Masdar Institute of Science and Technology, part of the Khalifa University of Science and Technology

The Masdar Institute of Science and Technology (MI) is the local host of the joint International Solar Energy Society (ISES) Solar World Congress 2017 and International Energy Agency (IEA) Solar Heating and Cooling Programme's 2017 Conference on Heating and Cooling for Buildings and Energy. The Institute was established in 2007 in Abu Dhabi, in collaboration with the Massachusetts Institute of Technology (MIT), as an independent non-profit graduate level research university focused on advanced energy and sustainable technology. The Institute has served to develop the intellectual and human capital of relevance to the UAE's knowledge economy transformation through its high quality academics and research of relevance to local, regional and global needs.

Over the years MI has evolved an academic and research platform that articulates its mission and vision according to critical energy and sustainability challenges. It integrates theory and practice to incubate a culture of innovation and entrepreneurship to develop the critical thinkers and leaders of tomorrow. In this way the Institute has sought to be a leading renewable energy and clean technology player by providing a test bed for the world to develop commercially viable and sustainable energy solutions, engaging in research and development collaboration with the four corporate arms of its allied Masdar group and the UAE as a whole. It has maintained a particular focus on the research and development of renewable energy and related technologies, launching the Masdar Institute Solar Platform as part of the broader Masdar Solar Hub that additionally includes a Solar and Device Testing (SDT) Laboratory and a Solar Panel Testing Lab. This is just one example among many of the research facilities developed at the Institute to research, develop and test technologies, systems and prototypes for renewable energy applications.

In February 2017 MI merged with the Khalifa University of Science, Technology and Research (KUSTAR), and the Petroleum Institute (PI) to produce the new Khalifa University of Science and Technology, which is designed to serve as a world-class, research-intensive institution that develops world leaders and critical thinkers in science and engineering.

The resulting university endeavors to be a catalyst to the growth of Abu Dhabi and the UAE's rapidly developing knowledge economy as an education destination of choice and a global leader among research intensive universities. Bringing three excellent universities under a single umbrella intends to provide enhanced efficiency, interdisciplinary innovation, access to greater research facilities, and strengthened support for faculty, staff and students. It will also provide the UAE's youth with a single world-class university with the capability to take them from undergraduate to graduate education in advanced disciplines of great value to the country and region.

Today the Khalifa University of Science and Technology is home to the most advanced research facilities in the country and some of the brightest minds in the world. Its faculty include some the region's leading experts in clean and renewable energy, hydrocarbon exploration and production, water and environment, healthcare, aerospace, supply chain and logistics, advanced materials and manufacturing, robotics, artificial intelligence and data science, information communication technologies (ICT) and security. They work collaboratively across the university's many research centers in pursuit of scientific and technical advancement in sectors targeted for the UAE's high-tech knowledge economy. With its expansive academic programs, research centers, faculty, and interdisciplinary scope, the Khalifa University of Science and Technology will be able to improve the UAE's ability to meet the needs for the future.

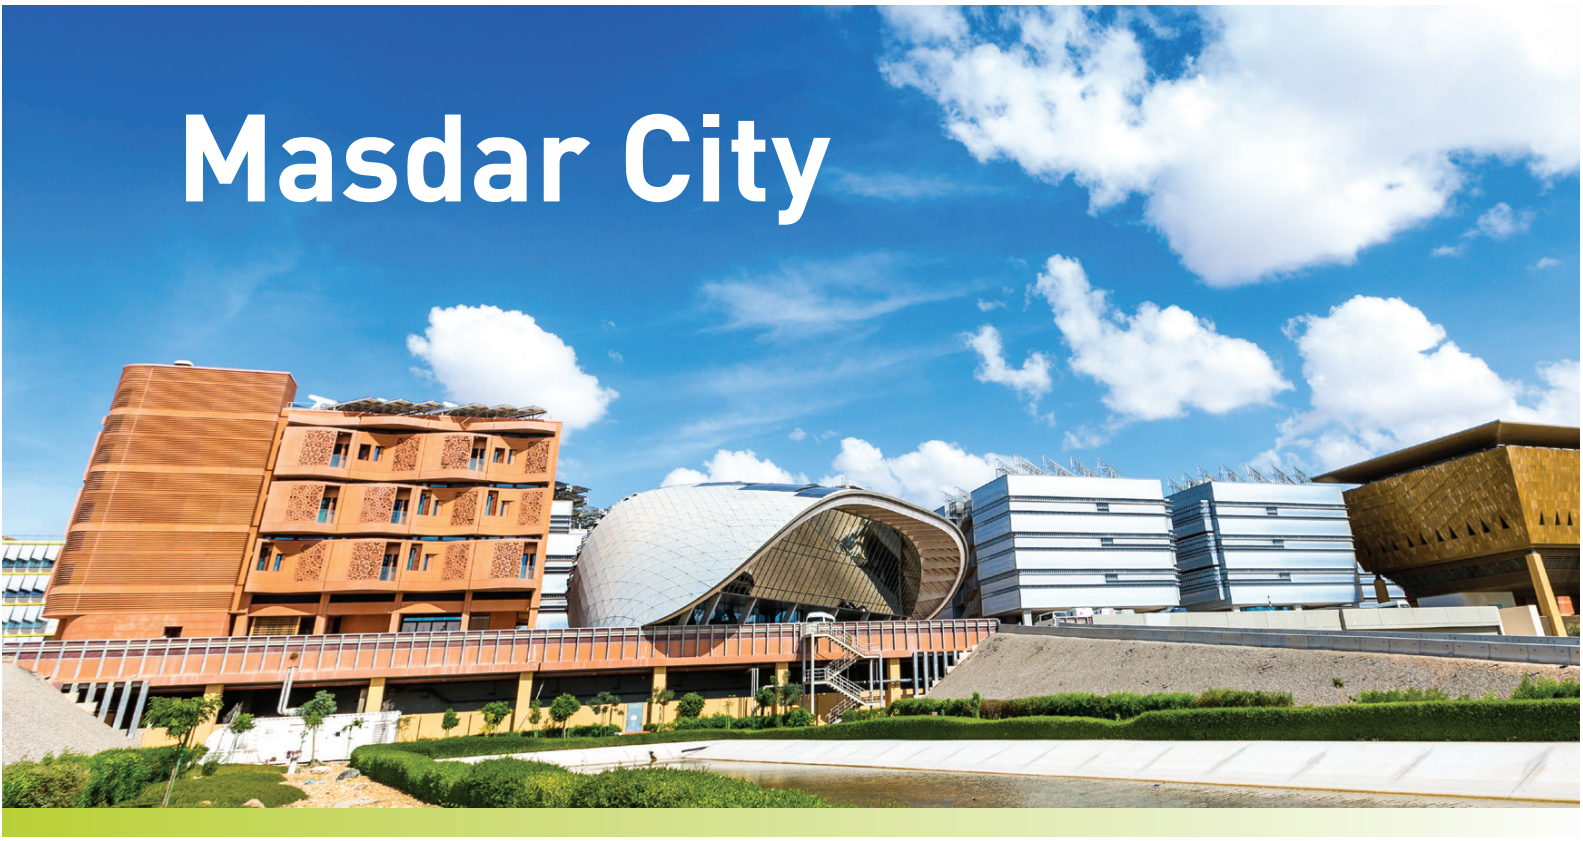
Masdar City



Sustainable Inside and Out

With more energy-efficient buildings in a single district than any other development in the region, Masdar City features both passive and active energy and water saving features that ensure all buildings are certified to at least 3 Pearls (equivalent to LEED Gold) under the Estidama programme, Abu Dhabi's sustainable building, villa and community rating system designed for the specific needs of the UAE climate. In fact, Estidama was incubated in Masdar City.

Master Plan

The city's master plan integrates office, residential, educational, leisure and retail in a way that maximises walkability and facilitates the use of public transportation, including personal rapid transit and group rapid transit systems. Ultimately, up to 50,000 people will live in Masdar City, while up to 40,000 will work and study there. The master plan's orientation of the city and its highdensity design help to optimise shading and capture prevailing winds, producing naturally cooler outdoor public spaces, while also reducing indoor cooling requirements. Buildings are constructed using low-carbon cement, recycled aluminium and sustainably sourced wood, while energy-efficient buildings mean Masdar City consumes 40% less energy and water than other developments in the UAE of a comparable size.

In addition, the city is powered in part by clean energy generated from an on-site 10MW solar power plant and a 1MW solar rooftop system. With such a commitment to urban sustainability, Masdar City represents a unique living laboratory for industry and academia to study how cities use, conserve and share resources, and for product developers to evaluate technologies in a real-world setting.

The city also offers a range of investment opportunities to purchase or lease land plots to develop projects designed to enhance mixed-use community living. Some of these investment opportunities include apartments, office buildings, schools, retail outlets, light industrial facilities, research and development initiatives, and hotels.

Masdar CITY

International Solar Energy Society

I would like to welcome all of you to the International Solar Energy Society (ISES) Solar World Congress (SWC) 2017 and the International Energy Agency Solar Heating and Cooling Programme's 2017 Conference on Heating and Cooling for Buildings and Energy. The Masdar Institute is serving as the local host of this joint conference, taking place here in the dynamic city of Abu Dhabi, United Arab Emirates on 29 October – 2 November 2017.

As with previous ISES SWCs, this joint conference will continue a long tradition of connecting the renewable energy research and academic community with decision makers, financiers, and practitioners. You will find a rich opportunity to network with researchers, solar practitioners, decision makers and financiers to learn more about best practices and the future opportunities for all solar technologies.. The joint conference program includes a variety of events, such as parallel technical oral and poster sessions that provide the latest renewable energy research results, keynote speeches discussing specific technologies, unique workshops and side events addressing critical cross-cutting topics, and a line-up of world-renowned experts at the plenary sessions. All of these events demonstrate how we are heading towards 100% renewable energy for meeting all of our end-use energy requirements, encompassing the power, heating, and transportation sectors. In addition, networking and social events, and technical tours have been designed to enhance your career and business development opportunities.

ISES is committed to achieving the vision of 100% renewable energy for all, used efficiently and wisely. This vision is particularly critical as the world addresses the challenges of mitigating climate change under the initiatives agreed to in the Paris Agreement signed in 2015.

Nevertheless, a transformation of our energy system is already occurring due to the strong public demand and to the efforts of grassroot activists as well as regional and national governments for creating a carbon-free energy system. This joint conference will address the key ingredients of this transformation: technology innovation, financial opportunities, policy developments, and, most important, community and grass-roots actions that are leading to case studies and best practices that already are leading towards achieving a 100% renewable energy system in cities and regions. Nevertheless, many challenges remain, and the joint conference will bring to the forefront a dialogue among diverse experts to discuss and formulate actions to meet these challenges.

I wish you all a very successful and inspiring conference experience.

Dr. David Renné, President
International Solar Energy Society

IEA Solar Heating and Cooling Programme

On behalf of the IEA Solar Heating & Cooling Programme, welcome to the 5th International Conference on Solar Heating and Cooling for Buildings and Industry (SHC 2017). For this conference, we are fortunate to be holding it together with the ISES Solar World Congress 2017. The joint conference is certain to reach a wider network of participants interested in exploring technical, industrial and policy synergies relevant to renewable energy deployment.

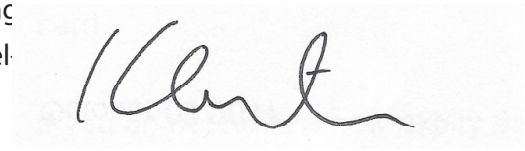
This year's conference is taking place in the United Arab Emirates and recognizes the leadership of the joint conference host, Masdar Institute, in the journey from fossil fuels to renewables.

Since 1977, the IEA Solar Heating & Cooling Programme has conducted international collaborative research to expand the use of solar energy for buildings and industry. Our global network of 21 countries and 6 international organizations has completed more than 45 research and dissemination projects. The current 10 research projects include approximately 600 participants, of which more than 25% are from industry.

With ISES and Masdar Institute, the IEA SHC Programme has strong partners and SHC 2017 will once again serve as a platform to build understanding, collaboration and strong cooperation between research and industry.

SHC 2017 is sure to inspire you as you participate in the conference sessions and discussions and learn firsthand about the developments in the Middle East. It is the goal of SHC 2017 to have you leave ready to help deploy solar thermal technologies to become an increasingly significant contributor to a sustainable and renewable energy future.

I am looking forward to meeting, discussing and learning with you at this joint conference.



Ken Guthrie, Chair
IEA Solar Heating and Cooling Programme

Khalifa University of Science and Technology

It is with great pleasure that I welcome you to the joint International Solar Energy Society (ISES) Solar World Congress 2017 and International Energy Agency (IEA) Solar Heating and Cooling Programme's 2017 Conference on Heating and Cooling for Buildings and Energy. The theme of the joint event, "innovation for the renewable energy transformation", is perfectly aligned with the research and educational ambitions of the Masdar Institute of Science and Technology, which is this year's conference host and also now part of the new Khalifa University of Science and Technology.

The United Arab Emirates (UAE) is uniquely positioned to serve as the host country for this key event. The UAE Energy Strategy 2050 was launched in 2017 with the ambition to increase the contribution of renewable energy in the country's energy mix to 44 percent by 2050 while simultaneously slashing the country's carbon footprint from power generation by 70 percent in the same timeframe. Solar energy will be the primary form of renewable energy within this strategy and the UAE's commitment to solar has been visible through action, starting with establishment of the Masdar Initiative in 2006. More recently, the 100MW Shams 1 concentrated solar power plant in Abu Dhabi began operations in 2013 and the first three phases of the Mohammed bin Rashid Al Maktoum (MBR) Solar Park, which will ultimately have 5,000MW of solar energy capacity by 2030, were tendered and awarded between 2013 and 2016. In 2017, a 1,170MW solar PV power plant was tendered and awarded for development in Abu Dhabi and a 700MW Concentrated Solar Power (CSP) plant with storage was tendered and awarded for development in Dubai. This CSP power plant, which when operational will deliver electricity at a record low price for this technology of 7.3 US cents per kilowatt hour (kWh), will be part of the fourth phase of the MBR Solar Park.

In addition to these notable achievements, the global headquarters of the International Renewable Energy Agency (IRENA) is hosted in Abu Dhabi's Masdar City. The hosting of IRENA in Abu Dhabi is a reflection of the UAE's commitment to expanding access to sustainable, clean energy both domestically and internationally.

Strategically located at the crossroads of the world, Abu Dhabi is a perfect meeting place to bring together global energy experts. As the host of the annual Abu Dhabi Sustainability Week (ADSW) and the 2016 SolarPACES conference, Abu Dhabi will undoubtedly support this joint event in meeting with similar success and provide participants with the ideal setting to engage in networking, partnership development and exchange of ideas. I wish you a successful and enjoyable conference.

Abstract

Peak electricity demand has become a global concern. It causes grid transmission constraints and congestion, and also increases the cost of electricity for all users, specifically industrial consumers with high peak demands. Time-of-use demand side management coupled with thermal energy storage and off-grid solar PV can be an alternative to increase the flexibility and security of the whole energy system. The aim of the current paper is to study the potential of implementing time-of-use demand side management coupled with thermal energy storage and solar PV technologies using optimization techniques for shifting electricity peak loads of cooling processes in an industrial unit. It was found that considerable reductions can be achieved in electricity power demands in different tariff periods using optimization-based demand side management (DSM) together with thermal energy storage and off-grid solar PV. In addition, it was seen that coupling cold thermal energy storage and solar photovoltaic technologies is more energy-beneficial than using them separately.

Keywords: Thermal energy storage, solar PV, time-of-use DSM, optimization, peak-load shifting.

1. Introduction

In developed nations electricity plays an important role to economic growth. A considerable rise in electricity demand can be seen in all end-use sectors, and further on, the share of electricity is steadily increasing in all sectors (IEA, 2016). In addition, increasing wealth in developing nations are likely to lead to bigger demand for energy services using electricity, such as cooling and refrigeration. The industry sector is one of the major energy-consuming sectors in the world with about one third of total final energy consumption and almost 40% of total energy-related CO_2 emissions. Reducing these hazardous emissions due to high non-renewable generations is an important issue in the global climate system. For this reason, many governments in the world are exploring alternatives to slow down the global warming by enforcing new rules and regulations for different sectors.

Peak electricity demand is a global policy concern which creates transmission constraints and congestion, and raises the cost of electricity for all end-users (Strengers, 2012). In addition, a considerable investment is required to upgrade electricity distribution and transmission infrastructure, plants and build non-renewable power generation to provide power during peak-demand periods (Strengers, 2012). For this reason, commonly service suppliers charge a higher price for services at peak-time than for off-peak time to compensate for the costly electricity generation at peak hours (Kim et al., 2016). So that, reducing some of this peak demand would benefit the whole energy system (Faruqui et al., 2007).

Solar PV is becoming an important technology in the world energy market for electricity generation, and it has proven its capability to reduce energy costs and hazardous energy-related emissions over time and this is projected to continue. However, in systems with high shares of PV generation, variability and uncertainty in electricity generation within the system may occur because of weather conditions. To overcome this uncertainty energy storage could be a solution to match energy supply and demand. As an example, battery storage technologies could be used to store generated electricity by solar PV, however, currently large-scale electricity storage technology is expensive and needs further technology development (Hameer and van Niekerk, 2015), as a result, electricity storage has limited potential and the generated electricity has to be consumed instantly

doi:10.18086/swc.2017.01.01 Available at http://proceedings.ises.org

(Faruqui et al., 2010).

Demand side management (DSM) is a proactive way to increase the energy efficiency among customers in the long-term (Barbato and Capone, 2014), and can reduce both the electricity peak power demand (kW) and the electricity consumption (kWh) (Warren, 2014; Zhou and Yang, 2015). Among DSM methods techniques load shifting is the most effective load management technique (Esther and Kumar, 2016) which can enhance the demand flexibility without compromising the stability and continuity of the process and, furthermore, a highlighted feature of DSM is that it can be 100% efficient, since no energy conversion to and from an intermediate storable form is required (Lund et al., 2015). However, in order to shift loads from high-demanding hours (on-peak hours) to low-demanding hours (off-peak hours), specifically for industrial and commercial units with considerably high power demand profiles due to their industrial processes, high-capacity energy storage is an essential component to provide an effective and continuous load shifting.

A considerable number of studies have been devoted to investigate the benefits of thermal energy storage (TES) for renewable energies applications and system integration. As an example, Alva et al. (Alva et al., 2017) extensively reviewed the application of TES materials and systems for solar energy applications. Additionally, Li and Zheng (Li and Zheng, 2016) studied different methods of TES system integration for building and industry applications. However, the application of cold storage systems has been broadly developed in the power generation sector, the building sector, and the industrial sector because of their high potential of cooling load shifting (Oró et al., 2012), and decreasing greenhouse gas emissions (de Sisternes et al., 2016). For this reason, there is growing interest in using DSM techniques together with TES, battery storage, and solar PV technologies for industrial and commercial sectors. However, there has been little discussion about coupling DSM together with solar PV and cold TES technologies to reduce peak loads in the industry sector and enhancing the overall performance of the energy system through interconnection of these technologies (Arteconi et al., 2017). Therefore, further research and technology advancement are required for electric load management to address the potential peak load shifting and energy savings considering the new time-of-use tariff structure and elevated electricity prices, high surplus demand charges, and variable solar PV share and its uncertainties in the energy system (Arteconi et al., 2012).

The objective of the current study is to address the potential for applying optimization-based time-of-use DSM in the industry sector to reduce peak electricity demands and eventually to decrease the annual electricity bill. Particularly of interest are, on one hand, to reduce contracted power demands and to shift electrical chiller peak loads from high-price times (on-peak hours) to low-price times (off-peak hours), by taking advantage of cold TES (sensible systems, ice or phase change materials) and off-grid solar PV; and on the other hand, to determine the optimum combinations of contracted power at different tariff periods by integrating TES and solar PV technologies with different capacities, and considering the solar PV variations and surplus charges of power demand.

2. Methodology

2.1. Case study

To give an estimation of the annual energy bill for an industrial consumer, it was assumed that for running its industrial processes, a conventional energy system with no demand management facilities, neither solar PV nor TES system is used. So that, the industrial consumer directly uses the electricity from the grid to run its processes whenever it is required and without considering the on-peak, mid-peak and off-peak demand and energy tariff periods (Figure 1a). The industrial processes take place from 8:00 to 17:00 all days except Saturdays and Sundays, requiring 450 kW of electric demand for cooling processes. To calculate the electricity consumption, the Spanish electricity tariff structure (6.1A time-of-use tariff structure) (Real Decreto 1164/2001, 2016) has been used. The tariff structure is divided into six different tariff periods, and consumers pay through the bill the energy cost and the demand cost. Further explanations of the above-mentioned tariff structure are provided in Section 2.4.1. Assuming that for all tariff periods the reference industrial unit contracts 450 kW power demand with 100% of load factor, the annual electricity bill for operational hours can be calculated using eq. 1:

$$Elec_{tot} = (E_p + E_e) + \left[(E_p + E_e) \times \text{VAT}\right] \quad \text{(eq. 1)}$$

$$E_p = \sum_{i=1}^{i=6}\left(P_{demand_i} \times CP_{p_{demand_i}}\right) \quad \text{(eq. 2)}$$

$$E_e = \sum_{i=1}^{i=6}\left(P_{energy_i} \times CE_{p_{energy_i}} \times h\right) \quad \text{(eq. 3)}$$

where $Elec_{tot}$ is annual electricity cost, E_p is power demand cost, E_e is energy consumption, VAT stands for value added taxes; P_{demand_i} stands for power contracted in different tariff periods; P_{energy_i} stands for consumed energy in different tariff periods; CP and CE are cost of power in kilowatt (kW) and cost of energy in kilowatt-hour (kWh), respectively, for period I, as explained in details in Section 2.4.1.

Three different optimization scenarios were considered to optimally analyze the possibility of shifting on-peak loads from daytime to nighttime by adopting DSM system on the basis of time-of-use tariffs and compare them with the reference model (Figure 1a):

- Scenario 1. time-of-use tariff DSM coupled with only cold TES system (Figure 1b).
- Scenario 2. time-of-use tariff DSM coupled with only off-grid solar PV (Figure 1c).
- Scenario 3. time-of-use tariff DSM coupled with both cold TES and off-grid solar PV systems (Figure 1d).

In Scenario 1 (Figure 1b), the cold TES tank has to be charged at nighttime during off-peak period and be discharged during day especially at on-peak period or the most expensive hours of the electricity tariff. In Scenario 2 (Figure 1c), the feasibility of reducing the energy costs by applying off-grid solar PV has been assessed. In the current study the off-grid solar PV was considered because in the selected tariff structure there is insufficient incentive for grid-connected solar PV system. Eventually, in Scenario 3 (Figure 1d) the possible economic benefits by coupling both cold TES and off-grid solar PV have been investigated. In addition, in should be noted that in the present study the costs of equipment and payback period as well as its environmental impact are not taken into account and might be covered in future studies. Figure 1 illustrates a scheme of the optimization scenarios.

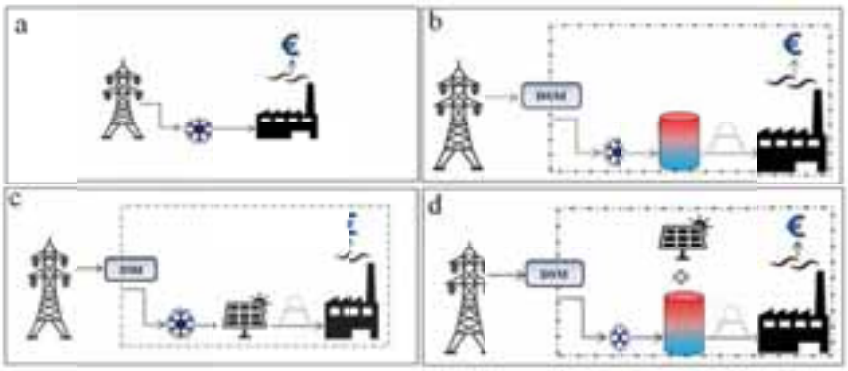

Figure 1. Schematic view of the methodology.

