.

This test is intended to determine the minimum temperature required for a heat-pipe to start operating.

The test needs indoor environment. The test shall be carried out using a set of test apparatus which consists of a cold water bath at 10 °C ± 0.5 °C and a hot water bath at 25 °C ± 0.5 °C or 30 °C ± 0.5 °C or 40 °C ± 0.5 °C, depending on specific application for different working temperature of the heat-pipe; however, 40 °C ± 0.5 °C shall be the maximum test temperature.

In the test, fit a surface temperature sensor to the condenser; immerse the lower end of the heat-pipe in the cold water bath with a tilt angle 90° ± 1°; wait for at least 3 min after stable conditions are reached; remove the heat-pipe from the cold water bath and immerse its lower end in the hot water bath; measure and record the temperature on the condenser surface every 10 s until at least 120 s after stable conditions are reached; record the condenser surface temperature together with the hot water bath temperature.

The measurement results shall be reported together with ambient temperature, cold water bath temperature, hot water bath temperature, insertion depth of the heat-pipe, distance of measuring point from top of the condenser and variation of the condenser surface temperature.

4.2. Temperature uniformity of heat-pipes

Under normal operating conditions, steam of the working fluid inside the heat-pipe is in a saturated state, and pressure of the saturated steam determines temperature of the saturated steam. As the pressure drop produced when saturated steam moves from the evaporator to the condenser is very small, so the temperature drop is also very small. That is why the heat-pipe possesses excellent isothermal. If there is an obvious temperature difference between the evaporator and the condenser, i.e. the heat-pipe loses the temperature uniformity; it means that non-condensable gas produced during the manufacturing stays in the condenser. Undoubtedly the smaller temperature differences the better for solar thermal application. Therefore, temperature uniformity is also one of the important parameters of heat-pipes.

This test is intended to measure the temperature difference between the evaporator and the condenser when the heat-pipe operates under normal conditions.

The test needs indoor environment. The test shall be carried out using a thermostatic hot water bath at 90 °C ± 0.5 °C.

In the test, fit a surface temperature sensor to the condenser at a point between 18 mm and 22 mm from top of the condenser; insert the heat-pipe into the thermostatic hot water bath to a depth of 3/5 - 2/3 of the total length of the heat-pipe at a tilt angle 90° ± 1°; measure and record the temperature on the condenser surface every 10 s until at least 60 s after stable conditions are reached; record the temperature difference between the hot water bath temperature and the stable condenser surface temperature.

The measurement results shall be reported together with ambient temperature, test temperature in water bath,

insertion depth of the heat-pipe, measuring point from top of the condenser, and condenser temperature variation.

4.3. Heat transfer power of heat-pipes

As a highly efficient heat transfer element for solar thermal application, it is concerned that how much power can be transferred. Therefore, heat transfer power is certainly one of the important parameters of heat-pipes.

As heat transfer power depends on operating temperatures and tilt angles of the heat-pipe, so this test is intended to determine the heat transfer power of the heat-pipe at different operating temperatures and different tilt angles.

The test needs indoor environment. The test apparatus includes tilt-angle adjustable mounting support, evaporator electric heating barrel, condenser cooling liquid jacket, thermostatic liquid bath, flow meter, etc. shown in Fig. 2.

21) humidity meter

Fig. 2: Typical test apparatus for measuring the heat transfer power of a heat-pipe

In accordance with the energy conservation law, the heat transfer power of the heat-pipe shall be calculated according to Equation (1).

$$\dot{Q} = \dot{Q}_1 - \dot{Q}_2 \qquad \text{(eq. 1)}$$

where

$\dot{Q}$ = heat transfer power of heat-pipe, W
$\dot{Q}_1$ = thermal power transferred to cooling liquid from heat-pipe, W
$\dot{Q}_2$ = thermal power transferred to cooling liquid from environment or apparatus, W; normally $\dot{Q}_2$ is negligible if the cooling liquid jacket is well insulated

The thermal power received by cooling liquid shall be calculated according to Equation (2).

$$\dot{Q}_1 = \dot{m} C_p (\vartheta_2 - \vartheta_1) \qquad \text{(eq. 2)}$$

where

$\dot{m}$ = mass flow rate of cooling liquid, kg/s
C_p = specific heat capacity of cooling liquid, J/(kg • K)
ϑ_2 = inlet temperature of cooling liquid, °C
ϑ_1 = outlet temperature of cooling liquid, °C

In the test, the evaporator of the heat-pipe is inserted into the sleeve of the electric heating barrel; a copper tube shall be placed between the evaporator and the electric heating elements to ensure uniform heating power distribution; the outer surface of the electric heating barrel shall be thermally insulated; meanwhile, the condenser of the heat-pipe is inserted into the sleeve of the cooling liquid jacket and surrounded with heat transfer paste which has not been used previously; the outer surface of the cooling liquid jacket shall be thermally insulated.

After measuring all necessary parameters, such as mass flow rate $\dot{m}$, inlet temperature ϑ_2 and outlet temperature ϑ_1 of the cooling liquid, then determine the heat transfer power $\dot{Q}_1$ at different operating temperatures and different tilt angles, according to Equation (2).

The test operating temperatures shall be respectively at 60 °C ± 0.5 °C, 90 °C ± 1 °C and 120 °C ± 2 °C (when the heat-pipe is claimed to be able to operate at above 100 °C).

The tilt angle of the heat-pipe shall be from the lowest recommended angle to 90°, i.e. respectively the lowest recommended angle, 20° ± 1°, 30° ± 1°, 45° ± 1°, 60° ± 1°, 75° ± 1°, 90° ± 1°.

In this test, the maximum heat transfer power $\dot{Q}_{max}$ also could be determined. This test shall be conducted directly after carrying out the test of heat transfer power at the test operating temperature 120 °C ± 2 °C and test tilt angle 90° ± 1°.

For determining the maximum heat transfer power $\dot{Q}_{max}$, the procedure shall be as follows:

Slowly increase the power input to the evaporator electric heating barrel, i.e. at a rate of less than 5 W/min; observe the test operating temperature of the heat pipe; once there is an obvious sudden temperature increase, or the temperature shows obvious oscillation and instability, it means that the heat-pipe has reached its heat transfer limit; then quickly reduce the power input to the evaporator electric heating barrel to a point just before the heat transfer limit; when steady state conditions have been achieved, begin to record the values of mass flow rate $\dot{m}$ of the cooling liquid, and inlet/outlet temperature difference $(\vartheta_2 - \vartheta_1)$ of the cooling liquid, at intervals of 30 s for a period of 10 min; finally calculate the maximum heat transfer power $\dot{Q}_{max}$ of the heat-pipe according to Equations (2), using the averages of the recorded values for mass flow rate and inlet/outlet temperature difference of the cooling liquid.

5. Conclusion

Heat-pipe is one of the important components in solar thermal application. Through a lot of experiments and accumulated practical experience, this paper analyses two main aspects which affect the durability of heat-pipes, including high temperature resistance and freeze resistance,

In addition, this paper also analyses three important parameters which indicate the performance of heat-pipes,

including starting temperature, temperature uniformity and heat transfer power.

Based on these achievements, under the joint efforts of WG 3 members, ISO/TC 180 has recently developed International Standard ISO 22975-2: 2016. The newly developed International Standard will play an important role in enhancing product quality and reducing test cost of heat-pipes.

In-situ Testing of Large Collector Arrays – Challenges and Methodological Framework

Daniel Tschopp[1], Philip Ohnewein[1], Robert Hausner[1], Christoph Rohringer[1]

[1] AEE – Institute for Sustainable Technologies, A-8200 Gleisdorf

Abstract

In this paper, the major challenges of in-situ collector array testing are analyzed and a framework to address them is developed. The study of the challenges is based on theoretical investigations as well as on data evaluations of a solar district heating (SDH) plant which was equipped with high-precision measurement equipment.

Keywords: in-situ testing, collector array, in-situ measurement, large solar thermal plants, solar district heating

1. Introduction

1.1 The need for in-situ testing of large scale solar thermal plants

Large scale solar thermal plants (>500 m² collector area, >350 kW_{th} nominal thermal power) are a cost-effective way to provide renewable heat (ESTIF, 2015). The market has experienced considerable growth recently, with close to 500,000 m^2 of solar collectors (350 MW_{th}) installed in large scale systems in Europe in 2016. The driving force has been solar district heating applications in Denmark, where the world's largest plant in Silkeborg (156,694 m² flat plate collectors; 110 MW_{th}) started operating in December 2016 (Weiss, Spörk-Dür and Mauthner 2017).

Key factors to increase the market penetration of large solar thermal plants are the reduction of investment risks and the realization of cost saving potentials during the plant operation by means of performance guarantees (for the thermal power output and/or solar yield), efficient monitoring and ongoing optimization.

These measures rely on an accurate and reliable assessment and characterization of the collector array performance for the observed operational behavior. To this aim, an in-situ test procedure to evaluate the thermal power output of large collector arrays under transient conditions is developed. Hereafter we refer to this procedure as the in-situ collector array test.

1.2 In-situ collector array test

The cornerstones of the test procedure are the following:

- focusing on large scale collector arrays with flat plate collectors (flat plate collectors are the most common collector technology deployed in large scale applications)
- the outcome of the test is a characterization of the thermal power output with a set of characteristic parameters which are estimated from measurement data, using a parametrized model of the collector array
- the test considers 'real operation conditions' like soiling, shading, etc. which affect the collector array performance (for single collectors under laboratory conditions, these 'disturbances' can be controlled or are not relevant)
- applicability of the procedure to the most common plant configurations and measurement setups
- the system boundaries of the collector array model are the return and supply lines on the primary side of the heat exchanger (or the equivalent position if there is no heat exchanger)
- the modeling of the collector array puts emphasis on the most important influencing factors on the thermal performance, but restrains from a detailed representation to facilitate the application of the procedure

doi:10.18086/swc.2017.36.03 Available at http://proceedings.ises.org

- a major requirement is a short test period and the reliance on data from the normal plant operation whenever possible
- provision of a standardized and traceable framework for data acquisition, data processing and parameter estimation

The in-situ test procedure will have some similarities with the ISO 9806 standard for single collector tests, but focuses on large collector arrays instead of single collectors and moves from laboratory to 'real-world' conditions. The aim is not to test single collectors in the field, but rather to examine the behavior of an 'average collector' within the array arrangement. In-situ testing of collector arrays is also useful when single collector tests are very difficult to implement, e.g. for large collectors assembled directly at the construction site.

Work on using in-situ data to determine collector (array) parameters date back more than twenty years and include Perers (1993), Bosanac and Nielsen (1997) and Spirkl et al. (1997). These approaches are based on the modeling and data evaluation techniques of single collectors in the spirit of EN 12975. In later work, approaches to identify the collector (array) parameters based on dynamic system simulations were also used (see e.g. Almeida et al. (2014)). In the literature, there is no methodologically sound procedure for testing large collector arrays available.

1.3 Content and structure of this work

In this paper, the major challenges of in-situ collector array testing are analyzed and a framework to address them is developed. The study of the challenges is based on theoretical investigations as well as on data evaluations of a solar district heating (SDH) plant which was equipped with high-precision measurement equipment. To develop an in-situ collector array test, reliable data of large scale installations are essential.

The structure of the paper is as follows. In chapter 2, the main steps of the in-situ collector array test are outlined with the help of a flowchart. In chapter 3, the measurement setup of the SDH plant which was used to gain measurement data for the development of the methodology is shown. In chapter 4, the challenges of the test procedure are analyzed in detail. In chapter 5, a framework to address these challenges is presented. Chapter 6 summarizes the results and gives an outlook on future work.

2. Flowchart of the in-situ collector array test

Fig. 1 shows a simplified flowchart of the collector array test. The first steps are to create a model of the solar thermal plant and to collect, pre-process, select and assess the measurement data. Based on these preliminary tasks, the model input data, i.e. the time series with the explanatory variables and the dependent variable which enter the parameter estimation procedure, are created. The parameters are then estimated and a test report is issued.

[A] Plant representation

The representation of the solar thermal plant is done by adapting a general modeling approach which is suitable for the most common configurations. The representation encompasses the (i) typical collector array parameters (gross collector area, total fluid content, etc.), (ii) collector array geometry (row spacing, azimuth and tilt angle of the collectors, etc.) which is necessary for the irradiance modeling, (iii) hydraulic arrangement and (iv) information on the measurement setup (type of sensors, sensor positions, sensor precisions, installation conditions, sampling rate, …) and available data.

[B.1] Measurement data acquisition and data pre-processing

For commercial installations, the quality of the measurement data is almost always an issue. The measurement data needs to be checked for missing values, sensor readings outside physically plausible ranges, synchronization problems of the data logger, etc. Redundancies of the measurement setup (e.g. both beam irradiance, diffuse irradiance and total irradiance are measured) can be used for additional inspections. An often used check for in-situ collector array testing is to compare the daily sum of the global irradiance and the daily collector yield and verify if the relationship is approximately linear (Perers 1993).

[B.2] Measurement data selection

After pre-processing we have validated data. The next step is to select specific intervals to be used in the subsequent parameter estimation procedure. For example, data when there is no volume flow in the collector array might be excluded. If there is a lot of data available, it can be necessary to cluster the data and reduce it to

'characteristic days' with typical operational and ambient conditions to obtain a representative sample.

[B.3] Test data assessment

The test data needs to meet certain criteria, and these have to be checked before applying the parameter estimation procedure. Crucial is a sufficient variation, especially of the irradiance and the return temperature, as well as a limited correlation of the explanatory variables (e.g. test data with low irradiance values and low and high temperatures as well as high irradiance values and low and high temperatures).

[C] Model input data

The test data is then transformed to the explanatory variables and the dependent variable of a general collector array model, which yields the same core parameters for all arrays. The explanatory variables include for example (i) the beam irradiance on the tilted collectors calculated from the DNI measurement, the position of the sun and the collector orientations and (ii) the primary volume flow, derived from the return and flow temperatures and fluid properties of the primary side and the power output measurement of the secondary side. This allows some flexibility regarding the measurement setup. Oftentimes, the model input data are exactly the same as the test data. As long as the transformation from the test data to the model input data does not depend on the estimated parameters itself, the transformed variables can be treated like measured values, but with additional modeling and measurement uncertainties.

[D] Parameter identification

The next step is the parameter identification which yields the collector array parameters (heat losses coefficients, incidence angle modifier, etc.). As the collector array model is based on differential equations, a dynamic parameter estimation procedure is needed. For each set of parameters, a time series for the predicted output values is calculated and the parameters are chosen in such a way, that the mean prediction error (predicted output values minus measured output values) is minimized.

[E] Test report

The final step is the documentation of the results in a test report. The documentation contains the obtained parameters, their significance, uncertainties, etc. and descriptions of the plant representation, measurement data, data selection, etc.

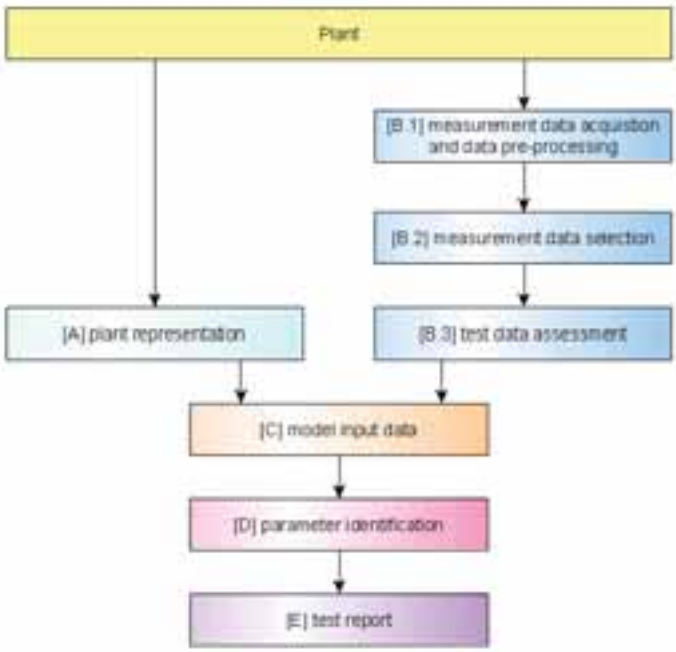

Fig. 1: Flowchart of the in-situ collector array test

3. High-precision measurement of a SDH plant

A cornerstone to develop the in-situ collector array test is the availability of high-precision measurement data of large solar thermal plants. To this aim, a large solar thermal plant in Graz (Austria), depicted in Fig. 2, was equipped with high-precision measurement equipment (i.e. high-precision irradiance, temperature and volume sensors as specified below). In this plant, six collector arrays with high-efficiency flat plate collectors of five different producers are measured (total gross collector area: 2,150 m^2). Fig. 3 shows the positions of the volume flow and temperature measurements. Each array has a separate volume flow sensor (electromagnetic flow sensor *KROHNE OPTIFLUX 4000*). The inlet and outlet temperature of each array and the flow temperatures for each row are measured. For one specific row, additional measurements of the inlet and outlet temperatures of single collectors are put in place. All temperatures are measured directly in the fluid with PT100 sensors of tolerance class DIN EN 60751, F 0.1. Total irradiance in the collector plane is captured by a pyranometer (*Kipp & Zonen SMP 21*). For the measurement of beam irradiance, a pyrheliometer with an active solar tracking system device is used (*Kipp & Zonen SHP 1*). Wind speed and ambient temperatures are measured in three different spots. The sampling rate is one second. The aim of the measurement instrumentation is to achieve precisions comparable to outdoor measurements of accredited collector test laboratories. The setup allows a direct side-by-side comparison of the different collector types. Data are available since August 2016.

Fig. 2: High-precision measurement of a large solar thermal plant in Graz (Austria)

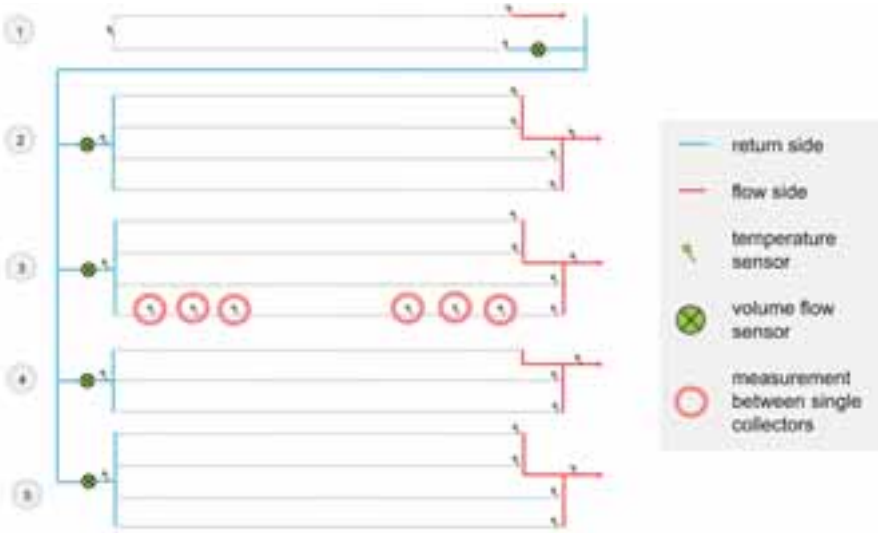

Fig. 3: Measurement setup of the volume flow and temperature sensors

4. Major challenges of in-situ collector array testing

General requirements of technical test procedures are the validity, reliability and accuracy of the procedure. The main challenges to achieve this are listed below.

4.1 Correct determination of the beam and diffuse irradiance on the collector plane

Problem description

The beam and diffuse irradiance on the collector plane are the most important influencing factors of the thermal power output of the collector array. Three main issues are relevant here:

- **Internal shading** due to collectors placed in front
- **External shading** due to surrounding objects (buildings, trees, etc.)
- **Unequal distribution of beam and diffuse irradiance and non-representative sensor readings.** Typically, not all parts the collector array receive the same amount of beam and diffuse irradiance. The front row is not exposed to internal shading and external shading depends on the position in the array relative to the sun and the surrounding objects. Different sky view factors between the collectors and along the collector height of single collectors, different albedo values of the ground, etc. lead to a varying diffuse irradiance. This makes a representative measurement of the irradiance on a single 'reference position' difficult. The irradiance recorded by the radiation sensors and the irradiance the collectors are exposed to might diverge to a point where the sensors are shaded and the rest of the field is not or vice versa.

These issues have been analyzed using data of the SDH test plant described in chapter 3. Fig. 4 shows two images of the 3D model of the plant, taken in the morning and afternoon for a sample day. At 8.43h (left), external shading can be spotted, at 16.30h (right) internal shading can be seen. Furthermore, the pyranometer positioned in the middle of the array, is shaded by an external object, whereas most collectors are not.

Fig. 4: Irradiance analysis of the test plant (2017-09-27)

Implications for in-situ collector array testing

When internal and external shading is not accounted for and the sensor readings differ from the irradiance the collectors are exposed to, the assessment of the collector array performance is not adequate because the energy input to the system is not calculated correctly. Usually the irradiance is overestimated, as the pyranometer which measures the total tilted irradiance is placed above the collectors where it is less exposed to shading and has a larger sky view factor than the lower parts of the collector. If a collector has an optical efficiency of $\eta_0 = 0.8$ and the irradiance on the collector at normal incidence is overestimated by 10% (e.g. 880 W/m^2 instead of 800 W/m^2), then the calculated optical efficiency is mistakenly assumed to be $\eta_0 = 0.73$, which makes a huge difference.

4.2 Collector array dynamics

Problem description

Large collector arrays show a highly dynamic behavior due to abrupt changes of the irradiance, return temperature and volume flow (variable speed pumps are the standard in large scale applications). For in-situ testing, there is only a limited possibility to impose stationary conditions due to technical and economic constraints. The dynamic behavior places an import role in the overall collector array assessment.

For large collector arrays, the dwelling time of the fluid in the collector array (i.e. the time that elapses between the entrance of a fluid element volume in the collector array and its exit) is determined by the volume flow rate. It is often in the range of 2 to 3 minutes and can reach up to 10 minutes. The dwelling time influences the dynamic behavior to a large extend, the time constant and the heat capacity will vary accordingly.

In Fig. 5, the issues regarding the dynamics are exemplified by analyzing the response of the outlet temperature when swift changes of the irradiance, return temperature and volume flow rate occur. Depicted are five arrays of the test plant. After the volume flow rate decreases (1), the outlet temperature rises steadily over the course of ten minutes (2) and starts decreasing again after the volume flow rate is put back to the initial level (3). A swift increase of the return temperature (4) leads to lower outlet temperatures. The two effects interfere (5).

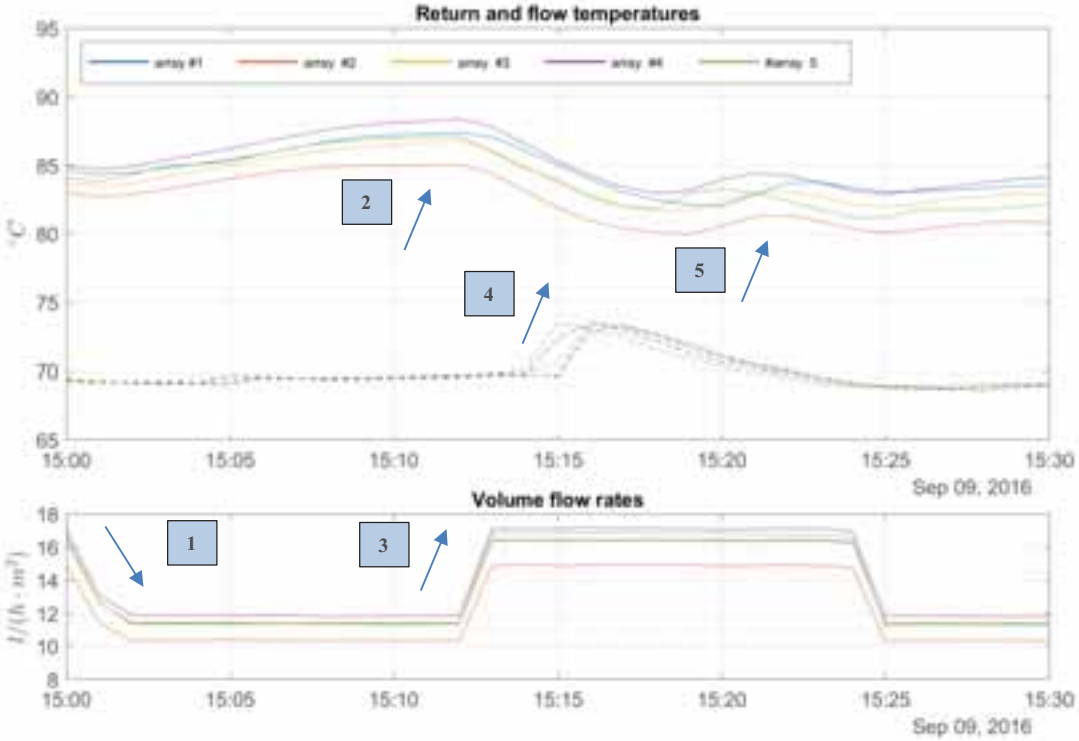

Fig. 5: Delayed response of the collector array outlet temperature (2, 5), when swift changes of the volume flow rate (1, 3) and return temperature (4) occur. Depicted are five arrays of the test plant.

Implications for in-situ collector array testing

If the modeling of the collector array outlet temperature does not take the delay that the dwelling time causes into account, then changes of the irradiance, return temperature and volume flow rate are mistakenly assumed to have an immediate effect. This leads to an inaccurate prediction of the short-term thermal power output and wrong estimates for the time constant and heat capacity values.

4.3 Availability of measurement data

Problem description

The challenges regarding the available measurement data are the following:

- **Limited operating range**. Most large scale installations feed into a district heating network. The most common connection is Return/Supply (R/S), which implies that the return and flow temperatures of the solar loop will usually be close to the (stable) grid return and flow temperatures. Data with a low temperature rise between the return and flow side (these conditions are needed to determine the zero loss coefficient) are usually not available.
- **High correlation of total tilted irradiance and the mean collector array minus ambient temperature**, as low irradiance levels lead to lower outlet temperatures and higher irradiance levels lead to higher outlet temperatures.
- **Sensor readings are not representative**. This problem is most prominent for the irradiance measurement as was pointed out before. But the issue also applies to the wind speed or ambient temperature measurements. The wind speed in the collector plane varies a lot across the array and cannot be measured adequately for collector arrays (for single collector testing, ISO 9806 requires to measure the wind speed on four edges of the collector).
- **Accuracy and precision of commercial measurement equipment.** Commercial installations often use low-cost sensors (especially for the irradiance measurements) and sensors might not be installed correctly (e.g. temperature sensors with too low penetration depth).
- **Missing measurement points.** Some inputs might not be directly measured, it can be needed to calculate them (e.g. the primary volume flow, derived from the return temperature, flow temperature and fluid properties of the primary side and the thermal power measurement of the secondary side). This can lead to additional uncertainties.

In Fig. 6, a bi-variate histogram of the total irradiance on the collector plane and the collector array mean minus ambient temperature of one-year data of one subfield of the test plant is shown. This distribution is typical for SDH plants. Most of the data lies in a close range and the irradiance and temperature are positively correlated.

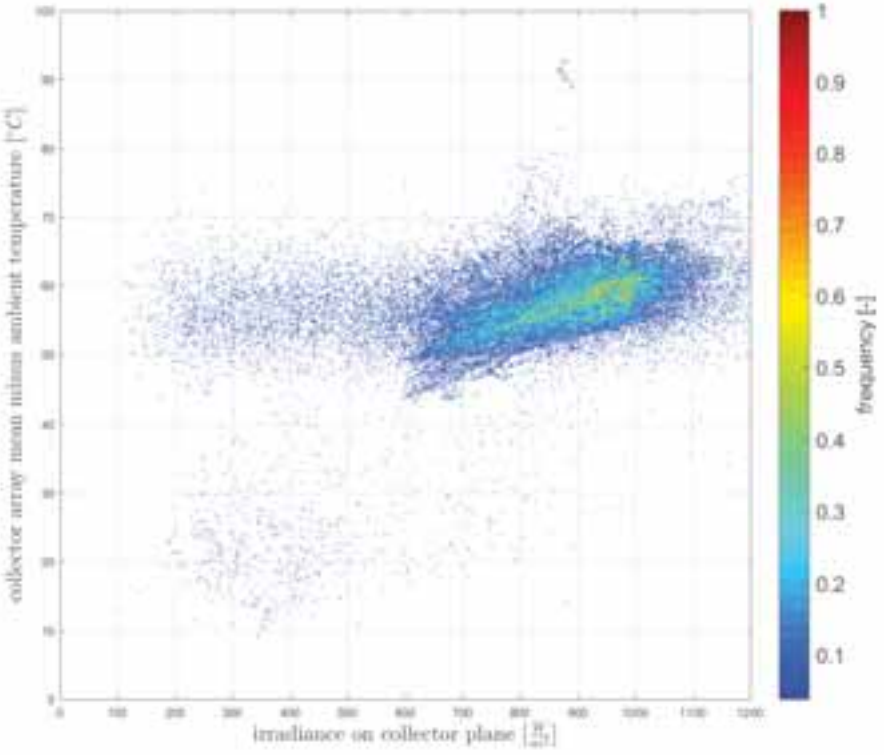

Fig. 6: Bi-variate histogram of the total irradiance on the collector plane and the collector array mean minus ambient temperature

Implications for in-situ collector array testing

A limited operating range and a high correlation of the irradiance and the collector array temperatures can lead to unstable parameters and overfitting. Optical parameters (zero loss efficiency, incidence angle modifier) and heat loss coefficients cannot be distinguished properly. Sensor readings that are not representative and low measurement data quality can lead to a bias.

4.4 Conflict of interest regarding the goals of the procedure

Problem description

For in-situ collector array testing, the following trade-offs need to be addressed:

- **Precision vs. easy applicability**. A detailed modeling of the collector array and strong restrictions regarding measurement data (sensor precisions, data range, data variation, etc.) lead to a more precise characterization of the collector array, but hinder an easy applicability. For example, a detailed modeling of the temperature and flow distribution increases the exactness, but requires a big effort and detailed analysis.
- **Comparability vs. broad applicability**. Different flat plate collector types, collector tilts and orientations, hydraulic layouts, flow conditions in the absorber pipes, varying levels of soiling, etc. might compromise the comparability. At the same time, the test procedure needs to be flexible regarding different plant configurations.
- **Choice of system boundaries**. The choice of system boundaries depends foremost on the available measurement points, but also encompasses choices regarding the attribution of losses. For example, if the heat exchanger losses are not attributed to the collector array, systems with no heat exchanger and active anti-freezing protection might have a disadvantage.

Implications for in-situ collector array testing

The advantages and disadvantages need to be balanced. The general approach of the developed in-situ collector array test is to lean towards easy and broad applicability rather than exactness.

5. Framework for in-situ collector array testing

A framework to address these challenges is covered in this chapter. The major building blocks are:

- **Collector rows as basic modeling blocks**. The core entity when modeling the primary side of large collector arrays is one collector row. A collector row has a well-defined volume flow and inlet and outlet temperature. These variables can be measured at the system boundaries or inferred if they are not given directly. The temperature rise between the cold and hot side of a collector row is usually sufficiently large, such that the thermal power output can be determined with reasonable accuracy. A collector row has also a well-defined (mean) dwelling time. Furthermore, a collector row can in most cases be treated as homogenous regarding tilt, azimuth and irradiance (the internal shading of the collectors is usually similar for all collectors of one row). Irradiance measurements in the collector plane in one spot of the row have in most cases the same (potential) bias for all collectors. A collector row behaves similar to a large collector and can (for the most part) be described with collector parameters. However, changes in the flow regime (laminar/turbulent) need to be carefully evaluated.
- **Finite volume collector array model**. A reasonable simplification to model a single collector row is a finite volume model which treats the collector row as a pipe with one-dimensional heat transfer in the flow direction. The predicted variable of the model is the collector row outlet temperature. By applying an energy input/output balance to a fluid element volume one obtains a hyperbolic differential equation for the fluid temperature. The fluid temperature $T_f(z,t)$ at position z and time t can be modeled as follows

$$\frac{\partial T_f(z,t)}{\partial t} = -\frac{V(t)}{A_f} \cdot \frac{V_{col}}{A_{col}} \cdot \rho_f \cdot c_f \cdot \frac{1}{(mc)_{sp}} \cdot \frac{\partial T_f(z,t)}{\partial z} + \frac{1}{(mc)_{sp}} \cdot \alpha(R(t)) - \frac{1}{(mc)_{sp}} \cdot \gamma(T_f(z,t) - T_a(t))$$

where $V(t)$ is the volume flow, A_f is the pipe cross section area, V_{col} is the total fluid content of the row, A_{col} is the total collector area, $(mc)_{sp}$ is the specific heat capacity, $\alpha(t)$ is an absorption function for the beam

and diffuse irradiance $R(t)$, γ is a heat loss function (usually a second order polynomial) and $T_a(t)$ is the ambient temperature. This modeling approach is widely used (see e.g. Lemos, Neves-Silva, and Igreja (2014))

If there is no significant maldistribution of the volume flow across the array, then the effect on the thermal performance will be marginal, and a whole collector array can be modeled as a single row (and a single row as a pipe). Modeling the collector array as a single pipe or multiple pipes with one-dimensional heat transfer in the flow direction is a reasonable balance between precision and easy applicability as well as comparability and broad applicability.

- **Irradiance modeling**. For a correct determination of the beam and diffuse irradiance on the collector plane an irradiance model of the plant is necessary, which is able to calculate the irradiance distribution on the collector array (beam and diffuse) based on the sensor readings (total tilted irradiance and beam DNI irradiance). Many tools and algorithms were developed, they date back to the 1970s (see e.g. Appelbaum and Bany (1979)). However, they need to be adapted to large collector arrays. The simplest approach is to check if there is any internal or external shading and exclude these conditions from the parameter estimation procedure.
- **Design of experiments**. Whenever possible, data of the normal plant operation should suffice for in-situ testing. If the operating range or the variation in the data are so little, that the test procedure cannot be applied, a carefully designed test to obtain more data can be conducted. For most plants, the return temperature can be lifted (diminishing the load or mixing return and flow side). This variation has to be done for different irradiance levels to gain uncorrelated measurements of the irradiance and collector array temperatures. Additionally, periods with low temperatures at the heating up or cooling down operation phase of the plant can be used.
- **Reducing modeling complexity**. To reduce the modeling complexity, basic checks can be performed to make sure that minor influencing factor on the thermal performance remain within acceptable ranges. For example, instead of modeling the volume flow distribution, one can check if the flow distribution is roughly balanced by evaluating the outlet temperatures of the collector rows.
- **Statistical data evaluation, modeling of uncertainty**. To deal with commercial measurement equipment and missing measurement points, the explanatory variables and the dependent variable need to be modeled stochastically and the measurement and modeling uncertainties need to be taken into account.

6. Conclusion and Outlook

The major challenges for in-situ testing of large collector arrays were identified and a framework to address them was developed. The next step is to elaborate the in-situ test procedure based on this framework, implement it in a software environment, apply it to the test plant and validate it.

Urban and Regional Planning to Maximize Renewable Energy

Innovative and sustainable Energy Supply Concepts for a new quarter in Mannheim, Germany

Dominik Bestenlehner, Harald Drück

Research and Testing Centre for Thermal Solar Systems (TZS)
Institute for Thermodynamics and Thermal Engineering (ITW)
University of Stuttgart, Pfaffenwaldring 6, 70550 Stuttgart, Germany

Abstract

The former military area "Benjamin Franklin" in Mannheim, Germany, is converted in a completely new urban area with the aim of providing a high living standard and an innovative energy supply. The actual proposed energy supply concept for the sub quarter "Sullivan" was assessed. Two alternative concepts focusing on renewable energy sources have been developed. For this, some approaches from [1], [2], [3] have been applied and further extended. The developed concepts have been compared to the actual one, related to primary energy demand and economics.

Keywords: energy concepts, quarters, urban area, district heating, solar thermal, photovoltaic, heat pump

1. Introduction

Mannheim is a city in the Rhine-valley in Germany approx. 100 km South from Frankfurt with around 300,000 inhabitants. After the withdrawal of the American Army, the military area "Benjamin Franklin Village" was handed over to the city of Mannheim. Such a large area with around 1.4 million square meters almost in the city centre offers wide possibilities for further urban development. Strategic, future-oriented urban development implies not only architecture but also innovative energy supply. A similar realized and detailed evaluated project can be found in [3]

Not only due to the European and German goals of CO_2-emission reduction, the city of Mannheim decided to request a sustainable and renewable energy supply concept for the "Benjamin Franklin Village". Further drivers for this innovative supply concept are the aim of creating attractive living areas and not least economic reasons. Besides several architectonical requirements the city of Mannheim demands a primary energy factor of fp = 0.55 for the heat supply for the buildings.

The area "Benjamin Franklin Village" is subdivided into five smaller urban areas with different focal activities such as living (Franklin center, Sullivan, area of Officers cantonment), services sector (Funari Barracks), and trade and commerce (Columbus area). Additionally the current development status varies depending on the remaining tasks to prepare the land for building. Since the pre-preparation of parts of the area is finished but the planning phase is not yet finalized, the authors decided to investigate several energy supply concepts for the living sub quarter "Sullivan" in detail, Fig 1.

As a result of an ideas competition, the city of Mannheim decided to award the local energy provider's concept for supply energy to the sub quarter "Sullivan". The core components of the concept are the already available district heating grid of Mannheim with a primary energy factor $f_p = 0.65$, which is able to provide additionally the heat for Sullivan, and a combination of an air to water heat pump and a photovoltaic (PV) system to reduce the primary energy factor. In this present concept, neither an adaptive control, nor a prognoses tool related to demand and weather is implemented. Therefore, the authors decided to assess the proposed energy concept in detail and to develop alternative concepts with the focus on a higher level of sustainability and innovation combined with an improved economic feasibility.

Fig. 1: Bird's view of the Benjamin franklin Village in Mannheim, Germany, incl. the subdivision into the five quarters, source: www.mz.de, modified by the author

In the following, the awarded concept is presented and further used as the reference concept for the three developed alternative concepts. The comparison between the in total four concepts comprises as key aspects the primary energy demand, CO_2 emissions and the economics.

2. Reference concept

The awarded concept of the local energy supplier uses as basis heat source the already existing district heating grid (primary district heating grid). This heating grid is located directly outside of the quarter "Sullivan" and can be extended by a secondary heating grid for providing heat into "Sullivan". Additionally, an air-to-water heat pump feeds heat into the grid. Since the temperature level of the heating grid is 70 °C, a special, double stage, high temperature heat pump will be installed. To reach the required primary energy factor for the heat supply in the urban sub quarter Sullivan, ca. 1 500 m² PV modules (250 kW_p) shall be installed. The provided electricity is used to operate the compressor of the heat pump. Fig 2 shows the scheme for this concept.

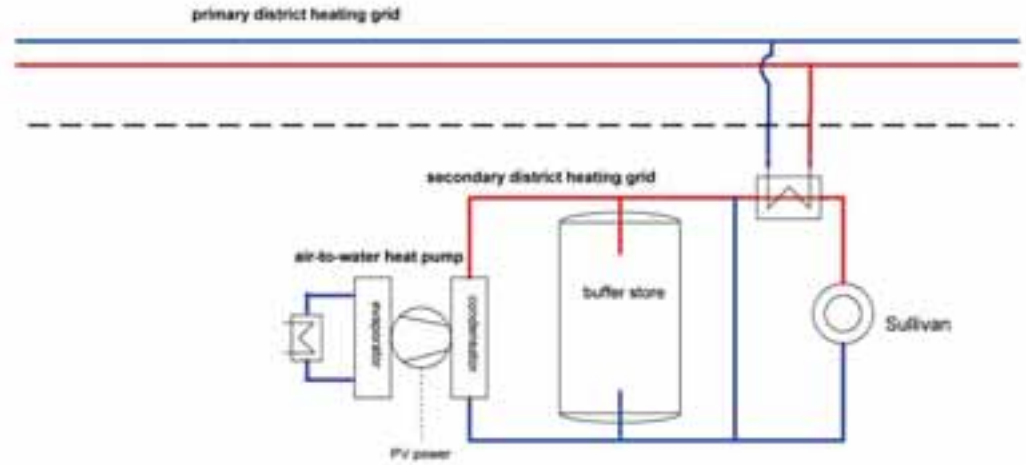

Fig. 2: Scheme of the reference concept comprising heating grid, air-to-water heat pump and PV

Detailed simulation studies show that the primary district heating grid feeds the entire year heat into the secondary

heating grid. The air-to-water heat pump provides only a small share of the energy. During summer, the available PV power and the ambient air temperatures are much higher than in winter when the maximum heat load occurs. Therefore, the energy share delivered by the heat pump is significant higher than during winter times. The total energy delivered by the heat pump is 980 MWh/a with a seasonal performance factor of 3.0. This represents 15 % of the total energy demand of the urban area. Even during the summer months, the heat pump covers less than 50 % of the heat demand. The amount of energy provided by the heat pump balances exactly with the amount of energy required to reduce the primary energy factor of the entire system from 0.65 (primary district heating grid) to 0.55. Since all further developed concepts compete with this conventional concept, it is defined as "reference concept".

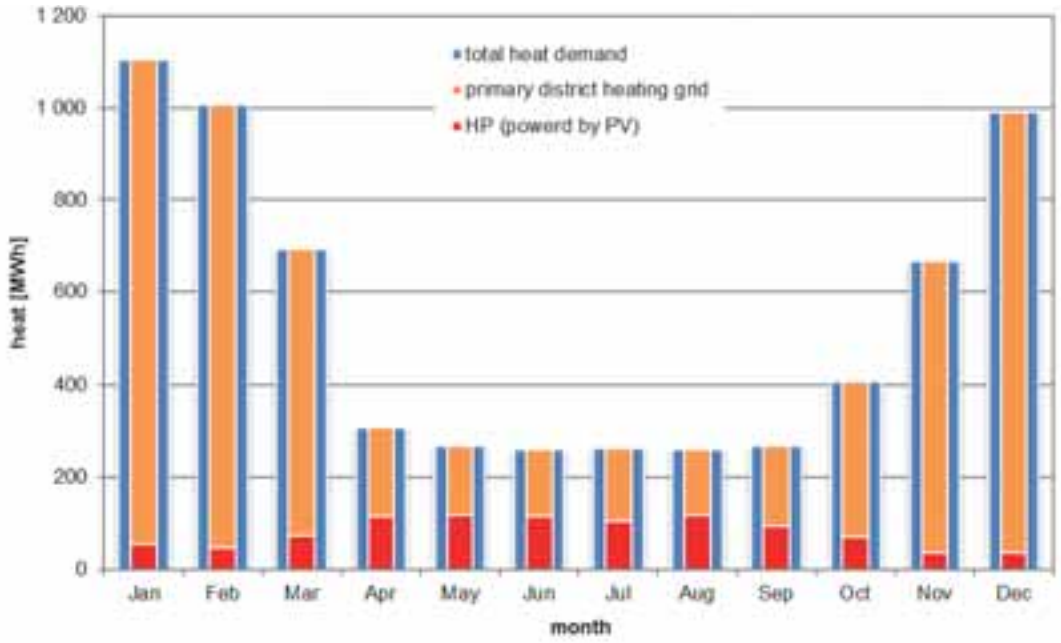

Fig. 3: Energy balance of the reference concept

3. Alternative concepts

For additionally reducing the primary energy factor of the heat supply of the quartier Sullivan, alternative innovative concepts are required. Since the energy provided by the sun has a primary energy factor of 0.0 by definition, the concepts shall aim for a high solar thermal fraction. A seasonal thermal energy store (STES) offers the possibility to increase further the solar thermal fraction. An integration of PV into the further investigated alternative concepts was not taken into account due to the missing concurrency between generated PV-power and heat demand. Only on a yearly bases, the energy balance of such combinations might be balanced. Furthermore also under exergetic aspects it is considered as much more appropriate rather to use PV-power directly to substitute conventional produced electricity than converting it into heat.

The following chapters present three alternative concepts with different characteristics. These concepts have been compared to the reference concept related to economics, CO_2 emissions, primary factor and solar fraction.

Concept 1: Solar district heating grid with short term thermal energy store

The first alternative concept for providing the required heat to "Sullivan" is also based on a district heating grid. But in contrast to the reference concept it is partly fed by solar thermal energy. The primary district heating grid of the city of Mannheim provides only the energy demand, which solar thermal cannot cover. The concept comprises 5,000 m² solar thermal flat plate collectors, and a 400 m³ hot water buffer store. To avoid stagnation during times without sufficient heat demand, the solar thermal collector field feeds into the return flow of the primary district heating grid. Fig. 4 shows the scheme with the separation between primary and secondary district heating grid and the hydraulics.

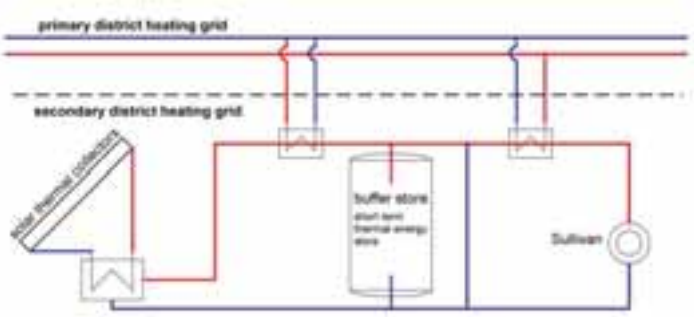

Fig. 4: Scheme of the first concept based on solar district heating grid and a short term thermal energy store

Fig. 5 shows the energy balance on a monthly basis. During summer time, the energy gains from the solar collector field covers entirely the heat demand of the quarter. The heat provide into the return flow of the primary district heating grid to avoid stagnation is not diagrammed. Due to the relatively high inclination angle of 45° of the solar thermal collector field, this heat can be neglected. No seasonal thermal energy storage is included. This approach leads to a relatively high annual solar fraction of 34 % with lowest system and investment effort.

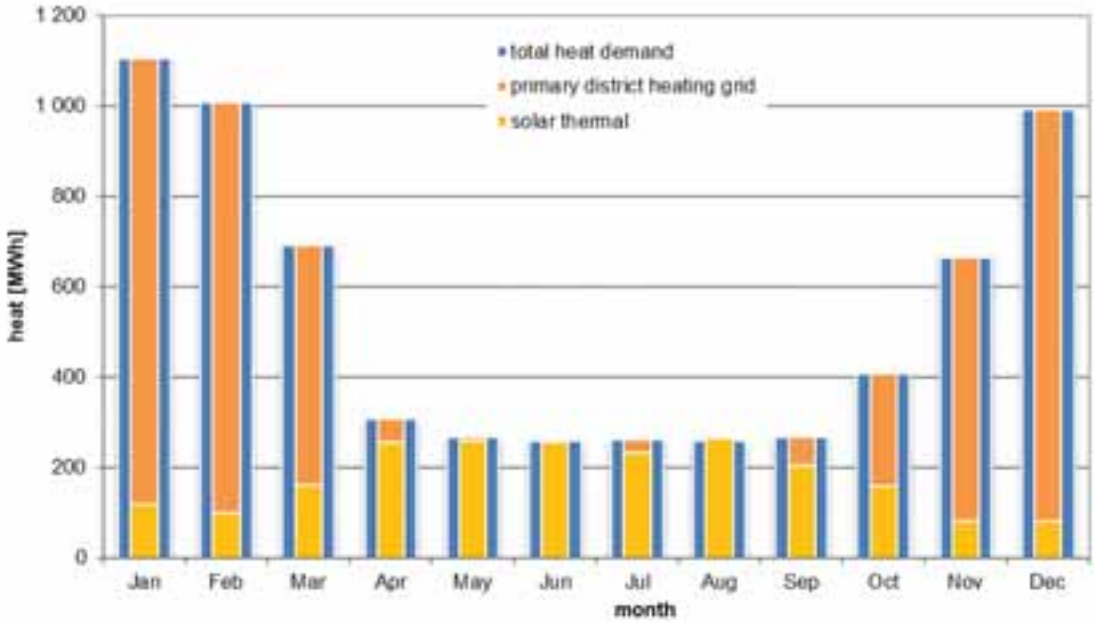

Fig. 5: Monthly energy balance of concept 1, comprising solar district heating grid and a short term thermal energy store

Concept 2: Solar district heating grid with seasonal thermal energy store and compression heat pump

The second concept aims for a solar fraction of 50 % and a separated district heating grid. No heat exchange between the primary and the secondary heating grid takes place. To reach a solar fraction of 50 %, a solar thermal collector field of 7 600 m² is required, which is about 50 % larger than in concept 1. A seasonal thermal energy store with a volume of 7 200 m³ stores the additional heat from the solar collector field, Due to this large store, the volume of the short term buffer store is reduced by half, compared to concept 1, to 200 m³. A heat pump (HP) decreases the temperature in the seasonal thermal energy store and therefore increases the effective usable storage capacity. Additionally, the efficiency of the solar thermal collectors increase with decreasing operation temperature. The heat pump only operates in winter times and decreases the temperature in the seasonal thermal energy store down to 18 °C. A further temperature decrease in the seasonal thermal energy store is not efficient any more. Due to available groundwater at a temperature level of 18 °C, the heat source of the heat pump is changed at 18 °C from the seasonal thermal energy store to the groundwater. The heat pump has a nominal electrical power of 400 kW, the highest monthly thermal power occurs in February with 1.27 MW. The buffer

store covers the peak power demands that rises up to 2.8 MW_{th}. Therefore, no auxiliary heating system additionally to the heat pump is required. Fig. 6 shows the hydraulics of this concept.

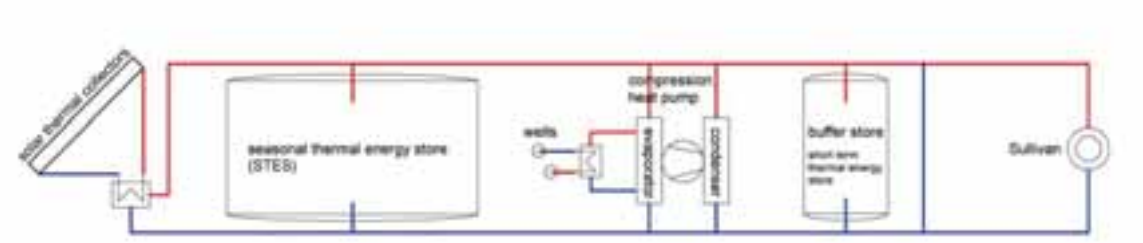

Fig. 6: Scheme of the second concept based on a solar district heating grid, a seasonal thermal energy store and compression heat pump

Fig. 7 shows the monthly energy balance of concept 2. The solar thermal collector charges during the months April to September the seasonal thermal energy store. During October and November, this heat is discharged and supplied directly into the district heating grid (light blue). Eventually in November, the temperature level of the heat discharged from the seasonal thermal energy store is not sufficient any more. With the help of the heat pump, the seasonal thermal energy store is discharged further and delivers into the grid (green). After reaching a temperature level of 18 °C in the seasonal thermal energy store, the heat pump uses the available groundwater as heat source and provides the energy demand for the district heating grid (violet) Although, the seasonal thermal energy store feeds only in total 560 MWh/a heat into the grid, its implementation increases the efficiency of the heat pump and the solar thermal collector significantly, [8].

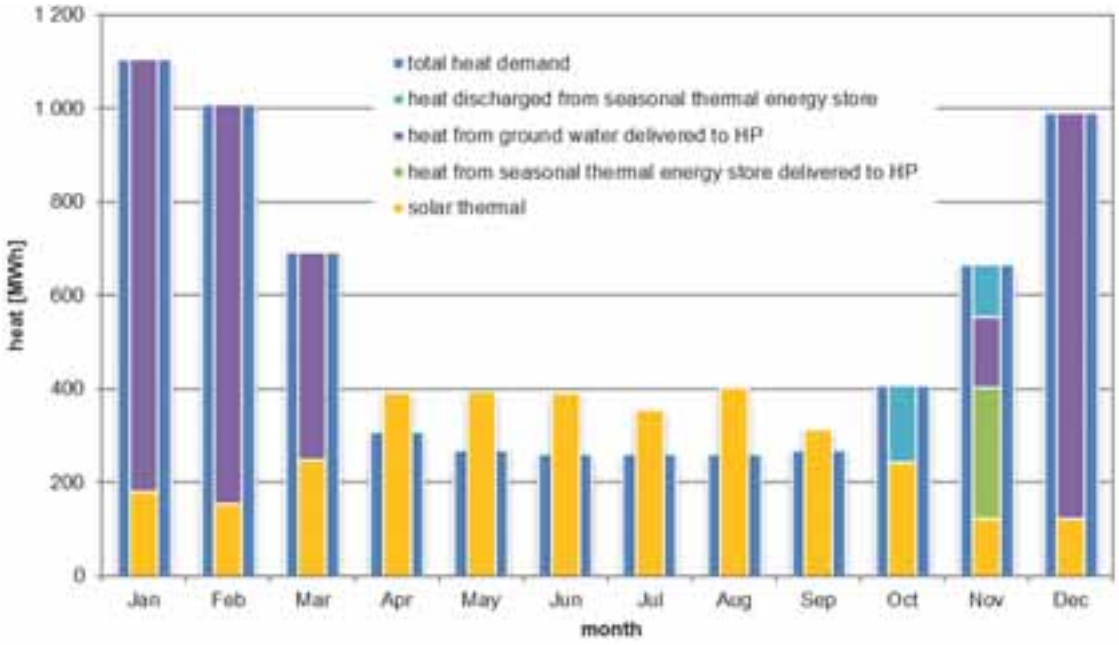

Fig. 7: Monthly energy balance of concept 2, based on a solar district heating grid, a seasonal thermal energy store and a compression heat pump

Concept 3: Solar district heating grid with seasonal thermal energy store and absorption heat pump

The third concept bases on the second concept, but an absorption heat pump replaces the compression heat pump. The collector area with 7,600 m², the size of the seasonal thermal energy store with 7,200 m³ and of the buffer store with 200 m³ stay the same. The difference is the integration of the heat provided by the primary district

heating grid. The primary grid feeds on the on hand directly into the secondary grid and on the other hand indirectly via the generator of the absorption heat pump. The implementation of an absorption heat pump allows for an efficient use of the heat of the primary district heating grid. Simultaneously, the solar thermal collectors and the seasonal thermal energy store operate more efficiently compared to a system without heat pump. The absorption heat pump has a nominal output power of 700 kW. The primary district heating grid covers the additional heat demand directly.

This concept is similar to a solar district heating grid realized in the project "Ackermannbogen" in the city of Munich, Germany. Only the size of the concept here exceeds the system in Munich by a factor of three. Fig. 8 shows the scheme of the concept three.

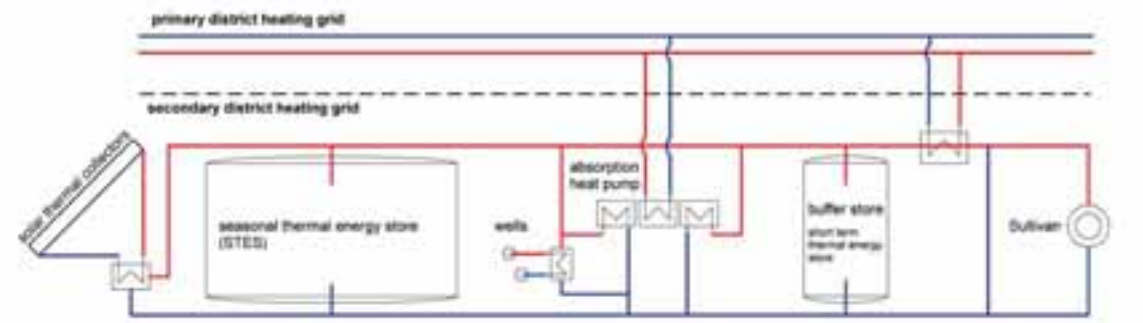

Fig. 8: Scheme of the third concept based on a solar district heating grid and the already available district heating grid, a seasonal thermal energy store and an absorption heat pump

The solar collector field charges the seasonal thermal energy store during summer. The absorption heat pump uses the seasonal thermal energy store and the groundwater as heat source. Additionally in the core winter months December, January, February the primary district heating grid provides the remaining heat demand, as the absorption heat pump cannot cover the total demand due to its limited size.

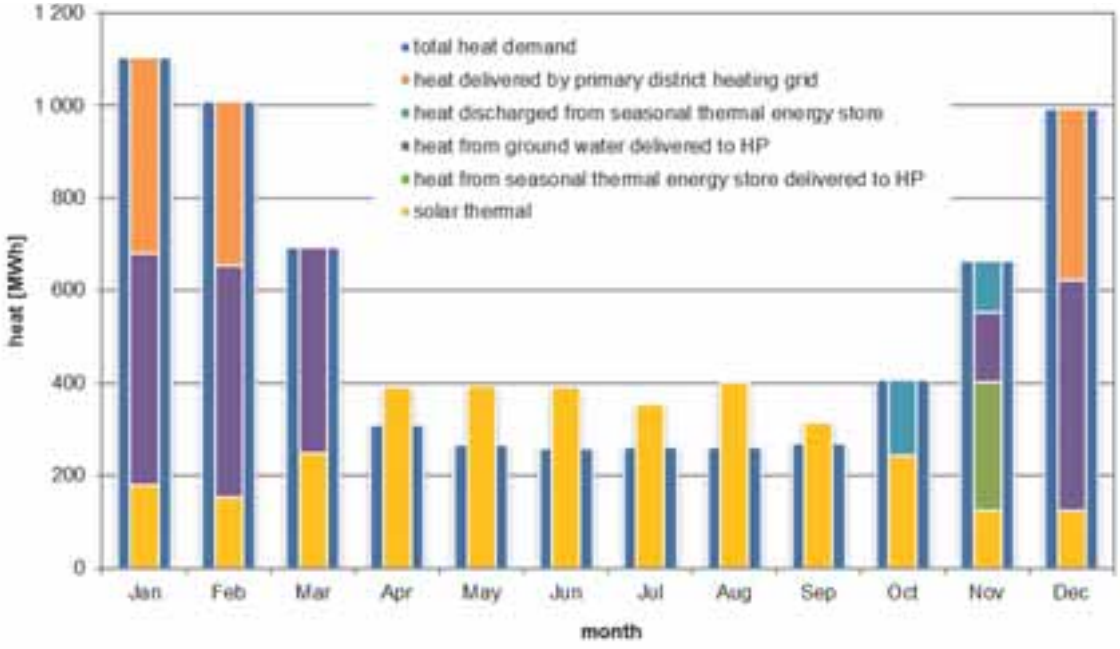

Fig. 9: Monthly energy balance concept 3, based on a solar district heating grid and the already available district heating grid, a seasonal thermal energy store and a absorption heat pump

4. Evaluation of concepts

The evaluation of the reference concepts and the three developed alternative concepts bases on four performance figures:

- Primary energy factor
- CO_2 emission in kg per MWh heat
- Solar fraction
- Specific costs in € per MWh heat

The primary energy factor fp [-] serves in several standards and directives in the building sector as performance figure. The primary energy factor puts all efforts and losses, occurring during generating, treatment, storage, transportation and distribution, into relation to the delivered usable energy. In contrast to the cumulative energy demand, the primary energy factor only takes into account the energy carrier. Hence it omits the required raw materials, semi-finished products and services, such as a power plant. Table 1 shows the primary energy factor used for the evaluations.

Tab 1: Primary energy factor for different energy carriers

Energy carrier	Primary energy factor	source
Solar thermal	0	EnEV [11]
Photovoltaic	0	EnEV [11]
District heating, Mannheim	0.65	certificate power plant, city of Mannheim
Electricity mix, Germany	1.8	EnEV [11]

Since the primary energy factor only indicates one aspect of the environmental stress, the **CO_2 emissions** are introduced as a further evaluation criteria. The CO_2 emissions [kg/MWh] represents the amount of climate-damaging CO_2 equivalents emitted per MWh final energy. The used data represent not only the energy carrier, but also the production, use and disposal of the energy conversion systems. Bases of the calculation is the database GEMIS, Version 4.93, see table 2 [12]

Tab 2: CO_2 emissions of different energy carrier

Energy carrier	equivalent CO_2 emissions [kg/MWh]
Solar thermal, flat plate collector	13
Photovoltaic, multi crystalline	62
District heating mix, Mannheim	295
Electricity mix, Germany	617

The **solar fraction** [-] is the ratio between the useful, solar generated heat supplied to the system and the total heat demand. The solar fraction is a common and wide spread performance figure to classify and compare solar thermal systems.

The **specific heat costs** [€/MWh] is the ratio between the annual total costs and the generated heat based on VDI 2067 [13]. The solar heat costs enable an economic comparison between different concepts and technologies.

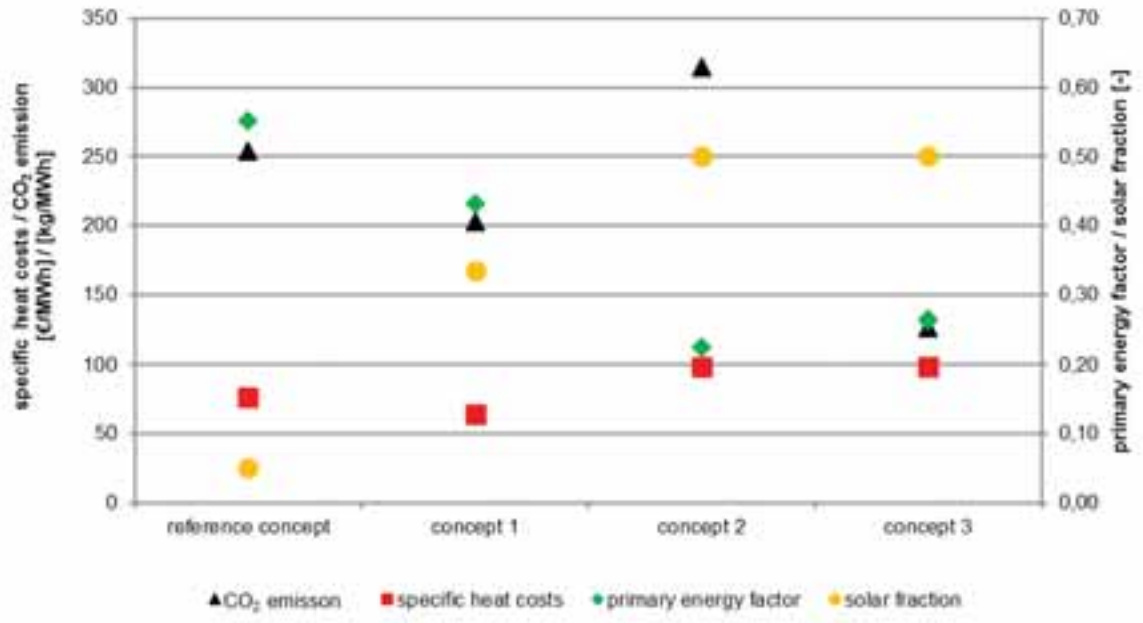

Fig 10: Comparison of the performance figures of the different concepts

Fig. 10 shows the comparison between the reference concept and the three alternative concepts. Concept one has the lowest specific cost, even lower than the reference concept. The primary energy factor of all three alternative concepts are lower than the one of the reference concept. Related to the CO_2 emissions concept one and three have lower emissions than the reference concepts, although concept two has the highest CO_2 emissions. This is due to the high share of heat generated by the compression heat pump and therefore the high electricity demand. If an additional installation of a PV system is considered (as it is within the reference system), the CO_2 emissions would be reduced significantly.

5. Conclusions

The evaluations of the three alternative concepts show a significant potential for improvements related to the primary energy demand and the solar fraction. Further, concept one and three have reduced CO_2 emissions compared to the reference concept. Only concept two has higher CO_2 emissions due to the implementation of a compression heat pump. Even for systems with 50 % solar fraction the specific heat costs are in the same range of the reference concept.

Analysis of the match of heating load and wind turbine production – a case study for the Faroe Islands

Hans Georg Beyer, Barður A. Niclasen

Department of Science and Technology, University of the Faroe Islands, Tórshavn (Faroe Islands)

Abstract

In search for options to replace the fossil based heat supply of the housing stock of the Faroe Islands, the application of electrical heating in combination with an increase of wind power penetration in the electricity grid is analyzed. This option is favored by the – as compared to other geographical regions - good seasonal match of the wind generation and the temperature driven heating load at this location. For this case the requirements for oversizing of the wind generation capacity, inclusion of storage and/or use of back-up energy for a save load supply are analyzed.

Keywords: heat supply. wind power, Faroe Islands

1. Introduction

The Faroe Islands - located remotely at 62° North, 7.5° West in the North Atlantic - have a population of ~55 thousand people. Due to the Gulf Stream, the climate is comparatively mild showing an annual mean temperature of about 10°C with only limited deviations in summer and winter. This results in an overall moderate heating load for the housing stock but calls for heating in all month. Currently the heat supply is almost completely based on oil. According to the aim of reducing the dependence on fossil fuels and limiting CO_2 emissions, replacements are needed here. With the - due to the high latitude - limited solar resources in winter but an elevated wind power potential, the use of electrical heat (with the option of using heat pumps) powered by a grid with a high wind power penetration can be considered as option for an alternative heat supply. Additional benefits of linking wind power to heat supply systems are discussed e.g. by Østergaard 2013, Xydis 2015 and Zhang et al. 2015. This paper will give a more detailed assessment of this option by inspecting first the seasonal match of monthly heat demand and monthly energy gain of wind turbines. For the Faroe Islands – showing a favorable seasonal match – details on system performance are analyzed by simulations based on on-site wind and temperature data with 10min time resolution.

As bases for these studies the next section will show a simple approach for modelling the heat requirements of buildings based on temperature information used here for the assessment of the characteristics of both the monthly and short term energy demand. With a similar simplified approach, the characteristics of the monthly energy gain and short term power output of a wind turbine installation are assessed. Heat demand and wind generation are set in relation by scaling the heat demand according to turbine generation, i.e. a selection of an appropriate number of houses to be heated (or heated space area) by a wind installation.

2. Characteristics of the heat demand

For the assessment of the characteristics of the heating load, a simple linear dependence of required heating power to ambient temperature is assumed. Heating is assumed to be necessary when ambient temperature is lower than 18°C, the required power rises linear with the with temperature difference to 18°C. Rated heating power is set to refer to an ambient temperature of -18°C (see. eqn.1). The required monthly or annual energy can be evaluated based on time series information on the ambient temperature and the rated heating power as given by eq. 1. The temperature information can be compressed into the parameter heating degree days (HDD) – basically the (monthly or annual) time integral of the difference of 18°C and the ambient temperature taken for situations with ambient temperatures < 18°C.

$$E = \sum_i \delta * (\ (18°C - T_a(t)) * \frac{1}{36°}\ P_{(-18C)}$$

$$\delta = \begin{cases} 0\ if\ T_a \geq\ 18℃_{\circ\circ} \\ 1\ if\ T_a <\ 18℃ \end{cases} \qquad \text{(eq. 1)}$$

$$E = HDD * \frac{1}{36°} * P_{(-18C)}\ ,$$

HDD: heating degree days [°C days]

A first impression of the temperature conditions can be gained from the monthly mean temperatures. Fig.1 gives these numbers for the site Tórshavn, Faroe Islands. Monthly mean temperatures vary but in the rage of 6-12℃. These data are all taken from the RETScreen data base (Anonymous, 2014).

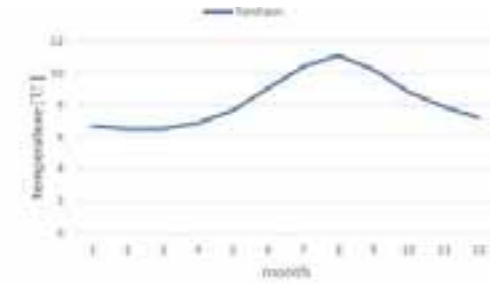

Fig. 1: Mean monthly temperatures for the Town of Tórshavn, Faroe Islands. Data taken from the RETScreen data base].

The respective values of the HDD - as indicator for the heating load as sketched above – for Tórshavn are shown in Fig.2, They are also supplied by the RETscreen data base. For comparison, data for a site in Norway (Ålesund) are given. As compared to Torshavn, that site shows an overall higher heating demand with a well pronounced reduction of needs in summer. For Torshavn there is less variability in the monthly heating requirements. The heating load in summer remains at about half of the heating load in winter.