2.2. Simulation of PV module

The electricity generation by solar PV, was simulated using TRNSYS v17 (Klein, 2010). This software has an extensive library of components in which appropriate models could be selected for simulating thermal and electrical energy systems. The potential electricity generation from PV modules can be calculated using Type 94a which models the electrical performance of a photovoltaic array and could be used in simulations involving electrical storage batteries, direct load coupling, and utility grid connections. It applies equations for an empirical equivalent circuit model to predict the current-voltage characteristics of a single module. This circuit consists of a DC current source, diode, and either one or two resistors. The strength of the current source is dependent on solar radiation, and the IV characteristics of the diode are temperature-dependent (TRNSYS 17, 2016). Sunrise SR-M762315-B solar PV (Sunrise, 2016) technical data as shown in Table 1 was introduced to Type 94a and four different nominal power of 25 kWp, 50 kWp, 80 kWp, and 100 kWp were considered. Further on, an array slope of 40º and azimuth of 180º were taken into account. Simulations were performed using time steps of 15 minutes for fifteen consecutive years (1991-2005) using historical solar radiation data of Denver derived from National Renewable Energy Laboratory (NREL) weather data base (National Renewable Energy Laboratory, 2007). Denver, Colorado is dominated by BSk climate classification according to Köppen

Geiger classification and could be representative of climate condition of Lleida province, Spain.

2.3. Thermal energy storage model

A cold thermal storage was integrated into the system with the aim of shifting the electric demand (kW) and the energy consumption (kWh) from on-peak and mid-peak to off-peak hours. The storage model and corresponding charging/discharging modes are similar to the method presented by Ihm et al. (Ihm et al., 2004). The storage capacity can be characterized by a charge/discharge rate as shown in eq. 4. In addition, to convert thermal load to electrical load an average coefficient of performance (COP) of 3 was considered. Then, the electrical acquired energy could be calculated using eq. 5.

Table 1. Sunrise SR-M672315 module specifications (Sunrise, 2016).

Maximum power [W]	315

$$\dot{Q}_{storage} = x \frac{SL}{\Delta t} \quad \text{(eq. 4)}$$

$$COP_{ave} = \frac{SL}{Elec_{ac}} \quad \text{(eq. 5)}$$

$$f(x) = \begin{cases} inactive\ mode, & x = 0 \\ charging\ mode, & x > 0 \\ discharging\ mode, & x < 0 \end{cases}$$

where $\dot{Q}_{storage}$ is the TES charge (+)/discharge (−) rate (kW), SL is the cold TES capacity (kWh), x the charge/discharge rate (fraction), Δt the simulation time step (15 minutes), COP_{ave} the average thermal to electrical load conversion COP, $Elec_{acq}$ the acquired electric energy (kWh).

The design is based on three operation schedules over the continuity of charge/discharge rates:

- Inactive mode: when the TES system is not working, for instance at the weekends, the charge/discharge

rate is set to zero in a sub-hourly schedule defined specifically for the TES operation.

- Charging mode: the dedicated TES chiller integrated in the TES module produces cold at the charging rate, *x*, during off-peak hours (the cheapest period) with the maximum charging rate of 375 kW.
- Discharging mode: in this stage the TES system supplies cooling at different capacities to meet the cooling demand during on-peak and mid-peak hours (avoiding or reducing compressor operation). In the present study, the economic impact due to the use of various TES capacities (75-9000 kWh) on the final electricity bill will be analyzed.

The steady-state storage model does not take into account the external weather conditions such as dry bulb temperature, humidity, etc. Moreover, charging and discharging efficiencies were kept a constant value of 100% throughout time steps.

2.4. Time-of-use tariff structure

2.4.1. The electricity bill

In many countries the electricity bill consists of an energy charge, peak demand charge, and taxes. In Spain, taxes are significant and include an electricity tax of 5.1% and a value-added tax (VAT) of 21%. Depending on which demand category the consumer fits in, it determines how many charge categories are applied to the contract. The industry sector has 6.1A demand category which is classified in periods P1 to P6. In each charge category a peak and energy charge is applied. Further on, for this demand category incentives are applied. Figure 2 shows the hourly and monthly periods during which each tariff structure is applied. PX refers to the tariff price profile consisting of an on-peak, mid-peak and off-peak price and P6 refers to all prices at off-peak rates. The tariff consists of both an energy price and a demand price per period as shown in Table 2.

Month/Hour	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23

Energy	0.120	0.096	0.092	0.074	0.0708	0.065	€/kWh	Standard free price

2.4.2. Charges due to power excess (surplus charges)

In case that an industrial consumer requires more demand that it has contracted in each determined time interval (for some minutes or even hours), a penalization due to power excess is charged to the bill. This penalization is calculated according to the power contracted in each tariff period and, if applied, depending on each tariff period, the actual demanded power rates are metered using electricity metering equipment. The billing of the excesses of power for the 6.1 tariffs is calculated according to the formula established in Royal Decree 1164/2001 (Real Decreto 1164/2001, 2016) (eq. 6 and eq. 7), and it is measured every 15 minutes:

$$F_{ep} = \sum_{i=1}^{i=6} K_i \times 1.4064 \times A_{ei} \qquad \text{(eq. 6)}$$

where F_{ep} stands for charges in € and A_{ei} is a factor that weights excess of demand depending on the period, K_i is

the coefficient that takes the values depending on the tariff period *i* as shown in Table 3, A_{ei} is calculated according to the following conditional equation:

$$A_{ei} = \begin{cases} 0, & P_{dj} <= P_{ci} \\ \sqrt{\sum_{j=1}^{j=6} (P_{dj} - P_{ci})^2}, & P_{dj} > P_{ci} \end{cases} \quad \text{(eq. 7)}$$

where P_{dj} is demanded power in each quarter of hour which is excessed (higher than P_{ci}), P_{ci} is contracted power in each period and in the considered period.

Table 3. K_i coefficients according to the tariff periods.

Period (i)	1	2	3	4	5	6
K_i	1	0.5	0.37	0.37	0.37	0.17

These powers are expressed in kW and the excesses of power are billed monthly. For tariffs 6.1 at every breach is charged a penalty i.e. every 15 minute breach. Thus, it means that if the user demands over the contracted power during one hour, the penalty is charged four times. However, there is an optimum contracting demand that reduces the energy cost taking into account the penalties. The application of optimized DSM together with TES and PV can optimally find the contracting demands in each period and can improve the overall performance of the energy system.

2.5. Optimization

It could be understood that for given electricity consumption requirements, an optimization problem can be derived based on the power contracting plan, i.e. how much power is contracted for each one of the 6 period tariffs. The optimization problem results deterministic when no PV production is considered. Otherwise, PV uncertainty will lead to stochastic optimization. In both cases, constraint integer programming (CIP) was used as a novel paradigm that integrates constraint programming, mixed-integer programming (MIP), and satisfiability modeling and solving techniques in order to model and solve this problem (Achterberg, 2008; "SCIP Optimization Suite," 2017). Without PV generation, the system may be described as sets, parameters and functions as follows:

$P = \{P_1 .. P_6\}$, is the set of tariff periods; $CE_i, i \in \{1..6\}$ is the cost of energy consumption during period P_i according to Table 2 in €/kWh; $K_i, i \in \{1..6\}$ is the coefficient as defined in Table 3; *SL* is the cold TES storage capacity in kWh; *H, D* and *M* are the set of hours, days and months respectively; *T=H*D*M* is the set of hour periods in a year; $Period: T \rightarrow P$, is a function that maps an hour period to its corresponding tariff as corresponding to Figure 2; $C_i, i \in H$, is the required energy during an hour as shown in eq. 8:

$$C_i = \begin{cases} 450kW \cdot h, & i \in 8..17 \\ 0, & otherwise \end{cases} \quad \text{(eq. 8)}$$

Therefore, the cost of contracting power (*CP*), and the cost of consumed energy can be expressed as eq. 9 and eq. 10, respectively:

$$CP = \sum_{i=1..6} CP_i \cdot PC_i \quad \text{(eq. 9)}$$

Subjected to these constraints: $CP_6 \geq CP_5 \geq CP_4 \geq CP_3 \geq CP_2 \geq CP_1$

$$CE = \sum_{t \in T} S_t \cdot CE_{Period(t)} + K_{Period(t)} \cdot 1.4064 \cdot f\left(S_t - PC_{Period(t)}\right) \quad \text{(eq. 10)}$$

Subjected to the surplus charge constraint of $f(x)$ that is applicable when supplied energy from grid at time *t* is higher than the contracted power in period *i* (PC_i) as shown in eq. 11:

$$f(x) = \begin{cases} x, & x > 0 \\ 0, & x \leq 0 \end{cases} \quad \text{(eq. 11)}$$

where $PC_i \in R, i \in 1..6$, is the contracted power for tariff P_i; $S_t \in R, t \in T$, is the supplied energy from the grid in time *t.* When suitable, one can also denote S_t as $S_{h,d,m}$.

Finally, the following assumptions have been made: 1. The TES operation hours is between 00:00 to 07:00. This is an obvious optimal assumption since it is the off-peak period and no demand exists. 2. The stored energy can only be consumed during the same day. The objective is to find an optimum assignment of $PC_i \in R, i \in$

1..6, that minimizes CP+CE, which could be written as eq. 12, subject to constraint shown in eq. 13:

$$\min_{PC_i}(CP + CE) \quad \text{(eq. 12)}$$

$$SL > \sum_{h=0}^{7} S_{h,d,m} > \sum_{h=8}^{17} C_h - S_{h,d,m}, \forall (d,m) \in D * M \quad \text{(eq. 13)}$$

For example, for each day, the stored energy must not surpass the storage limit and must supply the eventual lack of obtained energy from the grid. In order to reduce the number of variables, symmetries may be considered. As energy requirements are invariant from day to day (C_i), the number of variables can be drastically reduced. More specifically, $S_i$can be indexed in *H*M* instead of *T*. We encoded and solved eq. 12 and eq. 13 with SCIP version 3.2.0 [64] in a 1.9 GHz processor. The problem results in 581 variables and 484 constraints, being solved in less than 2 seconds.

However, when solar PV production is considered, it can be taken into account as a multivariate random variable $PV_y = (pv_{1,y}..pv_{|T|,y})$, being $pv_{i,y}$ the PV production at hour $i \in T$in year *y*. Then, for a given year *y*, the eq. 14 could be written as:

$$SL > \sum_{h=0}^{7} S_{h,d,m} > \sum_{h=8}^{17} C_h - S_{h,d,m} - pv_{h,d,m,y}, \forall (d,m) \in D * M \quad \text{(eq. 14)}$$

When PV production is available over a set *Y* of years, we compute the expected optimization using the cost function presented in eq. 15:

$$E\left[\min_{PC_i}(CP + CE)\right] = \frac{1}{|Y|}\sum \min_{PC_i}(CP + CE) \quad \text{(eq. 15)}$$

subject to constraint as stated in eq. 14. Under this scenario, symmetry reduction as previously stated is no longer feasible and each year optimization problem results in 16469 variables and 16846 constraints, with a resolution time from 5 to 25 minutes depending on SL value.

3. Results

3.1. Economic benefits of optimized DSM with cold TES (Scenario 1)

In this section, the economic benefits due to the use of optimization-based DSM with only cold TES are presented. Figure 3 shows that the amounts of economic savings increase linearly with the increase of TES capacity. From Figure 3 it is apparent that with the increase of storage capacity the annual economic savings increase correspondingly from 418 € (below 1%) per year, in case of 75 kWh capacity of TES, to 53670 € per year (about 30%), in case of 3000 kWh TES. For example, adding 1500 kWh of TES can lead to about 8945 € per year cost savings, and when the storage capacity increases to 6000 kWh these savings rise to 3578 € per year.

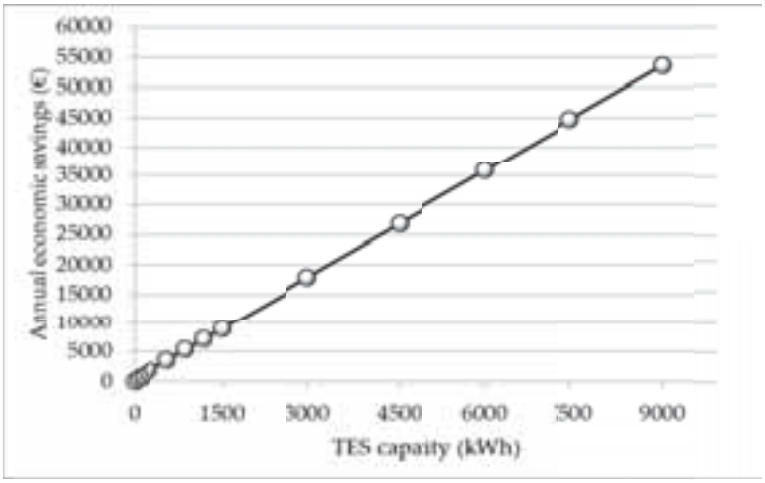

Figure 3. Economic benefits by using DSM and cold TES.

3.2. Economic benefits of optimized DSM with solar PV (Scenario 2)

In this section, the economic benefits due to the use of optimization-based DSM with off-grid solar PV system are presented and the results are shown in Figure 4. Off-grid solar PV yields economic benefits ranging from 4200 € to 16900 € in Denver.

It can be seen that adding 50 kW of off-grid solar PV could achieve annual cost savings of 8465 € in Denver. Compared to TES, lower savings could be achieved using off-grid solar PV. Actually, due to variable PV generation, the electric power demand contract cannot be decreased considerably, since in occasions of poor electricity generation from PV surplus penalties may apply to the electricity bill. However, solar PV can yield to substantial savings when there is enough solar radiation to produce electricity and reduce the real-time energy needs.

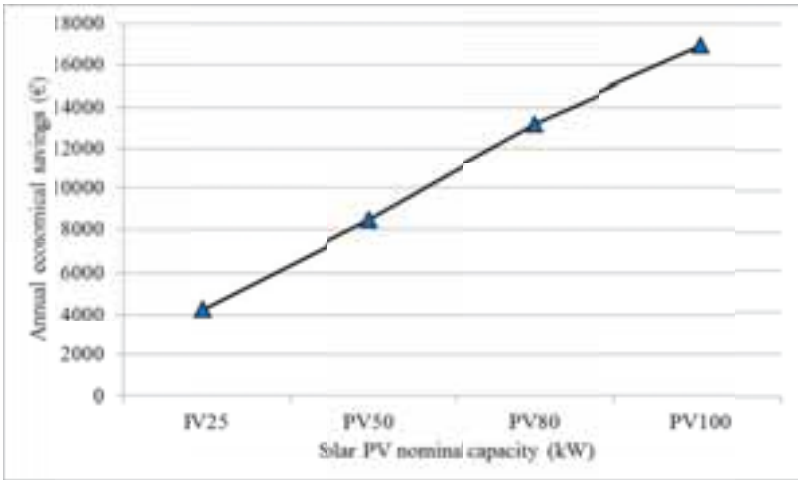

Figure 4. Economic benefits by using DSM and off-grid solar PV.

3.3. Economic benefits of optimized DSM coupled with cold TES and solar PV (Scenario 3)

In this section, the economic benefits due to the use of optimization-based DSM with cold TES coupled with off-grid solar PV system for an industrial consumer have been presented (Figure 5). In general, it can be seen that the annual cost savings have a linear correlation with TES capacity and solar PV nominal capacity. With the increase of TES and PV capacities the annual economic savings increase correspondingly.

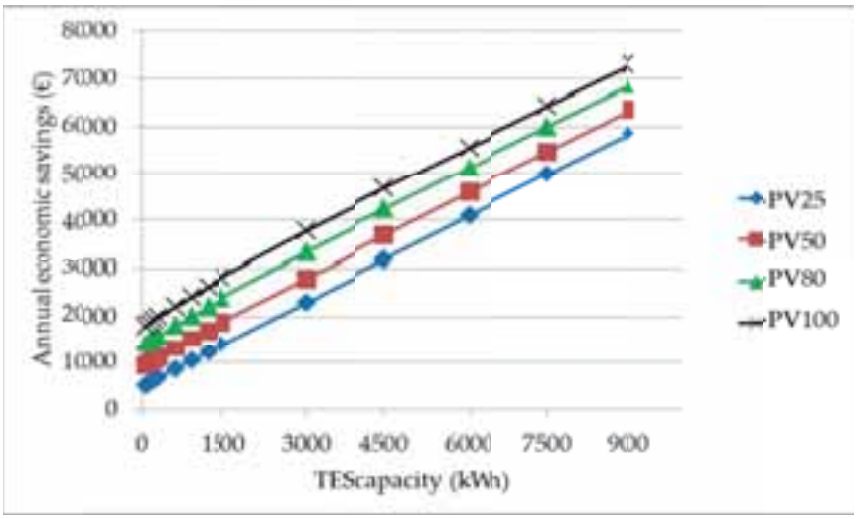

Figure 5. Economic benefits by using DSM coupled with cold TES and solar PV, Denver.

An interesting and very important issue that can be obtained from the results presented in this section is that when TES and PV technologies coupled together higher reductions in power contract demands could be achieved. Accordingly, coupling PV and cold TES together with an optimized DSM led to higher annual electricity cost reductions both for demand and energy terms. Further on, the authors would like to mention that important annual demand cost savings were achieved thanks to the application of TES, nevertheless, it was not

limited to only the demand term, but also, considerable cost savings can be observed for the energy term which mainly comes from renewable solar PV generation.

3.4. Improvements by coupling cold TES and solar PV technologies

An important issue that should be discussed herein is how the combination of solar PV and short-time cold TES technologies coupled to an appropriate time-of-use DSM can shift peak demands and reduce energy consumption and eventually improve the whole energy system. To find economic benefits due to interconnection of these two technologies, annual cost savings due to integration of only cold TES (Scenario 1) and only off-grid solar PV (Scenario 2) should be summed; and then, subtracted from annual cost savings due to coupling cold TES with solar PV (Scenario 3). Actually, these cost savings demonstrate how the interconnection of two renewable technologies together with an optimized DSM, can be energy-beneficial compared to when they are used individually.

The results presented in Figure 6 show the annual cost saving improvement ratios in Denver. In fact, when the solar PV share of the system is smaller, lower storage capacity is needed to provide the continuity and smoothness of supply in the system. The warm color area in the color map highlights the maximum improvement that could be achieved by coupling cold TES and solar PV technologies together. In general, by the increase of solar PV share higher short-term TES is required. In other words, the higher the dependency of energy system on the solar PV, the higher the storage is needed to ensure the security of electricity supply of the system without intermittency and hence avoid possible penalties.

For instance, in case of using 1500 kWh of TES a total annual savings of 8945 € could be achieved. On the other hand, when only off-grid solar PV of 50 kW is considered savings of 8465 could be achieved in Denver. On the other hand, when TES and solar PV technologies are coupled together these savings increase to 18803 €, which is about 7% higher than the sum of benefits achieved by using them separately (Figure 6).

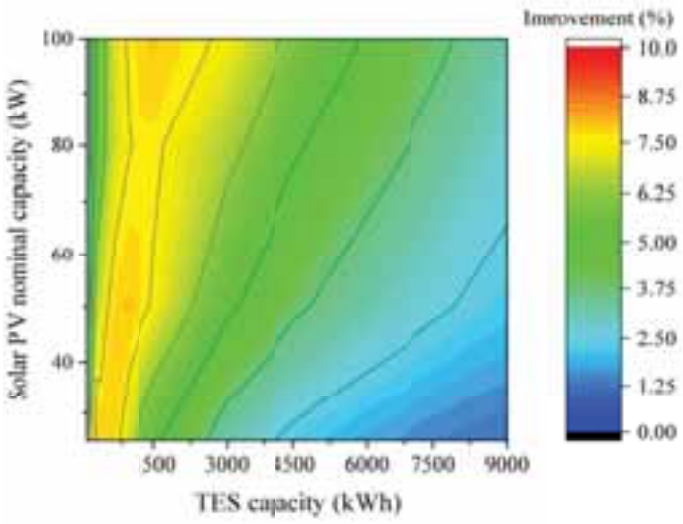

Figure 6. Annual electricity saving improvement by coupling cold TES and solar PV technologies, Denver.

4. Conclusions

In the present study, an optimization-based time-of-use DSM combined with short-term cold TES and off-grid solar PV technologies is used to shift on-peak electricity demand of an industrial consumer. Using numerical optimization and simulation it was found that both cold TES and off-grid solar PV coupled with an appropriate tariff structure can lead to annual electricity cost savings. However, savings attributed to the integration of cold TES are generally higher than those achieved by only off-grid solar PV. In addition, solar PV without storage can reduce the energy term but not significantly the power term of the energy bill. However, it should be highlighted that when cold TES and solar PV are coupled together, further economic benefits could be achieved in comparison with using these two technologies independently.

5. Acknowledgments

The work partially funded by the Spanish government (ENE2015-64117-C5-1-R (MINECO/FEDER), ENE2015-64117-C5-3-R (MINECO/FEDER), and TIN2015-71799-C2-2-P). The authors would like to thank the Catalan Government for the quality accreditation given to their research group (2014 SGR 123). Abstract

The rapid deployment of grid-connected roof-top photovoltaic systems in Dubai, as part of "Shams Dubai" initiatives and the anticipated high penetration of distributed PV generation have both raised several challenges and urged the need to study the technical solutions to address higher PV penetration levels. The intermittent nature of PV distributed generation could adversely impact the voltage profile and stability of distribution feeders throughout the daily load cycle resulting in voltage fluctuations and flicker that violate the established utility guidelines for voltage regulations. Moreover, the existing distribution networks were not designed to operate with intermittent sources of generation at medium or low voltage levels.

This paper discusses several smart grid strategies for Distributed Energy Resources (DER) integration including advanced control of smart inverters, automated demand response, and technical and regulation enhancement for DER integration to improve the PV hosting capacity of distribution feeders and enable wider deployments of roof-top PV systems, thus achieving successful renewable transformation of the existing power systems. A survey was conducted to investigate the existing solar PV projects in Dubai and identify the key challenges of the existing interconnection standards. The initial survey results and recommendations for PV integration strategy and grid interconnection regulations enhancement are presented.

Keywords: Grid-connected PV integration, DER integration, smart grid strategy, Shams Dubai, advance inverter management, DER interconnection regulations.

1. Introduction

In the UAE, the use of clean energy sources and low-carbon electrification are receiving increasing attention with the clean energy target set to increase to 24% by 2021 compared to about 1% toady. As part of the UAE's commitment to the Paris Climate Agreement, the clean energy strategy 2050 emphasised on diversifying the energy mix with more focus on clean energy shares. 25% of Dubai's total energy by 2030 and 75% by 2050 is predicted to come from renewable energy sources in order to transform Dubai into a global centre of clean energy with the smallest carbon footprint in the world (Dubai Carbon, 2017).

Shams Dubai programme was launched in 2015 to encourage household and building owners to install PV panels to generate electricity to feed their own loads and export the surplus to the utility grid. In two years, Four hundred and thirty five buildings have already installed photovoltaic panels on their roofs and generated a total capacity of 15.6 Megawatts (Gulf News, 2017).

The existing energy policy and grid standard of renewable distributed energy resources (DER) interconnection in Shams Dubai regulations imposed some restrictions to limit the capacity of distributed PV connections compared to the total connected loads of the customer in order to avoid the well-known concerns of integrating high PV penetration into distribution feeders (DWEA Shams Dubai, 2015 & 2016). However, those restrictions could limit larger PV deployments and hinder the achievement of the strategic targets of Shams Dubai initiatives to increase Dubai's share from clean energy sources to 75% by 2050. Smart grid technologies provide a more viable solution to address DER integration challenges at high PV penetration levels without limiting PV grid-connected capacity.

2. Integration Strategies for PV distributed generation

Electric utilities around the world are seeking to develop strategies to increase resilient integration of DER integration while maintaining the grid performance. The IRENA study on PV integration emphasised on the importance on developing integrated strategy that covers technical, regulatory and economic aspects in order to tackle PV integration challenges successfully. The common theme of all implemented measures was to introduce additional flexibility into the existing power systems to accomdate renwable distibution genersation at different voltage levels (IRENA, 2017).

A study by the IEA's photovoltaic power systems programme on urban photovoltaic electricity policies concluded that GC-PV can be the solution to growing demand in the dense urban environment. In the perspective of a large photovoltaic deployment, it is quite important to have upfront good integration policies to assure that GC-PV is deployed with the maximum benefit to the community while reducing actual installation barriers associated with grid codes and permits. (IEA PVPS, 2009 & 2016). Sweco et al. investigated DER integration strategy in order to provide flexibility to the distribution power system and highlighted that the technologies needed for DER integration are available; the key challenge is to adjust to the regulatory framework and DER interconnection policy to make the market ready (Sweco et al., 2015). A survey was conducted by the authoers to investigate the strategies that provide flexibility measures for DER integration in which smart grid experts were asked about the following smart grid stregies as shown in Figure 1.