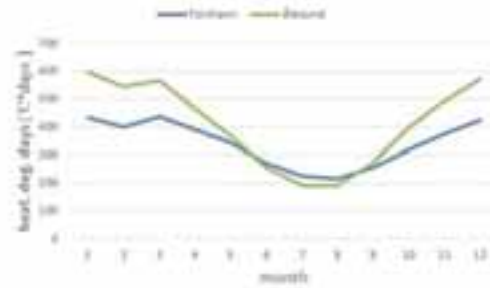

Fig. 2: Monthly heating degree days (HDD for Tórshavn and Ålesund (Norway). Overall, there is less need for heating in Torshavn, but a remaining requirement in summer.

3. Characteristics of wind turbine generation

For the calculation of the monthly turbine generation, based on information of monthly average wind speeds at 10m above ground level (information offered by the RETScreen data base) speeds are scaled up to 50m agl. (a conservative assumption for larger wind turbines) assuming a logarithmic profile for a roughness length of 0.15m. A monthly energy gain is calculated with the assumption of Rayleigh distributed wind speeds, using a power curve for a typical $1MW_{rated}$ turbine.

A first view on the wind resource on the Faroe Islands is given by Fig.3. Shown are the monthly mean wind speeds at 10m agl. as supplied by RETScreen. This indicates good wind conditions with an annual mean wind speed of ~6.5m/s at 10m above ground level in an industrial/harbor environment. The good wind conditions on the Faroe Islands are confirmed by data on the annual performance of a commercial wind farm close to Torshavn (Annonymous 2017).

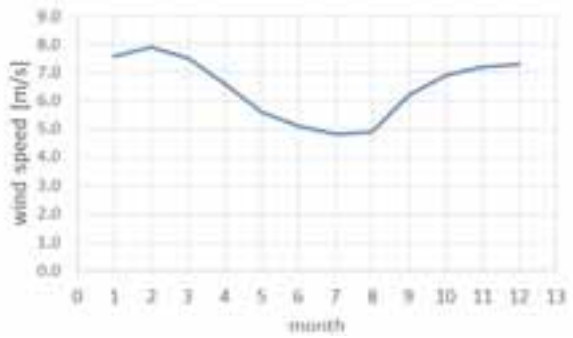

Fig. 3: Monthly means of the wind speed in Tórshavn at 10m above ground level. Data are taken from the RETSrceen data base.

Based on the monthly mean wind speeds scaled up to a hub height of 50m as described above, and assuming a Rayleigh distribution of the of wind speed, the monthly mean power output of a typical 1MW turbine is estimated (see Fig. 4). With the assumption of 0.15m roughness length used for this site, the results are conservative estimates of the energy gain.

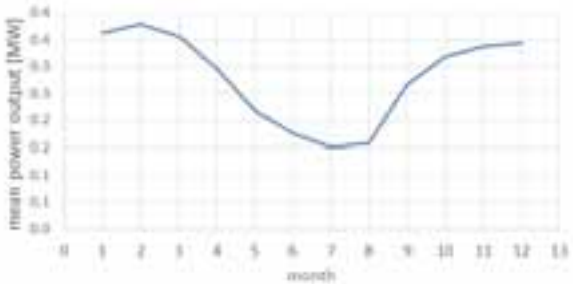

Fig. 4: Estimated monthly mean power output of a 1MWrated turbine at Tórshavn.

4. Linking wind resource and heating load

Comparing the pattern of the monthly heating load as determined the pattern of HDD values and the monthly power generation for Tórshavn, the good match of these sets is obvious (see Fig.5, correlation coefficient of the two sets is 0.87). However, not for all month a wind turbine sized to cover the annual demand would be able to cover each monthly load).

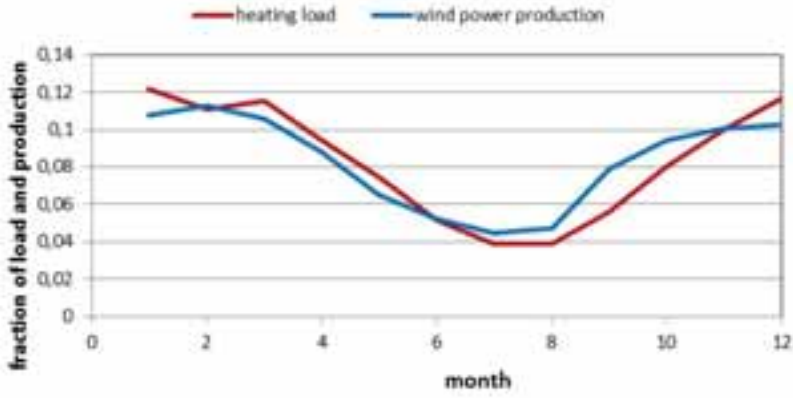

Fig. 5: Estimated normalized monthly energy gain from a wind turbine together with the normalized monthly heating load calculated on basis of the heating degree days (site: Tórshavn). Both production and demand are given as monthly fraction of the annual sum.

This pattern can now be compared to that of other locations. With the scaling of the heating load applied, it should be remarked that the results for each location refer to different relations of heated space to turbine size (the $1MW_{rated}$ system used as standard here), resulting from the specific wind and temperature (HDD) conditions.

The sites scanned here comprise of different locations in Northern and North-Western Europe including the Atlantic isles. Fig 6 gives with the comparison of the load and generation patterns for two locations on the Faroe

Islands, besides Torshavn the site of Akraberg on the southernmost of the Islands. Fig.7 gives the data for the sites Lerwick, Shetlands and Ålesund, Western Norway, Fig 8 for Bremen, Germany and Cardiff, Wales.

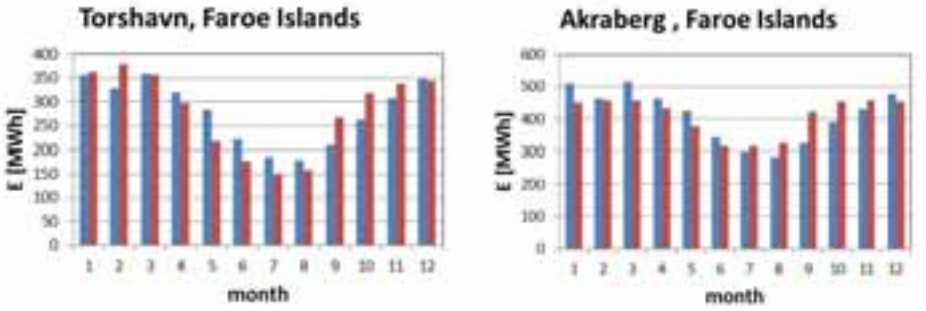

Fig. 6: Estimated normalized monthly energy gain from a wind turbine together with the normalized monthly heating load calculated on basis of the heating degree days. Both production and demand are given as monthly fraction of the annual sum.

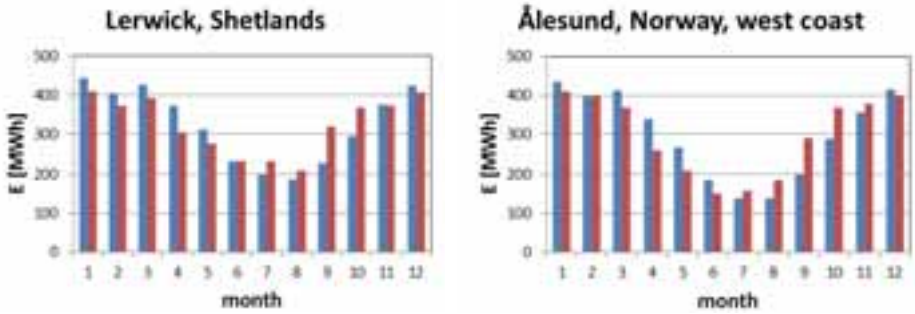

Fig. 7: Same as Fig.5, but for the Sites Lerwick and Ålesund, showing similar pattern as the Faroe Islands sites

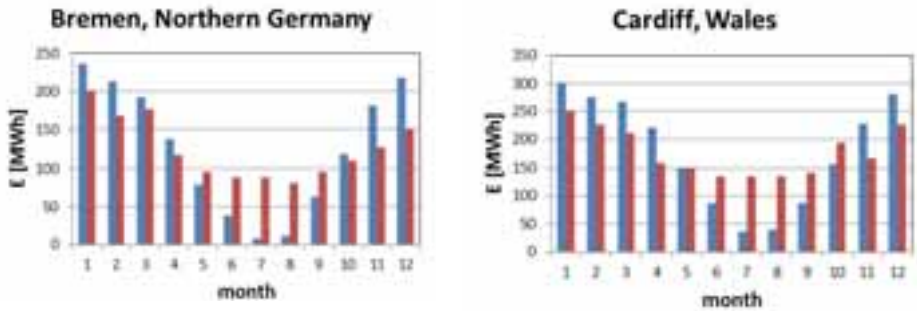

Fig. 8: Same as Fig.5, but for the sites Bremen and Cardiff. For these sites, except for magnitude, the pattern remains similar to those of the more northerly sites. Difference is in the heating load (blue) in summer being reduced to almost zero, causing a larger spread of the pattern of the monthly heating loads.

For Akraberg – with wind speeds superior to those at Torshavn, the monthly pattern in wind generation is even less pronounced than for Torshavn. For both sites monthly wind generation and load are closely correlated with a similar spread. This pattern is repeated for Lerwick and Ålesund, with Ålesund showing a higher parallel sprread in both monthly load and generation. For Bremen and Cardiff, with less favorable wind conditions and thus lower wind generation. With the load scaling according to annual production a remarkable surplus in generation occurs in the summer month. This is due to the heating load approaching zero in summer. In contrast production deficits occur in winter. With still a good correlation of production and load, the mismatch is a consequence of the different spreads of the two series – variability of the monthly heating load much bigger than variability of the monthly production.

The quality of the match of these series of monthly energy data can be related to basic characteristics of the meteorological series. To show this kind of dependency, the Root mean square of the differences in monthly generation and load, both normalized by the respective annual sums is extracted for an extended set of stations (all represented in the RETScreen set) in North-Western Europe (see Tab.1).

Tab. 1: Maximum difference of monthly normalized HDD and normalized wind speed and root mean square of the monthly difference of normalized load and production

site	RMS mon. en. miss.	max. mon. met. missmatch
Akraberg, Faroe Islands	0.116	0.209
Torshavn, Faroe Islands	0.139	0.143
Lerwick, Shetlands	0.139	0.206
Aberdeen, Scotland	0.168	0.424
Ålesund, Norway Westcoast	0.170	0.246
Røros, Norway Interior	0.200	0.366
Brest, France, Bretagne	0.217	0.499
Plymouth, England Chanal Coast	0.271	0.456
Cardiff, Wales	0.341	0.524
Bremen, Northern Germany	0.377	0.688
Lille, Northern France	0.380	0.780
Dresden, Eastern Germany	0.435	0.876
Bo ulonge Seine, Northern France	0.466	0.746
Karlsruhe, Suth-Western Gernaby	0.494	0.929

In addition, as a measure for the similarity in the monthly sets of wind speed and ambient temperature is set up. It is given as the maximum difference of the normalized monthly HDD and the normalized monthly wind speed, both normalized by the average of the respective set. The values for the sites selected are also given in table 1. Fig. 9 shows the relation of the energetic mismatch to the meteorological mismatch, presenting a good correlation of the two sets. Thus, the feasibility of wind heating systems at a site can be pre-assessed by inspecting the sets of monthly HDD's and wind speeds.

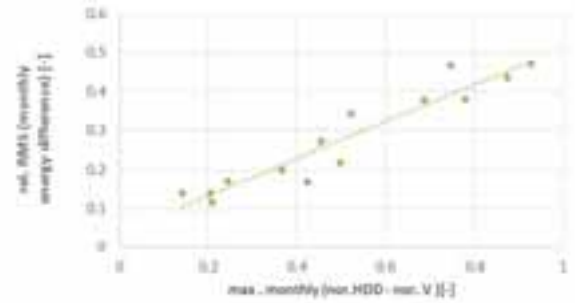

Fig. 9: Relation of the root mean square of the monthly difference of normalized load and production -as measured of the energetic mismatch – to the maximum difference of monthly normalized HDD and normalized wind speed as measure of 'meteorological mismatch' (data see tab.1).

5. Analyses of system performance at a well matched site with higher time resolution

For more insight in expected system performance, a more detailed study is done based on annual 10min time series of wind speed and ambient temperature measured at one of the smaller Faroe Islands, Nólsoy. These sets, showing a time resolution of 10min had been measured by the Danish Meteorological Institute. The annual set for 2008 is used here, showing a mean wind speed of 9.4m/s. These data are used directly as input to calculate the power output series of a 1MW wind turbine. The heating load is calculated according to the linear dependence that forms the basis of eqn.1. Thermal inertia of the building is neglected here, which, for the prevailing wood-based construction type on the Faroe Islands - and as the heating system of the houses contain but the storage capacity of conventional oil-fired systems – should be not too far from reality here.

Fig. 10 gives a first impression of the system performance based on the 10 min. data. Given are the evolution of the accumulated heating load and the accumulated turbine generation over the year. As for the monthly resolved data for Torshavn discussed above, there is a lack in generation in the late spring/early summer months. From an in-depth analysis of the series of the accumulated deficit (see e.g. Haas 1995), a storage dimensioned to host 30 times the average daily load is identified to be necessary for a continuous supply of the load.

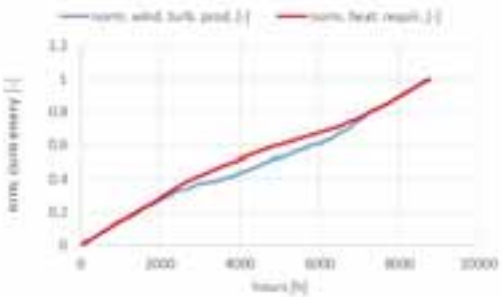

Fig. 10: Annual evolution of normalized cumulated heating load (red) and normalized cumulated wind turbine production for temperature and wind conditions at the site Nólsoy and matched annual load and production.

This requirement for storage could be reduced by an oversizing of the wind turbine. Combinations of oversizing of the wind generation and required storage size resulting from this type of calculation are given in Fig. 11. It has to be remarked that these calculations to not take into account storage losses that would provoke an increase in turbine size.

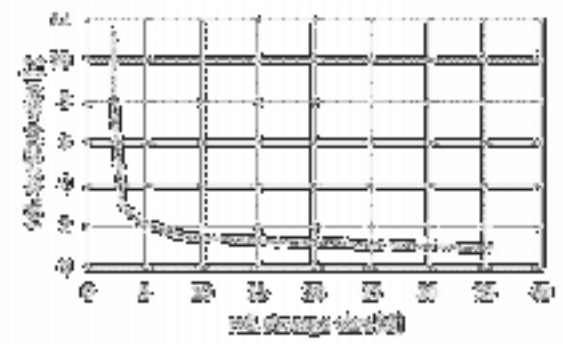

Fig. 11: Combinations of relative turbine and storage size for systems assuring the continuous supply of the load based on the data set for the site Nólsoy, Faroe Islands. Turbine size is normalized by the size of the turbine assuring the annual match of production and load, the storage size is normalized to the average annual load.

For a storage with the indicated almost monthly capacity pumped hydro may be considered as the only practical option – a solution currently discussed for the Faroe Islands to stabilize the isolated grid on the isle of Suðuroy (see Ludescher-Huber, 2017). On a smaller scale, thermal storage, buffering the heat on a daily scale may be applied, as demonstrated be a dedicated wind/heating micro grid in operation for some year on Nolsøy (Thomsen et al, 2015).

The requirement for storage may be reduced by an oversizing of the wind generation. Fig. 12 gives the combinations of storage size and turbine size representing the limit sizes for autonomous systems, i.e. systems not allowing for a loss of load.

As example a wind generation doubled as compared to the matching size would reduce the required storage size to about 5 days – a magnitude not totally out of reach for battery based electricity storage or thermal storage, depending on the absolute system size.

Another option for avoiding the need for large storage sizes is to either allow for a loss of load or the use of backup energy, i.e. the use of a backup power source. Fig. 9 gives the fraction of unserved power for systems with various turbine sizes and a 1-day storage. For a system with the turbine sized to match the annual load the annual unserved load – or need for backup energy - amounts to ~60 days of consumption.

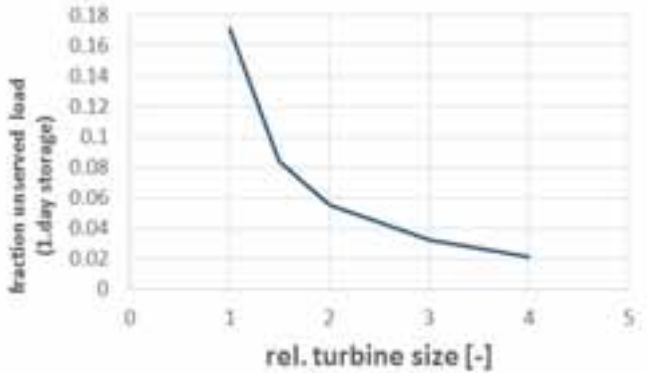

Fig. 12: Fraction of unserved power (normalized by the annual load) in systems using a storage to cover one day of load and various turbine sizes (data base and normalization as for fig. 11).

Thus, even in a region with a favorable seasonal match of heating load and wind turbine generation the effort for a complete coverage of the load by wind generation remains substantial and asks for dedicated studies on optimal system design,

6. Conclusion and outlook

As given here, the monthly pattern of power generation of wind turbines matches quite well to the heating load of houses for the inspected Atlantic and North-Sea climates. For the case of turbines scaled to match the annual load, however, some deficit will occur in the April to June period. As counter measures, either an over dimensioning of the wind capacity and/or the inclusion of storage or the limited use of backup energy has to be considered.

Renewable Energy Assessment in Italy and Brazil: An economic and Political Comparison

Vincenzo Franzitta[1], Domenico Curto[1] and Alessia Viola[1]

[1] University of Palermo, Palermo (Italy)

Abstract

The aim of this study is a comparison among Italian and Brazilian electrical energy system with a particular focus on renewable energy sources. The energy sector has a key role in the sustainable development of a country, so it influences economic and political choices. The work would underline differences, common point among two country, specially, in this particular socio-economic period and it should emphasize that green economy could be a possible answer to financial crisis. The main purpose of this study is a presentation of Italian and Brazilian energy system with a particular focus on renewable sources. The energy sector has a key role in the sustainable development of these countries and it could influence economic and political choices or their economic climb. The work will be divided into four sections: Section I will introduce all details of the question; Section II will explain the renewable assessments or the countries, Section III will talk how renewable energy investment could be for economic crisis and the last section will show final conclusions.

.

Keywords: energy policy, renewable energy, solar, economic, sustainable.

1. Introduction

The idea of economic growth has dominated politics and policies since 1945. Environmental concerns and sustainable development were introduced at a later time. Expectations of win–win, sustainable growth through technological(Schneider et al. 2010) and efficiency improvements, have not been fulfilled. The present economic crisis opens up a social opportunity to ask fundamental questions.

The energy assumed a central role in human life since the ancient time because the economic progress developed thanks to an idea of deranged use of available resources like water, energy or land (Mathiesen et al. 2011).

An immediate consequence of the financial crisis that shook the large majority of countries is the reduction of economic activity and increased unemployment. Since economic activity is closely linked to energy consumption, it is expected that the quantity of energy consumed will also decrease. At first glance this seems to be good news: with lower demand, prices should fall, as occurs when stores offer sales.

The Paris Agreement on climate change, which entered into force in November 2016, is at its most recent heart an agreement about energy (IEA - International Energy Agency 2011). Anyway, political and economic crisis influenced the global energy markets, so the aim of this paper is a presentation how their knowledge is essential to define a future energy programs. The description is based on the study of two different Country: Italy and Brazil, as far for their geographical but so close for many common points.

As regards climate change and environmental-energy programs, Italy as a member of the European Union was a signatory to the United Nations Framework Convention on Climate Change (International Energy Agency 2010) (UNFCCC) and to the Kyoto Protocol and on October of 2016 Italy ratified the Paris Agreement. In fact, already in the past, Italy has implemented a number of sectoral and cross-sectoral policies to have a direct or indirect effect on the reduction of greenhouse gas emissions. Legislation introduced to improve the energy performance of buildings, strengthening their thermal demand requirements. These include compulsory standards for new buildings and renovation of older buildings.

After less than a year since its signing, Brazil has officially validated the Paris Agreement at the national level. This was

doi:10.18086/swc.2017.37.03 Available at http://proceedings.ises.org

an essential step because Brazil, one of the world's biggest greenhouse gas emissions (GHG) emitters, has a fundamental role in this scenario. The INDCs (Intended Nationally Determined Contributions) submitted by the country set an absolute emission reduction of 37% until 2025 and 43% until 2030, having as base 2005 levels. Figure 1 shows a comparison between Italian and Brazilian CO_2 emissions' trend.

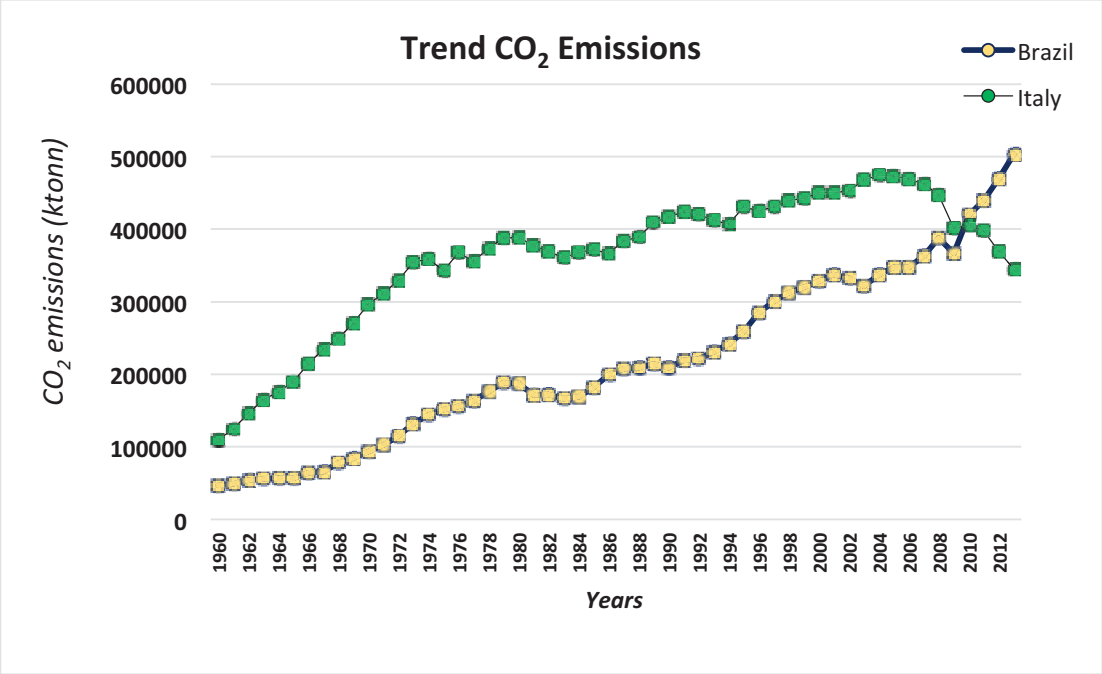

Fig. 1: Comparison of CO_2 emissions (period 1960-2012) (Data from http://resourceirena.irena.org)

Remark that figure 1 represents data until 2011, year that signs economic slowdown for Italy but growth for Brazil.. Connected to CO_2 emissions and political actions to fight global warming, it is interesting to evaluate climate variation in the time, considering actual and past data.

The monthly mean historical rainfall and temperature data show the baseline climate and seasonality by month, for specific years, and for rainfall and temperature.

Figures 1a and 2b display mean historical monthly temperature and rainfall for Brazil and Italy during the period 1900-2012. The dataset was produced by the Climatic Research Unit (CRU) of University of East Anglia (UEA).

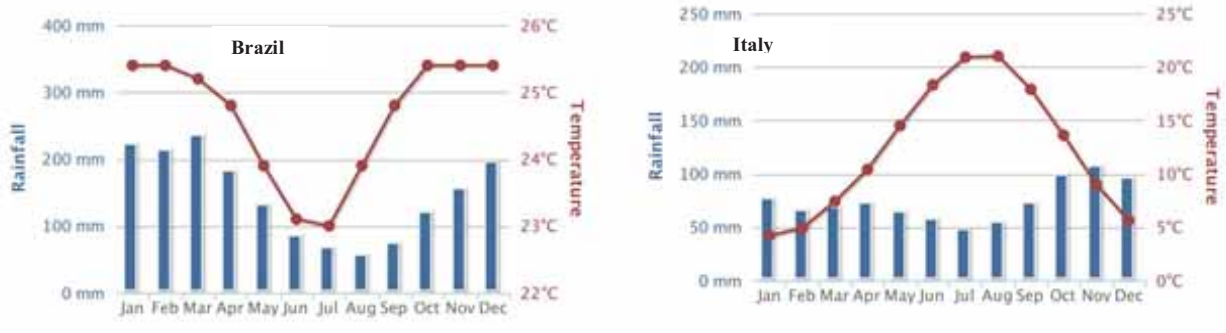

Fig. 1:Mean historical monthly temperature and rainfall (1900-2012) a) Brazil and b) Italy (Data from http://sdwebx.worldbank.org/climateportal/)

According these data, a significant amount of rainfall characterized Brazilian climate and influenced hydropower generation in Country. The next sections will explain all renewable energy sources available in the two countries and the financial effects that turned out.

2. Renewable energy study in Italy

Italy is a large mountainous country and runs from Alps to Mediterranean Sea. Its surface is 300.000 km^2 and we find some islands like Sicily, Sardinia and other small islands. Italy has almost 59 million inhabitants of whom 22 million are in active employment. The country is divide into 20 independent regions and all of which are part of the constitutional structure of State. Italy was a founding member of the European Union and is part of the G8 group of countries. It enjoys a GDP per capita just above the European average. It has developed a framework to implement an energy market policy that is consistent with European requirements. The Table 1.1 recaps all principal information(GSE 2016.).

Tab. 1: Italian General Information

General Data	
Inhabitants	60.6 [million]
Surface	301.340 [km^2]
Density	200 [ab/km^2]
Gross Domestic Product	30.527,27 mln $US

Italian energy sector is strong dependent on foreign energy markets and electricity generated from thermal generation. Specifically, Italy produces small volumes of natural gas and oil but most fossil fuels are imported and augmented by local production of energy from renewable sources.

European Government imposed that by 2020, the renewable energy should account for 20% of the EU's final energy consumption so to meet this shared target, each member state needs to increase its production and use of renewable energy in electricity, heating and cooling, and transport. In 2015 renewable energy production (only electrical) was been of 106.686 GWh thanks to a large contribution of hydropower and solar plant. Figure 3 shows an evolution of electricity generation from 2000-2014 years.

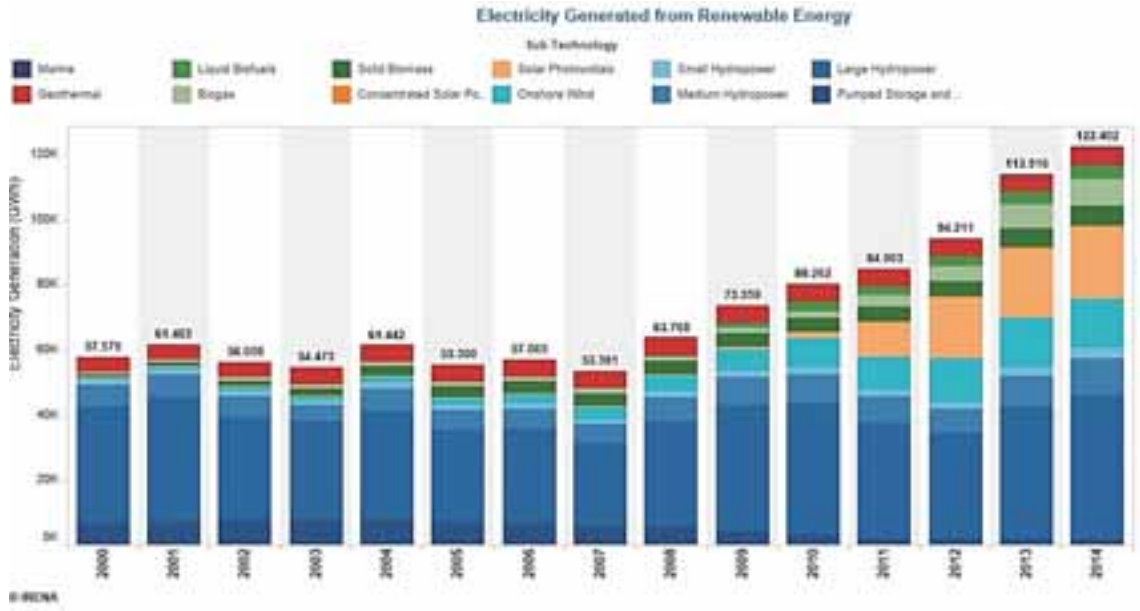

Fig. 3: Italian Electricity Generation from RES (renewable energy system) (Data from http://resourceirena.irena.org) (Data from http://resourceirena.irena.org)

The installed power at the end of 2015 is 51,475 MW and represents a little increase respect to the previous year thanks to the installation of new wind farms and photovoltaic plants. Between 2002 and 2015, the gross efficient power installed in Italy changed from 19,221 MW to 51,475 MW, an increase of 32,254 MW and an annual average growth rate of 7.9% overall power; The years 2011 and 2012 are characterized by higher power. Figure 4 shows RES plant installed between 2002-2015 (GSE 2016).

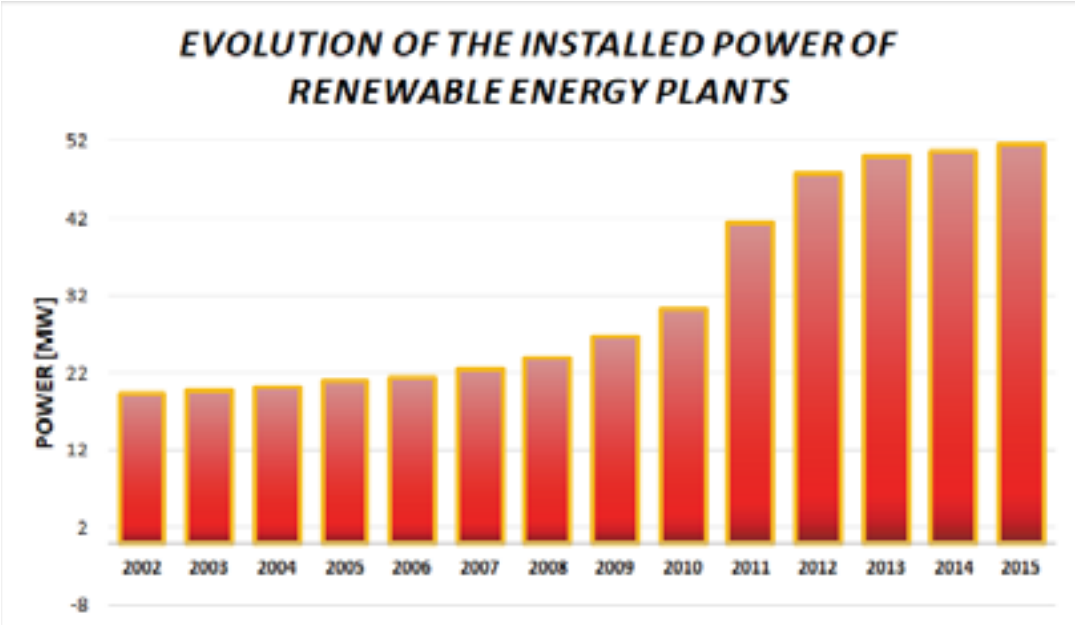

Fig. 4: Trend of the installed power of renewable energy plants.

Electricity demand 2016, equal to 314.3TWh (-0.8% by 2015), was met for 88.2% by national production (277.2TWh: + 2.5% by 2015) and for the remaining quota from net imports from abroad (37.0 TWh: -20.2% by 2015). National production recorded a substantial increase in the thermoelectric component and a substantial reduction in hydroelectric power. Renewable production is down due to the reduction in renewable hydroelectric production and, for the first time, of photovoltaic. Three counterproductive sources: wind, bioenergy and geothermal power generation.

Consumption is down 0.6% compared with 2015 and is 295.5TWh. The distribution by industry shows an increase in industry, a substantial stability of the attested service and a decline in both the domestic and the agricultural sectors. In terms of power installed, at December 31, 2016, the gross efficient generation power was 117.081MW, down 2,960MW (-2.5%) compared to 2015. This phenomenon is due to discharges in the thermoelectric park, increasing the capacity of renewable sources such as photovoltaics, wind and hydroelectric power (GSE 2016).

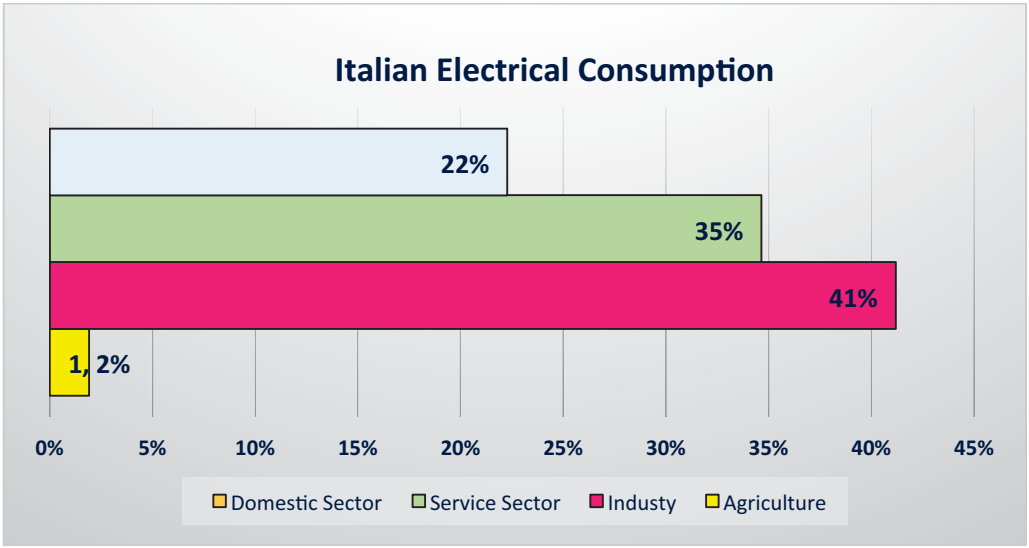

Fig. 5: Electrical consumption for year 2015.

3. Investigation on Brazilian energy sources

Brazil, officially the Federative Republic of Brazil, is the largest country in both South America and Latin America. As the world's fifth-largest country by area and sixth by population, it is the largest country to have Portuguese as an official language and the only one in the Americas. Brazil is one of the states with the best performance of economic development. It is part of the so-called BRICS (Brazil, Russia, India, China and South Africa) namely Countries that in recent years, and probably in the near future, recorded the highest rates of economic growth. The government plays a substantial role in the Brazilian electricity sector. Until the 1990s, the government controlled the electricity sector almost completely(Hira & de Oliveira 2009; Da Silva et al. 2005).

Tab. 2: Brazilian General Information

General Data	
Inhabitants	207.8 [million]
Surface	8 514 877 [km^2]
Density	23 [ab/km^2]

Fig. 6: Brazil GDP (2008-2016)

In 2004, the Brazilian government implemented a new model for the electricity sector. This hybrid approach to government involvement splits the sector into regulated and unregulated markets for different producers and consumers. This approach allows for both public and private investment in new generation and distribution projects.

As for conventional source, the thermoelectric generation, above all, coming from natural gas, and for oil reserve, EIA estimates that Brazil had 13.2 billion barrels of proved reserves, the second-largest level in South America after Venezuela. More than 94% of Brazil's reserves are located offshore, and 80% of all reserves are found offshore near the state of Rio de Janeiro.

Regarding renewable sources, Brazil is one of the countries with the highest contribution of renewable energy; in fact the main considerable are: water resources and biomass. The percentage of renewables in the energy mix has been increasing over time and is expected to increase further to rise from 42.4% to 47% of the domestic total Brazilian in 2030, as required by the National Energy Plan (PNE). The hydroelectric potential in Brazil is among the top five in the world: the country has nearly 20% of the planet and has approximately 11% of global hydropower production. The use

of hydraulic source comes from1883.

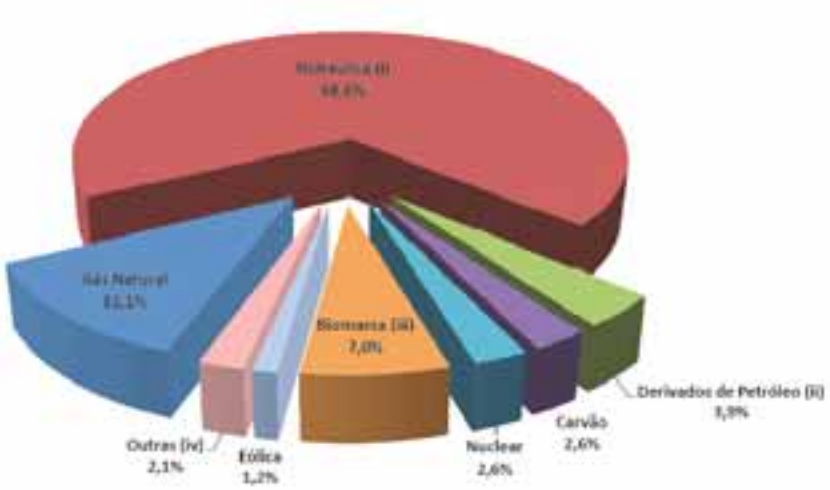

Fig. 7: Renewable and conventional sources

The exploitable hydropower potential is still estimated about 250 GW of installed power. Most of this potential is localized in the Amazon basin, while the north areas aren't still used. Hydroelectric plants are about 70% of the total electrical capacity installed in Brazil, amounting to 84 GW. Of these, approximately 14 GW are produced by Itaipù, built in Parana River on the border between Brazil and Paraguay; production values are split 50% between the two countries. Currently Itaipù hydroelectric plant produces about 90 to 100 TWh per year; the unused part of the production from Paraguay to Brazil is counted as the import of electricity. The Brazilian wind potential is estimated at about 350 GW14, concentrated mainly in northeast areas of country that is characterized by a high wind. There are 986 square kilometers of sand dunes with strong winds in the coast of Rio Grande do Sul. Another promising region is Minuano. A for solar energy, Brazil is a privileged country regarding solar irradiation.

However, exploitation of this resource is still insignificant because there are installed only 26 MW. The average energy conversion from photovoltaic systems is very interesting: the annual solar radiation is at its maximum value (approximately 2,300 kWh / m2) in the semi-arid northeast regions while the minimum (about 1,100 kWh / m2) in the northwest and southeast area. Figure 8 describes power installed in the period 2005-2016.

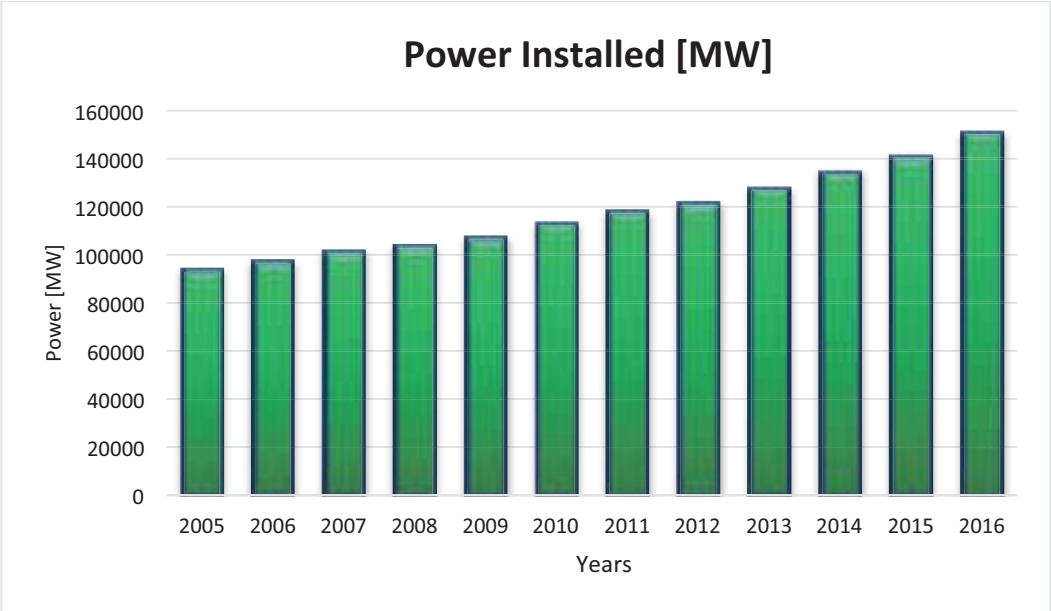

Fig. 8: Renewable energy plant installed in Brazil.

4. Economic impacts of renewable energy industry

In developing countries, where per capita consumption is relatively small, energy efficiency alone will not resolve the problem, because in many cases the final energy services (lighting, heating, cooking etc.) are still insufficiently available. Thus, global production and consumption of energy must increase to fulfill this repressed demand(IRENA 2017).

In this field, the renewable energies (such as wind, solar, biomass and small scale hydropower) will have a major role to play. Not only are these energy sources less polluting, but by their nature, are produced in small units. The decentralization of energy production leads to increased supply security and the creation of jobs. For example, this occurs in the production of ethanol from sugar cane in Brazil. The production of ethanol generates 4 – 21 times as many jobs as those needed to the produce the equivalent amount of energy from oil. For the same quantity of electricity, the number of jobs generated with wind energy is nearly 100 times greater than that generated by nuclear. The 120 GW of installed capacity in wind turbines throughout the world produce 260 TWh of electricity and avoid the emission of 158 million tons per year of CO2, which would occur if this energy was produced from fossil fuels. This is a market of about US $ 48 billion, which creates some 400,000 jobs (as shown in figure 8).

As for Europe, the wind industry remains one of the mainstays of the renewable energy sector in Europe. Employment declined slightly to 329,700 in 2015 (EurObserv'ER, 2017). Germany was the leader in wind jobs with 43% of the total in the European Union, followed by the United Kingdom, Denmark, Italy and France. The European solar PV industry continued to see a fall in employment in 2015. At 114,450, it has lost two thirds of jobs since 2011. Germany, the United Kingdom, France, and Italy are the leaders, with 67% of the European PV jobs in 2015. If we consider the huge potential of renewable energy sources for Brazil and Italy, more investments may cause an increase of the jobs in this sector.

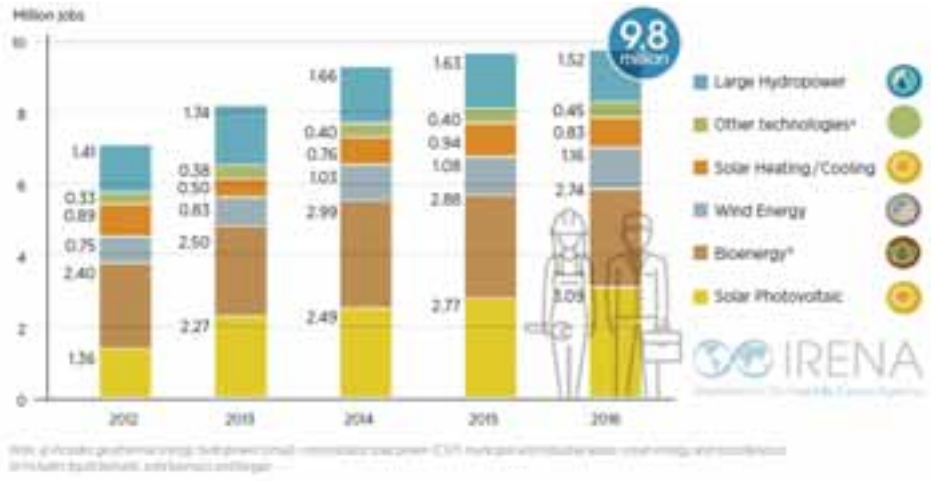

Fig.9: Global renewable energy employment

5. Conclusion

In conclusion, this paper gives information about energy supply in Italy and Brazil, focusing on the renewable energy sector.

The first part of the work describes a brief energy summary for Brazil and Italy in terms of capacity installed and electrical consumption. Furthermore, many international researches underline that the market for renewable sources grows and the financial crisis may be an opportunity. The presence of a stable, favourable policy framework continued to be a key factor for renewable energy job creation. New wind power installations in the United States, Germany, India and Brazil, meanwhile, contributed to the increase in global wind employment by 7%, to reach 1.2 million jobs.

Liquid biofuels (1.7 million jobs), solid biomass (0.7 million) and biogas (0.3 million) were also major employers, with jobs concentrated in feedstock supply. Brazil, China, the United States and India were key bioenergy job markets.

Jobs in solar heating and cooling declined 12% to 0.8 million amid an installation slowdown in major markets such as China, Brazil and the European Union. Large hydropower employed 1.5 million people (direct jobs), with around 60% of those in operation and maintenance. Key job markets were China, India, Brazil, the Russian Federation and Vietnam.

Differently for Italy, according to EurObserver data, employment in renewables in Italy has even declined from 121,850 occupied in 2011 to 97,100 in 2015, a less than 20%. A plausible explanation is that Italy's growth in renewables sector is reduced to minimum because in the electricity sector invested a significant share of incentives.

In conclusion, the investment in sustainable energy sector can be a correct politic choice to improve programs thus it may be an attractive opportunity and challenge for the future.

Development and Experimental Validation of a Multi-Functional Façade Model within an Object Oriented Platform

Deniz Kizildag, Joaquim Rigola and Assensi Oliva
Heat and Mass Transfer Technological Center (CTTC)
Universitat Politècnica de Catalunya-BarcelonaTech (UPC)
ETSEIAT Colom 11 08222 Terrassa, Barcelona, Spain
cttc@cttc.upc.edu, http://www.cttc.upc.edu

Abstract

The present work is on the experimental validation of a multi-functional façade model developed within an object-oriented simulation platform. An existing building façade is retrofitted by means of PV and vacuum insulation panels, which form a ventilation channel. For the optimum performance of the PV panel element, the channel thickness is chosen by means of the numerical tool so as to maximize the heat evacuated from the ventilation channel throughout the year, thus enhancing the efficiency of the whole system. The multi-functional façade is properly instrumentalized and is exposed to real meteorological conditions in order to assess its long term reliability, durability, and energy performance. Moreover, with the gathered experimental data, the developed numerical model will be validated.

Keywords: PV panel, ventilated façade, numerical simulation, object-oriented numerical platform, experimental validation.

1. Introduction

Energy efficient buildings have a large potential due to the necessity of reducing energy consumption and carbon emissions in line with European climate and energy targets for the year 2020. In order to improve the overall impact of the buildings, different strategies and architectonic solutions are being implemented, stimulating the development of accurate tools and methodologies in order to analyze their performance properly (Clarke and Hensen (2015)). The employment of multi-functional façades with double skins seems attractive due to their high potential to provide structural and energetic advantages, as well as aesthetic and comfort perception. Moreover, they can provide space for integrated PV panels (Agathokleous and Kalogirou, 2016). The channel formed within two skins can generate a microclimate around the building. The temperature gradients can facilitate natural and hybrid ventilation (Gratia and De Herde, 2007) and it can be used for heat recovery purposes, reducing the heating and cooling loads of the building (Ioannidis et al., 2017).

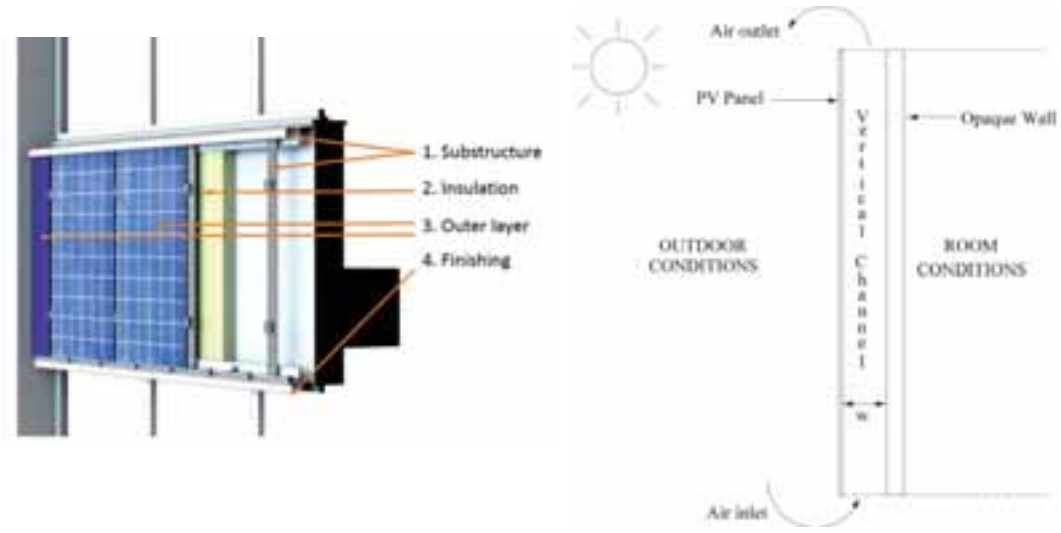

Fig. 1 Schematic view of the PV Ventilated Façade design (left), sketch of the functioning PV Ventilated Façade (right).

doi:10.18086/swc.2017.37.04 Available at http://proceedings.ises.org

The present work aims at taking to a further step a previous investigation on the implementation of a numerical model capable of predicting the thermal and fluid dynamic behavior of a multi-functional ventilated façade (Kizildag et al., 2015) within the existing parallel and object-oriented platform NEST (Damle et al., 2011). This methodology was recently employed within the framework of an innovative project (Retrofitting Solutions and Services for the enhancement of Energy Efficiency in Public Edification, RESSEEPE Project) in the task of envelope retrofitting. In the framework of this task, numerical simulations taking into account different configurations formed by a PV panel, a natural convection ventilation channel, and vacuum insulation panels were performed. The numerical study yielded a design which optimizes the PV panel efficiency under the weather conditions of Coventry, where one of the demo sites of the mentioned research project is located. In Figure 1, the schematic view of the final design for the retrofitting of the existing building is depicted. Note that this final design is the outcome of the synthesis of both thermal and structural analyses carried out in the design stage.

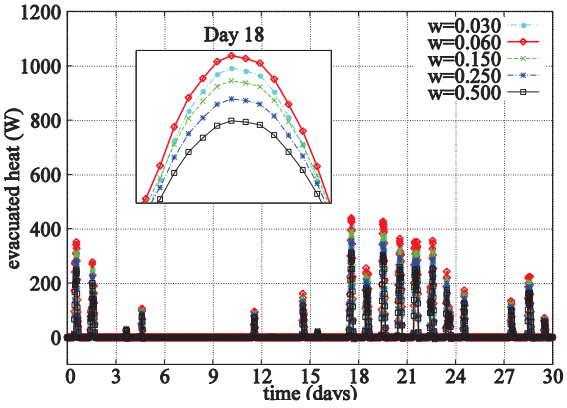

Fig. 2 Numerical analysis of the evacuated heat for different channel widths in the pre-design stage.

In Figure 2, an example of the influence of the possible ventilation channel widths on the evacuated heat is depicted for a typical month, based on the meteorological data obtained from Meteonorm ® software for the closest location to the John Laing Building in Coventry. Note, however, that the chosen channel thickness (see Figure 1) considers the overall effect of the results obtained for the whole year, which does not necessarily correspond to the optimum solution for a given period.

2. Mathematical and numerical modeling

In the NEST numerical platform, the system is a collection of some basic elements that can individually be solved for given boundary conditions, which are obtained from neighbor elements. By means of efficient coupling strategies, different levels of modelling can be put together in problems of complex heat transfer and fluid flow phenomena, for which multi-functional façades represent a good example. For instance, the critical elements of the façade or the building can be simulated by means of CFD models based on large-eddy or direct numerical simulations (Lehmkuhl et al., 2007), providing high precision results where necessary. The coupling of these results with lower order of modelling is powerful in allowing for carrying out simulations corresponding to extended domains in space and time.

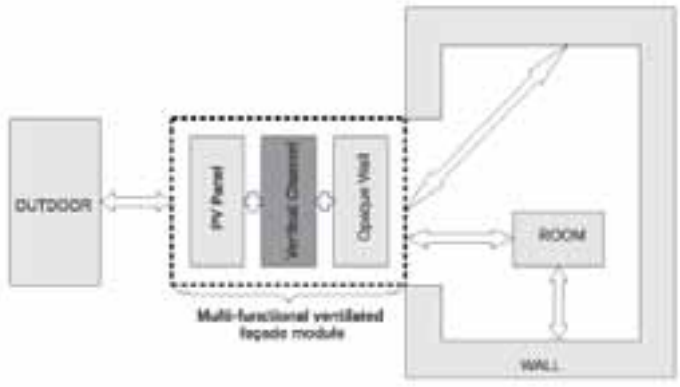

Fig. 3 Scheme of the NEST system as a collection of elements to model the Coventry demo site ventilated PV façade.

The NEST numerical platform is especially powerful in that it also allows parallel computation, which can redistribute the available computational resources according to the demands of the employed elements. The implemented module of the numerical tool aims at modelling an existing building envelope retrofitted by means of PV panel that is installed in the façade to form a vertical channel. The scheme of the resulting multi-functional ventilated façade module is shown in Figure 3.

Details of the mathematical and numerical model for the employed elements to form the PV Ventilated Façade is given by Kizildag et al. (2015). Note that *PV Panel* is modelled as an opaque one-dimensional conduction element with internal heat generation, assuming that the portion of the incident solar energy which is not used in the electricity generation is absorbed by the panel. This study basically addresses the thermal performance of the element.

Regarding the *Vertical Channel* element, it is worth noting that Bernoulli equation is applied in the inlet of the channel, assuming acceleration from an unperturbed point at the bottom of the channel. As for the thermal boundary conditions, improving the mathematical model employed in the previous work (Kizildag et al., 2015), the inlet temperature is no longer set constant at the mean outdoor temperature value of the simulated period, but it is dynamically adapted from the available meteorological data. The governing continuity, momentum, and energy equations regarding the *Vertical Channel* element are discretized by means of appropriate numerical schemes as explained in (Patankar, 1980) and using SIMPLEC algorithm.

Opaque Wall element is modeled in the same fashion as the PV Panel element, except for the existence of the inner heat generation terms. This element, which models the insulation layer, uses the thermophysical properties corresponding to the aerogel-based superinsulating mortar or vacuum insulation panels (VIP) provided by the manufacturers of these architectonic solutions, applied in the retrofitting of the demo building.

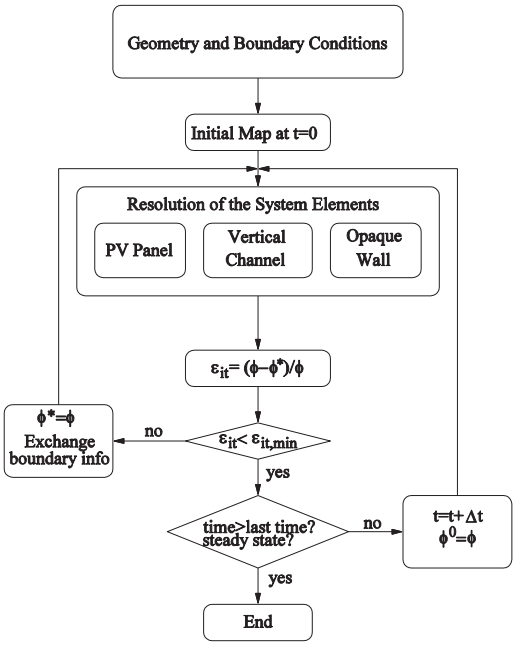

Fig. 4 Global resolution algorithm of the numerical tool.

The global resolution algorithm of the numerical model is shown in Figure 4. At each iteration, once the inputs (e.g. temperature, heat flux etc.) are obtained from the neighbors, the governing equations for each element are solved and the final outputs are supplied again to the neighboring elements as boundary conditions. Iterations continue until convergence is reached at a given time step and next time step calculation starts as the variables are updated. Details of the numerical platform are provided in (Damle et al., 2011).

3. Experimental validation of the numerical model in demo site

The validation of the numerical model was performed separately for each element constituting the PV façade using subsystems for which an analytical solution exists (see Kizildag et al., 2015 for details). As for the PV Panel and Opaque Wall, an analytical solution exists. Regarding the Vertical Channel, the analytical solution presented in (Bar-Cohen and Rohsenow, 1984) was used. Detailed results of the code validation were given in (Kizildag et al., 2014).

The present work, however, is aimed at completing this initial analytical validation by a proper experimental

validation. Thus, in order to validate the implemented numerical model, the whole PV façade module of the retrofitted façade of the John Laing building (see Figure 5), composed of a PV panel, a ventilation channel, VIP panels and brick layers, was instrumentalized.

Fig. 5 Retrofitted façade of the John Laing Building in Coventry University.

The façade is equipped with a pyranometer measuring the global solar radiation in the plane of the façade, and a temperature sensor registering the outdoor ambient temperature in the vicinity of the prototype. Within the ventilation channel, two anemometers are placed, one in the midheight, the other in the 90% of the PV panel height locations. Two temperature sensors are also located in these locations. Another temperature sensor is also placed in the inner surface of the VIP panel which confines the ventilation channel. See Figure 6 for the images corresponding the instrumentalization of the PV façade.

Fig. 6 Pyranometer and outdoor temperature sensor (left), anemometer and inner tempearure sensors (right).

The experimental data from the sensors installed in this facility is gathered by a data acquisition system during prolonged periods of time. In Figure 7, the measured meteorological data for the PV façade for the winter and spring periods are depicted. Note that, during the winter period, the available solar energy on the plane of the façade is significantly lower with respect to spring conditions, which makes the months of March and April periods more suitable for the analysis of the façade. For the validation of the numerical model, the gathered meteorological data is feeded in the numerical model as the boundary conditions of the studied case, and the numerical outcomes of the model is than compared with the experimental data obtained from the temperature and air velocity sensors located within the cavity of the ventilation channel. To that end, three representative variables are selected:

- average air velocity within the ventilation channel
- temperature at the outlet of the channel

- temperature at the VIP surface, adjacent to the ventilation channel

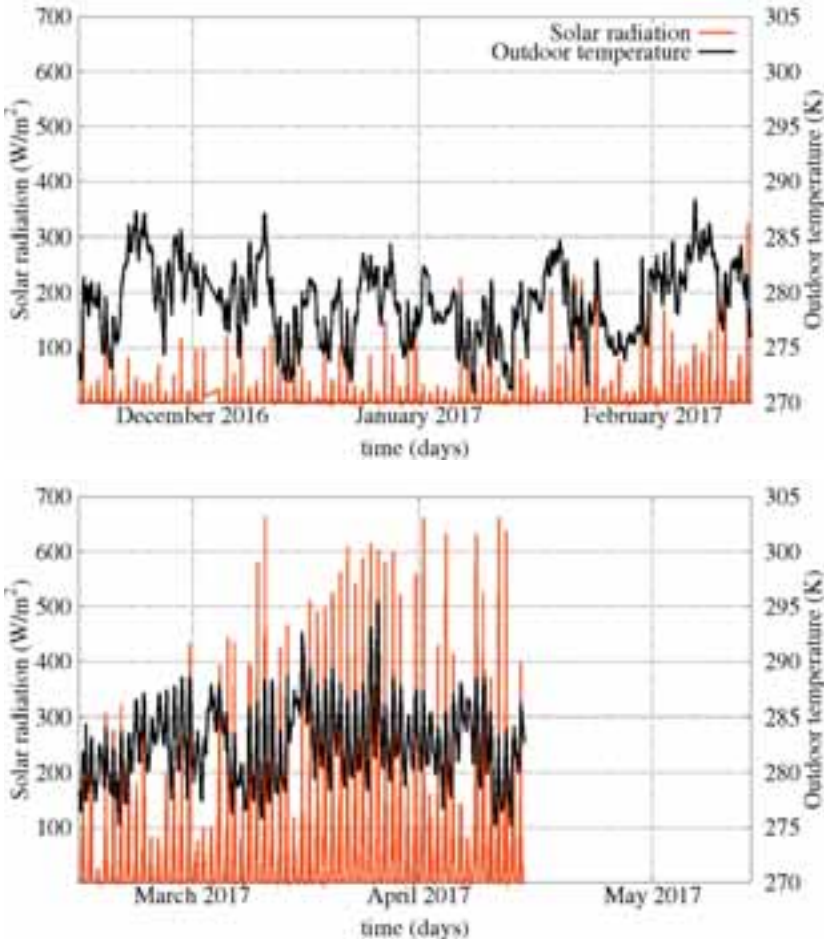

Fig. 7 Solar radiation and ambient temperature in demo site during winter (top) and spring (bottom).

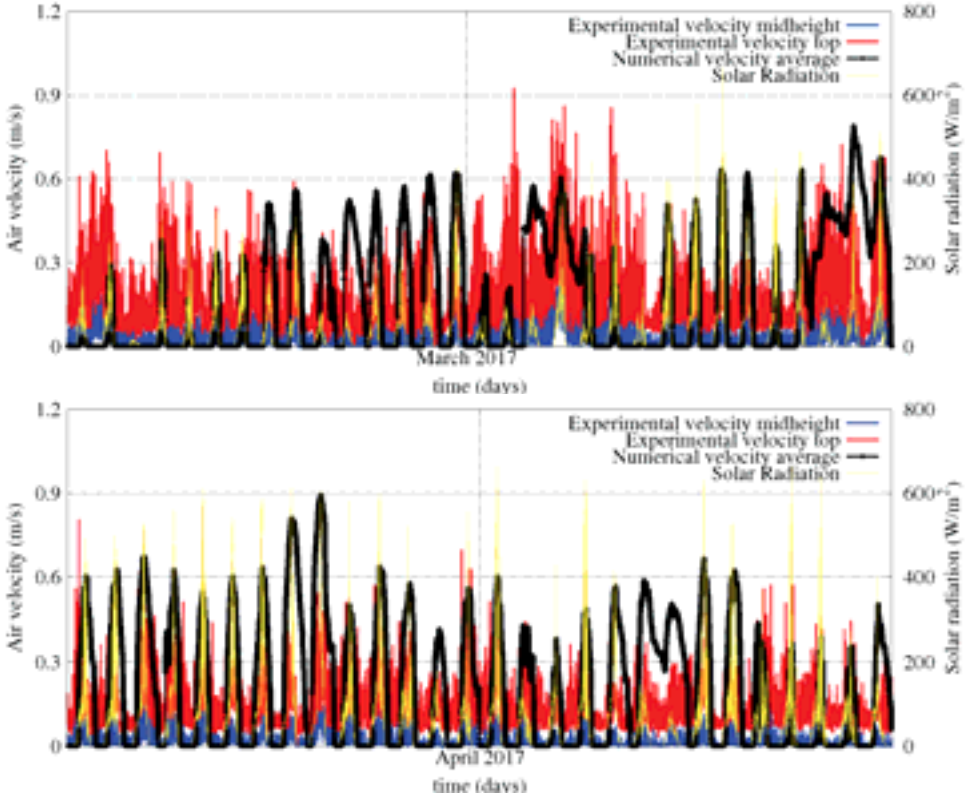

Fig. 8 Comparison of the numerical model's average velocity field with the experimental readings for March 2017 (top) and April 2017.

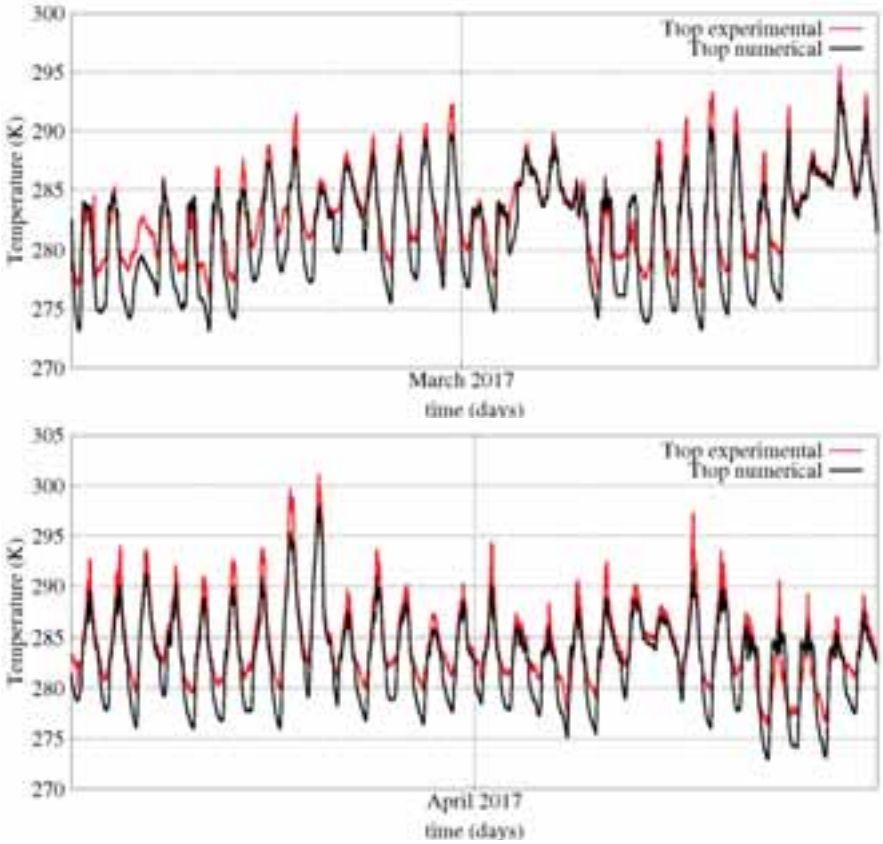

Fig. 9 Comparison of PV Façade air outlet temperatures obtained numerically and experimentally for March 2017 (top) and April 2017 (bottom).

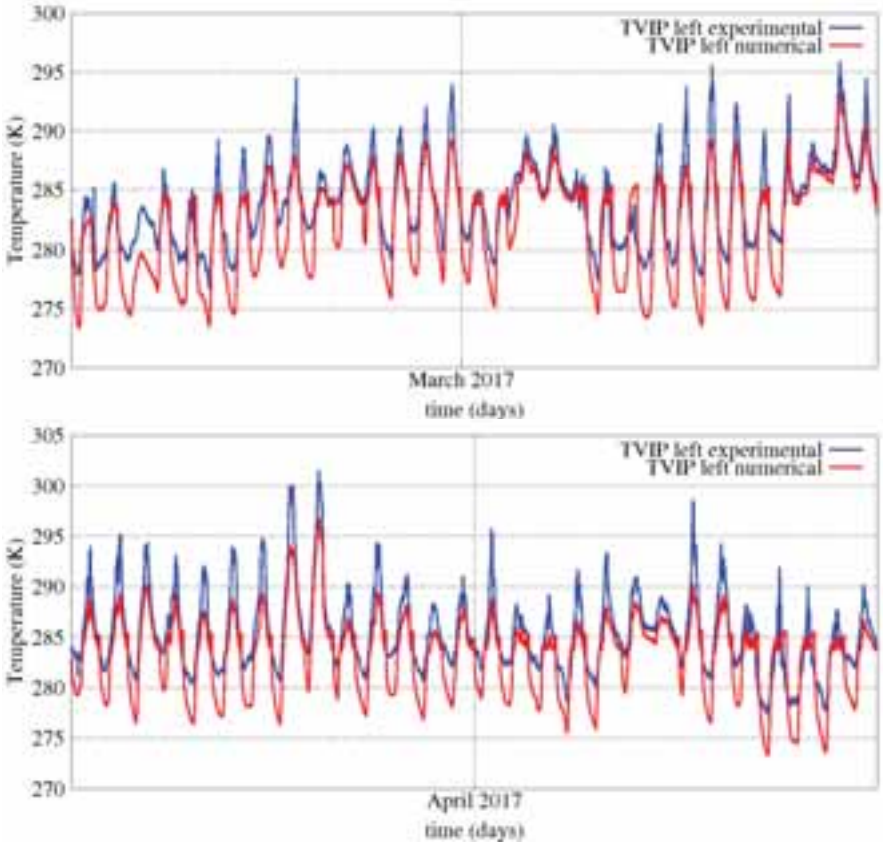

Fig. 10 Comparison of VIP surface temperature, confining the channel, obtained numerically and experimentally for March 2017 (top) and April 2017 (bottom).

The data corresponding to these selected variables are comparatively presented in Figures 8-10. The numerical data here presented for these considerably large periods of time –of the order of months- is in significantly good agreement with the gathered experimental data, thus providing a reasonable confidence in the potential of the numerical model in anticipating the thermal and fluid dynamics performance of the studied PV façade.