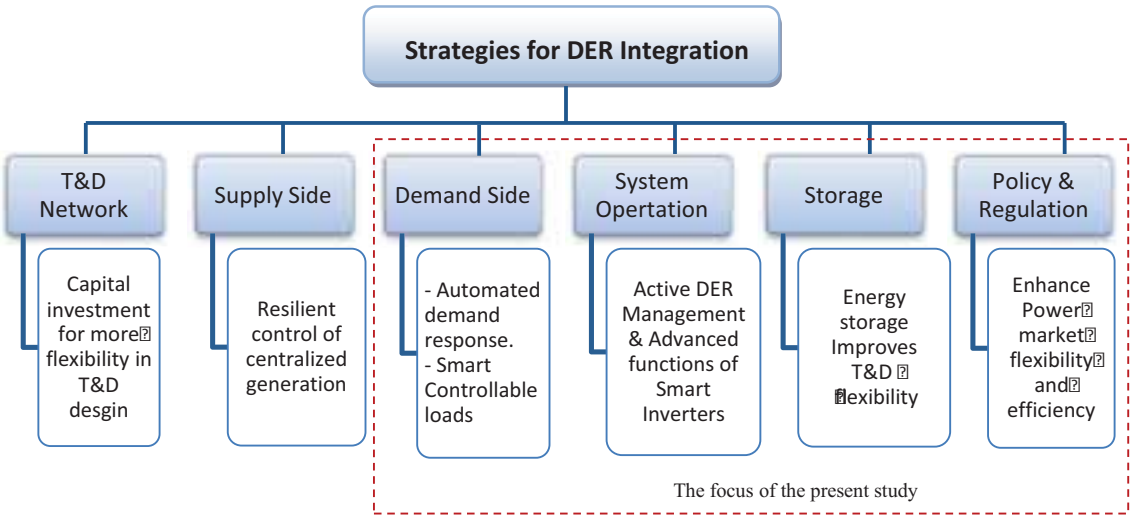

Figure 1: Smart Grid Strategies to improve the flexibility of the grid systems and DER Integration

Supply side and T&D networks integration strategies often require large capital investments are not considered for low and meduim DER penetration levels. This paper focuses on DER integration strategy based on advanced control of smart inverters, and policy/regulations enhacement to cope with the technology advancement. The majority of respondents (72%) viewed that advanced inverter functions offer a cost-effective solution to address the challenges of DER integration. Fifty eight perecent (58%) of the respondents considered that energy storage are not currently economical for grid-connected PV systems specially in Dubai and the gulf region.

2.1 PV Hosting Capacity of Distribution Feeders:

The concept of PV hosting capacity is well established in the literature and can be defined as the maximum limit on the amount of photovoltaic generation that can be integrated into a distribution feeder with no violation of grid operational conditions. (Whitaker et al. 2008; Reno et al. 2013; Dubey, Santoso, and Maitra 2015 ; Obi & Bass 2016; Palmintier et al. 2016a; Pecenak, Kleissl and Disfani, 2017)

The term photovoltaic penetration (PV_{pen}) could be defined as the ratio of the installed PV power to the peak load of a feeder (Pecenak, Kleissl and Disfani, 2017). Instantaneous PV_{pen} at a given time (t) can be obtained as:

$$PV_{pen}(t) = \frac{PV_{ins}(t)}{Load(t)} \text{(Eq 1)}$$

Where P_V is the photovoltaic installed power. Percentage penetration level % PV_{pen} for a given feeder configuration can be approximated as given in Eq2 below.

$$\%PV_{pen} = \frac{P_{V(Peak)}}{Load_{(peak)}} \text{x } 100 \text{(Eq 2)}$$

Many simulation studies and demonstration projects concluded that the integration strategy of PV distributed generation is dependent on the PV penetration level and location of PV system. EPRI research projects for several GC-PV case studies prove that PV penetration levels below 15% did not demonstrate integration issue. The voltage regulation issues due to distributed PV generation and the impact of PV location on the voltage profile of distribution feeders are illustrated in Figure 2 below.

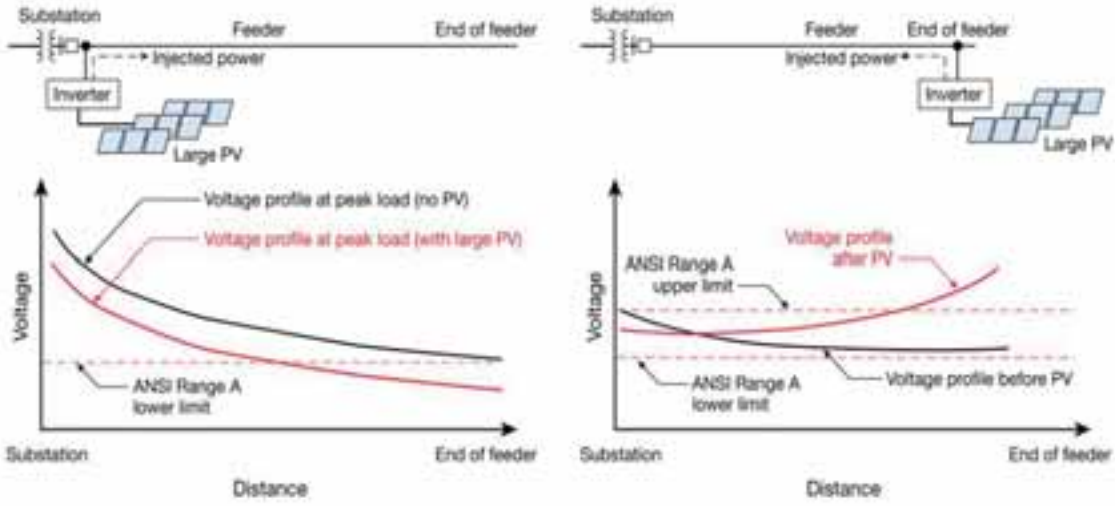

Figure 2 Voltage profile due to distributed PV generation. Figure 2.4a for GC-PV system at feeder's head while figure 2.4b shows CG-PV system at the end of the feeder (EPRI, 2013).

The analysis of many simulation studies of PV penetration on distribution feeders with EPRI's PV hosting capacity model concluded strong correlation with voltage regulators and feeder characteristics. Other significant factors include the location of point of connection (POC) of PV generators. On the other hand, EPRI's analysis concluded no significant correlation between hosting capacity and the peak load of the distribution feeder (EPRI, 2013). Figure 3 shows the hosting capacity in terms of voltage violations with the increasing penetration level of grid connected photovoltaic (GC-PV).

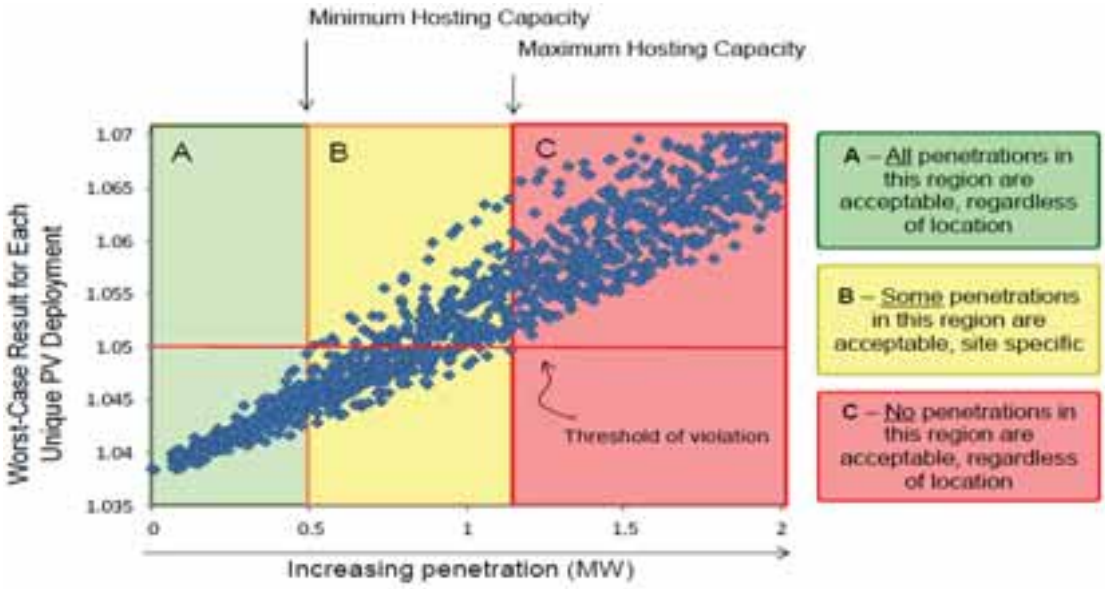

Figure 3: The voltage limit violation with the increasing penetration of GC-PV (EPRI, 2013)

The feeder's voltage profile issue due to PV DER integration can be explained in the view of the highly simplistic two bus feeder model shown in Figure 4. The voltage at substation bus is assumed to be constant as the nominal voltage with a magnitude of 1 per unit (p.u).

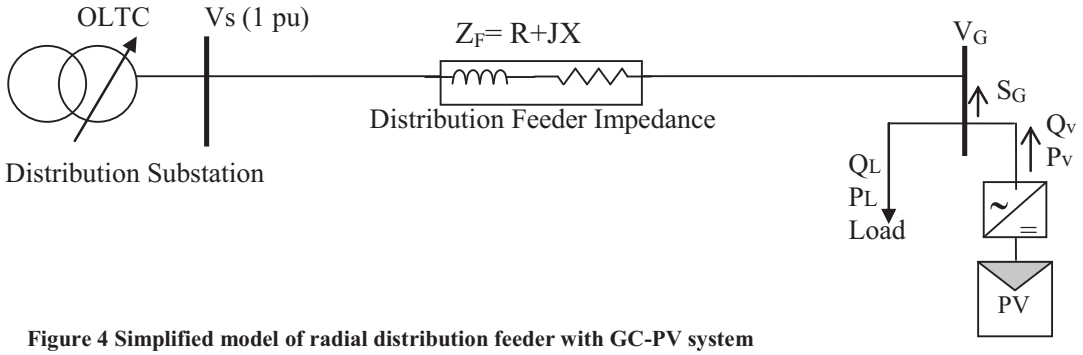

Figure 4 Simplified model of radial distribution feeder with GC-PV system

The voltage difference between substation bus (S) and distributed generation bus (G) is defined as:

$\Delta V = Vs - V_G = I \times Z_F = .(R+jX)$ (Eq. 3)

Where I is the current flowing from the DG-PV source (I) Ignoring the wiring power losses can be found using:

$I = \frac{S_G}{V_G}$ (Eq. 4)

The total apparent power S_G injected to the grid at the DER bus S_G can be calculated in terms of active power (P) and reactive power (Q) as:

$S_G = (Pv - P_L) + j(Qv - Q_L) = P + jQ$ (Eq. 5)

And the absolute value is $|S_G| = \sqrt{P^2 + Q^2}$ (Eq. 6)

Where Pv and Qv represent the active and reactive powers generated by the PV inverter respectively; and P_L and Q_L represent the active and reactive power consumed by the load respectively.

The power factor (PF) by definition is the ratio of the real power to the apparent power in the circuit:

$$PF = \frac{P}{S_G} = \frac{P}{\sqrt{P^2+Q^2}} \cong \frac{I^2 R}{I^2\sqrt{R^2+X^2}} \cong \frac{R}{\sqrt{R^2+X^2}} \quad \text{(Eq. 7)}$$

The current (I) flowing from the GC-PV to the DER bus. Ignoring the wiring loss through the can be found using:

$$I = \frac{P+jQ}{V_G} \quad \text{(Eq. 8)}$$

Combining (2. 3) and (2.8), hence: $\Delta V \cong \frac{P.R+QX}{V_n}$ (Eq. 9)

The overvoltage caused due to distributed generation depends on the variables in equation (9). V_n is the nominal grid voltage as set by the distribution utility and could not be controlled. Different methods have been developed to increase the PV hosting capacity focus on controlling one or more variables of the equation 2.9 numerator. For instance, Inverter volt/var controls reactive & power power (P, Q); while feeder reinforcement aims to control X/R values.

2.2 *Advanced Inverter Functions for improving PV hosting capacity:*

Current grid-connected PV systems use advanced inverters that become smart enough to operate autonomously according to pre-established software settings and with the addition of communications capabilities, DER systems can be directly monitored and controlled by utilities to modify or override their autonomous operations. DER systems can receive remote emergency commands, demand response pricing signals or schedules of modes/ commands to cause the inverters to change their electrical characteristics such as voltage levels, energy production rate, and active or reactive power outputs according to daily, weekly, or seasonal timeframes so long as they operate within the standard requirements of the interconnection regulations of the grid (see Table1) .

Smith et al. investigated inverter volt/var control through simulation study and concluded that the effectiveness of inverter based control for PV integration into the distribution system. Similarly, several simulation studies concluded that volt/var management is an effective strategy for distribution voltage regulations however, feeder characteristics shall be taken in conciderations (smith et al. 2011; Rizy et al 2011; Schauder and Mather 2014; Kim et al., 2016; Leite et al 2016).Alobeidli and Moursi compared different coordinated volt/var control strategies using conventional methods like OLTC and inverter-based control. They reported that inverter-based strategy is proven to be an efficient strategy for DER integration to improve feeder voltage profile and maximize reactive power reserve up to 80% (Alobeidli & Moursi, 2014).Rylander et al. and others analysed the potential performance benefits of advanced inverter control on different distribution feeders. The advanced volt/var function of the inverters improved PV hosting capacity between 43% and 133% (Rylander et al. 2016; Seuss et al. 2015)

Table 1: Advanced inverter functions to support DER integration (EPRI 2012; Rylander et al. 2016; Casey et al. 2010; Bower et al. 2012)

Classification	**Inverter Functions**	**Associated Standards**
Autonomous Functions: • *Behavior controlled by inverter's pre-configured operating parameters (defined during system commissioning).* • *Parameters can be re-configured, activated or deactivated at later date through on-site changes or remotely.* • *No communication capability is required.*	Low- / High-voltage ride-through	IEEE 1547a-2014
	Low- / High-frequency ride-through	
	Volt-var control (dynamic reactive power injection)	
	soft-reconnect	
	Ramp-rate controls	
	Fixed power factor	
Non-Autonomous Functions:	Remote connect/disconnect command to DER	

• *Direct control of inverter behavior from remote operator commands or feedback, based on conditions at the point of connection (POC)* • *Communication architecture and remote control infrastructure are required.*	system	IEEE smart inverter working group (SIWG) proposed Functionalities
	Set /Limit real power	
	Respond to real power pricing signals	
	Update/overwrite autonomous functions (volt-var curves, fixed power factor, voltage ride-through, frequency ride-through, ramp rate)	
	Provide black-start capability	
	Provide spinning reserves	
	Event/history logging	
	Status reporting	

Palmintier et al. investigated several active and reactive (volt/var) power management strategies of PV integration at different penetration levels. This could be achieved typically through controlling on-load tap changers of transformers, capacitor banks and line regulators. A techno-economic assessment of different volt/var strategies to enhance PV hosting capacity concluded that on-load tap changers of distribution transformer could be effective can prove only when PV penetration level exceeds beyond 75% (Palmintier et al. 2016a). For lower penetration levels (typically between 15% to 75%), PV inverter's reactive power support and active power control have been demonstrated in several studies to mitigate voltage regulation and power quality issues that could occur due to large PV deployment in the distribution grid (Palmintier et al. 2016b ; Wang et al. 2014).

Further, Hashemi, Ostergaard, and Yang suggested that advanced inverter control is a cost-effective solution to control active/ reactive power through the output curtailment functionality of advanced PV inverters and could therefore decrease the required storage capacity for grid balancing (Hashemi, Ostergaard, and Yang 2013)

3. Data Collection

3.1 DER Integration Survey:

A survey was conducted to investigate the existing solar PV projects in Dubai and identify the key challenges of the existing interconnection regulation of distributed energy resources (DER) related to advanced inverter management. The survey was circulated to participants represent Shams Dubai's experts from utility industry, PV inverter manufacturers; enrolled consultants and contractors in Shams Dubai programme as provided on DEWA website (DEWA Shams Dubai, 2017). The initial results of the survey revealed that advance remote management of DER system of smart PV inverter could be achieved through below list of advanced inverter functions ranked based on the feedback of the participants as shown in Figure 5. Remote configuration of inverter's power factor and real time volt/var management of smart inverter are among the most important capabilities to improve PV hosting capacity of distribution feeders.

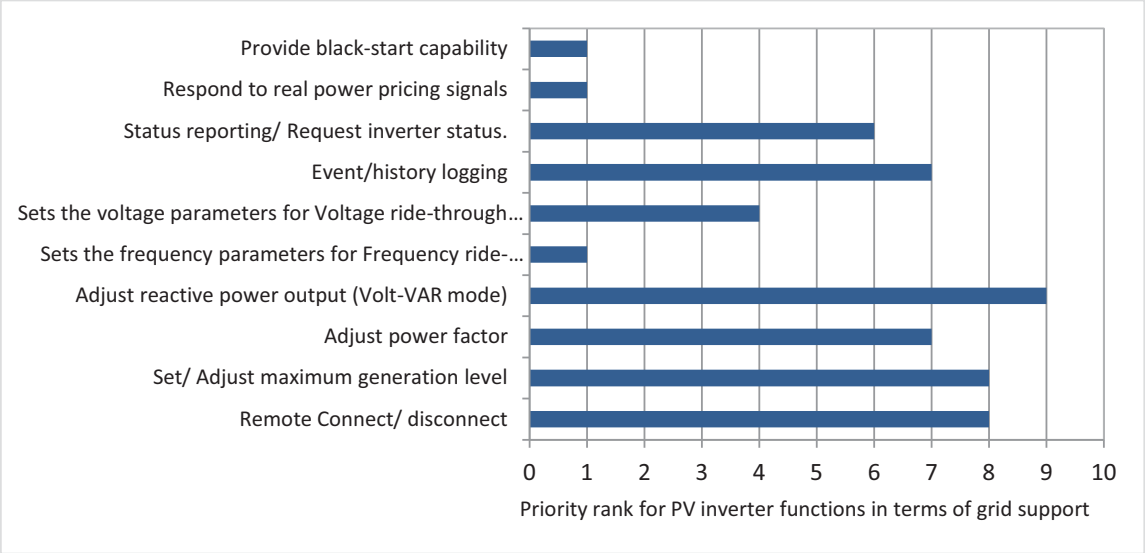

Fig 5: The key inverter's functions that could be remotely controlled/ re-configured for smooth DER integration.

The survey results also revealed that that some integration and interconnection regulation challenges shall be addressed to enable wider deployment of roof-top solar PV as shown in Figure6. The following challenges were identified:

- The interconnection standard is lagging behind the technological advances of smart inverters. The grid codes in Dubai did not cover some inverter's supporting functions like dynamic reactive power support during low voltage ride through (LVRT), hybrid inverter, inverter's volt/var and volt/watt modes.
- PV storage is not covered by the regulations.
- Dubai grid codes imposed restrictions to limit the maximum capacity of PV connections based on total connected Loads.
- Unclear guidelines about technical/ communications Architecture for of PV inverters remote monitoring & control by the utility through IEC61850.
- Lack of compensation mechanisms for DER aggressors (energy retailers) or ancillary service providers. The current grid codes did not support feed-in tariff or compensation scheme for energy service provides.

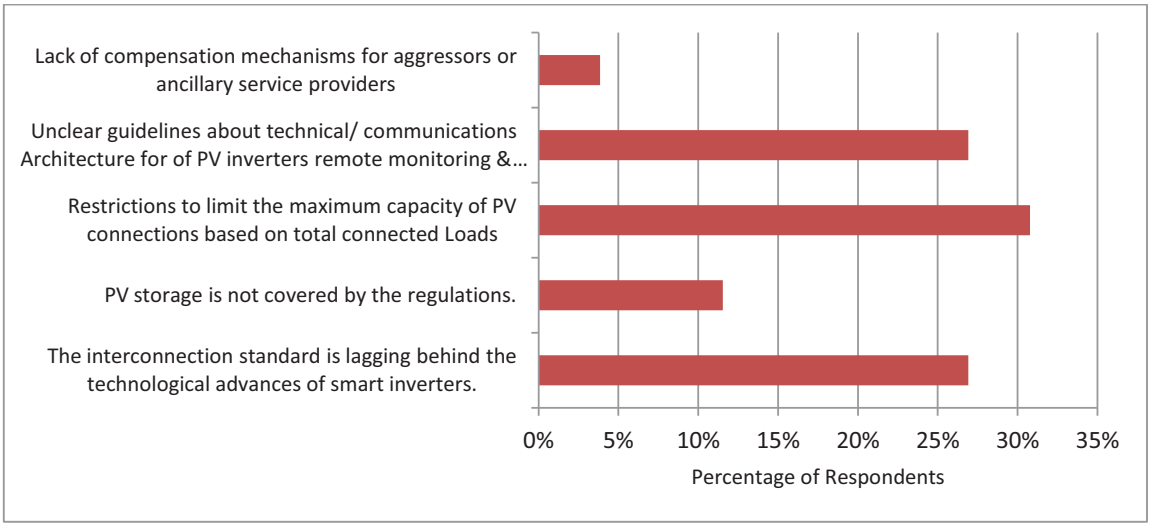

Fig 6: The key challenges you are facing with the existing PV interconnection Regulations and Standards.

3.2 Model Development:

The test system includes PV plant connected to 11KV (9 bus) distribution Feeder, Capacitor bank and OLTC substation transformer (see figure 7) include the flowing sub-systems:

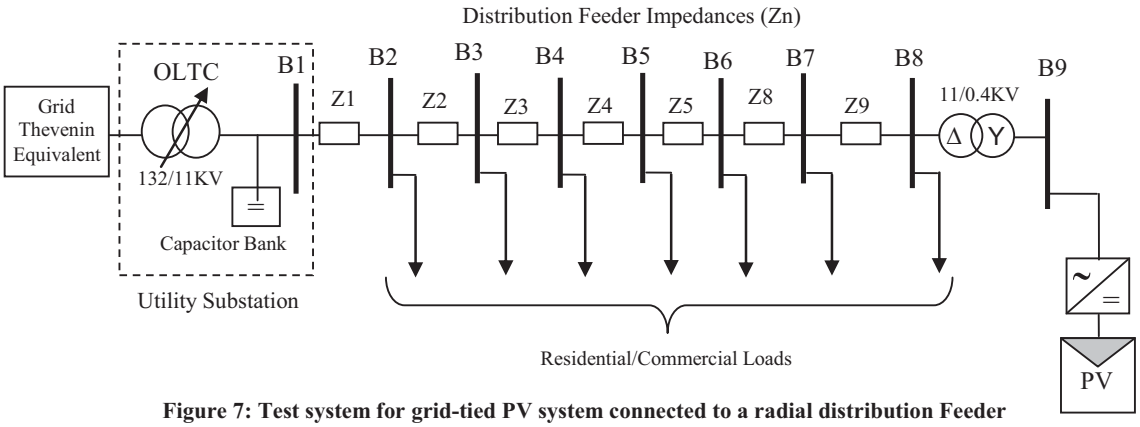

Figure 7: Test system for grid-tied PV system connected to a radial distribution Feeder

In order to examine the impact of inverter's volt/var control and other advance functions for remote monitor/ control, transient analysis for PV power fluctuation during irradiance dip or sundden PV system's failure at different penetration levels. The voltage source converter (VSC) in modern inverters can be controlled using digital signal processing (DSP) and microcontroller to compute the slope (dP/dV or dP/dI) of the PV power curve and feed it back to VSC control to drive it to zero (Sumathi, Ashok, & Surekha, 2015). Block diagram of smart inverter mamangemt through remote terminl unit (RTU) and demand response commands from Distributed Energy Resources management system (DERMS) as shown in figure 8.