It has to be noted that, the model outcome is consistent with the complex physical phenomena taking place in the PV ventilated façade, as the temperature evolution data can fully follow the trend of the experimental temperature evolutions registered in two depicted key locations (see Figures 9 and 10). As for the air velocity within the ventilation channel, the numerical outcomes correlate very well with the availability of solar radiation, however they somewhat overestimate the velocities registered by the anemometer located at the top location of the channel (see Figure 8). Similarly, the estimated temperatures, while reproducing the phenomena correctly, are a few degrees lower than the experimental readings. These discrepancies can be attributed to many circumstances, such as:

- 1D numerical model vs 3D physical phenomenon: The employed numerical model is necessarily a 1D model, due to the impossibility of the detailed numerical resolution of the complex phenomena within the air channel for prolonged periods of time, typically one year. Any higher order model, such as CFD models, is not feasible for the present study.
- 1D model necessarily employs empirical data, such as friction factor or heat transfer coefficient which are derived for general situations which may not be in line with the actual studied case.
- The empirical data employed is derived for steady-state conditions, while the present study involves a transient behavior.
- The placement of the physical sensors, cables and other connection devices within the air velocity affects the overall behavior of the flow in the ventilation channel. These details are not considered in these simulations.
- The inlet and outlet geometry of the channel deviates from the initially studied case, which can justify important discrepancies with respect to the flow configuration.
- The employed anemometers have associated errors which can lead to discrepancies.
- Shadows are reported to be partially present on the studied façade, which can cause virtually higher or lower available radiation data on the façade.
- Temperature indoors is considered as a given constant value throughout the simulations.

To have a closer look at the model performance, data corresponding to the 1st week of April 2017 is depicted in Figure 11. The data is in line with the main conclusions mentioned above regarding the agreement of the numerical and experimental data, considering the assumptions that are included in this numerical study.

Thus it can be said that, the numerical tool, after being validated using the experimental data gathered in the John Laing Building, certifies the proper functioning of the ventilation channel placed behind the PV panel. The channel is shown to effectively dissipate the heat accumulated in the PV panel element, thus avoiding it to reach temperatures in which the correct functioning and overall efficiency of the PV element would be negatively affected.

Overall, the present numerical methodology for the long term thermal and fluid dynamics behavior analysis of a PV Ventilated Façade is shown to be an effective tool to design and optimize similar configurations. It is especially interesting to note that, due to the modular design of the validated software, new and more efficient materials or different innovative architectural solutions which are daily emerging in the market can be readily implemented in this validated numerical tool to address each time a wider range of situations regarding the retrofitting of the buildings.

4. Analysis of PV Ventilated Façade technology extrapolated to whole building

As an additional step of the present work, the numerical tool is employed to analyze the heat dissipation behavior of the channel, in the event that the PV ventilated façade technology is applied to the total available opaque surfaces present in the western façade of the demo building. In line with the objectives of the RESSEEPE project, it is of importance to extrapolate the results of the demo site module to the whole façade, thus highlighting the overall savings that could be provided by this retrofitting technology.

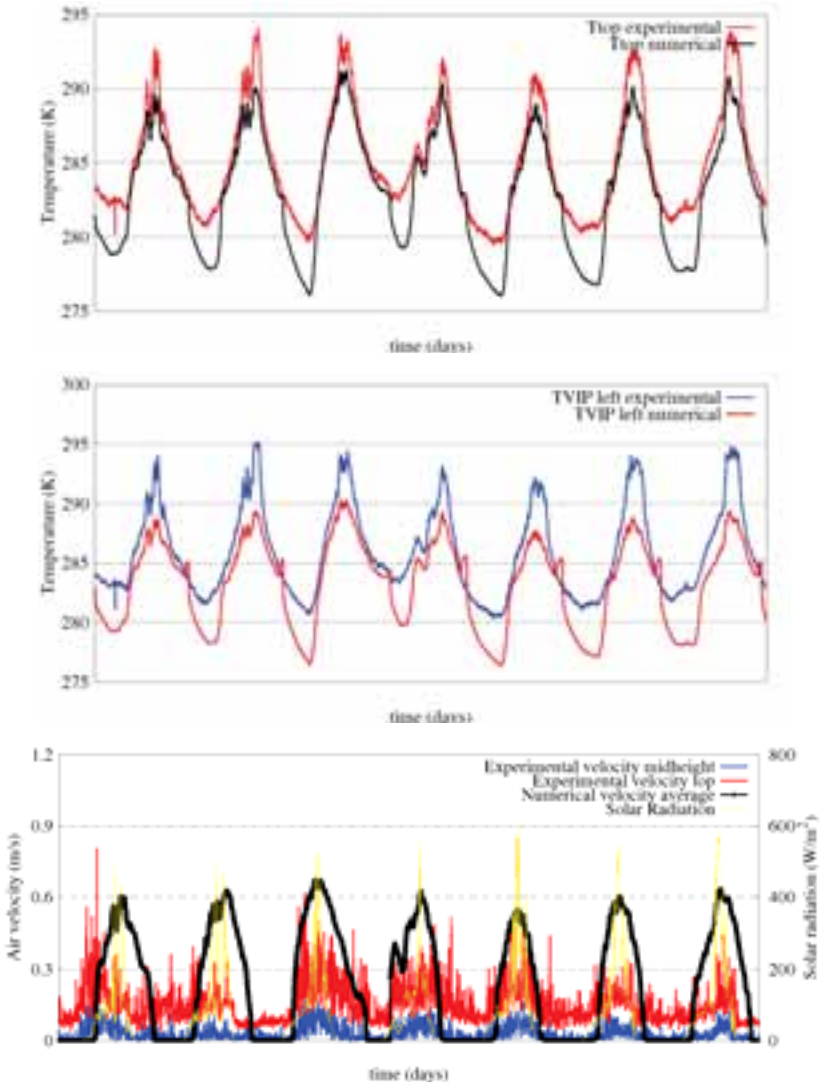

Fig. 11 Numerical vs experimental data for the 1st week of April. Temperature at the outlet of the channel (top), temperature at VIP surface (middle), average channel air velocity (bottom).

In Figure 12, the instantaneous total heat which would be evacuated by means of the ventilation channels is compactly depicted during the periods of winter and spring. This calculation is carried out by means of the already presented and validated numerical tool, using as boundary conditions the meteorological data gathered in the demo site, for the hypothetical case of installing the identical PV Ventilated Façade to all the available opaque spaces, excluding the already existing windows. Note that the evacuated heat, represented by the blue lines, have higher influence at higher levels of incident solar energy. During the winter months, the available solar energy is reduced and the outdoor ambient temperatures are relatively lower, thus the effect of the ventilation channel is not expected to be critical during these months, as confirmed by the outcomes of the numerical tool. However, from the detailed results depicted in Figure 13, it can be observed that the façade would effectively remove important portions of heat during the times of high solar availability, such as in May, by means of the ventilation channel.

Table 1 Total incident solar energy and the dissipated portion by the ventilation channel during 6 months.

Month	Incident Heat (kWh)	Dissipated Heat (kWh)	Percentage (%)
December	1375	203	14.8
January	1369	146	10.7
February	2578	760	29.5
March	6636	2371	35.7
April	11395	4784	42.0
May	11606	4788	41.3

In Table 1, the monthly total incident solar energy is given together with the dissipated portion by means of the PV Ventilated Façade. The tabulated data shows that, in the hypothetical case of installing this technology to the whole western façade of the John Laing building, over 40% of the absorbed heat by the PV panel would be effectively dissipated, leading to the optimum and efficient functioning of the PV panel.

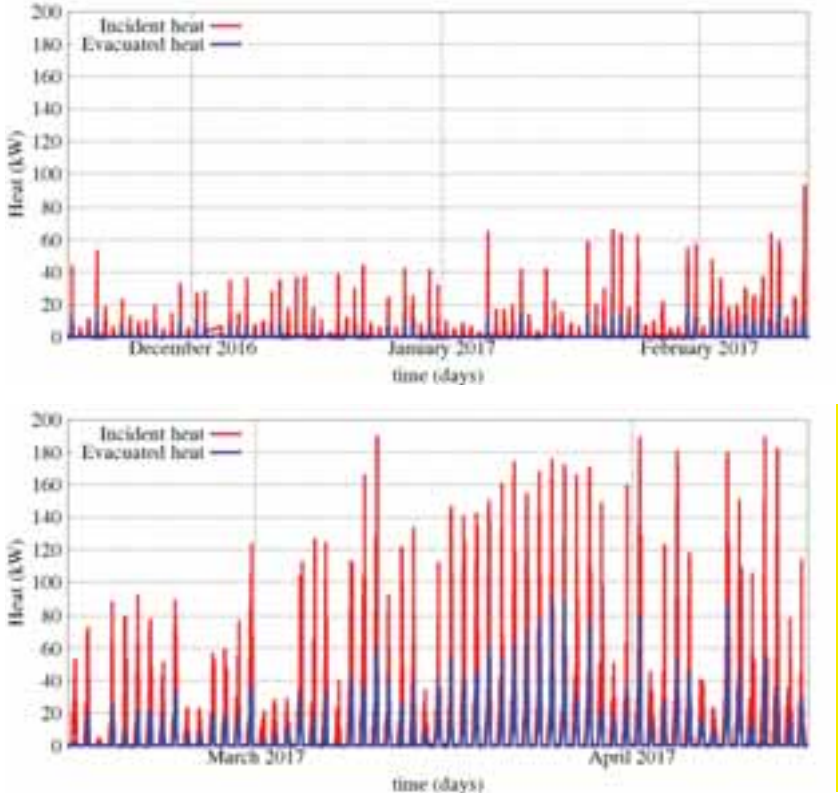

Fig. 12 Incident vs evacuated heat calculated for the hypothetic implementation of the technology to the whole façade.

In order to complement the data presented in **¡Error! No se encuentra el origen de la referencia.**, and to study the improvement experimented by the system thanks to the presence of the ventilation channel, the validated tool has been employed to comparatively study the influence of the ventilation channel on the PV panel temperatures. Note that, according to the technical specifications of the implemented panels in Coventry demo site, the efficiency of the electricity production of the panels reduce approximately by 0.451 % for each ºC of temperature rise experimented in the mean temperature of the cells. To that end, an additional simulation has been performed, simulating the thermal behavior of the façade for an identical system, but without the channel, i.e. the PV Panel is modelled to be attached directly to the VIP element. Considering the projection of this technology to the whole western façade of the John Laing building, the additional electrical energy delivered to the system is depicted in Table 2. Note that, the daily average PV panel temperatures are evaluated for the periods where there is solar availability within a day, i.e. during sunshine hours. The data reveal the key function of the ventilated façade, which make the PV panel function close to the ideal temperature conditions, and thus contributing it to deliver a considerably higher amount of electrical energy when compared with a hypothetical solution without ventilation channel.

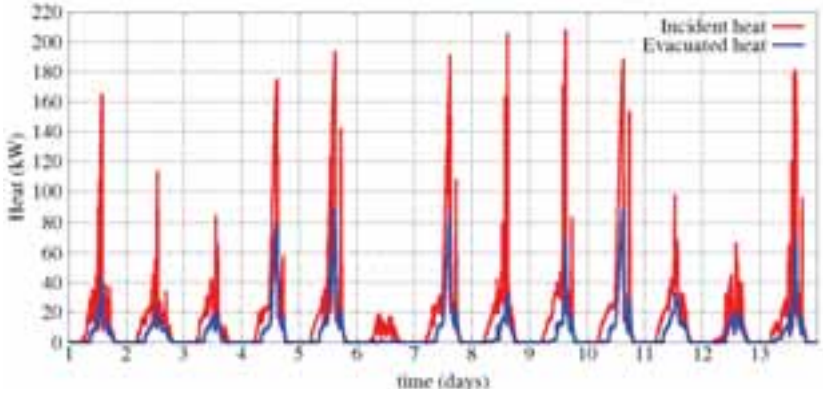

Fig. 13 Hypothetical instantaneous evacuated heat during the first two weeks of May 2017.

Table 2 Projection of the improvement of the electrical energy generation due to the presence of the ventilation channel for the meteorological data gathered in May 2017.

Day	Daily average PV panel temperature without channel (º C)	Daily average PV panel temperature with channel (º C)	Additional electrical energy delivered to the system (kWh)
1	27.975	21.089	9.38
2	24.622	19.056	6.53
3	24.205	19.216	5.63
4	36.878	25.405	28.23
5	36.527	25.009	31.09
6	14.354	13.966	0.19
7	38.207	26.269	30.87
8	26.303	21.255	7.73
9	29.523	23.260	12.78
10	36.562	25.237	32.09
11	30.433	22.162	13.81
12	28.305	21.219	8.08
13	31.207	22.351	17.35

In summary, the analysis extrapolated to the whole building by means of the validated numerical model shows that PV Ventilated Façade can be an interesting solution, evacuating the excess of heat through the ventilation channel by means of natural convection, thus contributing to the corresponding ventilation of the PV Panel, enhancing its efficiency. The analysis is carried out, not only for the particular module instrumentalized, but also for the whole western façade of the demo building, on the hypothesis of applying the mentioned technology to the entire façade.

5. Conclusions

It has been shown in the demo site located in John Laing Building in Coventry University by means of instrumentation that the designed and installed module of PV Ventilated Façade is functioning properly, as the ventilation channel effectively serves to evacuate the excess of the heat to enhance the overall performance.

The numerical methodology, employed in the design stage of the PV Ventilated Façade, is properly validated by means of experimentation. It has been shown that, besides the limitations of the assumptions, which are necessary so as to provide feasible numerical simulations for complex phenomena in physically large domains such as buildings and for typically extended periods of time, the numerical tool is capable of reproducing the general behavior of the retrofitted PV Façade studied in the present study.

Although the tested period does not cover a representatively long time span, however the initial outcomes in terms of both energy efficiency and the reliability of the system are promising.

The final outcome of this study is the experimental validation of an existing numerical tool which is capable of design, optimization, and long term performance prediction of PV Ventilated Façades or similar retrofitting or newly-built architectonical solutions. Additionally, due to its modular structure, the present tool can be extended to a wider range of retrofitting solutions, with the straightforward implementation of the numerical models of the newly emerging innovative materials and devices.

6. Acknowledgments

This work has been financially supported by the European Community FP7 Programme, EeB.NMP.2013-3 No 609377 “RESSEEPE Project”. The authors thankfully acknowledge this support.

The authors gratefully thank all RESSEEPE partners who participated in the tasks related with the PV Ventilated Façade experimentation, specially EURECAT, TECNALIA, and LEITAT, together with Coventry University for their support and contributions in the facility implementation.

Sustainable Strategic Urban Planning: Methodology for Urban Renovation at district level

Estefanía Vallejo[1], Cristina Criado[2], Eneko Arrizabalaga[3] and Ali Vasallo[1]

[1] CARTIF Foundation, Boecillo (Spain)

[2] ACCIONA Construction, Madrid (Spain)

[3] TECNALIA Research and Innovation, Bilbao (Spain)

Abstract

Sustainable urban renovation is characterized by multiple factors (e.g. technical, socio-economic, environmental and ethical perspectives), different spatial scales and a number of administrative structures that should address the evaluation of alternative scenarios or solutions. This defines a complex decision problem that includes different stakeholders where several aspects need to be considered simultaneously. In spite of the knowledge and experiences during the recent years, there is a need of methods that lead the decision-making processes.

In response, a methodology based on the global idea and implications of working towards a more sustainable and energy efficient cities as a holistic procedure for urban renovation at district level is proposed in the European Smart City project CITyFiED. The methodology has the energy efficiency as main pillar and the local authorities as client. It is composed of seven phases that ensures an effective dialogue among all the stakeholders, aiming to understand the objectives and needs of the city to define a set of Strategies for Sustainable Urban Renovation and their integration within the Strategic Urban Planning of the cities.

Keywords: Sustainability, Decision making, Urban Renovation, Indicators, Energy planning

1. Introduction

Urban planning and regeneration process are concepts that involve a number of dimensions, e.g. technical, socio-economic, environmental and ethical perspectives. Sustainable urban regeneration is characterized by multiple factors, different spatial scales and a number of administrative structures that should address the evaluation of alternative scenarios or solutions. This defines a complex decision problem that includes a number of different stakeholders where several aspects need to be considered simultaneously. It is usually based on series of qualitative and quantitative data related to empirical observations, physical conditions and trends. In the decision-making process, cities need to invest a great deal of resources and time in the collection of information to deliver such assessments and decisions. However, very little is known about how decisions are made and the processes that lead to them.

There is a need to better identify, analyse, model and map resources and the current situation of urban settlements and solutions to achieve a more efficient built environment and match its demands with efficient sustainable energy sources at the least cost. Such energy planning is already mandated in the Energy Efficiency Directive (Directive 2012/27/EU). This needs to be done at local, regional and national levels to help develop energy strategies and ensure their consistency at national level and with EU policies; in fact, promoting sustainable urban development is a key element of the European Cohesion Policy and a continuous process.

During the last years, a great deal of research have been develop on one hand, by Technical Committees and Working Groups, which have been working in the field of Smart Cities, such us ISO TC/268, developing requirements, frameworks, guidance and supporting techniques and tools related to the achievement of sustainable development. On the other hand, there are many EU projects working to create models on energy efficient and sustainable city planning, such as PLEEC, or financial entities, such us The Word Bank, who has developed the Urban Regeneration Decision Tool.

Despite the vast amount of knowledge and tangible experiences that have being generated, there is still a need of deployment of holistic methodologies which comprise a global approach at city level and embrace the concept of sustainability. This implies the development of procedures, tools, key performance indicators and guidelines to

doi:10.18086/swc.2017.37.05 Available at http://proceedings.ises.org

cover the large scale and complexity of this approach. In this context, under the umbrella of Sustainable Strategic Urban Planning, a novel methodology for urban renovation at district level is proposed and validated by the European Smart City project CITyFiED (Grant Agreement Nº 609129).

2. CITyFiED Methodology for city renovation at district level

According to the United Nations, in 2014 more than half of the world's population was living in urban areas and two third of the world's population will be living in an urban area by 2050 (United Nations, 2014) being Europe the most urbanized continent (URBACT, 2015). The forecast for 2050 in this case is to increase the percentage up to 75 percent (Eurostat, 2016). Besides, urban areas are engines of regional and national growth as they generate 53 percent of gross national product (GNP) in low-income countries, 73 percent in middle-income countries, and 85 percent in high-income countries (World Bank, 1999).

These features bring about many desirable advantages for citizens. Although the concentration in cities usually supposes an increase of density and less consumption of resources, cities use two-thirds of the world's energy and generate three-fourths of the world's CO_2 emissions (Smart Cities Council, 2013). In addition, urban areas have important drawbacks, being waste production, carbon emissions, pollution, lack of preservation of heritage and environment, traffic congestion, etc. (Broere, 2012). It is analysed that the exposure of citizens to these problems is more than two times higher than in the case of people living in rural areas (Eurostat, 2016).

It seems that residential sector of small and medium sizes cities are the strategic lines of action to solve these problems due to their potential. The total number of dwellings in Europe in 2014 was 249,652.26 thousands and from those, around 45% were built before 1969, 32% between 1970 and 1989 and only 9.3% in the 90's. Moreover, the energy consumption of the residential sector was 263.22 Mtoe what supposes 158.76 kWh/m^2, still far from the H2020 set objectives (BPIE database). This data shows an elevated average age of the building stock in Europe with low energy performance and therefore, susceptible of being renovated. On the other hand, an 83% of cities in Europe are small and medium cities in terms of population (50.000-250.000 inhabitants) (Dijkstra and Poelman, 2012).

Above all, urban lifestyle needs to be sustainable, and sustainability should be understood from three points of view: *environmental, socio-economic and institutional*. Citizens' current way of life must be reconsidered and cities need to find a way to regenerate themselves in order to ensure long-term sustainability and overcome the current challenges they are facing.

In CITyFiED Methodology, the sustainable city renovation is understood as regeneration of actions, policies, and processes within a city, which address interrelated technical, spatial, and socio-economic problems in order to reduce environmental impact, mitigate environmental risk, and improve environmental quality of urban systems, lifestyles and assets. It aims to enable the replicability and mass-market deployment of energy-efficient retrofit of districts, considering as a reference the large CITyFiED demonstration cases in the cities of Lund (Sweden), Laguna de Duero (Spain) and Soma (Turkey), decision-making processes and business models.

Fig. 1: Phases of CITyFiED Methodology and the twofold scale

The Methodology is a procedure composed of 7 phases and a decision making process that aims to understand the city (objectives and needs) in order to deliver a set of customized Strategies for the Sustainable Urban Renovation at district level with the energy efficiency as the main pillar and local authorities as clients.

Each phase ensures an effective dialogue among all stakeholders and considers ways to strengthen confidence in decision-making processes. The present approach has been validated through the active participation of the CITyFiED network of cities.

The methodological approach foresees the creation of an External Consultancy Group (ECG) to closely cooperate with the local authorities when understanding the city and setting up the most suitable set of strategies for the

urban renovation at district level. The process is supported by different tools and levels of indicators that would enable the assessment of the suggested actions (Strategies for Sustainable Urban Renovation) as compared to the original situation and objectives.

Three levels of indicators have been defined: City Level Indicators (Level 1) at city & district level, Project Level Indicators KPIs (Level 2), and Impact Assessment Indicators at city level (Level 3).

2.1. Involvement of Stakeholders

The Methodology addresses the roles and responsibilities of the stakeholders involved along the application phases. In the first place, the *Municipalities*, representing the interest of citizens. They also promote the renovations at city or district levels to increase the sustainable performance of cities. Therefore, the experts representing the Municipality are conceived as collaborative clients in the methodology approach, divided into several committees as they are usually organized.

Public Participation understood as citizens, NGOs, neighbors associations, etc. are other group of stakeholders involved in sustainable renovations through different participation techniques cause "*all members of society have a key role in addressing the energy climate challenge with their local authorities*" (CoM, 2010).

Besides, *External Stakeholders* are required to carry out the renovation as constructors, financial entities, energy companies, investors, etc. As one key innovative aspect of the methodology, it proposes the foresight of an *External Consultancy Group (ECG)* to offer their services and closely cooperate with the Municipality. This is a multidisciplinary consultancy that supports the local authorities when understanding the city and setting up the most suitable set of Strategies for Sustainable Urban Renovation (SSUR), facilitating consequently the decision-making process.

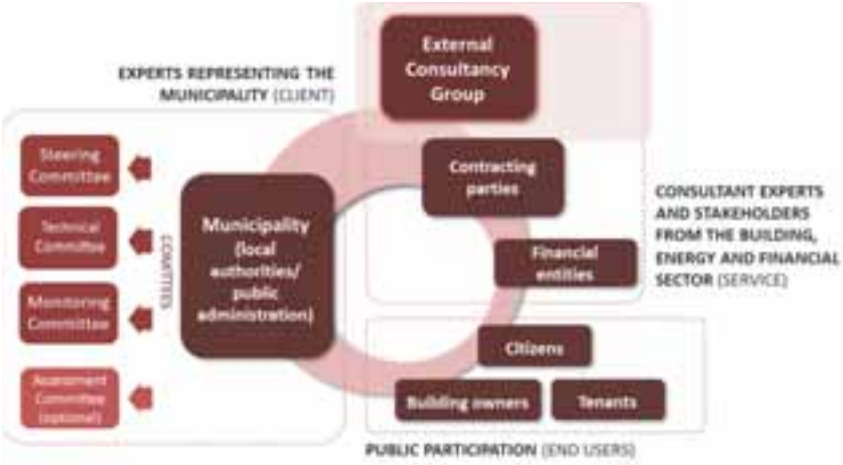

Fig. 2: Stakeholders defined in the Methodology

These stakeholders are sorted in different groups as shown in Fig. 2**:**

Experts representing the Municipality (Client)

- *Steering committee.* This committee includes those capable actors to make decisions in the local authorities' bodies, providing "(…) strategic direction and political support during the process" (CoM, 2010). Their mission is focused on the first stages of the process, i.e., understanding the city and diagnosis, selection of scenarios, etc.
- *Technical committee*. It is recommended to create this commission from a multi-criteria perspective, including urban planners, technicians, engineers, architects, designers, environmental consultants, etc.
- *Monitoring committee*. This committee is in charge of the monitoring strategy definition and implementation during the execution and for the final evaluation.
- *Advisory committee*. Other politicians or technicians from higher levels of the Public Administration could form an additional group of stakeholders to advice the Steering committee, i.e., regional and state technicians.

Consultant experts and stakeholders from the building, energy and financial sector (Service)

- *External Consultancy Group (ECG).* This group is conceived as a multi-perspective consultancy. It consists of technical consultants, technological institutes, research institutions, academia, energy experts, engineers, etc. that assess the Municipality during first phases of the methodology to define the initial situation, evaluate measures and scenarios and define the Strategies for the Sustainable Urban Renovation (SSUR). The addition of this group reduces risks by guaranteeing the achievement of the final objectives
- *Contracting parties.* These are independent companies and entities involved in the execution of the works that normally should be selected through tender/bidding process (e.g. architecture firms, building and energy companies, etc.). They should establish a fluent dialogue with the technical committee.
- *Financial institutions.*

Public participation (End users)

This group is formed by citizens, neighbourhood associations, housing associations, NGOs, etc. Their feedback is collected during all the process, but especially during diagnosis, decision-making and final evaluation. Building owners and tenants are deeply involved in the strategies definition.

3. Phases of the Methodology

The Methodology is deployed in seven phases as can be seen in Fig. 3. Each phase ensures an effective dialogue among all the stakeholders previously defined in order to ease the decision-making processes. It combines both district and city scales, starting with the city and district analysis, proposing initiatives at district level and pursuing the impact of the renovation and the accomplishment with the initial objectives at both scales.

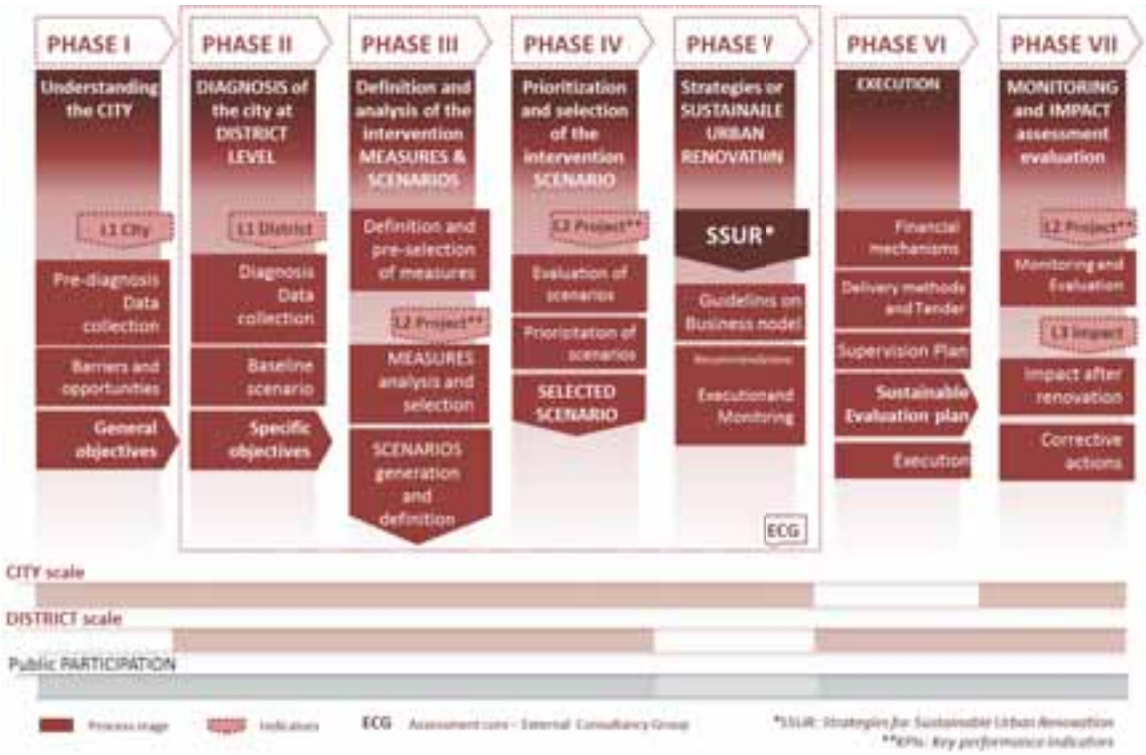

Fig. 3: Methodological approach for urban renovation and planning

Phase I: Understanding the city

This phase aims to make a first approach to the city understanding, evaluating its context and needs with a set of **City Level Indicators** as a supporting tool and taking into account public participation. This analysis, combined with the definition of the long-term city vision, enables the identification of the city sustainable pathway within

its Strategic Urban Planning and the definition of the general objectives that guide this transition.

The **pre-diagnosis and data collection** of the city is precisely the first step of this phase. Here, the most relevant factors at city level from different perspectives are evaluated in order to contextualize the current situation of the city. The complexity of urban areas, together with the ambitious scope of the methodology and the guidelines for sustainable development from the EC, makes necessary to consider a multi-criteria or holistic perspective during this analysis. However, in order to facilitate the application of the methodology it was necessary to limit the scope of the evaluation. Therefore, considering that the purpose of the CITyFiED project, the matrix of Fig. 4 was defined to gather all the relevant areas to be analyzed. The columns of this matrix are defined as "city strategic areas" which represent the main ambits that will be treated by the implementation of specific improvement interventions at district and city scale. On the other hand, the rows of the matrix are defined as "application areas" and represent the different sectors of the city in which the different interventions can be implemented.

Fig. 4: CITyFiED Application Areas and City Strategic Areas

Following this perspective, the pre-diagnosis will cover aspects of the city such as culture, economy, urban morphology or the main constraints and opportunities for the implementation of measures (legal framework, financial opportunities, etc.). This analysis will contribute to the required initial city context knowledge for the definition of the general objectives of the Strategic Urban Planning.

However, the quantification of specific City Level Indicators (Level 1) that can be compared to other city values provides a better understanding of the improvement potential and needs of different areas of the city evaluated. This is covered by the second step, in which a set of indexes related to the city level analysis "Level 1 City indicators" serve to **evaluate the sustainability standards**, identify city's strengths and weaknesses, and help setting general and specific objectives for the city.

Although many cities are implementing various low-carbon practices, it is still unclear how this sustainability or low carbon level can be certified. In this context, the methodology developed defines its own set of indicators considering the many efforts that have been previously made at developing indicators-based frameworks capable of evaluating cities' sustainability. The final selection of indicators that at this point includes 17 mobility related indicators, 14 building related indicators and 14 energy related indicators, was carried out following a rigorous internal and external validation process. The internal validation involved CITyFiED project partners (technicians, experts, etc.) and participants involved in the demo sites. The external validation on the other hand, involved the cities of the City Cluster and the Community of Interest, and took part during the Workshop about the CITyFiED Methodology performed in Laguna de Duero (Spain) in March 2017, with approximately 60 attendees.

Besides, each of the defined Level 1 City indicator has its specific reference value defined, considering the average values for the European cities. This allows understanding the distance between the initial situation of the city and the reference value in a way that cities can identify easily the area in which are performing worse than it is supposed to. The complementation of this indicator based analysis with different techniques such as the **SWOT analysis and Workshops** that include the main stakeholders involved in the planning process will facilitate both the definition of the **long-term city vision** and their **general objectives**.

Phase II: Diagnosis of the city at district level

In this second phase of the methodology the city is understood as an aggregation of districts. Taking into account the results in Phase I and following a bottom-up approach, the city is analyzed at district level to define the specific objectives for the districts object of the intervention. These specific objectives will serve to outline the different

set of measures that can be implemented in Phase III.

In a first step, a decision needs to be made by the Municipality regarding the district that will be selected for the transformation. This selection will be made taking into account the main characteristics of the district evaluated in terms of the potential to contribute to the transformation of the city, as well as the urgency of the specific needs of each district. The second step on the other hand, corresponds to the **diagnosis of the district** that will be evaluated for the city. The diagnosis will cover the following aspects; socio-economic analysis (age distribution of the inhabitants, the average household disposable income, the unemployment rate, etc.), morphological aspects (spatial distribution of the buildings, age and use of buildings, etc.), social analysis including aspects such as building owners and public participation, or environmental factors such as the potential for integrating renewable energy sources. Special attention should be paid in the analysis to aspects such as public participation activities developed by the Municipality with regard to the measures that are susceptible to be implemented, since these aspects are critical to identify non-technological barriers and to avoid difficulties during their implementation.

Level 1 indicators are also calculated at district level, when appropriate. This will contribute to the definition of the **baseline of the district** and will establish a direct link between the changes in the district and the impacts in the entire city, both will be evaluated in Phase VII. The values of these indexes will allow understanding better the context information at district scale with the quantitative values of indicators that are in line with the analysis carried out at city scale in the Phase I of the methodology. Besides, having the specific values of these indicators at district scale will aid to define **specific objectives** and measures and to stablish the prioritization criteria.

Taking into account all the information gathered at district scale, the energy demand and consumption of the base case scenario needs to be modelled for the district to allow the comparison with the forecast scenarios in the next phases. In this regard, energy planners usually need to combine various tools with different scales, and approaches, which makes difficult to develop a baseline analysis. Over the last 20 to 30 years, many different tools for building energy modelling have been developed. Several reviews, such as (Swan & Ugursal, 2009) and (Bourdic & Salat, 2012), describe different modelling approaches that can be used for evaluating the energy consumption of buildings at the district level. In the case of the tools that are designed for building energy modelling, the availability varies depending on the scale of the project. As mentioned by (Martos, Pacheco-Torres, Ordóñez, & Jadraque-Gago, 2016), the development of tools for evaluating and predicting the future energy consumption of cities and districts will be one of the biggest challenges in the field. However, the situation is much better in terms of the availability and reliability of tools for analysis of single buildings or a reduced building group. There are several tools, such as EnergyPlus and TRNSYS, that are broadly accepted and that allow for a very detailed and dynamic building energy simulation. Other modelling approaches such as BIM models, as well as the life cycle approach, are also identified as useful for this baseline definition stage. All these type of models and approaches need to be combined at this phase to achieve an appropriate analysis of the district.

This baseline analysis combined with the context information and the district scale Level 1 indicators will be used for the definition of the specific objectives of the district. These objectives are the conclusion from Phases I and II. They consist on targets related to improve the environmental, economic and social profile of the district and the city, and can be related to specific measures that are susceptible to be implemented in the district in order to contribute to the compliance of the targets of the city.

Phase III: Definition and analysis of the intervention and scenarios

The main target of this phase is to define the possible retrofitting scenarios to be considered for being implemented in the selected district according to the city (general objectives) and district needs (specific objectives). These scenarios consist of groups of measures that aid to forecast the impact on the sustainability performance. Before defining the scenarios, it is necessary to decide which measures should be discarded and for that purpose, the potential of each measure with respect to the objectives achievement is analyzed individually.

The ECG is the responsible of these activities. As a multidisciplinary group, it assists the Municipality to facilitate the analysis and the decision-making process. The ECG performs this supported on different recommendations, simulation tools and Indicators. In addition, the Technical and Steering committees from the Municipality can follow and control the process with them.

The measures to be considered are named as **Energy Conservation Measures** (ECMs). They are defined as "*measures that are applied to a building or group of buildings to improve energy efficiency and are life cycle cost*

effective and also they involve energy conservation, cogeneration facilities, renewable energy sources, improvements in operations and maintenance, or retrofit activities" (CITyFiED, D4.18). The catalogue of ECMs proposed in the methodology collects the CITyFiED "Basket of technologies" (CITyFiED, D1.7); a reduced list with the most efficient measures identified within CITyFiED Project approach. They are grouped into different categories: the first two focus on decreasing the energy consumption and the third one promotes the use of renewable energy sources, saving CO_2 and Primary Energy.

The steps to achieve by the ECG during Phase III are mainly two. The first one is the **measures preselection**, which consists of a preliminary choice of measures applying a filter, the specific objectives set in Phases I and II. The methodology establishes the relationships between ECMs and objectives, so it is possible to discard some of them at this early stage. In addition, the results of the Level 1 indicators, the feedback from the citizens (public participation activities) and Municipality, and other aspects identified during the analysis at both scales i.e., non-technological barriers, financial opportunities, etc., should be considered for this preliminary step.

The second step consist of a **feasibility analysis** of the preselected measures and the **final selection** of those that will be part of the retrofitting scenarios. For this analysis, it is necessary to evaluate the environmental, economic, technical and social aspects. In order to guide this study qualitatively, estimations from research on energy and CO_2 emissions levels of savings, payback periods, social issues, etc. are included in the catalogue of measures, as well as general recommendations for district retrofitting that affect the measures selection based on CITyFiED experiences (CITyFiED, D2.1 and D6.4) or other sources (STBA).

On the other hand, "Level 2 indicators" defined in the CITyFiED project could be calculated to assess Environmental, Technical, Economic and Social aspects along the application areas, and compare the results obtained for each ECM. The ECG could consider calculating at this stage only the most relevant indicators with respect to the objectives. Finally, previous recommendations and L2 indicators make possible to select a list of the most cost-effective measures ECMs to reach the sustainable objectives that the city desires.

Scenarios are tools to predict the results that could be obtained in case of their implementation. There is a high number of possible ECMs combinations, so it is necessary to generate the scenarios with the information already obtained, considering also experts' intuition and experience. The procedure proposed starts defining those measures considered as indispensable to proceed with the intervention as the starting point. Then, the rest of scenarios are defined increasing the performance from that set point. They are sorted in three groups depending on the €/Kg CO_2 savings ratio estimation – basic, efficient and advanced.

When each scenario is specified, it is necessary to recapitulate the information to analyze the retrofitting scenarios as units in next Phase IV, due to the result of the combination of some ECMs could be different from the addition of the individual results.

Phase IV: Prioritization and selection of the intervention scenario

The objective of this phase is to identify the most convenient solution from the potential scenarios. The ECG expertise, Level 2 indicators applied to the alternative scenarios and multi-criteria analysis, are the basis for the decision-making process. Finally, the discussion is expected to be carried out between technicians, citizens and local authorities.

The first step is focused on the **evaluation of alternative scenarios**. Here, the results of the different scenarios defined in the Phase III are evaluated considering the economic, social, technical and environmental dimensions. With this aim the defined Level 2 indicators at project level are evaluated for each scenario following different approaches, such as energy simulation tools for district renovation, building information modelling (BIM), geographic information systems (GIS) tools and the Life Cycle Analysis (LCA).

The results obtained from this analysis are used in the **scenario prioritization** step. It is necessary to take into account that the prioritization of strategies and scenarios needs to be based on the evaluation of a number of criteria that cannot be optimized simultaneously. Therefore, in the context of urban energy planning it can be said that there is no a unique optimum scenario within the set of alternative options for achieving a specific goal for the city.

Different methodologies are needed to support the decision-making once the evaluation studies have been carried out. With this aim, Multi-criteria Decision Analysis (MCDA) offers a wide range of methodologies and tools to

support decision-makers, allowing the combination of their own preferences with the data available (from modelling or not) to reach their own conclusions in a structured and consistent way. In the last few decades, the number of MCDA methods has substantially increased and nowadays, there are hundreds of methods available (Hobbs & Horn, 1997). Many studies and different classifications of these methods can be found in the literature. In the review carried out by (Pohekar & Ramachandran, 2004), an assessment of more than 60 studies regarding the application of multi-criteria decision making to sustainable energy planning is presented. In the same way, the study by Diaz-Balteiro *et al.* (Diaz-Balteiro, González-Pachón, & Romero, 2016) offers an extensive review of 271 papers using MCDA methods for measuring systems sustainability. The study shows that the use of methodologies such as the AHP developed by Saaty (Saaty, 1980) is in general, increasing in recent years. From the literature review, it can be concluded that using multi-criteria analysis in the context of urban renovation has attracted the attention of decision makers for a long time and that although there is not a specific method that can be prioritized, some of them seem to be more appropriate if we consider the development of the last few years. For CITyFiED methodology, the method proposed for the prioritization, in order to combine both the quantitative results of the scenarios and the qualitative relevance of each criterion, is the AHP.

In the first step of the application of the AHP method, a **disaggregation of the problem** has to be done defining a hierarchy of the interrelated elements, identifying the general objective, the specific objectives or criteria and the potential alternatives or scenarios.

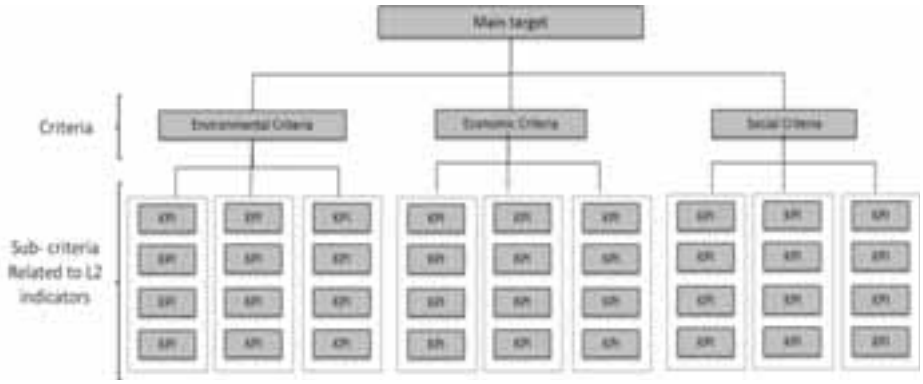

Fig. 5: Hierarchical problem structuring example

The specific objectives defined at district scale in the Phase II can be used as the basis to define the main criteria for the prioritization. In the same way, the sub-criteria that contribute to the consecution of the specific criteria can be related to the Level 2 indicators evaluated for each scenario. Therefore, for the identification and selection of the prioritization criteria, a clear connection can be made at this stage with the Level 2 indicators. This decision will be taken by an open dialog and consensus between technicians and local authorities. Including public participation at this stage of the process and taking it into account in the decision making is really relevant for engaging citizens in climate challenge.

In a second step, the **weighting of each criterion** needs to be also defined following the same procedure. Finally, through the complete application of the AHP method, the evaluation of the performance of each scenario for each prioritization criteria is carried out. The scenario with the highest result is identified as the most suitable one.

Phase V: Strategies for Sustainable Urban Renovation (SSUR)

The main target of this phase is to define the set of Strategies for Sustainable Urban Renovation (SSUR) where the ECMs of the selected scenario are further developed. In addition, these strategies should be integrated within the Strategic Urban Plan of the city, as a long-term vision plan for the city.

Local authorities, especially the Technical committee - and the ECG if it is desired by the Municipality – are in charge on the development of the SSUR, which is understood as a highly participatory management tool, that is to say this document is a process, not a project. It contents all the development of the previous phases.

First of all, the documents presents the causes for developing a Strategy for Sustainable Urban Renovation, the past of the city is explained as well as current situation. This means to give the answers to the questions *where do we come from?* And *where are we?* The vision of the city from Phase I is defined, by explaining the local authorities' motivations for implement sustainable strategies; *Where do we want to go?*

Secondly, the document exposures the work done by the ECG together with the Technical committee regarding the city analysis and diagnosis, the scope definition, to be specific, the district selected. Moreover, it is also presented the scenarios evaluation and the final selection.

Finally, it presents the Strategy which compromises *"a co-ordinated set of participatory and continuously improving processes of analysis, debate, capacity-strengthening, planning and investment, which integrates the economic, social and environmental objectives of society, seeking trade-offs where this is not possible"* (OECD 2001).

The Strategy does not end with the exposure of the selected scenario in Phase IV, but also it will guide and coordinates the process during its implementation through a **Strategy Implementation Plan (SIP)**, which will detail the intervention actions to be applied in the district, the schedule which includes a temporary planning for each actuation line during the period of SIP´s life, and finally the budget of the implementation plan.

On the other hand, one of the most important aspects during the definition of the strategies is the need to guarantee its success through not only ensuring an **effective participation of the citizens** (CoM, 2010), but also the identification of the **non-technological barriers** and the **potential business models** that will enable the realization of specific strategies.

Non-technological aspects, such as financial, organizational, legal, cultural and social, have be explored during the process (from phases I to IV). For that, a participatory methodology was designed in CITyFiED project to involve key stakeholders, this procedure is based on interviews that should be adapted according to the specific of the cities to identify the barriers and potential for energy efficient retrofitting.

CITyFiED Methodology will proposed also a mechanism to analyse possible business models and investment schemes for the cities to identify the most convenient, in order to minimize gaps and risks of the suggested strategies.

Last but not least, the document Strategies for Sustainable Urban City Renovation should detail recommendations to ensure that the skip from Planning to Implementation phases will be done properly. In that sense, the Strategy should define the **Method of Procurement (MOP),** detailing the factors that influence it, such us project characteristics, cost issues, timing, external factors, client resources, etc.

In addition, recommendations for the Monitoring and Impact Assessment Evaluation Phase (Phase VII) are also given, regarding the need to develop a **Sustainable Evaluation Plan (SEP)**, which coordinates the activities and guarantee the city goals achievement. The SEP, understood as a protocol to evaluate the sustainability and quality of the interventions at district level after their implementation (Phase VI). It should be based on the evaluation of the energy performance and energy savings through well-known Measurement & Verification (M&V) protocols (e.g. IPMVP, FEMP or ASHRAE), the economic issues, such as return of investment (ROI) and cost effectiveness of the solutions, the Quality control of the interventions, the Social acceptance and a Life Cycle Analysis (LCA), to evaluate the CO_2 emission reduction.

Phase VI: Execution plan

The strategies from the SSUR document are implemented in this phase, according to the recommendations from planning to implementation and the SEP guidelines pre-defined in Phase V. The detail definition of these activities depend in other aspects, i.e., technical definition, that could not be defined before the SSUR. Therefore, these issues and specific guidelines to put into practice the strategies – delivery method, procurement process, risk allocation, etc. - are further developed in Phase VI, acting as an overall Execution Plan.

The Municipality, the ECG and financial institutions are involved in these activities, as well as building owners and citizens. Contracting parties group are the principal figure for the execution of works, including designers, ESCOs, energy suppliers, technology providers, etc. Their participation starts at this stage because in public procurements they usually have to be selected through a tender/bidding process.

Part of the execution procedure is to clarify the **financial resources** to put into practice the SSUR according to the Business model identified and the ownership of the properties to be renovated. In the case of public ownership of the buildings the Municipality usually acts as financier; while in private ownership the ESCO business model is highly recommended. The most relevant public financing mechanisms are grants, interest subsidies, revolving funds and financial instruments (Núñez *et al.*, 2013).

A **Project Delivery Method** has to be identified by the Municipality to define the contracting formats between the stakeholders to achieve the delivery (CMAA, 2012). There are different methods but the most recommended is the Integrated Project Delivery (IPD), defined as "*a collaborative alliance (...) that harnesses the talents and insights of all participants to optimize project results, increase value to the owner, reduce waste, and maximize efficiency (...)*" (AIA, 2007) . Its principles focus on the collaboration since the beginning of the project to avoid future problems and the share of risks and responsibilities between the stakeholders.

The Procurement starts after, to define the process of services or works acquisition for the implementation of the strategies. In public procurement is usually mandatory to select the entities through a tender/bidding process. Attending to the scope the Municipality could contract just the implementation (Build), if it wills to develop the technical definition of the strategies. By contrary, it could offer the design and the execution to different entities (Design / Build) or the same one (Design + Build). The winners of the tender will be part of the Contracting parties group. The tender documents can be prescriptive if the requirements are technically specified or performance based, and in the second case also related to reduce the environmental impact what is known as sustainable procurement (Pless *et al*., 2012).

In parallel to the two previous activities, the district and strategies need to be further developed into detail from the technical and economical perspectives. It is recommended to support the technical definition on BIM approach that allows to address responsibilities, layouts, schedule, risks, etc. in a collaborative framework, and it is identified as the most adequate to maximize the benefits of IPD principles (AIA, 2007). Depending on the procurement selected the technical definition of the strategies is performed before or after tender/bidding processes.

Another relevant aspect is to include a **Risk Management Plan** in the context of IPD, to eliminate or reduce the risk that could be avoided, establish mitigation actions to reduce the probability of occurrence, or develop contingency strategies for those risks that could be predicted or avoided (Association of Project Managers, 2000).

The follow-up strategy during the execution of works (Phase VI) and evaluation phase (Phase VII) is the SEP already pre-defined in SSUR document and that is completed by the Monitoring and Technical Committees during this phase once the technical definition of the strategies is achieved. The follow-up of the intervention should be reported monthly or bimonthly, and gathered in annual reports in the SSUR. In parallel, regular meetings should be established between the actors involved to control and make decisions and changes approval.

Phase VII: Monitoring and impact assessment evaluation

The main objective of this last phase is to evaluate and monitor the strategies implemented during the previous phase, because at this stage, actions and construction works are completed, so it is necessary to **assess the impact in the sustainability at district and city level**, and finally to deploy **corrective actions** if the impact obtained it is not the expected. So that, the objective of the monitoring plan is twofold, evaluate the performance and impact of the strategies at district level (Level 2 indicators) and city level (Level 3 indicators).

Within CITyFiED project a Sustainable Evaluation Plan (SEP) has been defined (CITyFiED, D4.10) in order to assess the impact in the sustainability at district/project level. The objective of the plan developed was to reduce the complexity of some existing standards such as BREEAM and/or LEED and integrate new pillars in the evaluation according to the new trends, i.e. ICTs and LCA. Thus, Fig. 6 illustrates the protocol proposed, including its pillars: Energy, ICTs, Quality control of interventions, Economic evaluation, Social acceptance and LCA.

As it can be seen in Fig. 6, the left hand side represents the analysis before the implementation (Baseline calculated during Phase II), meanwhile the right hand side denotes the assessment after intervention; at the top, Level 2 indicators (KPIs) give an objective the framework for calculating the evidences of assessment, and at the bottom, LCA covers the project from the beginning to the end of the works. In the middle, the ECMs appear, which refer to the interventions themselves.

Starting from the left hand side, it is shown that the energy concerns begin with social awareness, both at citizens' level and at organizational level (public authorities, sustainability plans, etc.). Collecting all these aspects through metering determines the retrofitting strategy as well as the best ECM for the specific building or district.

On the right hand side, the status after the execution phase is evaluated. The main aspect is the energy performance in terms of energy savings, which is partially achieved by the investment in new ICT technologies (digital homes),

and the ECMs. To ensure the expected energy savings, the ECM has to be implemented in the correct way following Quality Control of interventions rules during Phase VI. These energy savings drive to cost savings at consumption. And thanks to the energy efficiency, less invoice costs and new technologies, together with the involvement of citizens, the social acceptance of these solutions is increased.

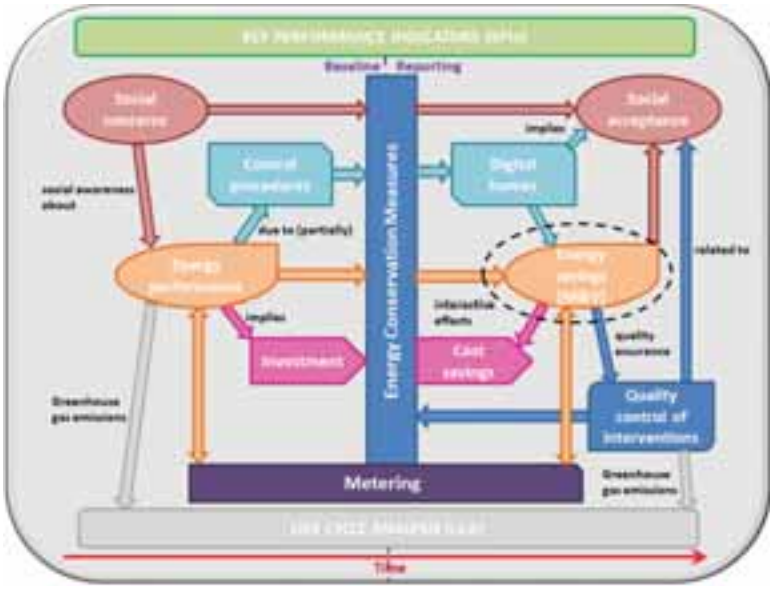

Fig. 6: CITyFiED Sustainability Evaluation Plan (SEP) at district level

The CITyFiED Methodology, as a systematic process, considers that if the results obtained after the deployment of the SEP not achieve the expected results at district level, corrective actions should be applied, starting from the analysis of SSUR if necessary. The deviation between the expected results and the obtained ones, is part of the evaluation and means that the General and Specific objectives defined during Phase I and II are only partially achieved. This experience is part of the correction actions for future city renovations that all the stakeholders from the Municipality should consider, too.

In the same way, the impact of the interventions at city level will be evaluated. For that purpose, there was defined a set of indicators (Level 3: Impact Assessment Indicators at city level) in order to evaluate the following categories of impacts after the strategy implementation: *Energy impact:* Energy savings obtained; *Environment impact:* CO_2 emissions avoided with the intervention; *Economic impact:* investment mobilized and its return to the users, companies and municipalities as well as benefits of retrofitting to the users associated to the cost savings; and *Benefits for SMEs.*

4. Conclusions

This Methodology is a holistic procedure for the city renovation at district level that considers a multi-criteria perspective. The integration of the three levels of indicators supports the diagnosis, selection as well as final evaluation of measures and retrofitting scenarios during the project, serving as a control and decision-making tool. The CITyFiED project aims to enable the replicability and mass-market deployment of energy-efficient retrofit of districts. The approach and the indicators were conceived and are being refined considering as a reference the large CITyFiED demonstration cases in the cities of Lund (Sweden), Laguna de Duero (Spain) and Soma (Turkey), including decision-making processes and business models. The approach is also being validated through the active participation of the CITyFiED network of cities, assuring its flexibility and adaptability to different European cities. Then, the future work is to complete its development, continue its external validation activities with the CITyFiED network of cities and extract conclusions.

Acknowledgments: This project has received funding from the European Union's Seventh Programme for research, technological development and demonstration under grant agreement N° 609129. The authors would like to thank the rest of the partners of the CITyFiED project for their help and support.

Abstract

An increased use of solar energy is a key ingredient for forging resilient cities. This recognises the importance of the urban fabric being able to use renewable energy sources to become increasingly self-sustainable. In that regard, the integration of active solar energy systems in the built environment will allow cities to reach a high level of sustainability. In this framework, the main objective of the IEA SHC Task 51 Solar Energy in Urban Planning, was to provide support to urban planners, authorities and architects to develop urban areas with architecturally integrated solar energy solutions. The scope includes solar energy issues related to new and existing urban development areas and sensitive solar landscapes. This paper presents an overview of the Task's results from 11 countries including reviews on legal framework, barriers and opportunities, on planning processes and on educational issues. Approaches, methods and tools are presented as well as a collection of case stories with lessons learnt and a web-based learning platform.

Keywords: solar energy, urban planning, solar landscapes, methods, tools, education, case stories, IEA

1. Introduction

A large portion of the potential for energy efficiency in existing buildings and potential to utilize solar energy still remains unused. Globally, goals and specific targets are set up to reduce our environmental impact on climate and secure future supply of energy. The built environment accounts for over 40% of the world's total primary energy use and 24% of greenhouse gas emissions (Hegger et al, 2008). A combination of making buildings more energy-efficient and using a larger fraction of renewable energy is therefore a key issue. Political statements and directives are already moving towards zero-energy buildings and communities (Sartori et al, 2010; Voss and Musall, 2011). An increased use of solar energy, enabling renewable energy supply, is firmly acknowledged as a key ingredient for forging resilience and future proofing of our cities on the one hand. On the other hand, it is an important part of the development ahead, where the urban fabric strives to utilize passive solar gains and daylight to reduce the energy use in buildings and for lighting outdoor environments, as well as to improve the inhabitants' comfort (Compagnon, 2004).

The main objective of the IEA Solar Heating & Cooling Programme, Task 51 Solar Energy in Urban Planning, is to provide support to urban planners, authorities and architects to achieve urban areas, and eventually whole cities, with architecturally integrated solar energy solutions (active and passive). The objective contributes to urban planning by providing guidance for urban planners and policy makers on a large fraction of renewable energy supply. This includes approaches, methods and tools capable of assisting cities in developing a long term urban solar energy strategy. Heritage and aesthetic issues are carefully considered. Also, the goal is to prepare for and strengthen education at universities on solar energy in urban planning, by testing and developing teaching material for programmes in architecture, architectural engineering and urban planning. The material will serve a dual

doi:10.18086/swc.2017.37.06 Available at http://proceedings.ises.org

purpose by being inclusive for postgraduate courses and continuing professional development (CPD).

The scope of the Task includes solar energy issues related to 1) new urban area development, 2) existing urban area development and 3) sensitive and protected landscapes (solar fields). Both solar thermal and photovoltaics are taken into account. In addition, passive solar - as passive solar heating, daylight access and outdoor thermal comfort - is considered in the urban environment. Solar energy integration in existing and in new city districts are two different contexts with different opportunities and constraints. Furthermore, ground based active solar applications are interfacing with urban environments, creating solar landscapes that juxtaposition with the existing urban form with varying levels of aesthetic acceptance. In open landscapes, solar fields need to harmonize with the rural landscape and nature. Understanding the existing parameters under which planners operate and the challenges this presents is a key consideration of this Task.

2. Objectives, materials and methods

The Task's work started in 2013 and ends in 2017: it involved a consolidated scientific collaboration between researchers and practitioners from Australia, Austria, Canada, China, Denmark, France, Germany, Italy, Luxembourg (observer), Norway, Sweden and Switzerland. The Task was structured in four Subtasks:

Subtask A: Legal framework, barriers and opportunities. Lead: Australia.

Subtask B: Processes, methods and tools. Lead: Sweden.

Subtask C: Case studies and action research. Lead: Norway.

Subtask D: Education and dissemination. Lead: Germany.

Subtask A sets the current boundary conditions for solar integration, deals with the assessment of available potential and elucidates opportunities. Subtask B deals with processes, methods and tools and developments for the applied phase related to specific situations (new development areas, existing urban areas, landscapes). Subtask C focuses on implementation issues e.g. tests of processes, methods and tools, through case stories and showing relevant examples as case studies. Finally, Subtask D covers the dissemination focused on tertiary education and continuing professional development (CPD). The whole Task was led by Sweden.

Although Task 51 is organized in different subtasks, most of the work has been collaborative across subtasks. A central part of the work was carried out as action research. Action research is a reflective process of progressive problem solving led by individuals working with others in teams or as part of a "community of practice" to improve the way they address issues and solve problems (Stringer, 2014). Action research involves the process of actively participating in an organization change situation whilst conducting research. In Task 51, this was reflected in the participants' collaboration with urban planners and other key actors within local urban planning developments in each participating country. In this way information about important issues to address was identified. The goal has then been to develop knowledge that is useful for practicing urban planners and for education of architects and planners.

For Subtask A, a historical reflection was completed in parallel with sourcing country information regarding the legislative frameworks and voluntary initiatives that impact on the uptake of solar energy in urban areas. This included a review of legal cases that define the treatment and judgement of decisions where solar energy implementation was claimed to have created conflict or where urban development threatened solar access of existing systems. Whilst the treatment of passive solar protection is well defined, the research looked to review how active solar technologies are applied to urban environments and the planning controls that might promote or constrain their use. It also investigated the cultural and aesthetic sensitivities and parameters directly affecting technological choice and the acceptable application of urban solar systems.

The main topic in Subtask B was the planning process descriptions. Through collecting and sharing knowledge among experts in Task 51, the local planning prerequisites, including legislation and praxis, have been analysed in order to find commonalities to describe a generic planning process valid across countries in Subtask B. This work was carried out first on a national level by the experts collecting and describing the formal and informal planning processes through the steps of 1) short interviews during the Task definition phase, 2) analyzing legislation and 3) expert participation in urban planning projects in the form of action research. The aim was to explore when and how knowledge on solar energy (passive and active strategies) could enter planning processes.

The work on collecting local legislation and praxis has been reported in a common report between Subtask A on Legislation and Subtask B on Processes, Methods and Tools. In Task meetings, workshops were held where the experts analyzed national planning process similarities between different countries. The experts then agreed upon a common generic planning process described at different spatial scales, showing what actually is taking place in urban planning in all these cases. The scales found in all countries were 1) comprehensive/strategical planning scale 1:2000-1:100 000, 2) urban and landscape design scale 1:1000-1:5000, 3) detailed development plans 1:500-1:2000 and 4) architectural design stage 1:10-1:500.

Another objective in Subtask B was to identify supportive instruments that can assist planners during the planning process. These supportive instruments were defined as *Approaches*, i.e. means of incorporating solar methods and tools, *Methods*, i.e. planned procedures to assess and evaluate solar in relation to other aspects in urban planning (including landscape planning) and *Tools,* i.e. a rule of thumb, a calculation or a modelling software giving geometrical or numerical results; e.g. solar maps, solar potential software, GIS software, etc. This definition also implies a hierarchy where approaches include methods that incorporate tools in a planned procedure. The identification of existing as well as the development of new approaches, methods and tools was carried out during the action research work within national planning contexts and is presented in a report on *Approaches, methods and tools for enhancing solar energy* targeting urban planners. The approaches, methods and tools within the scope are instruments to support decision-making and to combine qualitative and quantitative aspects of relevance for spatial concerns in urban planning.

Bringing the generic planning process and the existing and new approaches, methods and tools on active and passive (daylight, solar gains and micro climate) solar measures together creates the base for the guidelines, developed as a homepage. The aims are to inform and support decision-making, orienting on existing and new approaches, methods and tools to inspire planners to find new ways of developing the planning process to enhance solar energy in the urban and landscape context.

The main objective of Subtask C was to stimulate successful practice and facilitate its replicability, by documenting experiences, helping cities avoid pitfalls already encountered by others, and creating arenas for mutual interaction between researchers and city managers. In that regard, the work was focused on case stories of new, existing urban areas and landscape planning related to active solar systems (both photovoltaics and solar thermal) and interrelated technical (i.e. solar potential, cost investment, product technology, energy production, daylight, quality of visibility etc.) and non-technical aspects (i.e. planning process, right of light, policy and legislation, etc.). More than 30 case stories from 11 countries have been analysed and compared in extensive reports (Lobaccaro et al., 2017). Lessons learnt for different targets groups have been condensed into guidelines for solar energy in urban planning (Fig. 1). Finally, a webpage of case studies linked to a world-map has been established. This serves as a user-friendly consultation and dissemination instrument: it is a sort of case stories' platform from which the users can download dedicated brochures where detailed information related to both single case stories and/or the case study comparisons have been collected.

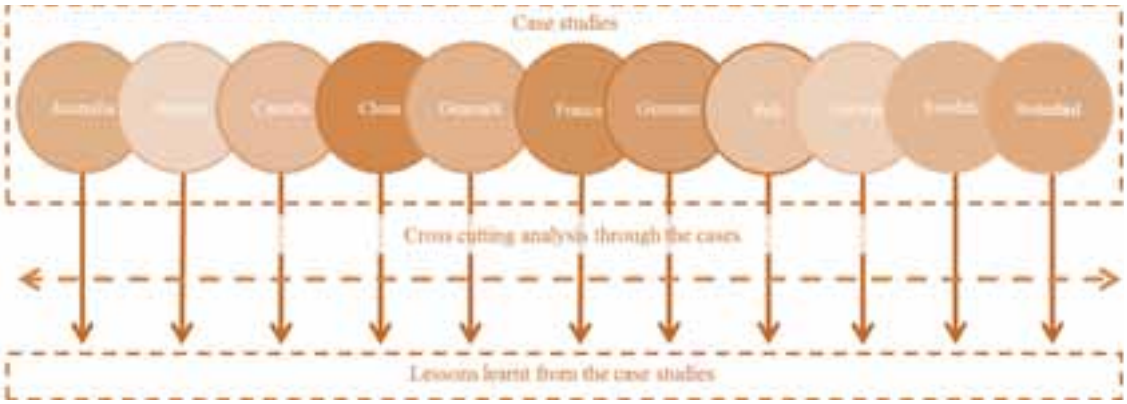

Fig. 1: A scheme of the methodology used for the case studies analysis

The work on education and dissemination in Subtask D started with a review of the present situation (Fig. 2). As a first step, existing courses and software tools in nine countries were surveyed and evaluated. The applied methodologies were based on a developed questionnaire handed out to a broad range of international institutes of

urban planning and direct interviews with researchers and academics were undertaken.

An overview of existing software tools within solar energy was generated. These tools where tested and evaluated by students through an urban design task. Various criteria were applied such as usability, integration into other popular 3D modelling software and readability of results. Based on the results, it became evident that there was a lack of existing courses on solar energy in the urban context for students. This formed the basis for the development of an e-learning platform including a software package. This platform was then tested and evaluated during a series of symposia with experts and practitioners.

3. Results

The Task is now in its final stage with some results already published. All results will be available as soon as they go through the review process within the IEA SHC programme. Main results are presented and discussed below.

3.1 Legislation and voluntary initiatives

The current status of solar energy in urban planning regarding legislation and voluntary initiatives were documented from 11 countries. As a starting point, recognition was given that many ancient civilizations have purposefully harnessed the sun's energy to add comfort to living spaces (Butti and Perlin, 1980) and incorporated into the rule of law safeguards to protect its practical inclusion as evidenced by ancient lights proclamations and Greek philosopher Hippocrates's air light treatise enshrining the sensible use of sunlight along with clear air and water. These well-founded learnings have witnessed significant upheaval through the technological innovation of electricity and urban densification pressures and consequently changing planning values and priorities. Urban plans and building widths, building heights, story heights, façade design and window heights did, until the early 20th century, comply with the physics of daylight distribution and natural ventilation (Lechner, 2008). This meant a certain limitation in widths and heights already on an urban level. When electricity and mechanical ventilation started to support the indoor climate as a standard, these limitations were broken and significant knowledge was lost during the second half of the 20th century.

The increased population growth in combination with the environmental gains of walkable and public transport cities, as well as higher real estate prices in the city centre work towards increased density. Increased density will at certain points at different latitudes be counterproductive for energy use, since both electricity demand will rise due to low winter daylight levels and summer cooling loads increase when natural cooling is diminished. The contrasting relationships between building energy use and transport energy use after certain levels of density and urban form have been eloquently presented by Steemers (2003). Research has shown that the relation between

density and lower daylight is not linear, but relates to urban and building design. This pinpoints the important role of urban planning in harnessing daylight as a natural source instead of using electricity and also utilising building integrated solar structures for onsite energy generation and thermal shading that does not prohibit natural light entering buildings.

As the deployment of active solar energy systems has grown in cities, the challenge of protecting sufficient solar access into the future becomes more prominent as urban consolidation and densification intensifies (Snow and Prasad, 2011). Within this context is also the critical pursuit of energy-efficient buildings as well as achieving comfortable urban environments (Samimi and Nasrollahi, 2014). Whilst the provision of solar access rights has historically focused on daylight (Lechner, 2014), there is an emerging need to revisit the legal framework and the extent to which it enhances or hinders deployment of sustainable energy technologies. Despite the need to establish a satisfactory legal regime for solar access protection was recognised many ago, the analysis from national perspectives is that the law on this issue is still unsatisfactory. There is considerable scope for legal reform in many countries and the typical subjective judgement of considering solar access under the characterisation of 'nuisance' creates significant investment uncertainty and barriers to uptake that could be remedied by more informed decision-making processes.

3.2 Solar energy in urban planning processes

Urban planning is a political process that exists to balance society's common interests against individual interest mainly when it comes to land use. The political process as well as the planning process differs between national, regional and local contexts (Newman and Thornley, 1996). The smallest common denominator is that all urban planning deals with land use regulation in some way.

The focus of urban planning and the power of land allocation differs somewhat between countries. This implies that the possibility to affect urban planning to implement solar energy to a higher extent differs as well. In some countries, the largest potential may be to influence local planners on the municipal level who have a large influence on the built environment while in other countries the potential may lie with influencing decision makers on a regional or national scale who can more directly influence policy and legal instruments on a wider scale.

A comparison between studied local processes has been carried out by experts which has shown that a generic planning process can be described using a spatial scale. Other aspects that relate to administrative and legal frameworks in planning, i.e. laws and regulations, policies, ambitions, voluntary initiatives etc. are too dependent on local contexts to generalize.

The generic planning process developed in Task 51 involves four stages; 1) comprehensive/strategical planning, 2) urban and landscape design, 3) detailed development plans and 4) architectural design (Fig. 3). Also, approaches, methods and tools (AMTs) have been collected, summarised and related to which specific stage of the urban planning process they are relevant. The AMTs can be divided into four types; 1) regulatory, policy and governance approaches, 2) integrated design and planning support, 3) assessment methods and tools and 4) awareness and consultation methods. Each type is exemplified with existing or newly developed AMTs and relate to the four stages of the urban planning process.