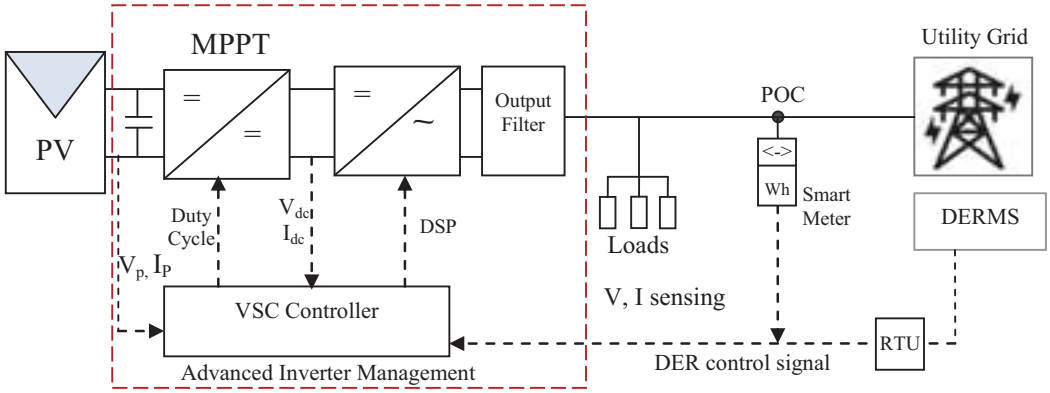

Figure 8 Smart Grid Approach for DER integration through advanced Inverter management and DERMS.

MATLAB/SIMULINK model reflecting grid-tied PV system is developed using Simscape power system components. A screenshot of the preliminary model is given in figure 9. The main components of grid-connected PV system connected to the model are:

(1) PV arrays comprises of SunPower SPR-315E modules. A photovoltaic module is commonly represented by an electrical equivalent one-diode four parameter model (Rekioua & Matagne, 2012). .

(2) DC/DC boost converter connected to each PV array controlled by a Maximum Power Point Tracker (MPPT) using P&O "Perturb and observe" algorithm to control PV array voltage in order reach the maximum power output.

(3) , (4) DC/AC Voltage Source Converter (VSC) control and a coupling 3-ph transformer to connect the converter to the distribution feeder.

(5) , (6) The grid model consists of typical 11kV distribution feeders and 132kV equivalent transmission system (DEWA Design guidelines, 2015).

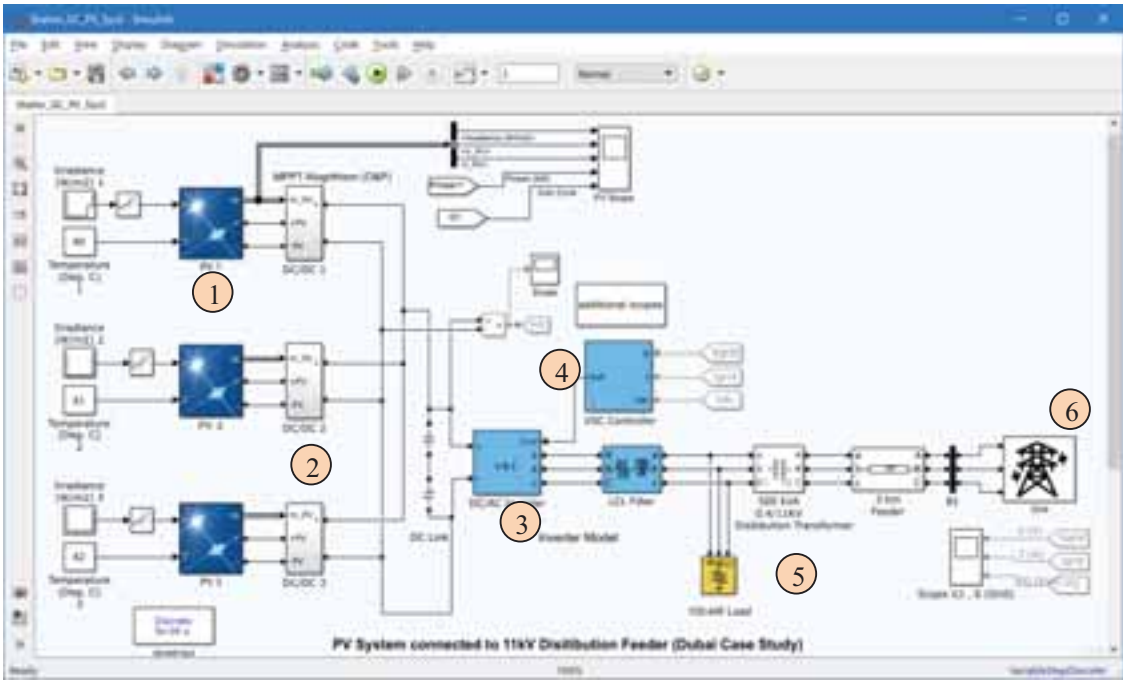

Figure 9: MATLAB/SIMULINK Model for GC-PV system connected to 11KV distribution feeder

4. Conclusion

In conclusion, it has been proven in the literature that advanced smart inverter functions and dynamic volt/var control are cost-effective strategies to improve PV hosting capacity of distribution feeders and help to mitigate adverse voltage impact compared to the conventional voltage regulation methods through OLTC which are more costly and have a slower response compared to smart inverters. However several simulation studies concluded that specific methods based on distribution network design and feeder's characteristics (mainly X/R ratio) should be developed to define the optimal inverter settings and functions for DER integration.Interconnection regulations need to be developed to cope with technolgoy advancesof the modern DER system rather than imposing limitation on the maximum PV power generation and the annual connection capacity to avoid the challenges of intermittent uncontrolled distributed generation. Based on the initial results of DER integrationsurvey, the following are key recommendations for further enhancement of DER interconnection regulations:

- The interconnection standard is lagging behind the technological advances of smart inverters. Advanced solar inverter features like advanced inverter's volt/var management need to be investigated and supported by the regulations.
- Hybrid inverters with PV storage shall be supported for feed-in tariff.
- Clear guidelines about communications protocols and technical architecture to be developed for utility's remote management of PV inverters.
- The proposed volt/var control settings (as recommend by IEEE P1547 working group) to be used as default inverter settings with most distribution feeders.
- Multiple volt/var profiles of smart inverters should be scheduled based on seasonal load profile to optimize the voltage profile of distribution feeders.
- Compensation mechanisms for ancillary service include volt/var control through smart inverters.

For future work, the dynamic volt-var control capability will be incorporated into inverter model and applied to an actual distribution feeder model in Dubai to investigate the impact on the chosen performance objective of the distribution network. Other DER management capabilities will be explored, such as scheduling multiple volt/var profiles for a residential PV systems based on seasonal load profiles for typical residential buildings.

Abstract

Air pollution caused by exhaust gas, increasing carbon dioxide by burning fossil fuels, and the risk of drain on fossil fuels are the major problems of fossil fuels. In addition, low self-sufficiency rate of fossil fuels is also a large problem in Japan. 84.6% of electricity is generated by fossil fuels in Japan, so electrification such as electric vehicle does not mean breakaway from fossil fuels. Electricity should be generated by clean energy such as renewable energy in order to settle the problems of fossil fuels. A light rail system which runs on 100% renewable energy named the "Solar Light Rail" is proposed by authors. Experiments using a prototype model are carried out to demonstrate availability of the rechargeable power supply method using electric double layer capacitors. Two types of experiments are reported in this paper. From the experiment combination of PV and biomass, it was confirmed that clean stable energy is effective for this system under the bad condition for PV. In the experiments using PV, experimental condition is changed from passed experiments and energy consumption per run is decreased. Low energy consumption brings about running for longer time after sunset. The handmade equipment can be more efficient, and better result is expected by improvement.

Keywords: transportation, renewable energy, biomass, electric double layer capacitor

1. Introduction

In Japan, hybrid vehicles (HV) and electric vehicles (EV) are spreading. Fig. 1 shows the number and the rate of HV and EV, reported by the statistics of Automobile Inspection & Registration Information Association in Japan. The rate of HV and EV is only 7% for all automobiles in March 2016. However, the number and the rate of those vehicles are increasing every year.

The consumption of fossil fuels is one of the biggest causes of the environmental problem such as increasing in carbon dioxide and air pollution by the exhaust gas. The drain on fossil fuel is also a major issue. Furthermore, the self-sufficiency ratio of fossil fuels in Japan is extremely low. The self-sufficiency rate in 2015 of oil was 0.3%, that of natural gas was 2.5%, and that of coal was less than 0.1%. The excessive dependence on fossil fuels is undesirable for stable energy supply.

If all automobiles are replaced to EV, will the environmental problem by fossil fuels in the field of transportation be settled? Fig. 2 shows the power energy source of Japan in 2015. 84.6% of electricity is made from fossil fuels. It is reported that using electricity means consuming fossil fuels. The problem of fossil fuels will not be solved by only electrification. In order to settle the problem, all electricity must be made without fossil fuels, and should be generated by renewable energy.

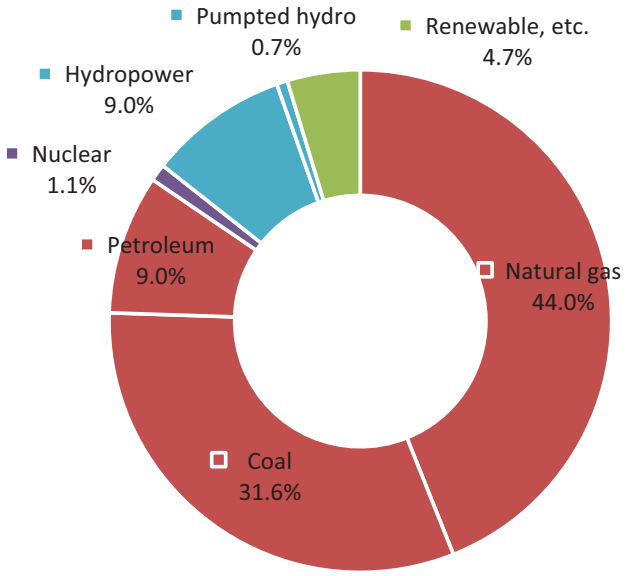

Fig. 2: Power energy source of Japan in 2015

1.1 The Solar Light Rail

A light rail is also known as a tram and a streetcar. A light rail which runs on 100% renewable energy such as solar, wind and micro hydro power generation is proposed by authors, and this light rail system is named the "Solar Light Rail".

The HIT solar panel produced by Panasonic is known as high efficiency silicon PV module. The energy conversion efficiency of this module is 19.7%, and the efficiency of thermal power generation with natural gas is 40%. Since the rolling resistance of iron wheels is lower than that of rubber tires, rail transport system is suitable for renewable energy.

A light rail is suitable transport system for the movement in the town. It is easy to ride without stairs like

subways and easy to across the rail without railroad crossing. Moreover, it is easy to know the name of street since rail trucks are installed on the road. For shifts from car-based town planning to people-based town planning, a light rail is reviewed in Europe and the United States.

It is easy to think of spreading solar panels all over the roof of the railcar to supply electricity like a solar car. However, the railcar cannot run in rainy days and during the night. In addition, it is hard to use wind turbines and water wheels in this method.

In conventional light rail system, most of electricity is supplied from thermal power plants to the railcar through the electric wire. Replacing thermal power plants to renewable energy power plants is also dreamed up. Even in this method, the railcar cannot run when the renewable energy power plants do not work such as a night without wind. Moreover, the power transmission loss cannot be neglected. The rate of transmission loss in Japan is 5.6%. Assuming 5.6% of loss is not a wise policy for renewable energy.

The first tram in Japan opened in 1895 in Kyoto. The railcars ran on electricity by hydro power generation at Lake Biwa. A light rail in Calgary, Canada runs on wind power generation. Several light rail systems already run on renewable energy. However, location requirements are limited to come true.

The power supply method, which is feasible in almost any location, to have a light rail run on renewable energy is shown in Fig. 3.

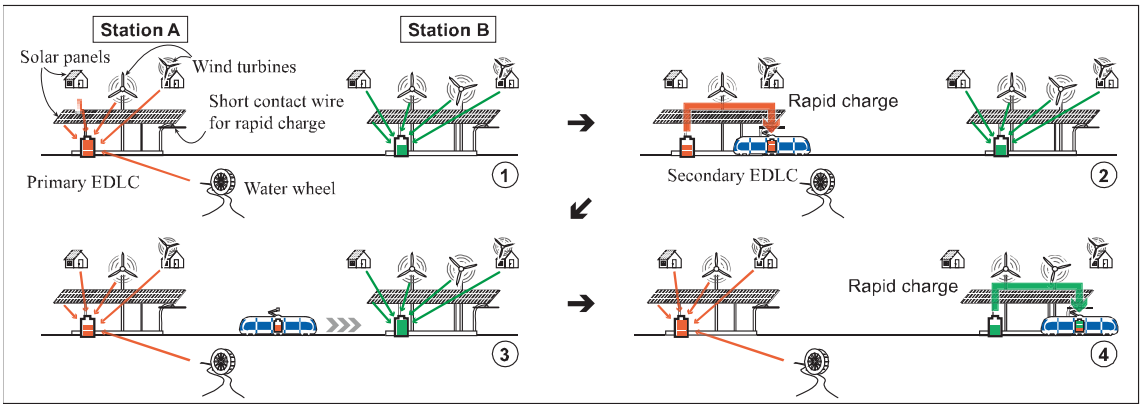

Fig. 3: Power supply method of the Solar Light Rail

1) Solar panels are mounted on the roof of the platform and around the station. Wind turbines are built around the station. Straight blade vertical axis wind turbines are suitable for this system, since their wind turbine noise is less than that of horizontal axis wind turbines. If there is a river or a water channel, micro hydro, not requiring a dam, should be used. An energy storage device is installed at the station, and this device is always charged from solar panels, wind turbines and water wheels. There is a short contact wire for rapid charge at the station.

2) Another energy storage device is also mounted on the railcar. When the railcar stops at the station, the energy storage device mounted on the railcar is charged rapidly from the energy storage device installed at the station through the short contact wire and a pantograph on the railcar.

3) The railcar runs to the next station by charged electricity.

4) There are same power generation system and an energy storage device at the next station, and rapid charge is carried out when the railcar stops at the next station. The railcar is operated by continuing this cycle.

Electric double layer capacitors (EDLCs) are suitable for the energy storage device of this system. In this system, energy storage devices repeat charge and discharge. The lifetime of EDLC is longer than that of batteries. High electric current is able to be put into and out from EDLC, and it makes rapid charge during railcar stopping. It becomes an advantage for this system that heavy metals are not included in EDLC. The capacitance of EDLC is lower than that of batteries. However, usually distance between stations of a light rail is shorter than that of railways, and charged electricity for an energy storage device mounted on the railcar should have quantity necessary to arrive at the next station. Therefore, low capacitance will not be a disadvantage in this system. In this system, an EDLC unit installed at the station is called the “primary EDLC”, and an EDLC unit mounted on the railcar is called the “secondary EDLC”.

According to the test outcome by the Railway Technical Research Institute of Japan, their hybrid light rail vehicle named “Hi-tram” consumes 8.9 MJ of electricity per kilometers at the maximum air conditioning load. If the interval between stations is 500 m for the assuming Solar Light Rail line, 4.5 MJ of electricity is required to reach the next station. When the voltage of secondary EDLC is 1500 V, the required capacitance of 4 F is calculated with eq. 1. The required time for rapid charge is calculated with eq. 2. It takes 6 seconds when this EDLC unit is charged at 1000 A.

$$W = \frac{1}{2}CV^2 \quad [\mathrm{J}] \qquad \text{(eq. 1)}$$

$$Q = CV = It \quad [\mathrm{C}] \qquad \text{(eq. 2)}$$

If railcars arrive and depart every 10 minutes in this assumed line, 15 kWh of electricity is required for every hour at a station. If this line works from 6:00 to 24:00 every day, the required electric power at a station is 270 kWh for one day, and 98,550 kWh for one year. If 98,550 kWh of electricity is supplied by renewable energy, the Solar Light Rail is feasible in the calculation.

1.2 Experiments using a prototype model

Demonstration experiments using solar panels and a handmade small scale prototype model were already carried out. From conventional experiments carried out under disadvantage condition for photovoltaic such as in winter or in cloudy day, it was confirmed that the proposed power supply system functions effectively in the daytime. The maximum voltage of the conventional primary EDLC was lower than the open circuit voltage of solar panel. Electricity had to be consumed to keep lower voltage, and electricity was not stored for after sunset. So the railcar could continue running for only one hour after sunset in passed experiments.

The experimental equipment was renewed this time. The gauge of rail is widened to 15 inches (381 mm) from 5 inches (127 mm). The voltage of the solar panel and the breakdown voltage of EDLCs rose.

Biomass is also a clean energy. Electricity is generated without an influence of climatic condition by biomass. In this paper, two types of experiments are reported. One is an experiment with combination of PV and biomass, and the other is an experiment with new equipment and new experimental condition.

2. Experimental equipment

Fig. 4 shows the schematic diagram of the experimental equipment.

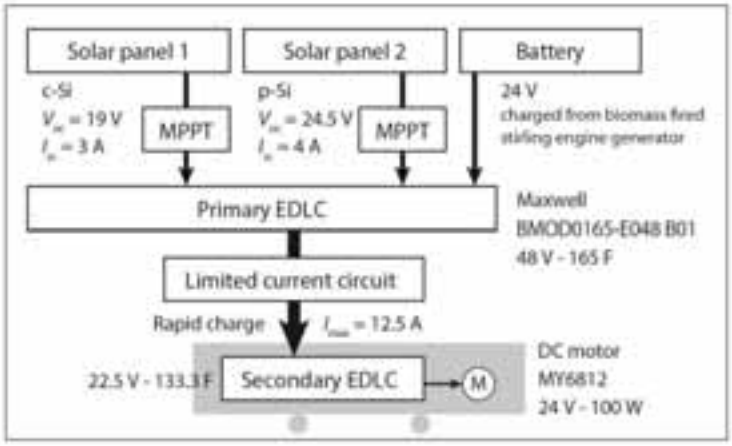

Fig. 4: The schematic diagram of experimental equipment

2.1 Solar panels

Two solar panels are used in the experiments. One is a mono-crystalline silicon panel made by ARCO Solar, Inc. 11 circular cells are wired in series, and three sets of wired cells are connected in parallel. Although this solar panel has been used more than 20 years, open circuit voltage of 19 V and short circuit current of 3A are

still measured in preliminary experiments. This solar panel is called as “solar panel 1” in this paper.

The other is a handmade solar panel using 56 poly-crystalline silicon solar cells made by Suntech Power Co. Measured open circuit voltage for one cell is 1.75 V, and short circuit current is 1 A. 14 rectangular cells are wired in series, and four sets of wired cells are connected in parallel. Open circuit voltage of 24.5 V and short circuit current of 4 A is expected this panel. This solar panel is called as “Solar Panel 2” in this paper.

These two solar panels are connected to the primary EDLC through the maximum power point trackers.

2.2 EDLC units

An EDLC unit model BMOD0165-E048 manufactured by Maxwell Technologies, Inc. is used for the primary EDLC. The capacitance is 165 F and maximum voltage is 48 V.

The secondary EDLC is fabricated with cylindrical EDLC cells. The capacitance for one cell is 600 F and maximum voltage is 2.5 V. 9 cells are wired in series, and two sets of wired cells are connected in parallel. The secondary EDLC becomes the capacitance of 133.3 F and the maximum voltage of 22.5 V. A resistor of 3.3 kΩ is wired in parallel for each EDLC cell as a voltage balancing resistor.

2.3 A limited current circuit

An excessive electric current flows when the primary EDLC is connected to the secondary EDLC directly. A limited current circuit is installed between the primary EDLC and the secondary EDLC during the rapid charge for safety. A small limited current circuit of 1.25 A is made with a three terminal regulator of LM317T, and the 12.5 A of limited current circuit for this system is made with connecting 10 small circuits in parallel.

2.4 A railcar and rail trucks

A 15 inches (381 mm) gauge four-wheel car is fabricated with four independent wheels. Driving force from the 100 W DC motor is decelerated at 22.25:1 and is transferred to the left rear wheel through the chain. The structure of a power controller is simple enough. The base current of the transistor is controlled by the variable resistor. The speed of the railcar depends on voltage of the secondary EDLC and the base current of the transistor.

Rail trucks are not made with rails for railways. A 1.8 m of iron angle bar is used for rail trucks. Total extension of the straight rail truck becomes 14.4 m.

2.5 Stirling engine generation system

Fig. 5 shows the schematic diagram of a biomass fired Stirling engine generation system. Biomass pellets are stored in the pellet hopper, and fed into the furnace automatically by pellet feeder. The Stirling engine works with combustion heat of biomass pellet and cold water. 1 kW of AC generator is connected to the Stirling engine, and electric power is supplied to load. Rated voltage of this system is DC 60 V, and five car batteries are installed for load balancing. Two of these batteries are used for charging to the primary EDLC.

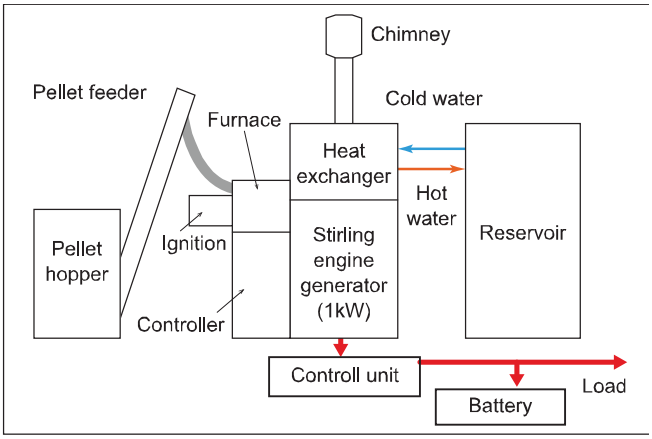

Fig. 5: The schematic diagram of biomass fired Stirling engine generation system

3. Experiment 1: Combination of PV and biomass

The experiment using a biomass Stirling engine generator was carried out during the science workshop for

children held on 10th October 2016 at Tokyo Tower (Tokyo, Japan). The event started at 10:00 and closed at 18:00. Many children visited our booth and enjoyed to riding the railcar one round trip on the 14.4 m of straight rail truck.

Fig. 6 shows the voltage transition of the solar panel 2, the primary EDLC and the secondary EDLC recorded with a data acquisition system IOtech Personnel Daq/55. The voltage of the solar panel 2 and the primary EDLC was recorded continuously since the solar panel 2 and the primary EDLC was always connected to the data acquisition system. However, the voltage of the secondary EDLC was recorded with break since the secondary EDLC was connected to the data acquisition system only during the rapid charges.

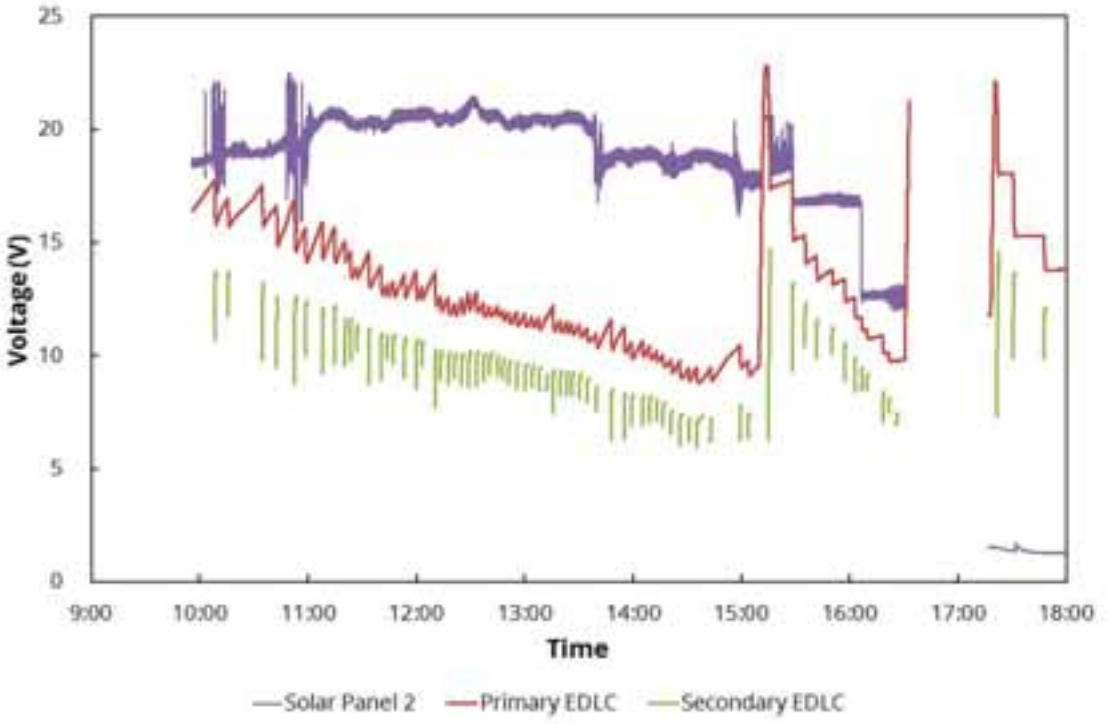

Fig. 6: Voltage transition of solar panel 2, primary EDLC and secondary EDLC under the experiment held on 10th October 2016

It was overcast from early morning. The voltage of the primary EDLC barely reached to 17 V at the beginning of the event. The railcar continued running without rest and the voltage of the primary EDLC dropped every time rapid charge was carried out. The railcar hardly moved around 15:00 since the voltage of the secondary EDLC also dropped, so a charging from the battery which was charged by the biomass fired Stirling engine generation system was carried out at 15:10. The voltage of primary EDLC rose to 22.8 V from 9.6 V. After that charging from battery was carried out at 16:30 and 17:18, and the railcar could continue running until the end of the event. The voltage was not recorded from 16:33 to 17:17 because of trouble of the laptop for data recording.

In this experiment, the railcar ran without the rest during overcast day. Even in harsh condition for photovoltaic, the railcar could continue running by charging from battery which is charged by the biomass fired Stirling engine generation system. It was confirmed that combination of clean energy such as biomass is effective to supply electricity stably for the Solar Light Rail. For practical use, the clean and stable generation system should be installed at main stations and stations which are located at a disadvantage to photovoltaic.

4. Experiment 2: Change of experimental condition

The experiment using new equipment without biomass stirling engine generation system was carried out on 1st November 2016 at Hachioji Campus of Tama Art University (Tokyo, Japan). The voltage of the solar panel 2 rose to 24.5 V from 17.5 V. The maximum voltage of the primary EDLC rose to 48 V from 17.5 V, and that of the secondary EDLC rose to 22.5 V from 15.0 V. Since the voltage of the primary EDLC became higher than the voltage of solar panels, it was not necessary to worry about overcharge of the primary EDLC.

The experimental condition is also changed. In conventional experiment, the railcar went forward and back 3 to 5 times on the 9 m of straight rail after rapid charge. In this experiment, the railcar went forward and back 1

time on the 14.4 m of straight rail. Running distance was decreased from 90 m to 28.8 m for each run. The time for rapid charge was fixed to 2 minutes.

The rail truck was laid on the corridor of the building and solar panels were put on the balcony facing south west. The sunrise was 6:03 and sunset was 16:46. It was rainy in the morning and became overcast in the afternoon. Fig. 7 shows the voltage transition of the solar panel 2, the primary EDLC and the secondary EDLC under the experiment. The voltage of the primary EDLC reached to 16 V at 10:55, and the first rapid charge was carried out at 11:00. The second rapid charge was carried out at 11:30, and interval of rapid charge was fixed to 15 minutes from the third rapid charge. The voltage of the solar panel 2 became lower than that of the primary EDLC at 15:38 since the sun disappeared behind a building.

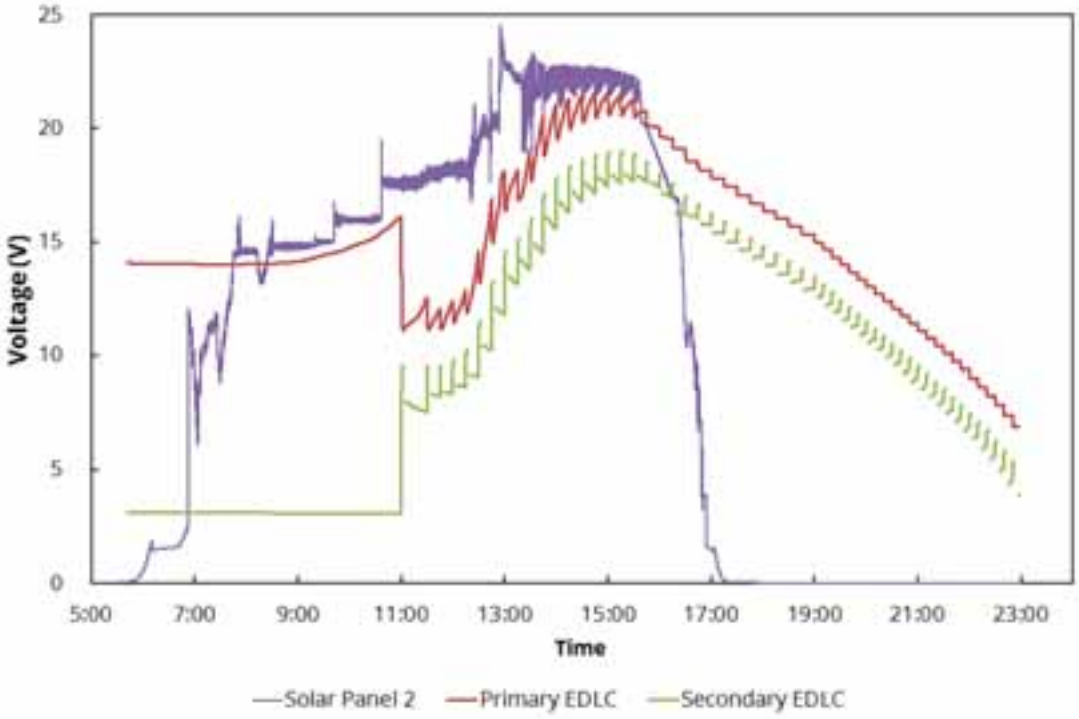

Fig. 7: Voltage transition of solar panel 2, primary EDLC and secondary EDLC under the experiment held on 1st November 2016

Finally, the railcar stopped at 22:56 and the final rapid charge was carried out at 22:50. The railcar continued running for 6 hours after sunset. Interval of rapid charge was shortened from 15 minutes to 10 minutes after 19:00. The final rapid charge would be carried out at 24:45 if the interval was not changed.

In the conventional experiments, the voltage of the secondary EDLC fell about 2.8 V in average after run. The capacitance of the secondary EDLC was 100 F, so the railcar consumed 280 C of electric charge per run. In this experiment, the voltage of the secondary EDLC fell about 1.0 V in average. The capacitance of the secondary EDLC was 133.3 F, so the railcar consumed 133.3 C of electric charge per run. 68% of shortening of distance per run caused 47.6% of decrease in energy consumption. Lower energy consumption brought about running longer time after sunset. This handmade equipment, such as rail trucks, a power controller, a power transmission system and electric circuits, can be more efficient. Better result is expected from improvement of equipment.

5. Conclusion

In this paper, a power supply method for a light rail which runs on 100% renewable energy is proposed. Two types of experiments using a prototype model were reported. In the experiment combination of PV and biomass, the railcar continued running by electricity which was brought from biomass under poor surroundings for PV. It was cleared that combination of clean stable energy is effective for the proposed system. The clean energy generation system should be installed at main stations to support power generation by unstable renewable energy.

In the experiment using only PV, railcar could continue running for 6 hours after sunset by 47.6% of reducing

energy consumption per run. It was confirmed that low energy consumption brings about running for long time after sunset. The handmade equipment could be more efficient, so better result is expected by improvement of equipment.

Community Micro Power and Hybrid Systems

Integration of autonomous renewable energy generation systems with different topologies in a smart grid cluster to enhance performance in usual operational situations

Abstract

Renewable Energy Systems (RES) using resources found in loco might be an attractive solution to address the needs for electrification in many communities that are unlikely to be supplied by the interconnected grid. Though the design of isolated systems using intermittent renewable sources is discussed extensively, little attention has been given to the integration of autonomous RES for joint operation. The integration allows increased flexibility and modularity, which are important characteristics to improve the overall robustness of the system and tackle unpredicted adversities. This paper presents evaluations and conclusions about Autonomous Renewable Energy Generation Systems (AREGS) integration. The methodology is based on tests on a set of four AREGS operating integrated in a cluster in the Laboratório de Sistemas Fotovoltaicos (LSF) of the Universidade de São Paulo, Brazil, which allows the evaluation of several topologies and different operational scenarios; and also computer simulations for the extension and extrapolation of the evaluated scenarios.

Keywords: Autonomous Renewable Energy Generation Systems, energy management, distributed generation, control strategies.

1. Introduction

Renewable Energy Systems (RES) using local resources might be an attractive solution to address the needs for electrification with fewer environmental impacts, cost and maintenance, especially in the case of remote areas where the grid is not available. These kinds of systems are particularly interesting for countries like Brazil, with many communities that are unlikely to be supplied by the interconnected grid, and for which the only option is the use of isolated generation systems.

RES can use a large amount of primary resources available on site, presenting an advantage when compared to the use of generators operating with fossil fuels. However, the availability of these primary resources is not assured at any given moment, due to their flow-nature rather than stock-nature, which may directly influence the reliability of the system. Moreover, the design of the generation system faces many uncertainties not restricted to the supply side. On many occasions, the demand and the consumption pass through an adjustment phase, since these communities have a considerable amount of pent-up demand and even new consumers with the arrival of new settlers, especially in the early stages of electrification.

This requires the search for solutions to fit the problem in the beginning, while allowing flexibility and modularity to tackle the problem in the face of uncertainty and adversities. Modularity plays an important role for it allows a quick response to changes in the demand that would otherwise represent major modifications to the pre-existing generation system. In this sense, the integration of Autonomous Renewable Energy Generation Systems (AREGS) into a cluster may present a suitable manner to address the risks involved, and even to obtain higher levels of reliability and efficiency than those obtained by a single generation system.

doi:10.18086/swc.2017.03.01 Available at http://proceedings.ises.org

The integration of AREGS is desirable, not only due to the increased flexibility, but also from the point of view of the match between demand and primary resources. In some moments, a single AREGS may underuse its primary resource(s) for there is not enough demand and/or storage capacity left, and in other moments the available energy is not enough to meet the demand. Moreover, in order for a single AREGS to meet the demand at all times, it needs a generation/storage capacity to supply load peaks that seldom occur, increasing the already high initial investments of this kind of system. The integration of generation and storage units into a cluster allows dispatch flexibility between the systems, increases the value of the produced energy, contributes to power quality, and results in an overall more robust power system.

However, the application of such topologies has yet to overcome difficulties and barriers, so that all benefits can be appreciated. It is important to mention that the control of such topologies is more complicated, even if distributed control strategies and multi-agent strategies are applied. The grid forming inverters need a way to coordinate their operation to manage the energy exchange between AREGSs and the operation of all components in a seamless manner. Furthermore, the coordination between the agents involved needs to go beyond the technical level. Economic and even regulatory barriers also need to be overcome, since they may influence several stakeholders from the different integrated areas.

This new operating philosophy for AREGS lacks proof of its efficiency, effectiveness and reliability, both under normal and anomalous conditions, what increases the risks associated with operation and, consequently, decreases the interest in investing in such solutions. There are still questions to be answered on how to deal with the specificities and the operational aspects involved with these kinds of systems, which are critical to the long-term sustainability of the system's operation. In the literature, the design of isolated systems using intermittent renewable sources is discussed extensively, using a variety of techniques and optimization algorithms and works such as Lidula and Rajapakse (2011), Ustun et al. (2011), and Soshinskaya et al. (2014) present several examples of micro-grids installed around the world. However, only recently attention has been given to the integration of AREGS into a cluster for joint operation. For instance, Azaza and Wallin (2017) present and approach for optimizing a multi-micro-grid system using particle swarm. Koraz and Gabbar (2017) present a risk analysis for interconnected micro energy grids. Irfan et al. (2017) present a work on the opportunities and challenges concerning the micro-grid concept. Vasiljevska et al. (2013) present a work on the functionalities under a micro-grid concept.

This paper presents evaluations and conclusions about AREGS integration. The methodology is based on tests on a set of four AREGS operating integrated in a cluster in the Laboratório de Sistemas Fotovoltaicos (LSF) of the Universidade de São Paulo, Brazil, which allows the evaluation of several topologies and different operational scenarios; and also computer simulations for the extension and extrapolation of the evaluated scenarios. The conclusions drawn from the methodology may be used as guidelines for integrated AREGS operation, and even help in the development of proper regulation for this kind of operation.

2. Sizing of AREGS

The sizing of AREGS, as commented earlier, is extensively addressed in the literature and must often meet conflicting criteria such as reliability and cost to name a few, making an optimized solution a non-trivial problem. Usually the generation system needs to meet some quality criteria while minimizing costs, though other optimization variables are sometimes used as well. For instance, Fig. 1 exemplifies part of the solution space as a function of the Loss of Load probability (LLP) for a simulation considering a photovoltaic system with storage. The LLP (eq. 1) expresses the proportion of the energy not supplied in relation to the total energy needed by the system during a time period and it is often used as a measure of the reliability of the system.

$$LLP = \frac{\int_{t1}^{t2} P_{not\ supplied} dt}{\int_{t1}^{t2} P_{demanded} dt} \qquad \text{(eq. 1)}$$

Alex Renan Arrifano Manito

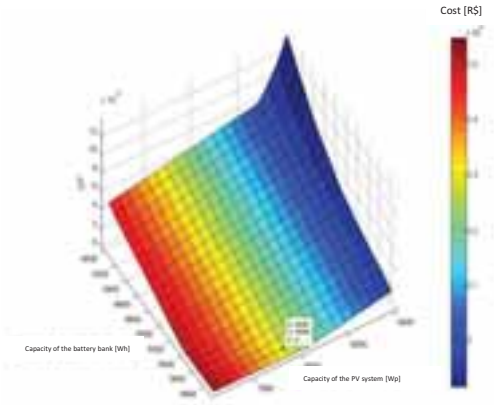

Fig. 1: LLP and cost as a function of the photovoltaic generator and storage capacity.

Fig. 1 shows that the same value for the reliability criteria (in this case the LLP) can be achieved by different configurations of the generator-storage pair with different costs. From the figure, it can also be inferred that the LLP does not present a linear characteristic of decrease, but rather one of saturation, with incremental increases of the capacity of the intermittent source or storage. In the case of the example given in Fig. 1, increasing the rated power of the photovoltaic generator becomes irrelevant past a certain value for a given capacity of the battery bank. The same behavior arises when increasing the capacity of the battery bank while keeping the rated power of the PV generator constant.

Consequently, the amount of generation and storage capacity are not decoupled and need to be proper matched to each other and to the load, otherwise the benefit of an additional investment in the capacity of one component may tend to zero. This is especially true when considering high penetration of non-dispatchable sources, which leads to the question of how to proper tune the generation-storage-load set in rural electrification projects and how to predict the evolution of the communities´ needs over the period of the project.

Optimization in the sizing of AREGS is important to maximize benefits of this approach while avoiding the waste of resources. However, optimization, though desirable, requires a reasonable amount of information for making suitable assumptions and decisions for the case at hand. Such information, on many occasions, are not available in rural electrification projects and some of it, such as the evolution of the demand curve over time, are hard to estimate.

Due to the nature of primary resources like solar or wind and to the limited capacity of energy storage, isolated system relying on them, on many occasions, need to underuse their capacity on certain periods and overuse it on others. This occurs due to the variation of the primary resource availability throughout a year and also to its match with the demand to be supplied. This may lead to situations in which the system generates considerably more energy than needed in a time period and yet the Loss of Load Probability (LLP) of the system is not zero.

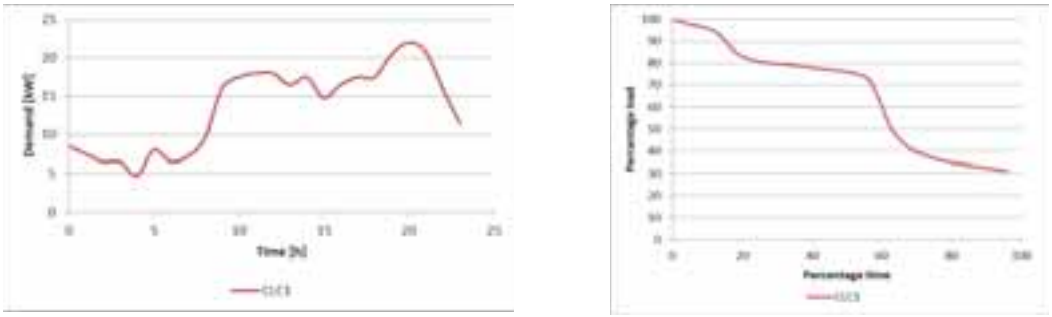
This scenario of uncertainty leads to the conclusion that being able to respond to unforeseen situations is just as import as a proper sizing in the beginning. This implies that the generation and distribution system should be designed with a level of flexibility in order to avoid the impossibility of an eventual expansion. In a scenario of integrated AREGS, the energy which is not used or stored could be dispatched to nearby systems and increase the robustness and the reliability of all the systems involved due to the increased flexibility in the operation. Moreover, it can add modularity to the systems, since increases in the load peak can be met gradually without having to exchange the grid forming inverters to supply for peak demands that seldom occur. This decreases some of the risks involved with sizing of the system for rural electrification projects by giving more flexibility for the solution to be tailored to fit new scenarios during the operation phase. Clusters of AREGS would be more robust and would have a way to share infrastructure. Moreover, the expansion could be more suited to address new emerging situations.

3. Simulation of a stand-alone AREGS

In order to illustrate and evaluate how an AREGS composed of a photovoltaic generator with storage could benefit

Alex Renan Arrifano Manito

from integration with other systems, a scenario was simulated by numerically calculating the energy flow at each time step. The scenario considered a real consumer's load curve (CLC1) of an isolated community. Fig. 2 presents two different forms of observing the load curve. From these figures it is possible to observe that CLC1 presents a high load factor, with a demand close to the peak during most of the day. CLC1 spends 16 % of the time above 90 % loading and 54 % percent of the time with a loading above 75 %. However, when considering rural electrification, due to the relatively small number of households in isolated communities, the characteristic of the load may vary greatly and the demand curve is more sensible to demand increases that are hard to account for and would render the generation system unsuitable to meet the demand.



(a) (b)

Fig. 2: Isolated community load curve. (a) Average load curve over day time. (b) Percentage load versus percentage time.

The photovoltaic system was sized considering a location in the state of São Paulo, Brazil. Fig. 3 presents the monthly average irradiation and temperature. Since the system is isolated, a value of three peak sun-hours was considered, even though the annual average is 3.95. This was done to guaranty the supply in the month of least primary resource availability.

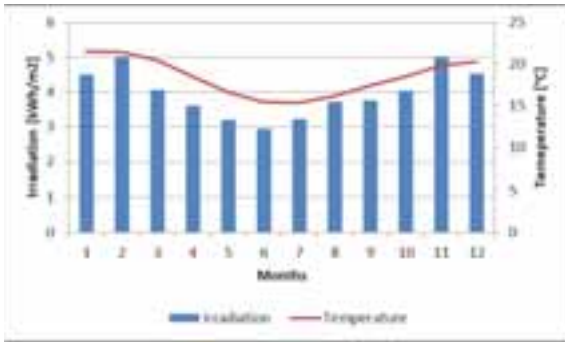


Fig. 3: Irradiation and temperature for the considered location.

The autonomy of the system was set as 2.4 days, which is higher than the minimum of two days recommended by the normative resolution RN 493/2012 (Aneel, 2012). This was done to oversize the battery bank to have a safe margin to unexpected situations. The depth of discharge for the sizing of the batteries was 60 %, which is a typical value for deep-cycle batteries. The round trip efficiency of the battery was considered as 95 %. Tab. 1 presents the values considered for the generator and storage to supply CLC1.

Tab. 1: Generation and storage capacity for CLC1.

Component	CLC1
Generator [kWp]	108.5
Storage [kWh]	1,302

Numerical simulations of the interactions between load, demand, and storage to supply the CLC1 are depicted in

Fig. 4, Fig. 5, and Fig.6. Throughout the year the state of charge profile of the battery varies greatly due to the variability in the primary resource and the amount of generation installed capacity. The system is underused during most of the year, what can be seen by the excess profile (green line), and during the month of June the system is constantly overusing the capacity of the storage. This behavior can be observed in Fig. 5 and Fig.6, which are zoomed in areas (respectively A and B) from the annual profile depicted in Fig. 4.

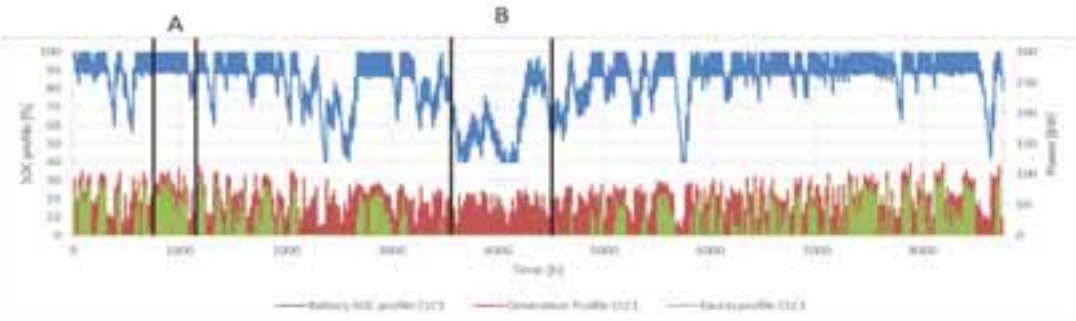

Fig. 4: Interactions between generation and storage to supply CLC1.

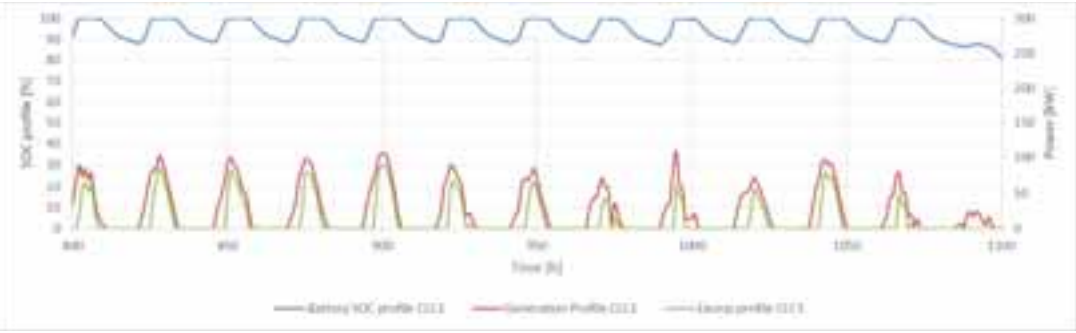

Fig. 5: Interactions between generation and storage to supply CLC1 (from hour 800 to hour 1,100).

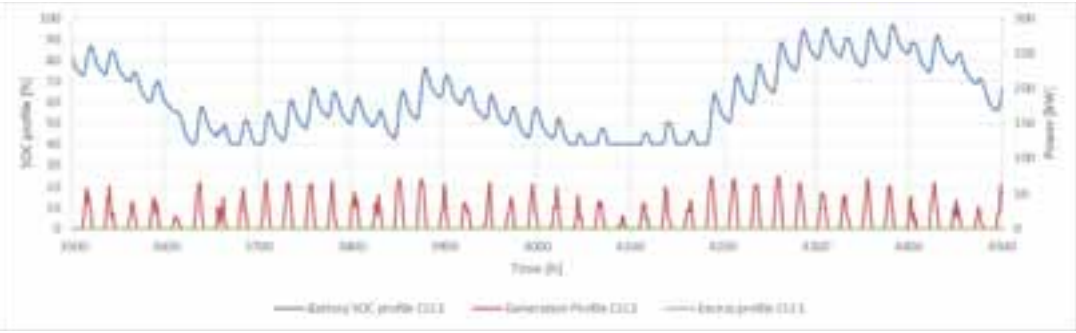

Fig. 6: Interactions between generation and storage to supply CLC1 (from hour 3,500 to hour 4,500).