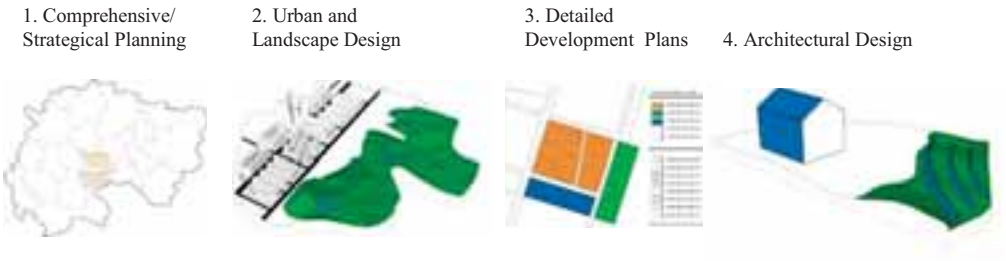

Fig. 3: Illustration of four stages of urban planning

Guidelines for comprehensive/strategical planning

Within comprehensive/strategical planning, visions and strategies to reach certain goals are developed and connected to land use and zoning. Plans can be regional and/or at municipal/city scale. Examples of key

considerations and decisions taken at this stage are; visions for cities/municipalities, general land use, larger infrastructure etc.

Comprehensive and strategic planning are often visionary plans stretching 20-30 years, which gives a general direction for a city, municipality or region. They are used to identify potential development areas and the need for larger infrastructure but should also include a clear idea of how to provide the city, municipality and/or region with clean energy. Solar maps are one of the most common and efficient methods of integrating solar energy at this scale, which acts as an inventory of the solar potential in existing urban structures (Kanters et al., 2014). Solar maps can also be used to overlay solar potential with other aspects such as heritage concerns, energy infrastructure, future renewable energy goals and the impact of new urban developments on existing urban fabric. As active solar and daylight will become more and more present in urban planning, there is a need for targets, goals and assessments in early comprehensive and strategic planning stages.

Guidelines for urban and landscape design

In the urban and landscape design stages, the urban fabric and morphology is decided for a city district and for a landscape area. Examples of key considerations and decisions taken in this stage are street widths, volumes, typologies, spatial patterns and orientation.

New urban environments

Planning of new urban environments in the 21st century requires focus on the need for energy efficient design and an energy generating built environment. Urban planning is complex, and there is a need to bring in the relevant aspects at stake at the right stages of the planning process. This is in order to support spatial planning and energy, both relating to free energy such as daylight and to active solar, such as solar thermal and photovoltaics, for future urban development and renewal projects. In situations where new urban areas lack existing energy infrastructure, the possibilities for including solar energy are at their most favourable and the design scheme will be crucial.

The role of the urban planner is to design areas that can be built to last. For different reasons, solar energy installations may not be feasible when the area is designed, but buildings change over time while typologies and the urban fabric tend not to. An urban design that does not include solar energy considerations today may effectively hinder it in the future.

Major aspects that have a large impact on solar energy potential are density, street widths, building heights, roof angles i.e. the typology of an area (Kanters, 2015). Today the solar energy potential can easily be estimated through rough simulations from early drawings to more detailed models. A rule of thumb is that the more complex the model, the more complex the simulation.

In urban areas, solar energy also needs to be considered from a load matching perspective. Load matching implies that the solar energy generation is compared to the energy use of buildings and neighbourhoods (Voss and Musall, 2011). This is meaningful because solar energy in urban areas is most relevant when the generated energy is used locally rather than exported to the electrical grid or a district heating system. Criteria for load matching evaluation annually can easily be estimated through a comparison between local energy performance standards and a solar potential study although it is also important to consider seasonal and daily variations in energy use and potential energy generation. In e.g. northern latitude countries this is imperative as energy use peaks at night and in winter while solar energy generation peaks during the daytime and in summer.

Urban typologies also have a huge impact on daylight access both inside buildings but also on streets and public spaces. Studies and research show that different urban design proposals for the same density give very different daylight conditions and that the daylight design aspect on urban and building design scales are crucial for daytime, sunlit areas in dense areas (Baek Pedersen, 2009; Sattrup, 2012).

Existing Urban Areas

The existing building stock will have the biggest impact regarding climate emissions from operational energy use for the foreseeable future due to the high energy use compared to new buildings. Currently, most of the attention is devoted to the reduction of energy needs, but the transition towards a more comprehensive renovation including localized renewable energy generation is imperative. Prices for solar technologies are dropping and regulations are encouraging local energy generation. More than half of the global PV capacity from now to 2050 will be installed on buildings (IEA, 2014), producing a little less than half the total PV electricity needed. There is a risk that such a massive deployment will sometimes lead to prioritising only the return of investment for private owners

through a solar refurbishment, which is often riskier and less lucrative than early-design implementation for a new settlement.

This deep intervention on the urban morphology requires a rational method to properly organize the arrangement of installations according to site characteristics and a compromise between heritage protection, energy and spatial planning. A match between building energy needs, solar energy generation potential and site identity has to be aimed to tailor coherent strategies of solar refurbishment and define homogeneous zones with particular architectural integration quality requirements.

In order to deal with the local energy production, new methods and tools have been introduced into urban planning, such as assessment methods supporting urban planners and real estate owners in estimating the solar potentials of existing built surfaces. One major outcome of this Task is the LESO-QSV Method (Fig. 4), which is based on the above (Munari Probst and Roecker, 2015).

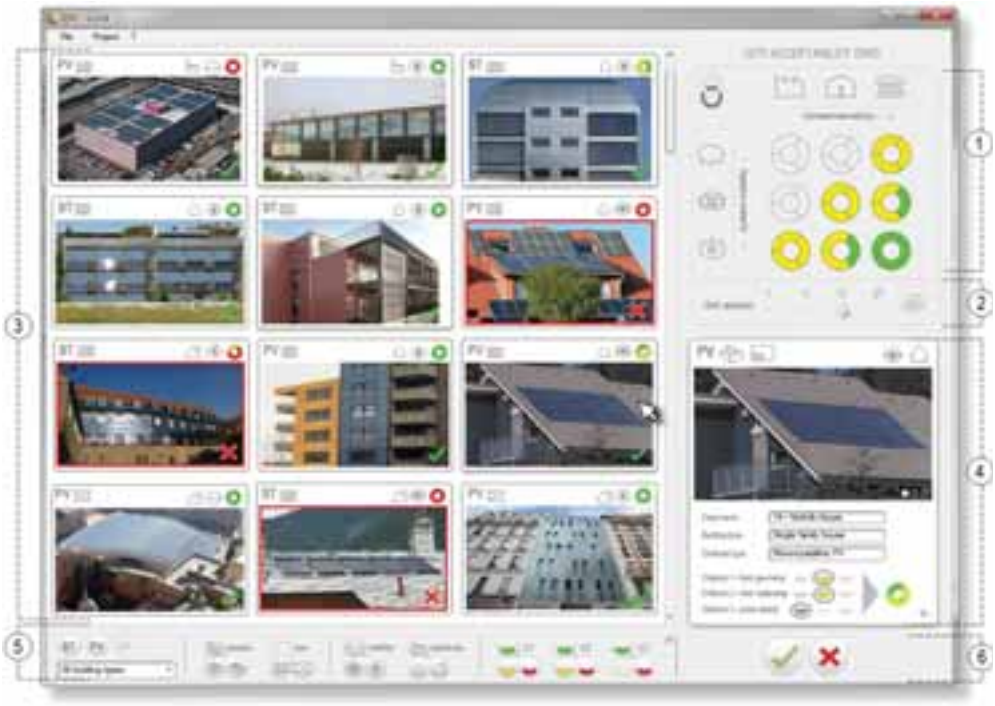

Fig. 4: Main screen of the LESO-QSV GRID program: 1 - Acceptability grid of the specific city: i.e. required integration quality for each criticity level (system visibility; context sensitivity). These are the criteria to be met for the installation to be accepted; 2 - Acceptability grid setting bar (for municipality use only): integration requirements can be selected by using pre-established grids (more or less severe), or built to measure; 3 - Integration examples showcase: a database of more than 100 cases is shown according to the selected filters setting (5). This showcase is meant to: help municipalities to set a convenient acceptability grid by showing the impact in acceptancy of pre-defined sets of quality requirements; work as a model for authorities for how to objectively evaluate integration quality; inspire architects, installers, building owners; 4 - Case details window: The window appears while clicking on a specific case. The detailed evaluation of quality becomes visible, together with other more precise information and additional pictures of the case; 5 - Filter bar: The case studies can be filtered according to solar system type, position, dimension, context sensitivity, system visibility, integration quality; 6 - Accepted / not accepted cases button filter. (Source: Maria Cristina Munari Probst and Christian Roecker)

Guidelines for detailed development plans

Detailed development plans set the implementation conditions for the urban design, and the land use is regulated into legally binding documents. Examples of key considerations and decisions taken in this stage are maximum building height, limitations on material choices and type of building (residential, office, school etc.).

Detailed development plans are legally binding documents that set the prerequisites for the building design in contrast to the more visionary process in the urban design stage. An important factor here is a meaningful dialogue between urban planners, the local authorities (both planning and building permit offices) and developers and real estate owners. Academic institutions and research institutes have proven to be front runners in driving and facilitating stakeholder dialogue and incorporating new solutions into urban planning. Since planning traditions vary and this is bound by local planning traditions and legal frameworks (Newman and Thornley, 1996), it is

difficult to give general advice.

Experiences have shown that specific requirements often attached to land procurement deals have in some cases proven an efficient approach to introducing solar energy in urban areas. Also, since the interest for solar energy is growing rapidly the concept of "solar rights" or "right to light" will probably need to be considered by many urban planners in the near future. Solar rights work differently in different contexts but involves cases where an existing building becomes shaded by a new building which can affect either daylight and sunlight access or energy output from a solar energy installation.

Guidelines for architectural design

At the architectural design stage, new and existing buildings or landscape integrated systems are designed, new or altered. Examples of key considerations and decisions taken in this stage are architectural composition and pattern/surface/facade design.

New buildings

The integration of solar energy in buildings has been studied extensively through the completed IEA SHC Task 41 – Solar Energy and Architecture. More information about this can be found here http://task41.iea-shc.org/. Also, a webpage on innovative solar products is available showing examples for building integration as continuation from the project IEA SHC Task 41 (Munari Probst et al, 2012; Wall et al, 2012).

Existing buildings

The reduction of building energy use and the replacement of fossil energy by renewables have become priorities for authorities and planners. As active solar is entering, architectural alteration, materiality, geometry and detailing in buildings can be affected, resulting in new forms of architectural expression which are slowly modifying our existing city landscapes. The increased use of active solar systems in buildings is necessary, but clearly poses major challenges for existing environments. The large size of solar systems at the building scale asks for thoughtful design, as these systems otherwise may end up compromising the aesthetics of the buildings, and may affect the identity and the quality of entire contexts. Luckily, good architectural integrations are possible also in the most critical situations, but they clearly need appropriate design and economic investments. A good knowledge of basic solar physics, of simple dimensioning tools for early design phases and currently available products designed for building integration can be very helpful for this purpose.

Before aesthetic standards can be established, objective criteria need to be developed. While it is often thought that aesthetics is a matter of taste, recent studies confirm the existence of clear criteria against which the suitability of solar power installations can be evaluated. Solar installations can be made qualitatively, evaluated through three simple and objective criteria: the project's geometry, materiality and modular pattern. These criteria provide a framework for assessing how harmoniously an installation fits into the surrounding urban environment. In several cities in Scandinavia, guidelines for stakeholders seeking building permits have been published with advice from IEA SHC Task 41 and in relation to the architectural guidelines regarding respect of existing qualities in the built environment. With additional support from the LESO-QSV method, several reference examples can be consulted. The method can also be used to create a "criticity" grid identifying different situations for which the municipal authorities will set quality standards in view of local considerations.

Approaches, methods and tools for solar energy

Urban planners are typically generalists who have to consider many different aspects. It is important that methods, tools and approaches are designed to aid urban planners in their work rather than increasing their workload. There exists a large amount of software tools today where solar insolation of an urban area can be calculated and visualised, but there is a lack of approaches and methods of how to integrate the results from such tools into traditional urban planning processes. The software tools available also vary in complexity, user friendliness and quality of end result. Extensive work has been carried out in developing approaches, methods and tools that aid in understanding solar potential in an urban planning context as well as defining which level of detail potential studies need to be at in different phases of urban planning. Generally, in early phases, such as comprehensive and strategical planning as well as urban design on a city district scale, the potential studies can be quite rough as many parameters can change later on while in latter phases such as building design, the potential studies need to be more detailed.

3.3 Lessons learnt from the case stories

Case stories provide an international overview of different types of examples where solar energy in urban planning is applied in new, existing and landscape areas. The case stories reflect the objective of Task 51 with cases placing different emphasis on legislation, education and approaches, methods and tools. In addition, case stories indicate other influencing aspects for solar energy in urban planning such as economy and the role of stakeholders. Table 1 below outlines which cases emphasize the aforementioned aspects featured in Task 51.

Solar energy does not necessarily feature in legislation, but is often one of the options to help meet national energy reduction targets. Legislation played a key influential role in many of the case stories but also there were indications that legislation could go further to incentivize solar energy in urban planning. For example, solar landscape case stories offered creative opportunities to overcome restrictive legislation by exploiting the dual use of agricultural land as a cheap alternative for a common use of food production and to generate energy from large scale solar energy systems.

The use of public institutions to aid the take-up of solar energy other than legislative governing bodies is through educational institution. Education was important for case stories as a mechanism to ensure professionals of urban planning have the knowledge and skill to consider solar as an option for renewable energy solutions for a district. However, there is still some ground to cover in education in terms of raising awareness of how to implement solar energy into an urban area. There were indications in responding to the 'how' questions in the case stories. One approach are holistic approaches of involving all relevant stakeholders of urban planning. This involvement extends to citizen engagement, which is crucial in building agreements, understanding and achieving solutions. This approach ensures wide representation of stakeholders and increases the chances of reaching ambitious goals by overcoming barriers in developing solar energy in urban planning through an open communication forum.

Approaches, methods and tools are key instruments from which design and energy strategies can be formulated to achieve the optimum solutions for implementing solar energy in both new and existing urban environments. All case stories used both technical and non-technical approaches, methods and tools, thus highlighting the need for a multidisciplinary attitude to contemplate appropriate solutions of solar energy in the complex environment of urban planning. Indeed, case stories highlighted that the planning process for solar energy is complex with consideration on how solar energy can contribute to the development of the area as well as work within the confines of an allocated area where options for design may be limited. Examining the potential and use of design expertise are essential steps in the planning process and should include local conditions and context, in particular, the scale of the area, options for design layouts as well as technical knowledge.

Finally, economy is influential in developing different solar energy solutions, as there are diverse economic factors. These economic factors include affordability of urban areas; the energy market; available financial incentives; financial benefits of introducing solar as a single solution or an integrated solution. There are also solar group purchase initiatives which motivate small property owners to realize solar installations while reducing investment costs. Above all, the case stories exemplify the scope and possibilities for implementing solar energy in urban planning on a global scale, which is beneficial both for the environment and for the societies living in urban areas.

Tab. 1: Type of lessons learnt found in the case stories

Lessons learnt	Case stories
Legislation	Freiham Munich Nord, **Germany**; Lund Brunnshög and Malmö Hyllie, Uppsala Frodeparken, **Sweden**; Le Albere, Agrovoltaico, **Italy**; The Eco Neighborhood of Ravine Blanche, The sustainable city of Beauséjour, Agrinergie 5, Lyon Confluence, **France**; VerGe project - Lugano-Paradiso, **Switzerland**; Sarnia Photovoltaic Power Plant, **Canada,** Zero Emission Office Building, **Norway**.
Education	Øvre Rotvoll, **Norway;** Lyon Confluence, **France**
Stakeholder and researcher involvement	aspern+ Die Seestadt Wiens, Stadtwerk Lehen, Graz Reininghaus, **Austria**; FredericiaC and Gehry City Harbour, **Denmark;** Residential Plot B45, **China**; The Eco Neighborhood of Ravine Blanche, **France**; Dale, **Norway**; VerGe project - Lugano-Paradiso, **Switzerland**.

Planning process	Solar District Heating Brædstrup, FredericiaC, Gehry City Harbor in Sønderborg, **Denmark**; Lund Brunnshög, Malmö Hyllie **Sweden**; Photovoltaic Village in Alessandria, **Italy**.

3.4 From research to education

A state-of-the-art of education on solar energy in urban planning in nine countries was carried out and summarised in two different parts. Part 1 on approaches and methods in education showed through a survey that solar energy as it relates to urban planning was rarely part of the curriculum at universities. The identified courses are instead mostly offered in other disciplines. Technical aspects, especially on the architectural level, are taught in most of the courses, particularly in the undergraduate level. The main reason for these shortcomings is the short duration of the relevant courses during the studies. Due to relevant aspects in the planning of sustainable settlements, usually the subject of solar integration is only addressed on the periphery during urban development design assignments (Siems et al., 2017a). The identified continuing professional development (CPD) programmes generally dealt with key aspects, such as climate change, and not specifically with solar energy in urban planning. In Part 2 of the review, solar tools in education are discussed and experiences in using the selected software tools in university are compared. The differences among the analysed software tools are large, both in functional scope and operation. Only the software plug-in DIVA for Rhino3D achieved high marks of usability and precise calculation results. Its short initiation period for new users, its high computing power, and its visual results in the form of false-colour imaging makes this tool eminently suitable for use in training and continuing education. However, number-based output of the calculation results for further use in other software tools and a version for the Mac OS would be welcome.

The identified gaps and barriers in existing courses and pedagogy provide knowledge that can be implemented in relevant seminars, lectures and tools for educating the next generation of architects, urban planners and specialist planners by developing a web-based platform. Therefore, a tool, called Solar Potential Analysis for both students and life-long learning was created. The software tool itself is accompanied by a detailed user manual. The entire software package is free to use without limitations. The goal of this web-based platform is to help students to integrate solar energy in their design projects by providing relevant materials such as explanations, tutorials, illustrations etc. One part of this is the open source tool “Solar Potential Analysis” which allows for analysis of solar potentials and visualisation of the results as false-colour images. In parallel with the digital software tool, a set of manual tools such as "register cards" were designed for bachelor and master courses to aid exercises and seminars in relation to solar energy. The set will be freely available online to download.

The University of Wuppertal organised an interdisciplinary summer school to educate students from various disciplinary backgrounds. Such summer schools and courses provide valuable input to improve teaching methods and assessment tools for solar energy planning such as the tool “Solar Potential Analysis” and the developed manual set of tools. Teaching methodologies and results from the summer schools were documented in a booklet (Siems and Simon, 2017b).

4. Conclusions and outlook

There is considerable scope for legal reform in many countries as to solar access protection. Planners are increasingly calling for more sophisticated decision support tools to assess active solar energy potential and measures to determine the impacts of future development, the range of technological options that may more readily accommodate shade impacts as well as aesthetic solutions. This is becoming more important as solar energy targets are being pursued in an aim to transition to low carbon cities to build resilience. It also allows building owners utilise their solar access assets to harvest energy and reduce their exposure to external energy price variability and supply constraints. Ultimately, the research found that active solar systems have a critical role to play and their deployment will conflict with future development heights if there is not a more cohesive relationship between planning approval processes and building innovation.

There is more work needed that aims to help urban planners and designers in understanding the complexity in

dealing with daylight, active solar and energy performance in cities that are rapidly densifying. The role of the urban planner is to design areas that can be built to last. Urban design that addresses the need for daylight and sunlight will not only contribute to a healthier urban environment, it will also enable photovoltaics and solar thermal technologies to be implemented if not now, in the future.

The case stories illustrate that while technical and non-technical aspects of solar energy are important, they are still often considered as separate entities. However, within the complexity of urban planning, these entities are part of a holistic picture. The development of urban areas takes into account social contexts, economic frames, legislative constraints/enablers and stakeholders' expertise and/or access to expertise. The integration of solar energy in urban planning requires taking into account complexity and the need for holistic approaches.

The research also illustrated the importance of introducing solar with systematic respect to the urban context to preserve heritage and avoid unnecessary aesthetic conflicts. There is a risk if these aspects are not taken seriously that the social acceptance of solar technologies may decrease and in the long run slow down the pace of solar utilisation.

With increasing global population growth, cities will require more resources while at the same time renewable energy sources are expected to expand rapidly and the needed land to support cities can be expected to increase. Renewable energy systems are set to be a major land use in the near future and more research is needed to understand the environmental and social impacts of these systems and how rapidly growing cities affect the land use in the immediate surroundings.

Teaching at universities and colleges cannot be considered separate from research or practice. Creating a connection between the areas of "research and teaching", as well as between "research and practice" is an essential integral objective for research projects. Therefore, research is used as a connective link between teaching and practice and/or the public with far-reaching impacts. Researching new insights is not the only important factor here, but also information exchange and dissemination. Education and dissemination need to be strengthened to rapidly ensure that knowledge and support are offered for present and future professionals and educators. The research results should be disseminated through a public and easily accessible platform. The work of Task 51 will hopefully support such developments and knowledge transfer.

5. Acknowledgements

The authors wish to thank all the experts within the research project IEA SHC Task 51, who worked with great ambitions and with good team spirit to collaborate and willingly contribute their expertise.

The authors also wish to express their gratitude to the IEA SHC Executive Committee for supporting the Task 51 and in this way strengthen the international collaboration among researchers and practitioners. We are especially grateful for the financial support from the Swedish Energy Agency; ARQ; Australian PV Institute (APVI) / Australian Renewable Energy Agency (ARENA); The Research Council of Norway (NFR); Norwegian University of Science and Technology (NTNU); German Ministry for Economic Affairs and Energy; Swiss Federal Office for Energy. Funding from these organizations enabled the leaderships of Task 51.

Wind Energy, Ocean Energy, Hydro and Other Direct Conversion Renewables

Research of Natural Renewable Energy Resources of Coast and Seas of the Far East

Valeriy V. Knyazhev and Vladimir V. Loshchenkov
Institute of Marine Technology Problems FEB RAS, Vladivostok (Russia)

Abstract

In article renewed energy sources on Far East of Russia are considered: thermal energy, energy of salinity gradients, tide, waves, currents, a wind and solar power. Estimations of power resources of these energy sources are given. Places in which they are offered can are effectively used.

A system of autonomous power supply for a coastal facility for the cultivation of hydrobionts from renewable sources on the island of Popov is proposed. A device for growing hydrobionts on artificial automated plantations in the water column without diving with an autonomous power supply from renewable sources has been developed..

Keywords: source of energy, thermal, salinity, tide, wave, current, wind, solar, hydrobionts

1. Introduction

The Far East of Russia is the region of Russia where the primary start of development and use of ocean energy sources is possible, this is facilitated by the fact that the Far East has a long coastline and most of the territory of the Far East is not connected to the unified energy system. And as the population density in these territories is small, it is economically justified to use autonomous energy sources, and, first of all, renewable energy sources of the ocean. The territory of the Far East stretching from the south to the north of 4500 km, more than 70% of the length of its borders falls on the shorelines of the seas of the Arctic and Pacific Oceans, covers different natural areas, and almost everywhere the potential of renewable energy sources is very high. The Far East has the longest coastal line among the regions - 17,700 km. (with islands).

The population of the Earth grows; requirements for marine foodstuff accordingly increase. The aquatic organisms grown in pollution-free natural settings of seas of the Far East of Russia are especially appreciated. Aquaculture development in this region is complicated small population, remoteness, absence of the production engineering, allowing to develop continuous process in the conditions of a frigid climate and high ecological requirements. This paper is devoted researches in power supply from renewed sources and working out of a perspective complex of a marine aquaculture.

2. Source of energy

2.1. Thermal energy of the ocean

In ocean thermal energy conversion (OTEC) the difference in temperatures of warm surface water and cold deep water is used to generate energy. The resources of this type of energy in the oceans are huge. But basically they can be used in the tropical zone of the ocean. In the Russian Far East, only in the southern regions and only part of the year is it advisable to transform the thermal energy of the ocean by traditional methods. It is still possible to increase temperature differences using warm water from shallow natural and artificial, sun-warmed water bodies or warm drains of some enterprises.

Therefore in the laboratory of the energy of the ocean it was proposed to use the temperature difference between the outdoor air and sea water in the cold seasons of the year. For the northern regions of the Far

doi:10.18086/swc.2017.38.01 Available at http://proceedings.ises.org

East, these seasons are long and the potential of the thermal energy of the northern seas is extremely high. In addition, energy can be obtained from this source precisely when energy requirements are high. Transformers of thermal energy of the ocean with low-boiling heat-carriers were proposed.

2.2. Salinity gradient energy

Places where there are differences in salinity (concentration) of natural waters and solutions can be used as energy sources, which are called salinity gradient energy (SGE) sources. As sources of energy, salinity gradients are considered, first of all, the mouths of rivers flowing into the sea. The energy density of these sources is high. So, it can be imagined that in the mouths of rivers flowing into the seas, so much energy is lost, as if they ended in waterfalls with a height of 240 meters, since the osmotic pressure of the sea water exceeds 2.4 x 10^6 Pa (24 atm).

Amur the river most abounding in water in considered region. The average discharge of water in its mouth 12.8-11.4 m^3/s. Resources of energy of this river are huge. But so the river Amur runs into shallow Amur liman between island Sakhalin and continent at building there to power station of a point of a water fence of fresh water and not diluted sea water would be carried on the big distance.

Estimations of potentials of energy of gradients of salinity of some large rivers flowing into Okhotsk Sea are resulted in the Table 1.

Tab. 1: Energy potential SGE in the mouths of the rivers flowing into Okhotsk Sea

The river	Area of the river basin, km^2	Rate of the flow, m^3/s	Average power, MW
Penzhina	73500	680	1514
Uda	61300	510	1135
Okhota	19100	200	445.2
Poronay	7990	120	267.1

For the largest rivers of the Primorsky krai (Primorye) flowing into the Sea of Japan, the energy potential was assessed (Fig. 1) (Knyazhev, 2010). The total energy potential in the estuaries of the rivers will be 1.5 x 10^3 MW, while theoretically possible annual energy production will amount to 4.25 x 10^7 MJ. Resources SGE in other areas of the Far East is much higher. The total runoff of the rivers of the Pacific Ocean basin is 1212 km^3 / year, which corresponds to the theoretical resources of the SGE about 2.7 x 10^9 MJ.

Several methods have been proposed for the conversion of EGS. This is primarily membrane methods of energy conversion using semipermeable osmotic membranes and ion-selective membranes (reverse electrodialysis), as well as energy conversion methods, in which the transfer of water molecules occurs through surfaces that separate the different phase states of solutions, etc.

The development of osmotic power plants, the testing of semipermeable membranes and small experimental power blocks was carried out in the USA, Israel, Italy, and Japan. And in November 2009 in Norway in Tofte, south of Oslo, the state-owned energy company Statkraft launched the world's first osmotic power plant, which generates energy by mixing sea and fresh water.

Reverse electrodialysis plants allow direct conversion of energy from salinity gradients to electrical energy. Research on the development and testing of reverse electrodialysis plants was conducted in the USA, Sweden and Israel.

In the Netherlands, on the dam Afsluitdijk separating the man-made lake IJsselmeer from the sea, a pilot RED-Stack installation operates. And in Trapani (Sicily), a prototype of the pilot installation of the REAPower (Reverse Electrodialysis Alternative Power) plant, which uses brines from evaporative ponds and seawater is tested.

The main element of the reverse electrodialysis installation is an electrodialysis battery, which is a stack of alternating anion and cation-exchange membranes placed between the electrodes. Solutions with different concentrations are fed into chambers formed by pairs of membranes and working frames, so that chambers with solutions of high and low concentrations alternate. The directional movement of ions from the chambers from a high concentration to the chambers with a low concentration leads to the accumulation of an electrical

potential on the electrodes.

Fig. 1: SGE resourses rivers of Prymorye, Russia

In the laboratory of non-traditional energetics of IMTP FEB RAS, studies of the energy conversion of salinity gradients by the method of reverse electrodialysis were carried out. This method has a number of advantages and is most suitable for converting energy in the mouths of rivers flowing into the sea [2]. An experimental reverse electrodialysis installation was developed and created. Tests of the experimental installation in full-scale conditions on sea water from Alekseev Bay on the island of. Popov and fresh water from an artesian well confirmed that this method can be used to directly convert SGE into electricity.

2.3. Energy of the tides

In the Far East, the highest tides in the Penzhina Bay in the north of the Sea of Okhotsk, they reach 12.9 m there. In the Sea of Okhotsk, tides of a mixed type predominantly prevail, predominantly of the irregular diurnal one. Employees of the Ocean Energy Laboratory together with specialists from Moscow and Leningrad, together with the creator of the first in the country Kislogubskaya TPS (Tidal Power Station) L.B. Bernshtein from the Institute "Hydroproject" carried out work on the investigation of tidal regimes in the Penzhina Bay and in the Tugur Bay, proposed preliminary TPS projects. Expeditions were made to the Tugur Bay and the Penzhinskaya Bay to measure tidal sea level fluctuations (Fig. 2-Fig. 4).

According to the results of these studies, the energy resources of the tides in the Okhotsk Sea are the following potential integral values: the energy production of a tidal power plant in the Tugur Bay is estimated at about 6.8 x 10^{10} MJ / year, which corresponds to a power of more than 2000 MW; the energy production of a tidal power plant in the Penzhina Bay is estimated at about 6.8 x 10^{11} MJ / year, which corresponds to a capacity of more than 20 000 MW. Since such an amount of energy could not be used by the nearest consumers, it was proposed to export electricity to neighboring countries - Japan and China.

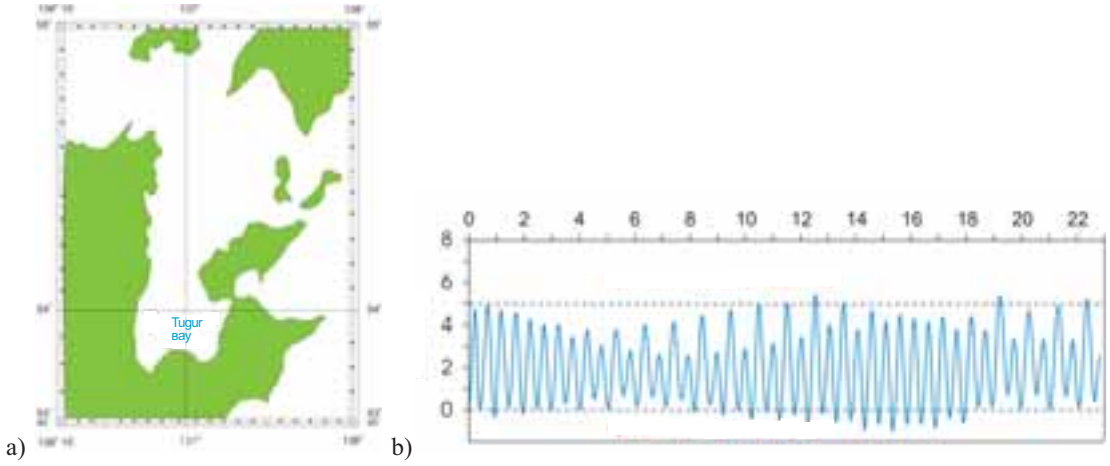

Fig. 3: a) Map of the Tugur Bay, b) Tidal level fluctuations. Tugur Bay. 5 - 28 August 1981 y.

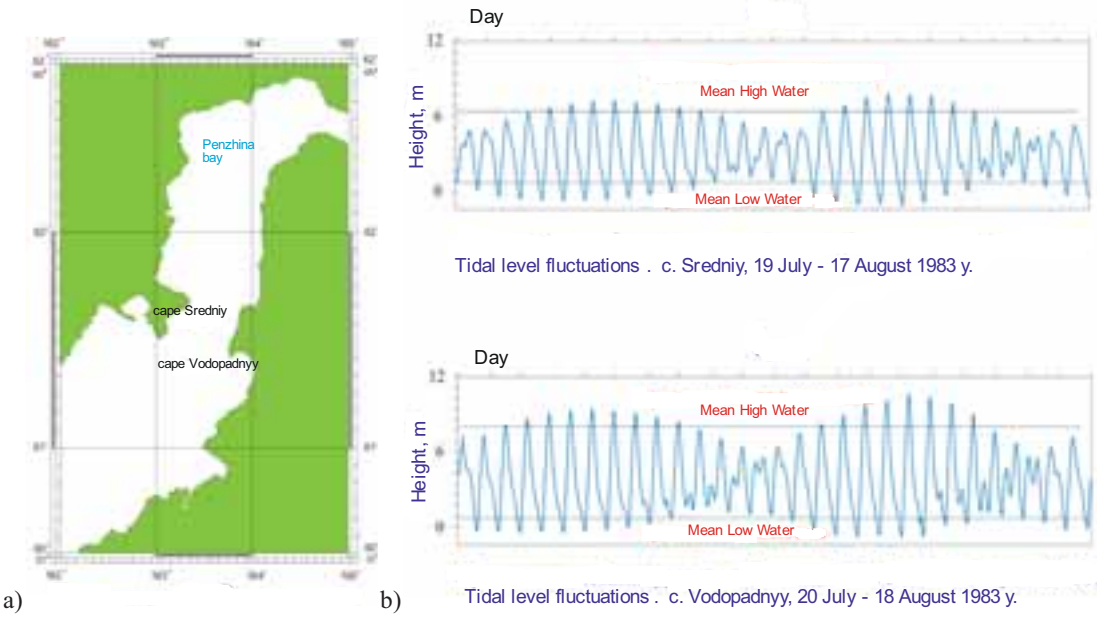

Fig. 4: a) Map of the Penzhina Bay, b) Tidal level fluctuations. Penzhina Bay

2.4. Current energy

Near the Far Eastern coast of Russia, tidal currents in narrow areas have speeds sufficient to effectively use them. In the Kurile Straits and in the Shantar Islands, the speed of tidal currents is up to 3.5 m / sec. It is there that it is possible to install hydroturbines in the water column to convert the energy of tidal currents. The power of such stations can increase gradually, adding as necessary new turbines. In this they have an advantage over the dams of TPS, when creating, which require huge initial capital costs for the construction of dams.

2.5. Energy waves

In the laboratory of the energy of the ocean, the problems of conversion of wave energy, wave energy resources in the World Ocean were studied. Several designs of wave energy stations have been proposed and patented, which have greater efficiency and lower material intensity.