In the beginning of the year part of the generated energy is not used and is thus wasted. Though the generation system would be able to supply an increasing demand in such months, during the months of low availability, the system would not be able to supply the demand. In this simulation, the LLP of the system was estimated as 1 %, which is an acceptable value. However, the system has little robustness to deal with demand increases.

In order to tackle this problem some alternatives can be used, namely over-dimensioning the system from the start, the use of solar home systems (SHS) to address variations in the predicted demand, the use a dispatchable source, such as a diesel generator or the integration of AREGS.

Over-dimensioning the generation system has the problem of increasing the initial investment, which is already an issue for AREGS, for an infrastructure that may or may not be used. This approach has also the drawback of assuming how the demand will increase over time, which may turn out not to be true and renders the additional investment not suitable or misused.

Alex Renan Arrifano Manito

The use of SHS to account for the additional load may be an option to tackle small loads or when due to some impossibility the AREGS cannot be extended to the new consumer. However, the new system stays isolated from the rest and it is usually less robust since it does not share infrastructure.

A dispatchable source, such as a diesel generator, is desirable in AREGs to supply for periods of low availability of primary resources and reduce the risks associated with intermittent sources like photovoltaics, for instance. However, the option with diesel to tackle demand increases would increase the operational costs of the system and its sensibility to fuel transportation logistics and price. Fig. 7 presents the increase in the hours of operation of the diesel, due to increases in the demand of CLC1. In the simulation, the diesel would supply the power that could not be met by the renewable generation and/or the battery.

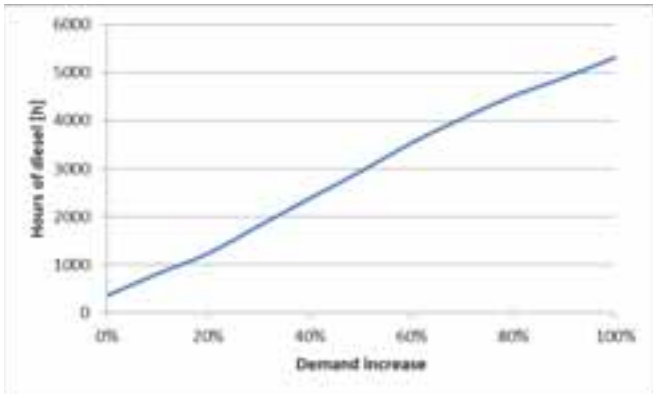

Fig. 7: Interactions between generation and storage to supply CLC1 (from hour 3,500 to hour 4,500).

Though the additional use of the diesel generator could be an option for a short term period, in the long run the operational costs would increase considerably and, as mentioned before, the service would be much more dependable on the fuel supply.

In the case of integrated systems, the additional AREGS could share infrastructure with the existing AREGS. The generation system of the additional AREGS could be smaller than the one that would be needed, if the new AREGS were isolated, due to the capacity of sharing the resources. It is important to mention that the use of one approach does not necessarily exclude the other. An optimized solution can be found by mixing the approaches, depending on the case.

4. Experimental setup and tests

The infrastructure of LSF is composed of four AREGS, each with its respective loads, storage, distributed generation, and grid forming inverters. The whole facility can operate in two main ways. Either the four AREGS are connected to a point of common coupling (PCC), where a diesel generator and the main grid can also be connected, or it can operate as a two levels hierarchy, where AREGS 2, 3, and 4 are connected to the load side of AREGS 1. Moreover, two standby circuits were introduced to allow the connection of temporary components like loads or distributed generation.

AREGS 1 is composed of three SMA Sunny Island inverters of 5 kVA each, forming a three-phase system, a 23.5 kWh battery bank and PV generators connected in the AC as well as in the DC bus with overall installed capacity of 6.71 kWp. AREGS 2 is composed of three Studer Xtender inverters of 6 kVA each, forming a three-phase system, a 19.2 kWh battery bank, and a 2.8 kWp PV generator. AREGS 3 is a single-phase system composed of a 5 kVA SMA Sunny Island inverter, a 9.6 kWh battery bank, and a 1.28 kWp PV generator. AREGS 4 is a single-phase system composed of a 4 kVA Schneider inverter, a 4.8 kWh battery bank, and a 0.4 Wp PV generator. Aside from the AREGSs there is also a 40 kVA diesel generator, which may be connected to all systems. Fig. 8 presents a schematic of the facility implemented at LSF and Fig. 9 presents some of the equipment installed in the laboratory.

The facility was designed to enable a high level of flexibility and scalability, which permits to reproduce many real cases in the operation of the whole system, and considers the benefits and drawbacks of many topologies, including different levels of non-dispatchable renewable energy penetration and storage capacity.

Two conditions of multi-micro-grid operation with the interconnection of AREGS were tested. Fig. 10 presents the two conditions tested in the facility. In the condition presented in Fig. 10a (non-cascaded topology), all

AREGS are connected to a dispatchable source (in this case the diesel generator). In this situation, energy exchange between AREGS, though theoretically possible, needs a fine tuning, to avoid the attempt to inject energy in the diesel generator, which could damage it. This topology is more suitable when the dispatchable source is the grid for the parametrization of the AREGS is independent from one to the other. However, this is not the case for most rural electrification projects. This case is more suitable for micro-grids in the urban environment, where each could just feed the excess into the grid.

For rural electrification projects, the situation depicted in Fig. 10b (cascaded topology) is more suitable. In this situation there are two levels of AREGS. The first level (in this case formed by AREGS 1) creates a situation for the other systems that would resemble connecting them to the conventional grid. AREGS 2, 3 and 4 are connected to the load side of AREGS 1 and are able to inject the excess of energy in the battery of AREGS 1 or this excess could be used to support the loads in AREGS 1, which include the other AREGS.

The diesel would be explicitly controlled by AREGS 1. However, the other AREGS would also have an implicit control over the diesel generator, since for AREGS 1 they are loads which can cause AREGS 1 to trigger the diesel generator. In this situation, attention has to be given to the parametrization of all the AREGS as a whole to avoid undesirable disconnections between systems or the waste of potential to dispatch the excess energy.

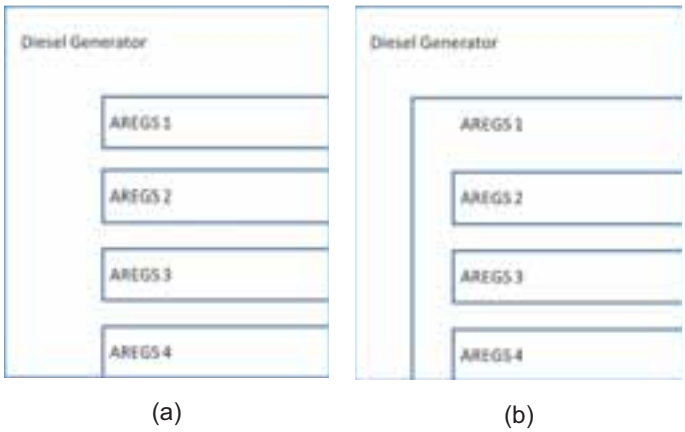

Fig.10: Tested topologies. (a) AREGS connected to a PCC. (b) Two-level AREGS set.

4.1 Experimental setup

In order to compare the two evaluated topologies (non-cascaded topology and cascaded topology), test were carried out. The tests sought to evaluate three scenarios (Case 1, Case 2 and Case 3). For Case 1, the AREGS were assembled in a non-cascaded topology. For Case 2 and Case 3, the AREGS were connected to operate as a cascaded system.

In Case 2 a 2.1 kW distributed generation was connected to the output side of AREGS 3 and the AREGS were parametrized to connect to one another. In Case 3, a 1 kW distributed generation was connected to the output side of AREGS 3. Although the system's topology remained the same as presented for Case 2, the AREGS were not properly parametrized to allow the injection of power from one AREGS to the other. This was done to emphasize the need for the proper parametrization of all the AREGS, considering the cascaded system as a whole.

Further details from the setup used in the tests for Case 2 and Case 3 are presented in Fig 11. For the purpose of the tests, the distributed generation of AREGS 3 was emulated by the output of a grid-tie inverter connected to a PV emulator at the load side of AREGS 3. This would provide a somewhat controlled environment for the experiments. AREGS 3 was then connected to the load side of AREGS 1.

Alex Renan Arrifano Manito

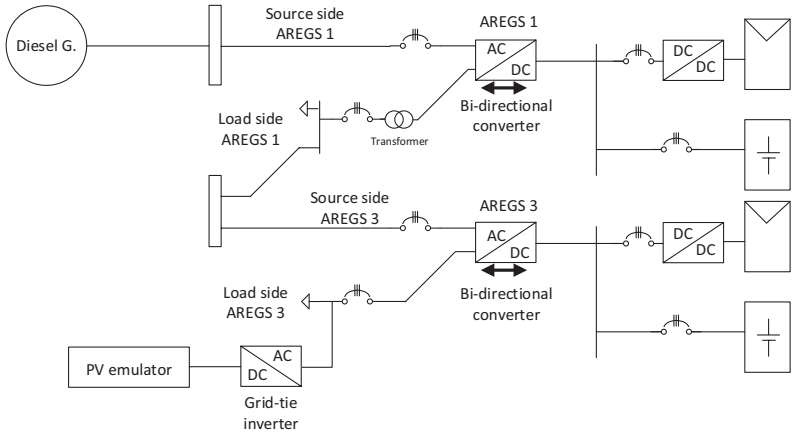

Fig. 11: Experimental setup for Case 2 and Case 3.

4.2 Experimental results

All the results are shown in per unit values and the bases of the system are presented in Tab. 2.

Tab. 2 Bases of the test systems.

Active Power (Pac)	Reactive Power	State of charge (SoC)	Voltage	Frequency	Irradiation
5 kW	5 kvar	100	220 V	60 Hz	1000 W/m^2

When all the AREGS are connected in a non-cascaded topology, the injection of power back to the external source is undesirable, in the case of standalone systems, since it could damage the source (usually a Diesel generator). In such situations the reverse power is usually blocked by the grid forming inverter, which should disconnect from the external source if a small amount of reverse power is measured. Fig. 12 presents the operation of AREGS 1 when all the AREGS have the same external source (a Diesel generator). The distributed generation (PV generator) from AREGS 1 injects power into its battery (consider negative values as power being fed to the battery) until the battery is full. Though there is still primary resource for the PV generator, the frequency is used as a way to limit the injection of power by the distributed generation since the power surplus cannot be used. In this situation, the only benefit is that all the AREGS can share the same external source, but the energy exchange from one to the other would not be possible due to safety reasons, which in turn, diminishes the benefits of interconnection.

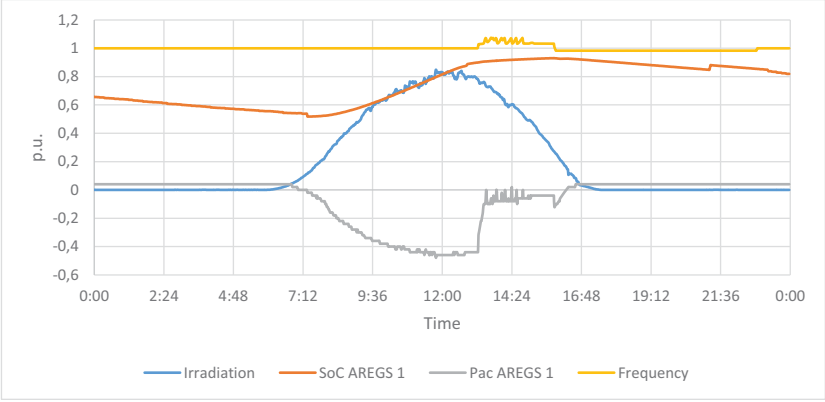

Fig. 12 – AREGS 1 operation when all the AREGS connect to the same source.

In the Case 2, the distributed generation from AREGS 3 charges the battery of AREGS 1, as shown in Fig. 13. Some of the power, however, is still injected into the battery of AREGS 3 until the battery is completely charged.

Alex Renan Arrifano Manito

A drop in the injection of active power occurred due to the supply of reactive power into the PCC as shown in Fig. 14. The reactive power was being injected due to the use of a transformer to connect AREGS 1 to the PCC, causing the grid-tie inverter to change its operation point to supply also reactive power.

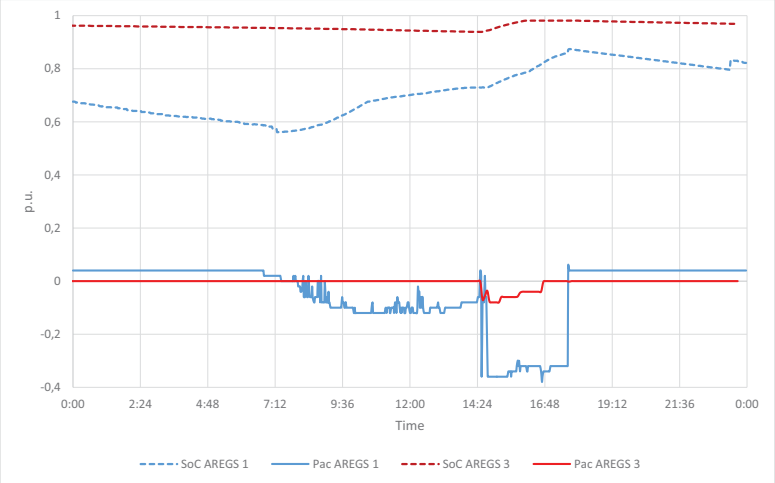

Fig. 13: Power exchange between AREGS (Case 2).

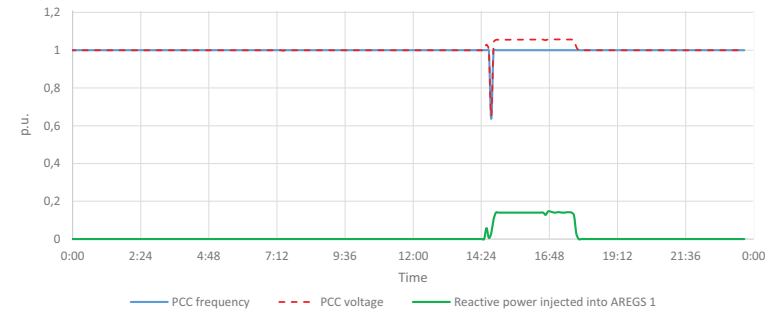

Fig. 14: Frequency, voltage and reactive power profile for Case 2.

During this period, there was no noticeable frequency deviation, however, there was a voltage rise at the PCC of 6%. This points to the fact that though some of the power may be injected into the other AREGS, there could be a deterioration in power quality at the PCC due to excess generation, similar to what happens in a conventional distribution grid with high distributed generation penetration if proper measures, such as power limitation, are not implemented to account for the moments when power quality deterioration occurs.

As stated before, the battery from AREGS 1 provides a security layer that would prevent any of the other AREGS from injecting into the diesel generator. Had the AREGS been assembled having a common coupling point with the Diesel generator (non-cascaded topology) and no measures were taken to block reverse power, such operation wound represent a risk in the case of an isolated power system, since the AREGS could perceive the Diesel generator as a load, especially when the Diesel generator powers off. During the period in which the rotor is decelerating the control of the AREGS could perceive a frequency drop try to inject power into the diesel generator.

In Fig. 15 it is shown that the proper parametrization of all AREGS connected to the cascaded micro-grid should be considered as a whole, otherwise the benefits of such topology can be hampered. In the situation depicted in Fig 15 (Case 3) though there is an excess in power in AREGS 3, it does not inject power into AREGS 1. Instead it limits the power injected into its own battery by causing a frequency rise at the point where the grid-tie inverter is connected. The limitation in the injected power and the frequency rise can be observed in Fig. 15 and Fig. 16 respectively. In this situation there is no noticeable voltage rise at the coupling point with the grid-tie inverter since the voltage at the output of the bi-directional inverter from AREGS 3 is the reference of the system, the

same does not occur in the Case 1. Fig. 17 presents qualitatively how the voltage behave in Case 2 and Case 3.

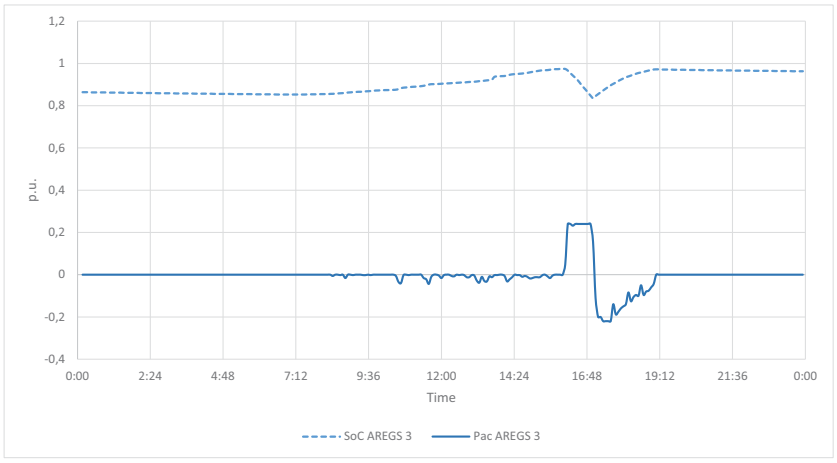

Fig. 15 – Power limitation due to AREGS 2 not connecting to AREGS 1 (Case 3).

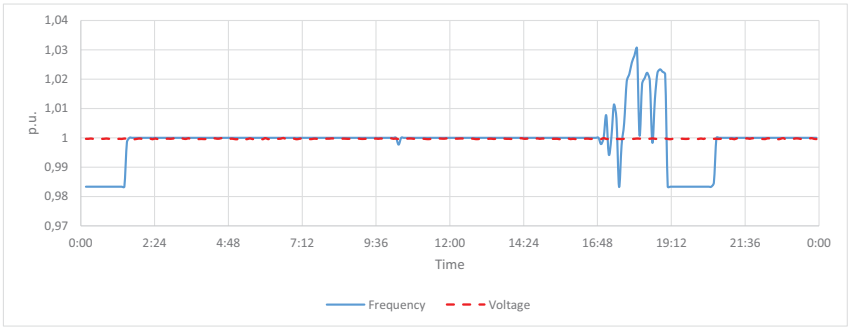

Fig. 16 – Frequency and voltage profile for Case 3.

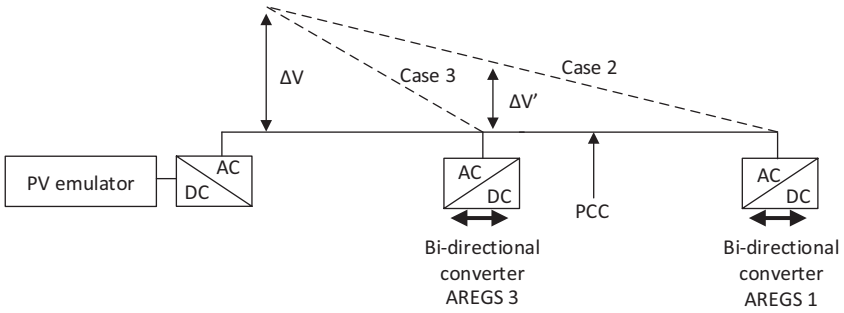

Fig. 17 – Voltage profile for the cascaded tested topologies.

5. Conclusions

Recently, attention is being given to the interconnection of micro-grids in multi-micro-grid topology. This is attributed to the new features that are being introduced in grid-forming inverters and that allow new topologies for the operation of micro-grids.

The ability to interconnect micro-grids and even stack them in a hierarchy improves the sustainability and robustness of the system as a whole, especially in rural electrification projects, where due to all the uncertainties regarding the demand and the evolution of the demand over the years of the project need to be robust and flexible to respond to changes. Consequently, the generation and distribution system should be designed with a level of

flexibility in order to avoid the impossibility of an eventual expansion.

During the tests, the use of a two-level set of AREGS was found to be a suitable topology to attribute modularity and scalability to the rural electrification solution. However, attention has to be given to the proper parametrization of the cascaded system as a whole and to the effects that the connection would produce at the PCC. It is emphasized that usually, standalone systems like the ones evaluated in this paper constitute relatively weak grids, and, therefore, more susceptible to power quality issues like voltage rise. In the case presented in the tests, voltage at the PCC could be a control signal for power limitation from the distributed generation if the voltage falls out of acceptable values.

The integrated AREGS can improve the management of energy and add modularity to deal with unpredicted situation. In order to study these problems the Laboratory of Photovoltaic Systems of the University of São Paulo implemented a test facility using the four available AREGS to form a smart micro-grid, which is being used both for research and capacity building.

Abstract

The pumps work differently in terms of performance characteristics when operated in reverse mode to generate mechanical rotational energy driven by the water energy. The performance characteristics related to head, flow rate, specific speed and efficiency have been predicted differently from available conversion methods. Also, the procedure of selecting pump as hydro-turbine varies from different conversion methods. This article presents the methodological approach of evaluating the pump as hydro-turbine related to selection procedures, performance characteristics and challenges.

Keywords: Challenges, pump as hydro-turbine, performance characteristics, selection procedures.

1. Introduction

The micro or small hydropower is very potential for electricity generation in the remote areas of Africa continent, especially in the sub-Saharan African regions (Kaunda et al, 2012). The communities need a simple design, ease manufacturing and affordable technology that will sustain extreme local conditions, inexpensive and low maintenance cost for electricity generation (Mbabazi and Leary, 2010). Locally manufactured of hydro-turbine in a developing country will enable the costs per unit of energy output to be lower than the use of small diesel or petrol generators, solar PV systems or wind turbines (Williams and Simpson, 2008).

The selection of hydro-turbine depends on the site characteristics i.e, head and flow rate. Micro hydropower schemes can use the standardized equipment, low-cost approaches and off-the-shelf equipment (Patel et al, 2015). But, the main problem is to get a proper hydro-turbine within the remote market areas (Suarda et al, 2006). The equipment like pump that is used in water pumping for domestic and industrial use, irrigation, livestock and sewage systems in the off-grid remote areas are used as hydro-turbine for micro hydropower (Muttalli et al, 2014; Popescu et al, 2013). The off-the-shelf pump still limited to the less than 100 kW (Garay, 1990).

This article presents the methodological approach of getting the off-the-shelf Pump as Hydro-turbine (PAT) for potential micro hydropower. The selection procedures help to find the possible pump that fits the specific hydropower site. Through testing by using numerical analysis i.e., Computational Fluids Dynamics (CFD) or test rig in the laboratory is possible to get the PAT performance characteristics include head, flow rate, power delivered, efficiency and losses. Also, the conversion methods used to convert the pump performance characteristics to PAT characteristics. Therefore, the main objective of this article is to review the procedures of selecting the off-the-shelf pump, performance characteristics and challenges of using pump as turbine for hydropower schemes development.

doi:10.18086/swc.2017.03.02 Available at http://proceedings.ises.org

1.1. Pump as Hydro-turbine Application

The principle operation of pump is depending on the centrifugal force, cross-sectional area and fluid velocity. The main parts of pump are presented in Fig. 1 (a). The centrifugal force exerted on the water by the rotating impeller, moves the water away from the suction eye and out along the impeller vanes to their extreme tip where the liquid is then forced against the inside walls of the increasing cross-sectional area between impeller with blades and casing to convert kinetic energy of the water into pressure energy at the discharge part. For PAT as presented in Fig. 1(b), water pressure inflow at the discharge part and strike the impeller with blades to generate mechanical rotation connected to the shaft and rotate in the opposite direction of pump rotational speed. Motor or generator connected to the shaft for electricity generation.

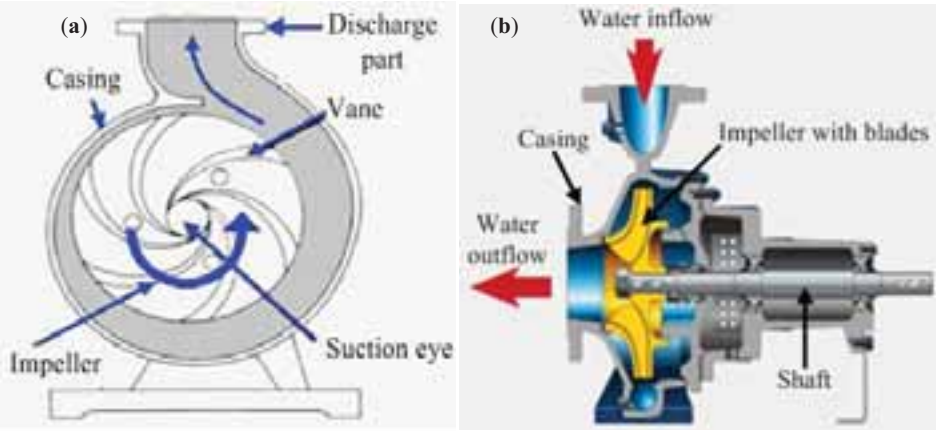

Fig. 1: Principle operation of pump. (a) sectional view of pump showing main parts (Chaurette, 2005). (b) sectional view of pump in reverse mode showing the direction of water flow and shaft connected to impeller (Orchard, 2009)

2. Methodological Approach

The methodological approach of selecting PAT is based on the methods used to convert pump performance characteristics related to head, flow rate, power and efficiency to the PAT characteristics (Fig. 2). The detail descriptions of the methodological approach is presented in the next sub-sessions.

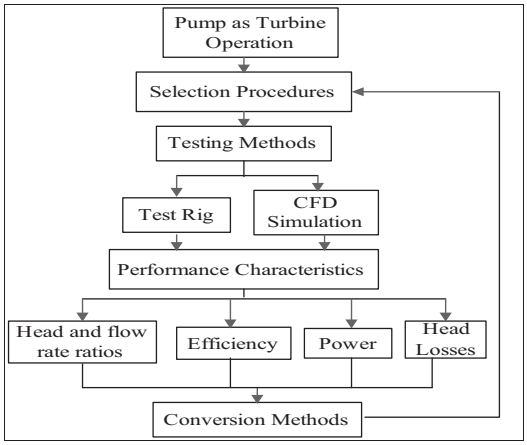

Fig. 2: Methodological approach of pump as turbine application

2.1 Selection Procedures

The selection procedures are based on the geometric shape of the pump controlled by calculating the specific speed. The procedures are as follows:

i. To calculate the hydro-turbine specific speed (n_{st}) related to head and flow rate for given hydropower site at a given rotational speed.

ii. To collect the pump datasheet that consists of head, flow rate, rotational speed, horse power and efficiency and used to calculate the specific speed (n_{sp}).

iii. To calculate the specific speed of PAT by using the conversion equations from Tan and Engeda (2016), Yang et al (2012), Singh and Nestmann (2011) and Chapallaz et al (1992). When the four conversion equations are compared to each other, indicated to have the fit-line of squared R of 0.944 as presented in Fig. 3. This step used to control the geometric shape of the pump related to hydro-turbine head and flow rate.

iv. Then, calculated PAT specific speed should be about equal to step (i) to select the pump related to the pump datasheet information.

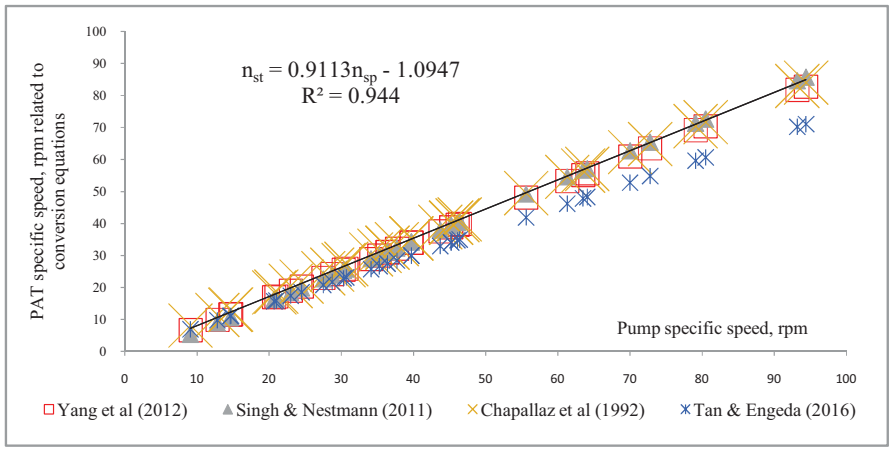

Fig. 3: Variation of PAT specific speed from various empirical equations

v. To regulate the rotation speed of pump as turbine by using modified affinity laws described in Carravetta et al (2014) or unmodified affinity laws described in Chapallaz et al (1992). Williams (1995) also regulated the head and flow rate ratios by using the efficiency and rotational speed.

2.2 Testing Methods

The PAT is tested by using a test rig or/and numerical analysis based on CFD simulation. The test rig simulates the site conditions and results can be very useful for predicting the real situation in the potential hydropower site. Krivichenko (1994) indicated the test rig can measure the PAT performance characteristics and cavitation effect. But, the use of CFD simulation helps to investigate the internal losses and flow patterns in the impeller

with blades, draft tube and casing which could not be measured experimentally (Nigussie and Dribssa, 2015; Agarwal, 2012).

2.3 Performance Characteristics

Pump performance characteristics for reverse mode is not declared from the off-the-shelf pump datasheet provided by the pump manufacturer (Buono et al, 2015). But, pump operated in reverse direction indicated to change their performance characteristics include head, flow rate, efficiency and specific speed. The PAT performance characteristics are still very complex to find a relationship to cover all pumps performance characteristics given in the datasheet (Baburaj et al, 2013). Fortunately, Nautiyal et al (2011) indicated the running of pump in reverse mode works without technical complications. The most common performance characteristics are presented below:

2.3.1 Head and flow rate

The ratios of head and flow rate for pump operating in reverse and pump modes is greater than 1. The conversion equations use slope/gradients method to correlate head and flow rate from optimum condition. More than twenty conversion equations are found in Bogdanovic-Jovanovic et al (2014); Nautiyal and Kumar (2011); Teuteberg (2010); Derakhshan and Nourbakhsh (2008); Singh (2005); Alatorre-Frenk (1994) and Williams (1994). The ratios of pump head and flow rate are calculated separately for most existing conversion methods. The head obtained in reverse mode is divided by pump head to get the head ratio and flow rate obtained in reverse mode is divided by pump flow rate to get flow rate ratio. The correlation of head and flow rate ratios related to specific speed for twenty eight (28) experimental data, separately collected from Tan and Engeda (2016), Singh (2005), Qian et al (2016), Fernández et al (2004), Derakhshan and Nourbakhsh (2008), Couzinet (2013) and Barbarelli et al (2017) as presented in Fig.4. The squared R is greater than 0.7.

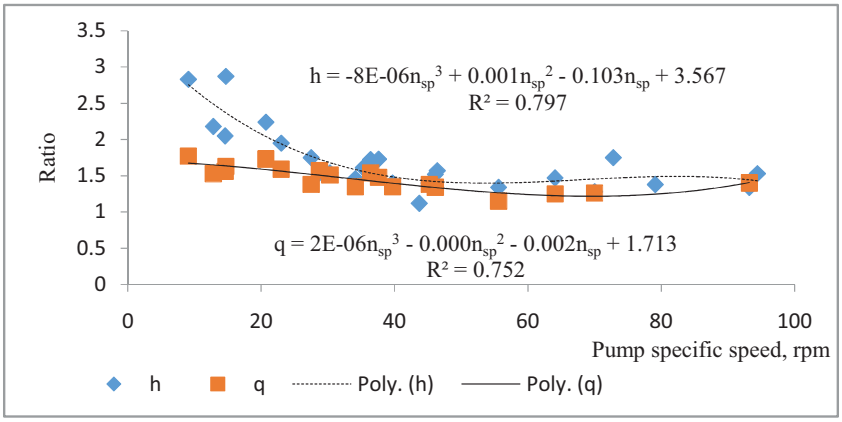

Fig. 4. Correlation of head and flow rate ratios versus specific speed

2.3.2 Power

The PAT power is the ratio of pump horsepower and its efficiency (Ventrone and Navarro, 1982). The efficiency data is collected from pump datasheet (Pedrollo, 2016). Alternatively, PAT power is estimated by using Equation (1) given the PAT efficiency conversion equations collected from Bogdanovic-Jovanovic (2014), Chapallaz et al (1992) and Williams (1994). Fig. 5 presents the variation of PAT power against standard pump rated power. The method is more suitable during the desk work studies. H, Q, g, η, ρ and P present the head, flow rate, acceleration due to gravity, efficiency, density of water and power. Subscripts t presents turbine mode.

$$P_t = \rho * g * H_t * Q_t * \eta_t \qquad \text{(eq. 1)}$$

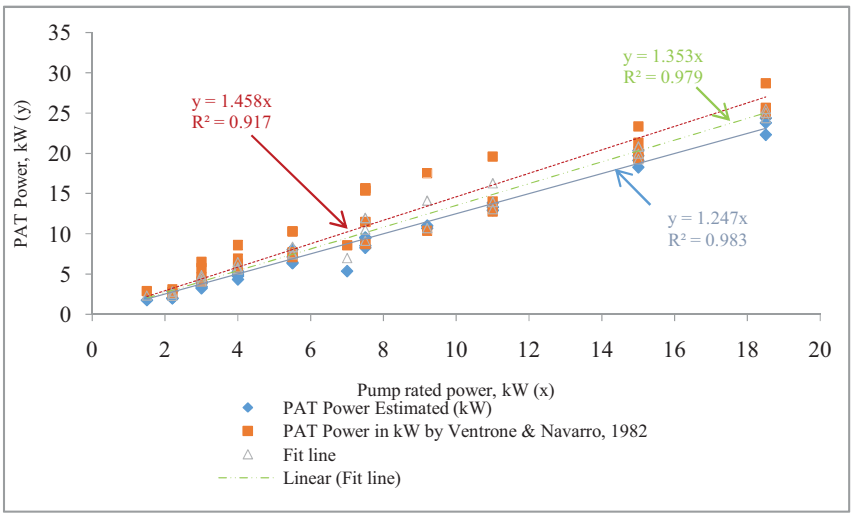

Fig. 5. Comparison of the PAT power with pump horsepower

2.3.3 Efficiency

The PAT efficiency tested from different research works for a range of the off-the-shelf pump (14.6 to 93.2rpm) is presented in Fig. 6. The efficiency-curves were digitized by using a Getdata software (GetData, 2017). Steller et al (2008) presented the overall efficiency of PAT against the percentage of flow rate. Tan and Engeda (2016) indicated the pump specific speed of 30.7, 43.7, 63.5 and 80.5 rpm operated with flow rate coefficient of less than 0.08 with constant flow rate coefficient. But, Singh (2005) indicated the pump specific speed range from 35, 36.4, 39.4, 45.2 and 46.2 rpm operated with flow rate coefficient less than 0.4 with percentage flow rate coefficient of less than 25 %; 61.3 and 79.1rpm operated with flow rate coefficient from 0.25 to 0.75. The flow rate coefficient variations do not affect the efficiency of the PAT. But, pump with low efficiency when operated in reverse mode has also a low efficiency. Also, the pump with higher specific speed delivered the highest efficiency and allowing the larger variation of flow rate coefficient compared to the low specific speed PAT. The overall-PAT efficiency is less than 86 %.

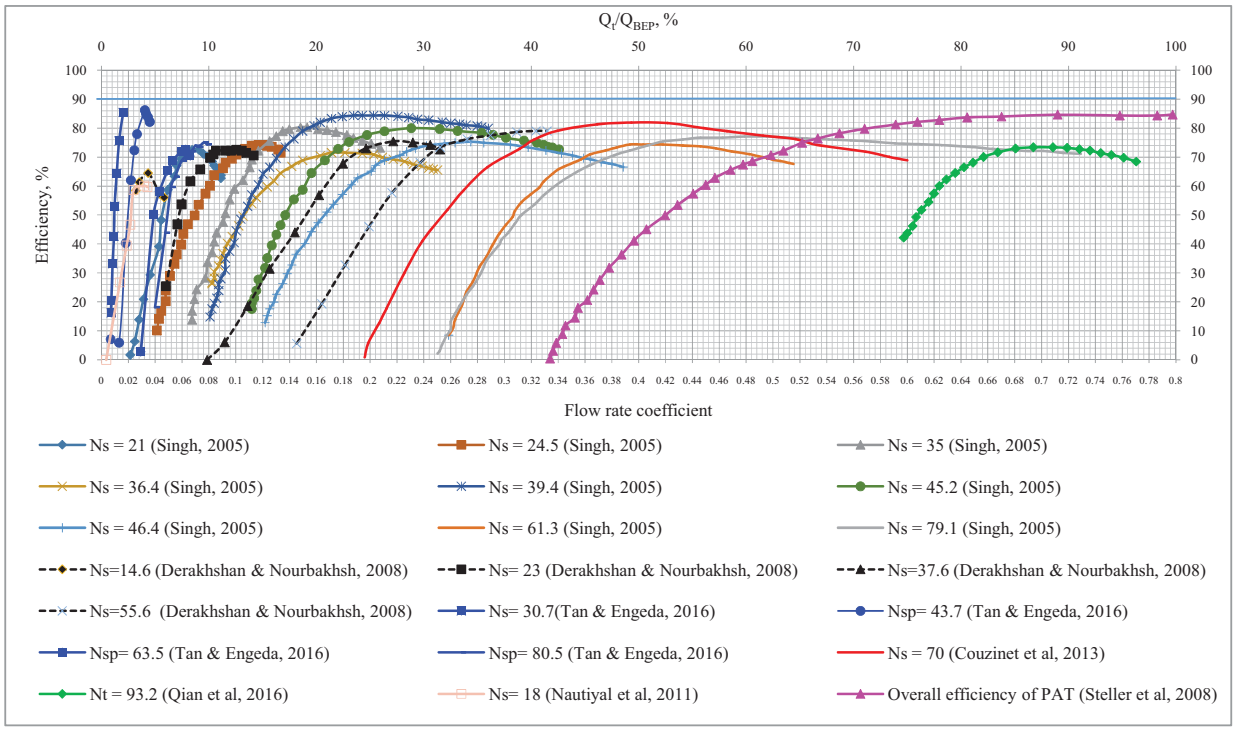

Fig. 6: Overall operating efficiencies for PAT from pump specific speed range from 14.6 to 93.2 rpm

2.4. Head losses

The difference of hydraulic pressure between the intake/forbay to the hydropower plant over the product of density and acceleration due to gravity presents the gross head. The head loss lower the available gross head that decreases the net head available to strike the impeller with blades. The head losses in the penstock, casing, impeller with blades and draft tube are discussed below.

2.4.1 Penstock

Water flowing through a penstock or canal encounters head losses due to friction and fittings (including elbow, tees, etc.). The head losses in the penstock are calculated by using friction loss tables, curves or a nomograph provided from the penstock/pipe manufacturer (Moran, 2016). For instance, 20 % increase in penstock diameter leads to a 60 % decrease in head losses (Gatte and Kadhim, 2012). Fernandez et al (2002) indicated that friction losses is reduced by increasing the diameter and/or reducing the equivalent length of the pump suction side. Alternatively, head loss estimated by using Equation (2) (Williams, 1995). Q_m is the pump flow rate given by the manufacturer based on the penstock diameter. L is the penstock length.

$$H_l(\%) = \frac{L}{H_t} * \left(\frac{Q_t}{Q_m}\right)^2 \qquad \text{(eq.2)}$$

Also, the Darcy-Weisbach equation used to calculate the head loss (Penche, 2004). Different penstock materials are based on the roughness height of commercial pipes for a given diameter and the Reynolds number obtained by using the Moody chart to interpolate the value of the friction factor (Moody, 1944). The roughness of commercial pipes is described in White (2011). Fig. 7 presents the variation of head loss against flow rate for 100 feet of PVC class 160 plastic pipe with a diameter less than 152.4 mm or 6 inches (Pipeline, 2017). Head loss reduces the available gross head as well as the expected power generation, but Penche and de Minas (1998) indicated that a power loss of 4 % is usually acceptable.

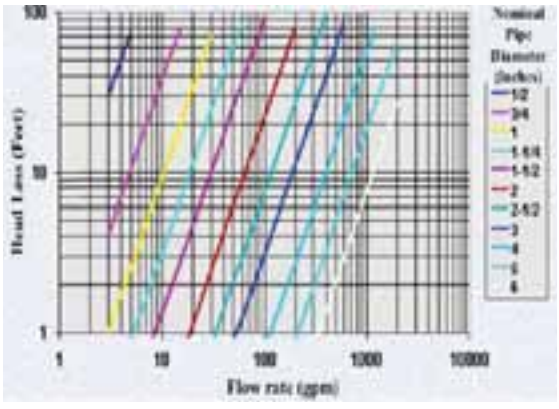

Fig. 7: Relationship of head loss versus flow rate (Pipeline, 2017).

2.4.2 Hydropower system

Water flow in the PAT from the inlet to strike the impeller with blades surrounding with casing is an exit at the outlet pipe connected to the draft tube. The most common micro hydropower head loss installed with PAT based on the rule of thumb and experimental data are presented in Table 1. Head loss varies from 5 to 33 % of the total penstock length and mostly are occurred for small and micro hydropower system (Williams, 1995). It is still indicated the head loss in the impeller with blades is higher compared to the draft tube and casing (Rawal and Kshirsagar, 2007).

Table 1: Percentage of head loss from PAT hydropower system

Head loss as percentage of total penstock length (%)	Applied condition	Source
5-25	Rule of thumb	Klingeman and Wheeler (1982)
10-20		Williams (1995)
10-15		Canyonhydro (2017)
10		Renewables First (2017)
12.2	Installed PAT	Smith and Ranjitkar (2000)
13.2	Installed PAT	Arriaga (2010)
< 33 for small systems	Rule of thumb	Gatte and Kadhim (2012)

3. Challenges of Using Pump as Hydro-turbine

The different challenges and description for PAT application in hydropower schemes are presented in Table 2.

Table 2. List of challenges and description for pump as hydro-turbine

Challenges	Description	Sources
Flow rate leakage	Leaking back of fluid from the high pressure side to the low pressure side that tends to lower the performance	Chapallaz et al (1992)
Range of flow rate	Particular pump can operate as much less that for a conventional turbine	Popescu et al (2003); Williams (1995)
Major design changes	Changing are based on the bearings design and checking the seals, stress and threaded of shaft	Chapallaz et al (1992)
Material types	i. Built-with carbon-impregnated nylon without many hard particles, broze or cast iron and eye-clearance fit the suction inlet ii. It also the shaft material should not easily scratched by knife	Williams (1995)
Head and flow rate	Pump operates at higher head and flow rates values in water turbine mode at the same rotational speed	Popescu et al (2003); Nautiyal et al (2011)
Efficiency	Efficiency of PAT is usually lower than that of conventional turbines	Patel et al (2015); Motwania et al (2013); Nautiyal et al (2011)

Torque	Reduction of rotation speed can lower the torque	Dribssa et al (2015)
Conversion equations	The performance characteristics related to head, flow rate, power, specific speed and efficiency are predicted differently from one pair to another by ±20 %	Williams (1995)
Runaway	Characteristic of runaway in PAT is more dangerous and essentially associated with increase of operating head compared to the actual operating head when is in load condition	Singh (2005)
Pump datasheet	Lacking of performance datasheet as the major limitation of using PAT	Buono et al (2015); Agarwal (2012)
Fixed geometric shape	PATs are very sensitive towards changing of head and flow rate within the fixed geometric shape i.e impeller and casing results to poor part-load performance	Ramos and Borga (2000); Singh (2005)
Constant flow rate	The construction of reservoir for PAT as small system is not a good option	Williams (1996)

4. Conclusions

This methodological approach helps to increase the awareness of harnessing the potential micro hydropower in off-grid remote areas by using off-the-shelf pump. The performance characteristics of pump that are changed when operated as turbine include head, flow rate, power, specific speed and efficiency. This article discusses the selection procedures, performance characteristics and challenges of using off-the-shelf pump. PAT efficiency indicates to have the maximum efficiency of about 86 % against the flow rate coefficient based on the twenty (20) collected tested characteristics for pumps specific speed range from 14.6 to 93.2 rpm and flow rate coefficient greater than 0 to 0.8. It also indicates the efficiency is constant when the percentage for flow rate coefficient variation is less than 25 %. Furthermore, this paper presents the main challenges of using PAT include the low range of flow rate, replacement of bearing, fixed the geometric shape, reduced of torque and lack of pump datasheet.

Abstract

Rapid expansion of solar thermal energy for increasing energy efficiency of buildings has been adopted in short/medium and long-term energy strategies of EU countries. Within this context, the overall objective of this work is to develop an innovative high performance and cost effective hybrid solar heat and power system. The initial application is to be implemented in individual dwellings and small business residential buildings for on-site electricity and heat generation using solar thermal energy. It is estimated that the proposed technology will deliver 60% of domestic energy requirements and provide 20% reduction in energy costs and greenhouse gas emissions compared to the best existing low carbon energy technologies. The aim of this study consists in performing a comparative analysis of the different building typologies, which can host this technology, and their energy demands for heating and domestic hot water, as well as their CO_2 emissions.

Keywords: Solar thermal energy, Micro-organic Rankine cycle, Phase change materials, Energy savings, Building energy demand, Residential building typology.

1. Introduction

In Europe the building sector represents 41% of the final energy consumption and the 40% of the total GHG emissions of end-use sectors (Directive 2010/31/EU). The Renewable Heat Incentive and similar schemes, which are deployed across a number of EU countries (e.g. UK, Germany, France, Italy, Spain), encourage uptake of renewable heat technologies to support the ambition of 12% of heating coming from renewable sources by 2020.

The present work is part of the Innova MicroSolar project, which is funded within the framework research and innovation programme Horizon 2020. The overall objective of this project is to develop an innovative high performance, cost effective and solar high durability 2-kW_{el}/18-kW_{th} heat and power system for on-site heat and power supply to individual dwellings and small business residential buildings using solar thermal energy. The proposed technology will be built around a small scale solar concentrating collectors which supply thermal energy to power the small high performance organic Rankine cycle (ORC) turbine with 2-kW_{el} output. To control the energy input and output, a thermal energy storage unit with phase change materials (PCM) will be designed. The system will provide 60% of the required building energy and reduce 20% the energy costs and greenhouse gas (GHG) emissions compared to the best existing low carbon energy technologies.

Figure 1 shows the preliminary scheme design of the system that mainly consists of the following parts:

- Concentrating solar collectors (CSP): The CSP system is based on linear Fresnel mirrors which are considerably easier and cheaper to manufacture than their parabolic equals. The system incorporates a sun tracking mechanism and can supply heat transfer fluid (HTF) flow at 295ºC.

doi:10.18086/swc.2017.04.01 Available at http://proceedings.ises.org

- PCM thermal energy storage: the storage block has two different main components, the PCM tank and the enhanced heat sink, which are connected by heat pipes. The novelties of this unit are the PCM compound with the tuned melting temperature for heat storage, and the reversible heat pipes capable of transferring heat at the required high heating rate in both directions.
- Micro-organic Rankine cycle plant: micro-ORC technology is equipped with a high speed permanent magnet AC alternator able to supply 2.3 kW_{el}.

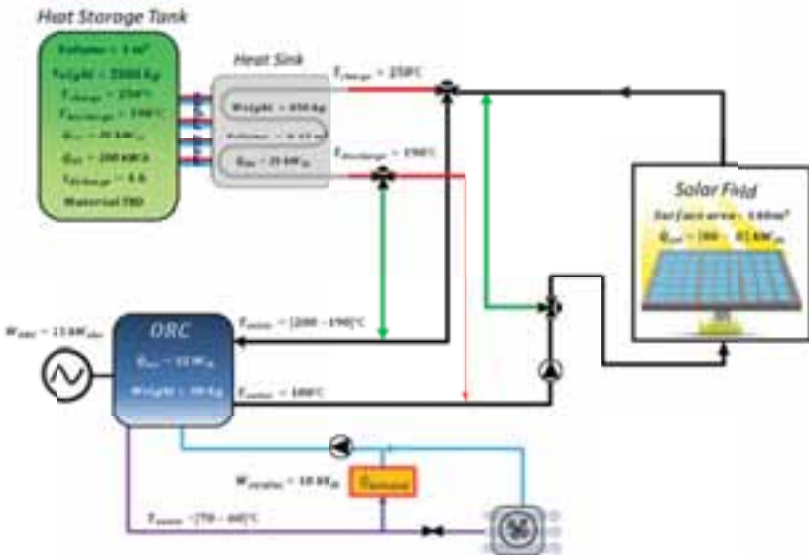

Fig. 1: Innova MicroSolar system diagram

The aim of this study consists in providing information on types of domestic residential buildings for Spain, Italy, UK, France, and Germany. This information will include specification of details on their architecture, building envelope, range of dimensions of living space, their insulation properties, hydronic domestic hot water (DHW), and space heating systems, seasonal and annual energy demands for DHW, heating, and electricity. This information will be used as input data to define and adapt the final design of the system, which will include different building typologies, climate conditions, and energy demand among other technical requirements.