The energy resources of waves in the Far Eastern Seas are high (Sichkarev, Akulichev, 1989) in Tab. 2 and 3 show the values of the wave energy fluxes, renewable power and annual energy in these seas.

Tab. 2: Flows of wave energy of the Far East seas (kW/m)

The sea	Winter	Spring	Summer	Autumn	Average annual
Bering	58/411	43/351	26/411	54/465	45/465
Okhotsk	34/351	31/294	18/351	32/189	29/351
Japan	49/351	40/351	17/189	37/351	36/351

Tab. 3: Renewed capacity and annual energy of water area of the Far East seas

The sea	The area, m^2, $\cdot 10^{12}$	Flows of wave energy (kW/m)	Renewed power, W, 10^{11}	Annual energy, J, $\cdot 10^{18}$
Bering	2.30	45	1,9	6,00
Okhotsk	1,59	29	1,01	3,19
Japan	0,98	36	0,71	2,24

2.6. Wind energy

Wind energy can be used not only on the sea, but also on land. And it was on land this source of energy was originally started to be exploited for technological purposes. As a result, significant progress has been made in the world in wind energy. In developed and developing countries, many wind turbines have been installed. As a result, in densely populated Europe there are almost no places to install large-capacity wind turbines. Therefore, and also because the resources of wind energy above the ocean surface considerably exceed them above the land, more and larger wind farms are installed on the sea shelf.

The coastal areas of the Far East have huge resources of wind energy; most of them belong to areas with winds of strong and medium intensity. According to experts in Russia, about 30% of the economic potential of wind energy is concentrated in the Far East. The advantage of using wind energy in these areas is that the maximum average speed here falls on autumn and winter - the periods of the greatest need for electricity and heat. The resources of wind energy over the water areas of the Far Eastern seas are much higher.

2.7. Solar energy

Primorsky Krai belongs to the regions of the Russian Far East and the whole of Russia, where it is advisable to use solar energy for energy supply purposes. The average number of sunny days per year for the Primorsky Kray is 310, with a sunshine duration of more than 2000 hours. Moreover, there are areas where the number of days without the sun is only 26 per year; the duration of sunshine is 2,494 hours. On the northern coast, the duration of sunshine is 1900 ... 2100 hours, on the southern coast the duration of sunshine is 2000 ... 2200 hours.

In general, the power input of solar energy to the territory of Primorsky Krai is about 30 billion kW. The practical resources of solar energy, taking into account environmental and other limitations, achieve: when receiving only thermal energy - 16 million kW; when receiving only electric energy - 4.9 million kW (Fig.5).

Fig. 5: Solar energy resources of Primosky kray

3. The system of energy supply of promising aquaculture complexes

The system of autonomous power supply of the long-shore factory of an aquaculture from renewed sources on an island of Popov is offered (Fig.6). The design of an experimental power system is fulfilled taking into account local natural settings and long-term meteorological and hydrological measurements for all-the-year-round providing of flow processes. Heat, cold and electricity ensure department of cultivation and

department of deep rehash of aquatic organisms.

An autonomous automatic plantation (Fig.7) on the deep-water shelf with remote dispatching control and control, a wave electro-pneumatic installation and a system of buoyancy, aeration and lifting devices that provide long-term processes are developed. Remote dispatch control over the biological and technological parameters of plantations and depth change control excludes diving operations.

The technical project of a specialized semisubmersible vessel-dock of service of marine plantations develops. The vessel will effect installation and removal of sectors of plantations and will handle a crop.

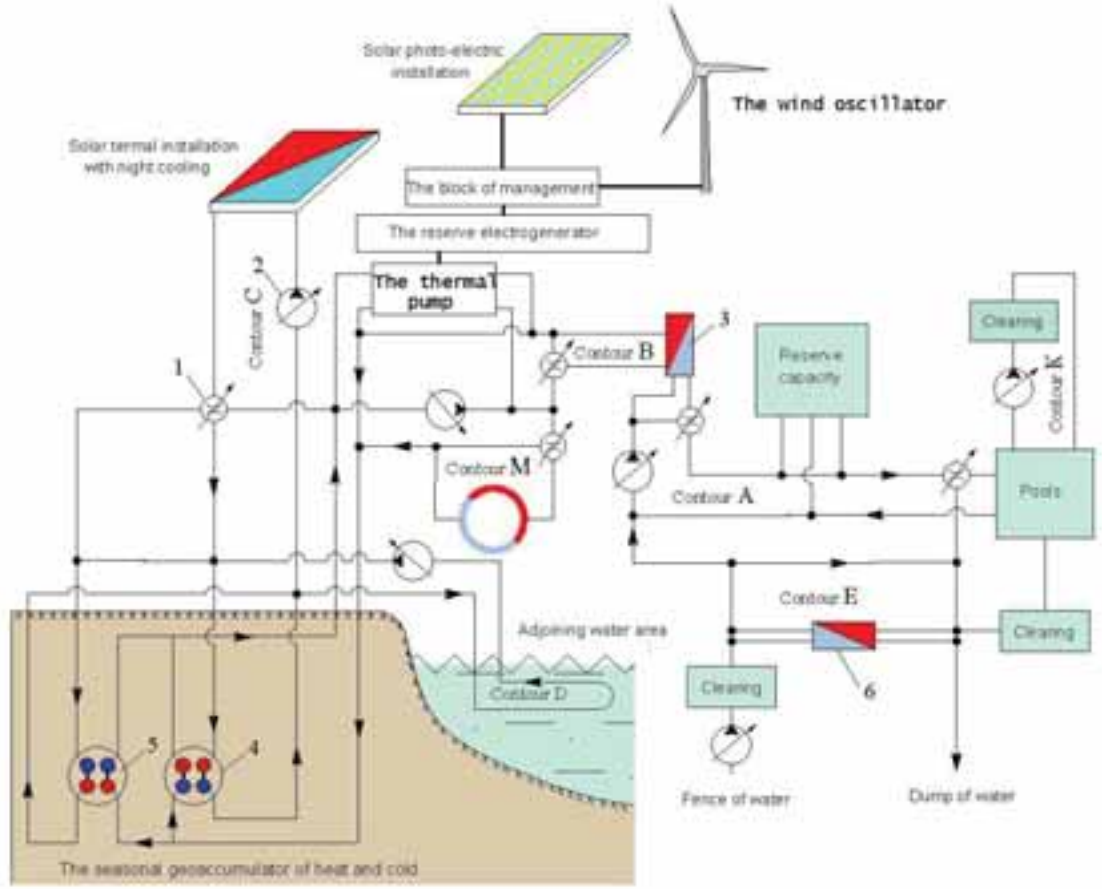

Fig. 6: The system of autonomous power supply of the long-shore factory of an aquaculture from renewed sources on an island of Popov. 1 - the managing valve; 2 - the pump circulating; 3 - the exchanger; 4 - probes of sector of heating; 5- probes of sector of refrigeration.

Abstract

Under its Vision 2030, the Kingdom of Saudi Arabia (KSA) announced an ambitious strategy to diversify their economy from oil dependency. One of the goals of the vision is an initial target to produce 9.5 GW of electricity from renewable energy sources. Offshore wind energy conversion is considered to be mature technology with more than 12 GW of installed capacity globally. Offshore wind has advantages when compared with onshore wind, such as, higher wind speed, reduced turbulence, minimal visual and noise impacts. KSA has two shorelines, one is laying on the Arabian Gulf and the other is on the Red Sea. The work presented here evaluates offshore wind potentials in in the East Coast of the Red Sea in KSA which was chosen due minimum restrictions and has no close oil extraction facilities. The evaluation was based on a Boolean Mask model linked coupled analysis undertaken in Geographical Information System developed for the Red Sea area.

Using the UK's London Array wind farm as a minimum required area for offshore wind farms, the work identifies ten different locations as possible areas for the first offshore wind farms in KSA. The analysis considered the deployment of two types of turbine of capacities 3.6MW and 5MW. The results for the higher capacity turbine indicate that over 12.3 GW of offshore wind power can be generated from the identified sites. These results and the produced location maps could be used to help stakeholders in KSA in planning for the exploitation of offshore wind energy in KSA. Thus providing a pathway to contribute to achieving the 9.5 GW national target.

Keywords: Wind energy, offshore wind, GIS, Boolean Mask, Red Sea, KSA

1. Introduction

Offshore wind energy is considered mature technology with over 12 GW of installed capacity globally. The recent contract for difference (CfD) announcement in the UK showed halving the cost per MWh to £57.5 compared to the previous round (CB, 2017). Onshore wind on the other hand is further ahead in terms of economics, however, it has some disadvantages, such as the value of the land areas, noise, high vibrations, visual impacts, bird paths hazards, and shadow flicker effect. Shadow flicker effect that is an infrequent event, which could happen, when the sun's light is at horizon. Shadow flicker could be responsible for photo-induced seizures or photosensitive epilepsy and other disturbance to humans near the turbines (Knopper & Ollson, 2011). Offshore wind on the whole does not suffer from these disadvantages, and has two extra advantages: the average wind speed is larger than over onshore areas and the turbulence wind effect is minimized when compared to installation over land. The latter is important as fatigue stress encountered is smaller enhancing offshore wind turbines life.

The Kingdom of Saudi Arabia (KSA) has a total area of 2.2 million km^2, and a population of more than 30 million. KSA lies between latitude of 17.5 °N and 31 °N and longitude of 36.6 °E and 50 °E (Bahakeem, 2015). The west coastline of KSA is more than 1800 km in length and is situated around the Red Sea and the Gulf of Aqaba with a boundary between Haql to the north and Jazan to the south (Fig.1).

The energy consumption of KSA has been on rapid rise to cope with the growing demand of the industrial, water

doi:10.18086/swc.2017.38.02 Available at http://proceedings.ises.org

and building sectors. Most of this energy is derived from fossil fuels leading to high carbon emissions. This dependence is as a result of the vast oil resources in KSA estimated to be more than 250 billion barrels of oil reserves or one-fifth of total known global reserves (Bahakeem, 2015). Hence there is an urgent need for KSA to move towards low carbon renewable energy production.

In order to decrease its reliance on fossil fuels and balance its economy, KSA has developed the Vision 2030 programme under which it plans to generate 9.5 gigawatts of electricity from renewable energy sources (Gazette, 2016). This is more likely to be derived from solar energy and wind energy. Hence, this work is directed towards the latter, but concentrated on offshore wind around the Sea Area of KSA where we will identify suitable locations for offshore wind farms (OWF) and evaluate their potential. To our knowledge, only one article was found that considers the offshore wind resources in KSA but the study was focused on the east coast of the country (Rehman, 2005).

In summary, the aims of this work is to identify the suitable areas in KSA for offshore wind focusing on the the Red Sea regions, estimate the electrical power potential form the identified sites and provide suitability maps for these locations.

Fig.1: Study area map, KSA is shaded with light green, the Red Sea east shoreline is the red line, adopted from (esri, 2012).

2. Methodology

In this work the required outcome is a spatial siting of the wind farms. Such a problem comprises a large number of suitable alternatives and multiple constraints to choose the alternative with zero constraint. Both the constraints and alternatives can be determined or evaluated and weighted by stockholders, or scholars based on their knowledge and experience (Estoque, 2011).

The map of the study region is divided to grid as an equal size, the smallest part of such grid is called a cell, which corresponds to one of the feasible alternative. For instant, to decide the suitable cell for offshore wind energy in the Red sea, wind speed, water depth, distance to shore, distance to the electricity grid, shipping routes, military areas, cables paths, and reserved natural parks, are the constraints to be considered in the analysis and before taking a final decision. Fig.2 provides a flow chart summarising the whole assessment process, under the Boolean Mask technique utilised in this study to solve the problem.

Boolean Mask (overlay), is used to locate sites with no restrictions (constrains). Boolean relations [and, or, and not] are used, from which the name has been derived.The created map layer has two colours (boundaries), one represents areas that has a value of 1 (the unrestricted areas) and the other represents areas of value 0 value (restricted areas). Boolean mask is a powerful tool for simple and quick spatial decisions (Jiang & Eastman, 2000).

In this work, we need to create a primary map for suitable offshore wind farms in the Red Sea, around the KSA coast, and evaluate the potential electrcila power from these farms. The **Constraints** can be explained as a tool to eliminate alternatives (cells). The limitations or restrictions of the constraints are defined as a (true/false) relationship. For example, if the commercial wind power development becomes feasible around wind speed greater than 3 m/s, so all areas with wind speed less than this threshold (3 m/s) will be given 0 value, while other areas will take the value of 1.

The equation used to calculate the Boolean Map is adopted from (Eastman, Jiang, & Toledano, 1998), and is given by:

$$Boolean\ Mask = \left(\prod_{j=1}^{l} C_j\right) \qquad \text{(eq. 1)}$$

Where:

C_j is the constraint j (Boolean Mask j),

Π is the product of constraints, and

ℓ is the number of constraints.

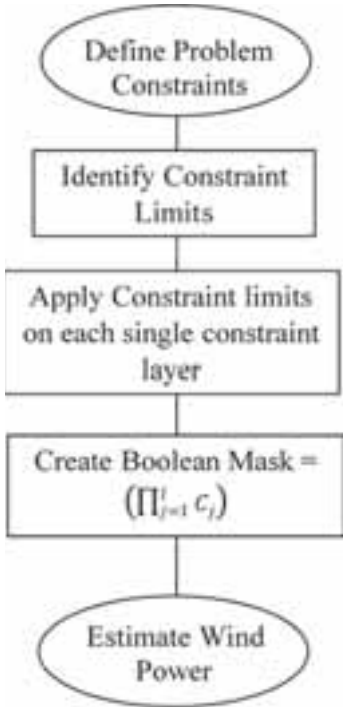

Fig.2: Flow chart summarising the whole assessment process, under the Boolean Mask technique utilised in this work.

3. Analysis

To satisfy the conditions of the sites around the Red Seas in KSA coasts, nine constraints were considered, and are summarised in Table 1. In addition, the table also provides the two limits for each constraint, where only two values are identified; zero value, which is the undesirable areas (cells) according to the constraint definitions, while the value of one is assigned the other areas (cell).

3.1 Relevant Data

A map layer in ArcGIS was created for each constraint, using the available and relevant spatial data. The bathymetry data for the Red Sea around the shores of KSA was adopted from (The British Oceanographic Data Centre, 2014), the source file of water depth data was in raster form, with a sell size of 800 x 800 m, and the file "GCS_WGS_1984" is the Geographic Coordinate System used. Due to the source file cell size and the coordinating system type, all constraints layers were confined to same cell size and GCS_WGS_1984 coordinate system. Fig.3, shows the water depth map for the Red Sea, which has a range from 0 to -3000 m. The areas with the required depth for offshore wind farm are concentrated in the South West part of the KSA. Wind speed data was adopted from the "Wind Atlas for Egypt" (Mortensen et al., 2006) and from the Global Atlas for Renewable Energy (Kieffer & Couture, 2015). The map layer in Fig.4 shows the average wind speed in [m/s] at a height of 10 m over a flat and uniform sea, which has a range between 3 and 7 m/s. Locations with desirable wind speed are centred in the North West part of the KSA.

Fig.5 shows all constraints in the study area, KSA has only two maritime reserved parks in the Red Sea named "Umm al-Qamari Islands" and "Farasan Islands". Locations and shape dimensions of these parks were taken from the official web site of the Saudi Wildlife Authority (SWA, 2017). Shipping Routes in the Red Sea adjacent to the KSA coast line were identified using the data available from ship density maps of Marine Traffic website (The MarineTraffic, 2015). Submerged undersea cable locations and paths were extracted from the submarine cable map of (TeleGeography Company, 2015). Marine military restricted areas was assessed from Royal Saudi Navy Forces official website (RSNF, 2017). According to Saudi Aramco (Aramco, 2017), all petrol oil extraction areas are located on the Arabian Gulf, so the oil extraction constraint was excluded.

Table 1: Constraints 0, and 1 definitions and data source data.

Constraint	Symbol	0 description and data source	1
Wind Speed (m/s)	W_B	Areas with wind speed less than 3.0 m/s **or** more than 25.0 m/s at a height of 10 m over a flat and uniform sea (Archer & Jacobson, 2005), wind speed data were adopted from (Mortensen, Said, & Badger, 2006) and (Kieffer & Couture, 2015).	Else
Water Depth (m)	D_B	Depths less than 5.0 m **or** more than 60.0 m, the bathymetry data was adopted from British Oceanographic Data Centre (BODC) (The British Oceanographic Data Centre, 2014).	Else
Distance to the shore (km)	S_B	Distance less than 1.5 km or more than 200.0 km, the distances data was adopted and processed using ArcGIS Program (esri, 2012).	Else
Distance to the Grid (km)	G_B	Distance more than 250.0 km, the distances data was adopted and processed using ArcGIS Program (esri, 2012).	
Military Practice & Exercise Areas	M_B	Locations were adopted from (RSNF, 2017)..	Else
Shipping Routes	R_B	Shipping areas adopted from (The MarineTraffic, 2015)	Else
Maritime Boundaries	B_B	Boundaries were adopted and processed using ArcGIS Program (esri, 2012)..	Else
Nature Reserves	N_B	Places in the sea area protected by the power of law to reserve the endangered marine ecosystem species, marine parks were adopted from (SWA, 2017).	Else
Under Sea Cables	U_B	Locations of the submerged sea cables (TeleGeography Company, 2015).	Else

Fig.6 shows the map layer of the National Electricity Transmission Grid of KSA (the grid is drawn as a line network in a black colour), which was adopted from the Global Energy Network Institute (GENI, 2017). The Euclidean Distance Tool was deployed to calculate the distance between nearest electricity line to each cell, (Fig.6). Fig.7 shows the coastline of the Red Sea of KSA in km and was drawn using data from (esri, 2012). Euclidean Distance Tool within the ArcGIS programme was applied to create a map shown in Fig.7, which illustrates the distance from each cell to the coastline of KSA.

3.2 Boolean Mask

A Boolean mask was created to eliminate restricted cells, constraint cell value = 0, and unrestricted cell value = 1, see Fig.5. The Raster Calculator tool was used to produce the final Boolean Mask, and is shown in Fig.8. The below equation was used:

$$\text{Boolean Mask} = W_B \times D_B \times S_B \times G_B \times M_B \times R_B \times B_B \times N_B \times U_B \quad \text{(eq. 2)}$$

Where: W_B, D_B, S_B, G_B, M_B, R_B, B_B, N_B, and U_B are defined in Table 1 above.

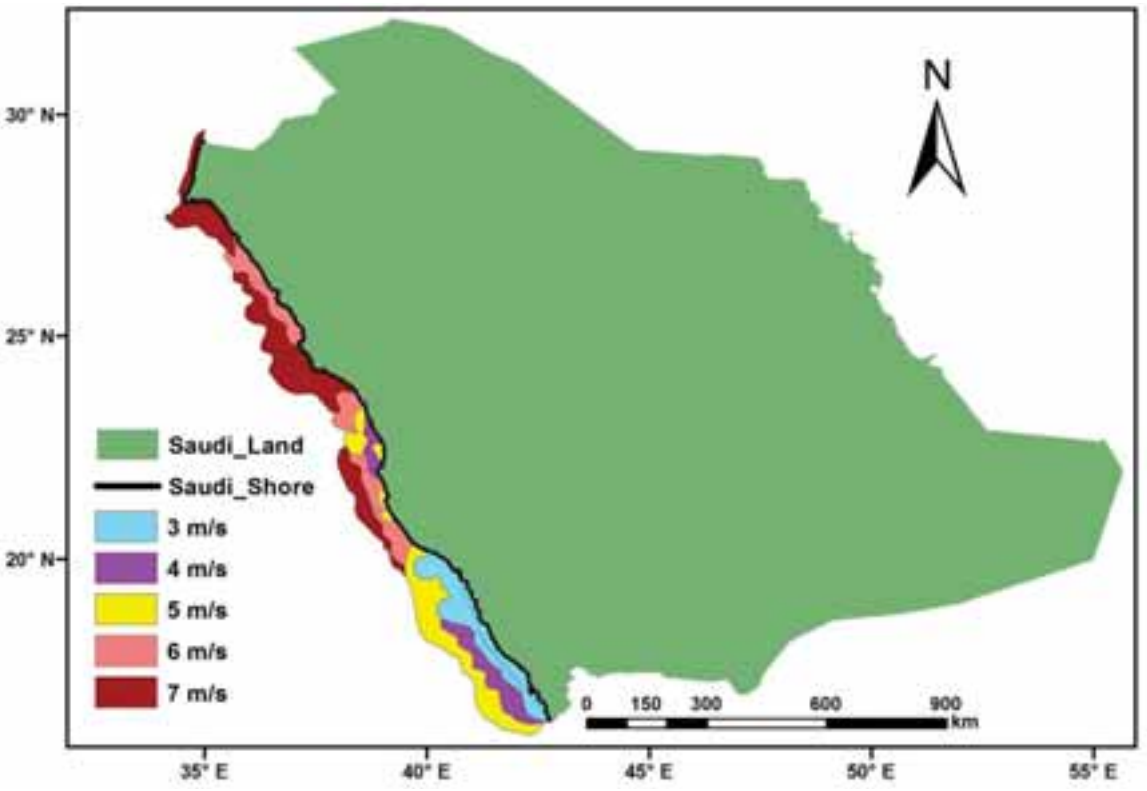

Fig. 4: Wind Speed [m/s] map around the Red Sea coastline of KSA.

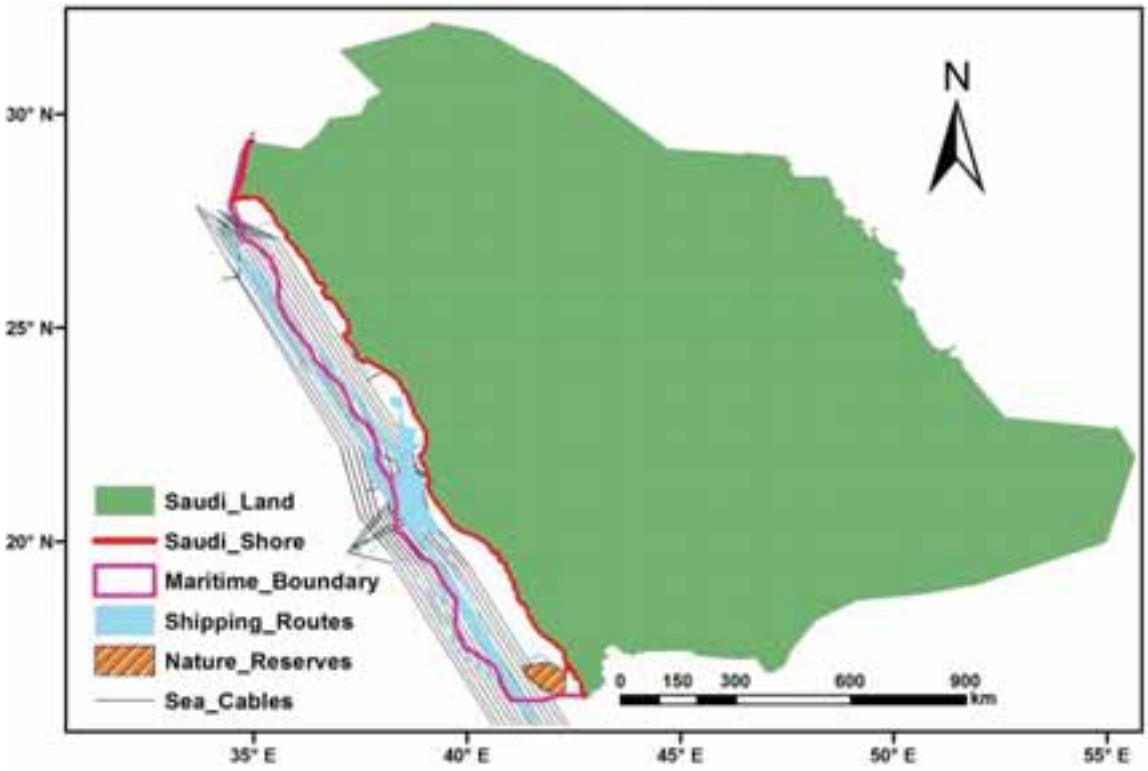

Fig. 5: Raster layer for the all restricted areas around the Red Sea region of KSA.

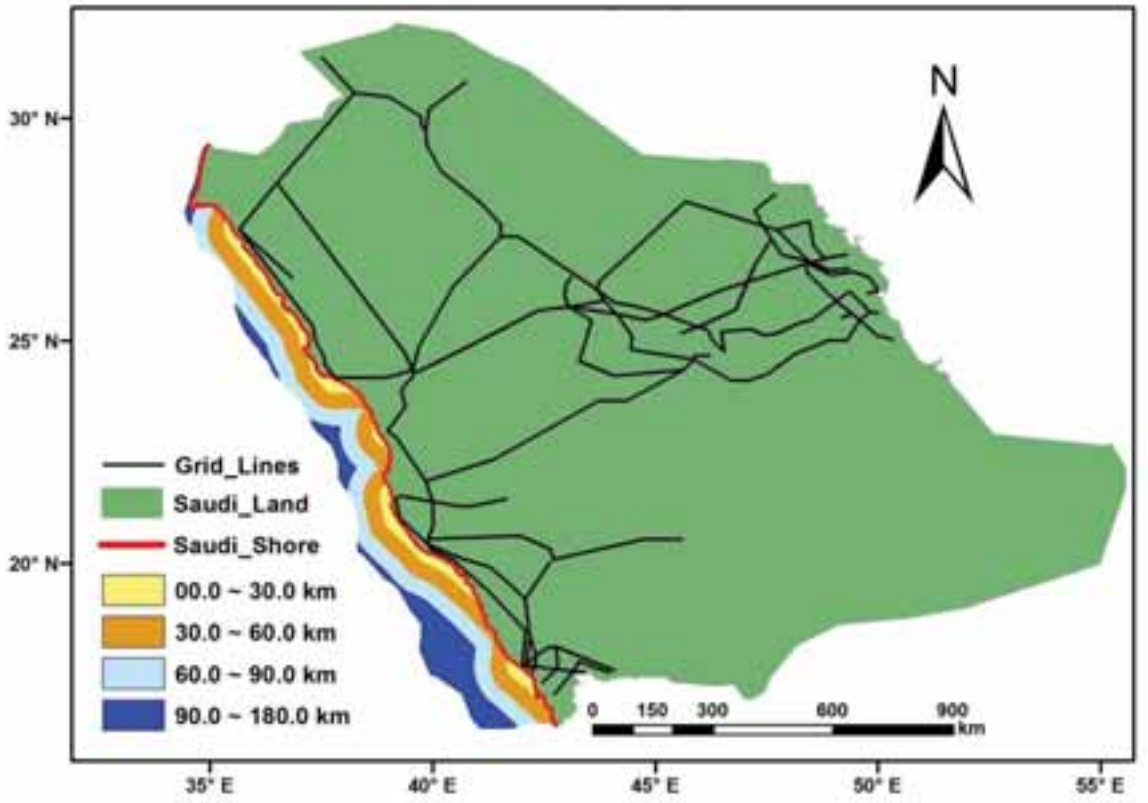

Fig. 6: KSA electricity grid lines for and the distance between cells and the grid near the Red Sea region of KSA.

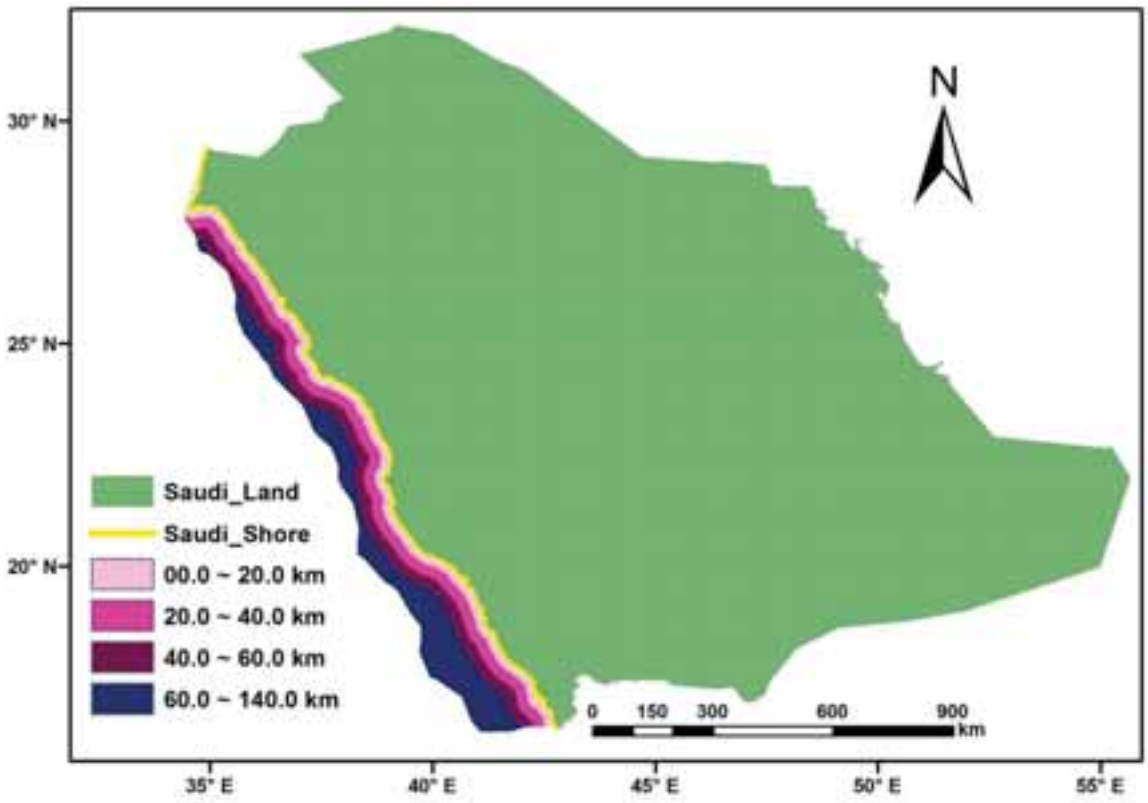

Fig. 7: Layer map of the distance between cells and shoreline around the Red Sea region of KSA.

4. Results, Discussion and Conclusions

The results shown here were based on analysis undertaken for the wind energy potential for the offshore Red Sea region of KSA. The analysis is based on a the development of a Geographical Information System (GIS) encompassing Boolean Mask technique through which a model was developed to create a map for offshore wind farm locations in the Red Sea, KSA. The developed model to solve the spatial sitting for offshore wind farms is efficient and was successful to deal with the conflicting constraints.

Using the UK's London Array wind farm which has an area of 122 km^2 (The Crown Estate, 2012) as a minimum required area (threshold) for offshore wind farms, the analysis was set to identify different locations as possible areas for offshore wind farms in KSA. Ten different locations which conform to the London array threshold were identified using the Boolean Mask map as shown in Fig.8.As can be seen from the figure, the largest locations can be found in the middle part of the coastline stretch, which is due to the main two constraints (wind speed and water depth), which are centred in two different directions of the map, see Fig.3, 4, and also the results in Fig.9.

To estimate the offshore wind power potential for the identified sites, we use the analysis to estimate the array spacing between offshore wind turbines developed by (Sheridan, Baker, Pearre, Firestone, & Kempton, 2012) given by Equation 3 below.

$$S = R_d^2 \times L_d \times L_c \qquad \text{(eq. 3)}$$

Where:

S is the array spacing between offshore wind turbines

R_d is rotor diameter

L_d is the downwind spacing factor

L_c is the crosswind spacing factor

Furthermore, and according to E.ON data (E.ON, 2012), to reduce turbulence interaction between turbines, the ideal turbine spacing is 5 to 8 times rotor diameter. In our analysis we confine the turbine capacities to a 5 MW and 3.6MW turbines to estimate offshore wind power for the identified sites. The 5 MW turbine has a 126m rotor diameter and the characteristics of the turbine were adapted from (Jonkman, Butterfield, Musial, & Scott, 2009). The 3.6 MW turbine has a 107m rotor diameter and the characteristics of the turbine were adapted from (Ajayi, Fagbenle, & Katende, 2011).

Table 2 shows the area for each possible location for offshore wind farm. The two dimensions a, and b are length and width of the rectangular of the locations measured in ArcGIS. The power in GW represent the full power captured by the turbines and was calculated for both 5MW, and 3.6MW using Equation 3. While the last two columns of the table show the estimated actual power assuming a capacity factor, C_f, of equal 0.4 and 0.5. The Capacity Factor which also known as the Load Factor ranges from 0.32 to 0.43 for 80m – 107m rotor diameter, and from 0.40 to 0.50 for turbines with rotor diameter more than 120m (Estate, 2017).

Table 2: Estimate offshore wind power for the chosen sites, where a, and b are the length and width of the rectangles of the location shown in Fig.9.

Location, see Fig. 10	a [km]	b [km]	Area [km^2]	Power (GW)		Estimated Power for	
						$C_f = 0.40$	$C_f = 0.50$
				3.6MW turbine	5.0MW turbine	3.6MW turbine	5.0MW turbine
Location 1	11.8	27.8	328.0	1.7	2.6	0.7	1.3
Location 2	7.2	33.0	237.6	1.2	1.9	0.5	0.9
Location 3	7.2	24.6	177.1	0.9	1.4	0.4	0.7
Location 4	9.2	18.5	170.2	0.9	1.3	0.4	0.7
Location 5	5.3	26.9	142.6	0.7	1.1	0.3	0.6
Location 6	14.3	24.1	334.6	1.8	2.7	0.7	1.4
Location 7	11.8	33.2	391.8	2.0	3.1	0.8	1.5
Location 8	18.6	47.6	885.4	4.6	7.0	1.8	3.5
Location 9	7.3	38.0	277.4	1.4	2.2	0.6	1.1
Location 10	7.7	21.8	167.9	0.9	1.3	0.3	0.7
Total			3122.5	16.1	24.6	6.4	12.3

As can be seen form Table 2, the total estimated wind power for the identified sites is around 6.4 GW and 12.3 GW for the 3.6MW and 5MW turbines, respectively. These results confirm that offshore wind energy conversion can play a major role in the short and long term plan for the renewable energy expansion in KSA. For instant, utilising the 5MW turbine route would more than satisfy the 9.5 GW target stipulated in the KSA Vision 2030. Hence this work can be used to plan for offshore wind expansion in KSA and provide a knowledge platform for stakeholders interested in wind energy deployment.