2. Comparative evaluation of building typology, energy demand and CO_2 emissions

From the literature review, projects funded by the IEE agency such as DATAMINE, TABULA, and EPISCOPE (episcope.eu/iee-project) have previously studied the energy performance of the EU building stock by using the energy performance certificates and the different building typology approaches based on the DATAMINE structure and previous experiences of typological classifications used in European countries. The main outcome of these projects was an interactive database named TABULA WebTool created to share valuable information with the scientific community and building experts from European countries.

After performing a comprehensive analysis of these consecutive EU projects (2006-2016) a standardized building classification was identified. In addition, the energy demand for heating and DHW and the related CO_2 emissions sorted by building typology, age classes, and different climatic conditions were compared. Table 1 shows the classification that divides the EU building stock into four general typologies: single family house (SFH), terraced house (TH), multifamily house (MFH) and apartment block (AB). Since databases present different age classes by country (six in Spain, 12 in Germany, ten in France, eight in Italy, and eight in UK), an overall building classification grouped into three different age classes, from 1970 to 1985, from 1986 to 2000, and from 2001 to 2016 was used to unify and compare all the countries within the same age bands. Also, the climatic conditions inside a country were divided into three different classes: hot, temperate, and cold,

representing the hottest, the average, and the coldest climatic conditions of a country, respectively.

Tab. 1: Example of standardized building classification for Germany from 2001 to 2016 divided in four typologies by TABULA

Single family house (SFH)	Terraced house (TH)	Multifamily house (MFH)	Apartment block (AB)
			

3. Results

Up to 14 different climatic conditions have been analysed and treated for the different analysed countries (Spain, France, Italy, UK, Germany, and Sweden). However, due to the huge variation on climatic conditions across Europe, the scope of this study is focused only on the representative temperate climatic conditions of the countries in Table 2. The results are organized according to the main outcomes from the aforementioned findings divided in energy demand for heating and DHW and the derived CO_2 emissions.

Tab. 2: Temperate climates of the analysed countries

Country	Spain	Italy	France	Germany	U.K	Sweden
Climate	Atlantic	Middle	H2	Kassel	England	Zone 2

3.1. Annual energy demand for heating and DHW

Figure 2 shows the energy consumption for heating and DHW in temperate climatic conditions by country. As it was expected, the energy demand is lower in apartment blocks in comparison to single family houses and terraced houses for all the EU countries analysed. These results emphasize the importance of the building shape that presents higher compactness (lower form factor between the building surfaces in contact with the non-heated areas and total air volume of the building) in apartment blocks and multifamily houses, so requiring less energy for heating. Additionally, many variations in terms of energy demands for heating and DHW were observed for the same building typology when countries and building construction periods were compared for temperate regions.

Figure 2 also highlights the reduction of the energy demand of buildings over time, for each type of building. Since poor construction systems and low insulation levels were common in old building typologies (1970-1985), European energy policies towards more efficient buildings had a direct impact on reducing the energy demand of buildings. For instance, nowadays newest types of buildings in Spain (2001-2016) consume around 50 % less energy for heating and DHW compared to old building typologies (1970-1985). Similar energy trends were observed in Italy, UK, France, and Germany, but not in Sweden where higher insulation levels were implemented before the considered period in this study.

Regarding to examples of different thermal transmittance coefficient of buildings envelopes, the walls of a single family house in Germany (1986-2000) has 0.35 $W/m^2 \cdot K$ while in Spain the same building characteristics and period shows the double (0.60 $W/m^2 \cdot K$). However, as shown in Figure 2, for the specific construction period of 1986-2000 the German single family house consumes 190 $kWh/m^2 \cdot year$ for heating and DHW in temperate climatic conditions while in Spain the same building typology requires only 60 $kWh/m^2 \cdot year$. As expected, northern countries such as Sweden, UK, and Germany show higher energy demands for heating purposes than southern countries such as Spain and Italy, even using higher insulation levels on building skins. That fact highlights the relevant impact of the climatic conditions in the final energy consumption of a building.

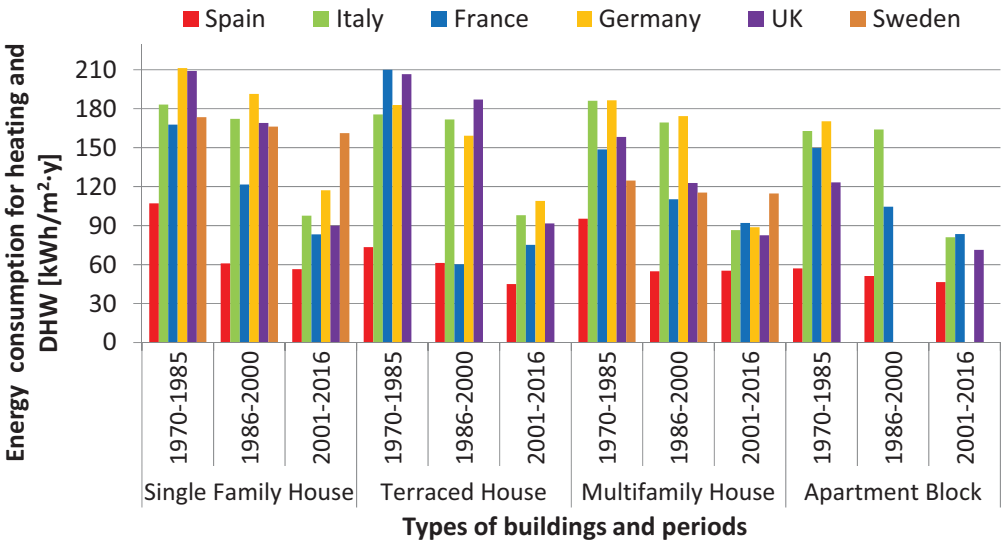

Fig. 2: Energy consumption for heating and domestic hot water in temperate climatic conditions by country

In southern countries such Spain, Italy, and some regions of France, in which Mediterranean climatic conditions are hot, the domestic hot water can account for more than a half of the total energy consumption of a building. As an example, a single family house in Spain (1986-2000) accounted for 41.8 kWh/m^2·y of consumed energy to cover heating and DHW demand (Figure 2) and 20.2 kWh/m^2·y come only from DHW requirements. However, in the opposite site, northern countries such as Germany or Sweden have higher rates in terms of energy consumption for heating in comparison to the energy consumption for DHW. For a similar case scenario in Germany, the calculated delivered energy for heating & DHW of a single family house, from 1986 to 2000, was 188.5 kWh/m^2·y while only 21.1 kWh/m^2·y were for DHW requirements.

These results highlight the wide application potential of new and innovative technologies such as the micro solar heat and power system in different countries and different building typologies.

3.2. Annual CO2 emissions

The expected trends in reducing the CO_2 emissions in all studied countries can be seen in Figure 3. All the building typologies show a reduction of the CO_2 emissions throughout the years, being the newest period (2001-2016) the lowest emissions. These results could be directly related to the reduction in the energy demand for heating purposes. However, Figure 3 shows that in UK, multifamily houses have a higher CO_2 emissions levels despite the fact that their energy consumption is lower than other building typologies. That difference is due to the heating technology considered on TABULA WebTool. Terrace houses supply the heating by condensing boilers while multifamily houses (from 1970 to 2000) use electrical heaters; and the CO_2 emissions per electrical kilowatt in UK is high because of the energy mix. For that reason, the Innova MicroSolar project can achieve its energy savings goal but depending on the current technology installed it may not fulfil the CO_2 emissions required. For instance, multifamily houses located in UK which were built from 1970 to 1985 emit 0.58 CO_2 kg/kW, these emissions go down to 0.28 CO_2 kg/kW in multifamily houses built from 2001 to 2016 due to the implementation of condensing boilers to provide the heat & DHW demand.

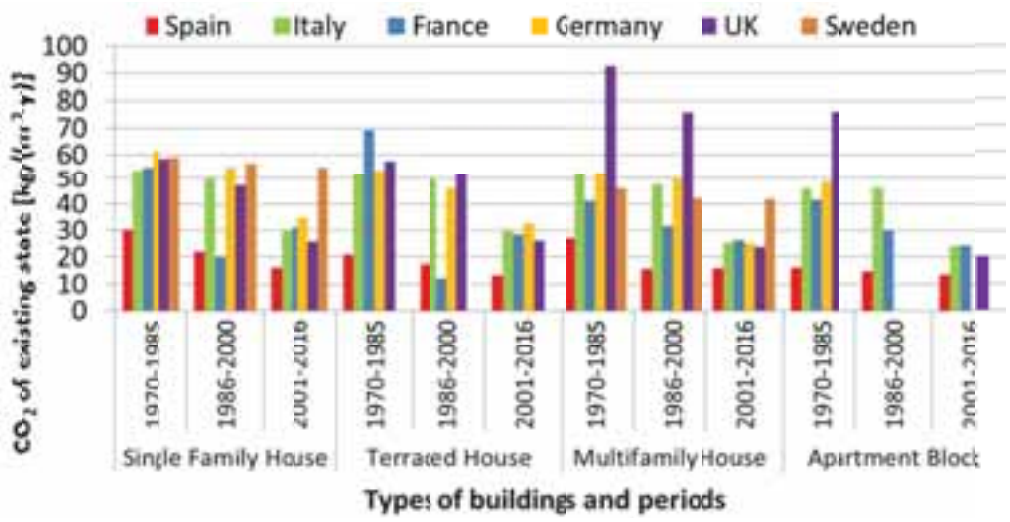

Fig. 3: CO_2 emissions in temperate climatic conditions

4. Conclusions

After performing an estimation of the energy demand for the most common domestic residential buildings in different European countries, the following are the main outcomes of this study:

- The energy policies proposed in many European countries towards more sustainable buildings are being a direct impact in reducing the energy demand in buildings.
- After a literature review, four main typologies of domestic residential buildings have detected for the aforementioned European countries: single family house (SFH), terraced house (TH), multifamily house (MFH) and apartment block (AB).
- The DHW demand of a building is mainly related to the human behaviour and the performance of the system while the heating demand is mainly attributed to the climatic conditions and the building insulation level.
- The estimated range of the energy consumption for heating and DHW was from 46.5 kWh/m^2·y for new apartment blocks in a temperate Spanish climate to 210 kWh/m^2·y for old French terraced house (1970-1985) in the same climatic conditions.
- The CO_2 emissions savings are related with the energy savings. However, the CO_2 emissions saved by the project depend on the current technology installed to supply the heat & DHW demand.

Key Aspects of a Novel Undulated Receiver for Parabolic Trough Collectors

Yassine Demagh[1] and Ahmed A. Hachicha[2]

[1] Laboratoire d'Etude des Systèmes Energétiques Industriels (LESEI), Université de Batna 2, Algérie.

Abstract

This study proposes the replacement of the conventional straight absorber by the newly designed longitudinally undulated. Numerical results revealed that the new absorber could dethrone the former for several reasons: Among others, it allows a more homogeneous distribution of concentrated solar radiations on its outer surface (Monte Carlo Ray Tracking results); unlike other techniques which improve the inner heat transfer by increasing simultaneously the load of the absorber and the pressure drop within it, the proposed curved absorber is going to generate in a natural way, without any additional mechanical components, vortices within the main streaming which allowed to increase the heat transfer coefficient of about 63 % with an increase of the pressure drop penalty of about 60 %. On the other hand, it allows a drastic reduction of the size of the solar collector field. All these facts lead to decreasing the wall temperature gradient bellow 40 K. Results are obtained for the Syltherm 800 Reynolds number range 2.5×10^4 to 12.3×10^4 and a fluid inlet temperature of 450 K.

Keywords: Parabolic trough collector (PTC), size reduction, undulated pipe, heat transfer enhancement.

1. Introduction

Parabolic trough collectors (PTCs) are the most promising technology for electricity generation and process heating application. The main option to drive the cost of PTC technology down is to reduce the size of the solar field (Price et al. 2002). One of the ways to achieve this goal is the improvement of the thermal performances of the solar absorber by passive techniques by adding additional mechanical components to the absorber pipe (Ghadirijafarbeigloo et al., 2014, Mwesigye et al., 2014); nevertheless, these techniques produce a significant pressure drops penalty. On the other hand, since the work of (Demagh et al., 2015), the heat transfer improvement should be achieved without any additional mechanical parts. In the present study, 3D steady-turbulent simulations are carried out to investigate the scenario where the conventional straight absorber is replaced by the novel undulated absorber (Fig. 1(a)) proposed by (Demagh et al., 2015) and highlight its thermal performances enhancement and effects on the solar collector sizes.

Fig. 1: (a) The novel undulated PTC receiver. (b) A PTC module with the novel undulated absorber.

doi:10.18086/swc.2017.04.02 Available at http://proceedings.ises.org

2. The numerical modelling and results

Fig. 1(b) shows the novel absorber mounted on a PTC module; its main characteristics schematized in Fig. 2 are summarized in Tab. 1.

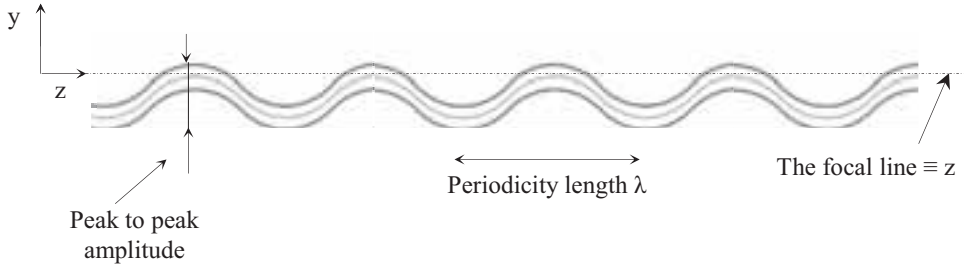

Fig. 2: Main characteristics of the undulated absorber.

Tab. 1: Absorber pipe c haracteristics.

Description	
Outer pipe diameter	0.070 m
Inner pipe diameter	0.066 m
Total length assumed in this study	0.975 m
Periodicity length	0.195 m
Peak to peak amplitude	0.020 m

The periodicity length is not the critical point, but the amplitude is (Demagh et al., 2015). The smaller the length, the more the transfer is efficient. For actual technical considerations of manufacturing, the selected periodicity length of 195 mm could be easy to achieve on a stainless steel pipe with inner/outer diameters of 66/70 mm.

2.1. Modelling and grid independence tests

(Di Piazza and Ciofalo, 2010) compared numerical results (the friction factor and Nusselt number) of different turbulence models with experimental data of curved pipes. The authors concluded that the SST k–ω eddy-diffusivity model gives the best agreement, but requires several computational grid nodes compared to k–ε model. Thus, by means of the CFD code (FLUENT 6.3), the k–ω based (SST) model was adopted to give accurate predictions of the onset and the amount of secondary flow, produced as a result of the curved shape.

The pipe absorber was meshed using tetrahedral elements with a structured mesh into the wall and an unstructured (tetra/mixed) non-uniform grids within the fluid medium, as shown in Fig. 3. During the meshing process, additional nodes are placed inside the viscous sub-layer to ensure the satisfaction of the $y^+ < 1$ requirement at the first grid point close to the wall.

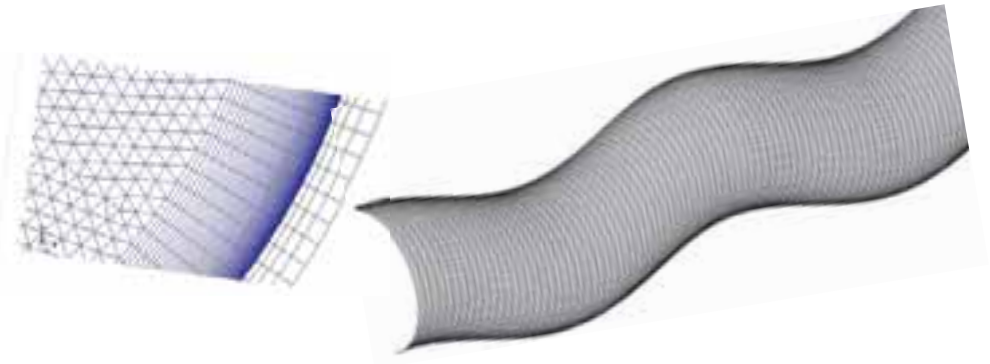

Fig. 3: The meshing generated by GAMBIT.

The grid independence was conducted in the analysis by adopting different grid sizes, and a sample of these tests is summarised in Table 2. The solution is considered mesh independent when the variations of the predicted mean heat transfer coefficient (h) and pressure drop (ΔP) are less than 1.5%. It is found that results for the global grid of 2,910,119 cells is not affected by the refinement and is therefore used in the present study.

Table 2- Grid independence test.

Global grid	% change of ΔP	% change of h
2,300,000	//	//
2,437,600	-1.6%	-0.45
2,910,119	-4.4%	2.4
3,256,400	1.5%	0.55

2.2. Results and interpretation

The Monte Carlo Ray Tracing method (MCRT) provided the non-uniform two-dimensional (2D) of the heat flux density distribution ($\boldsymbol{q}$) on the outer surface of PTC straight absorbers (He et al., 2011). The direct normal irradiance equals $933.7 W/m^2$; the parabolic trough rim angle used was 70°, aperture width 5 m and focal length 1.84 m. By means of the free code-source Tonatiuh, exploiting its validated results (Blanco et al., 2009), the reconstituted 3D heat flux density distribution on the outer wall of the undulated PTC absorber pipe as established by (Demagh et al., 2015) is shown in Fig. 4. With regard to the focal line (Fig. 2), the y-location of cross-section centres changes periodically along the undulated absorber, which is at the origin of the 3D nature of the ($\boldsymbol{q}$) relating to the 2D nature of the conventional straight absorber where the y-location of the cross-section centres remain unchanged (He et al., 2011).

Using the built-in curve fitting functions in Microsoft Excel, a UDF was written and compiled under Fluent GUI to set up the thermal boundary condition on the outer absorber pipe surface. The Heat transfer fluid (HTF) was the Syltherm 800 and its proprieties were considered as a temperature-depending.

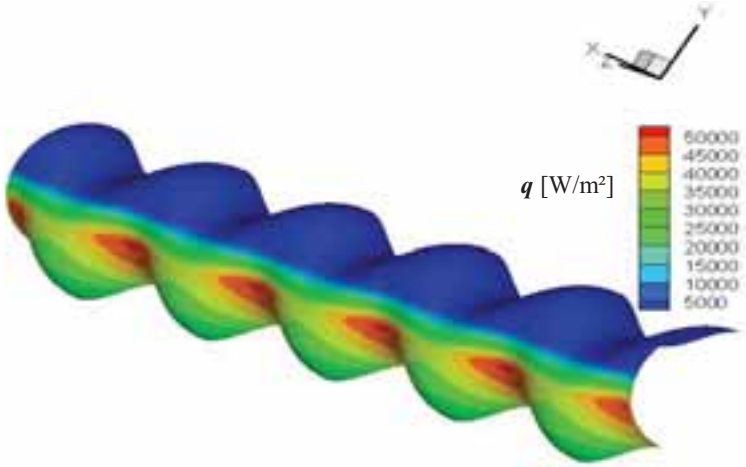

Fig. 4: Contours of the heat flux density distribution q [W/m²] on the outer face of the undulated absorber for a direct solar irradiance of 933.7 W/m² (Demagh et al., 2015).

The numerical results for the average heat transfer coefficient and the pressure drop obtained with Syltherm 800 flowing through the undulated PTC absorber are reported in Fig. 5 for $T_{in} = 450\,K$ and the Reynolds number range 2.5×10^4 to 12.3×10^4. It is evident that the heat transfer coefficients of the undulated absorber are larger than that of the conventional straight absorber obtained by Gnielinski's correlation (Incropera et al., 2007), about a 63% increase.

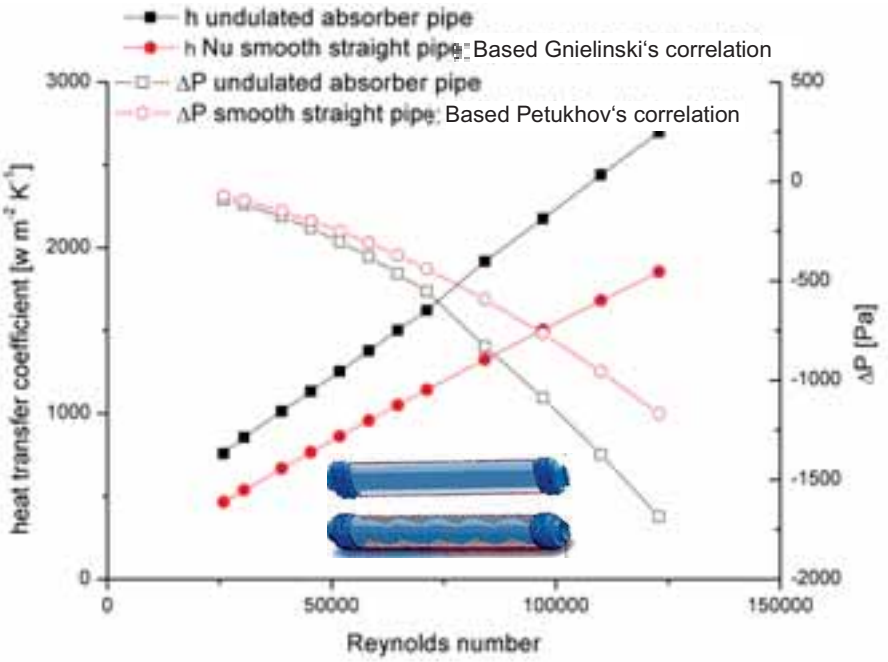

Fig. 5: The convective coefficients and pressure drops vs. Reynolds number. Correlation from (Incropera et al., 2007)

Also, as expected, the enhancement of the heat transfer is accompanied by an increasing of the fluid pressure drops, about 60 %. The better the distribution of $\boldsymbol{q}$ and the enhancement heat transfer cause the reduction of the circumferential temperature gradient ΔT bellow 40 K, as shown in Fig. 6.

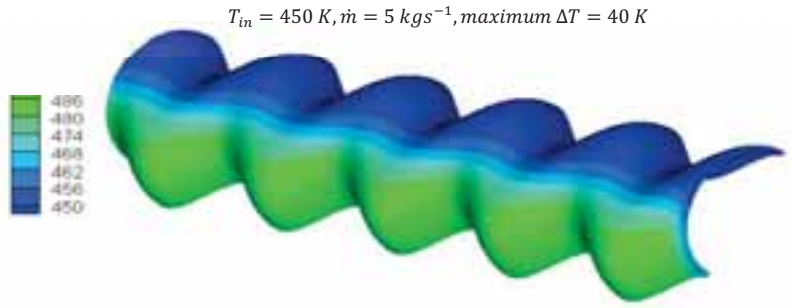

Fig. 6: Contour of the circumferential temperature gradient ΔT.

It is well known that curved configurations induce a secondary flow within it due to the centrifugal force, generated by curvatures of the pipe, as the fluid flows. The secondary streaming significantly enhances the heat transfer rate, causing a better mixture of fluid by the disturbance of the boundary layer. Vortices are identified in the bends, as shown in Fig. 7, where the y-velocity colours are synonymous of the intensification of vortices. Outside the bend-planes, the vortices are absent. On the other hand, compared to the conventional straight pipe absorber, the increase of the straight length of the undulated pipe absorber is insignificant, about 2.547 % for a peak amplitude of 10 mm (in this study), and the increase of the geometric concentration ratio will be the same. Thus, the improvement of heat transfer is mainly due to the existence of secondary flows rather than the increase of the heat exchange surface.

Fig. 8 shows the longitudinal change of the local Nusselt number along the second, third and fourth period for an inlet HTF temperature of $450K$ at Reynolds numbers of $\mathrm{Re} = 64740$, corresponding to an HTF mass flow rate of $5\ kg \cdot s^{-1}$.

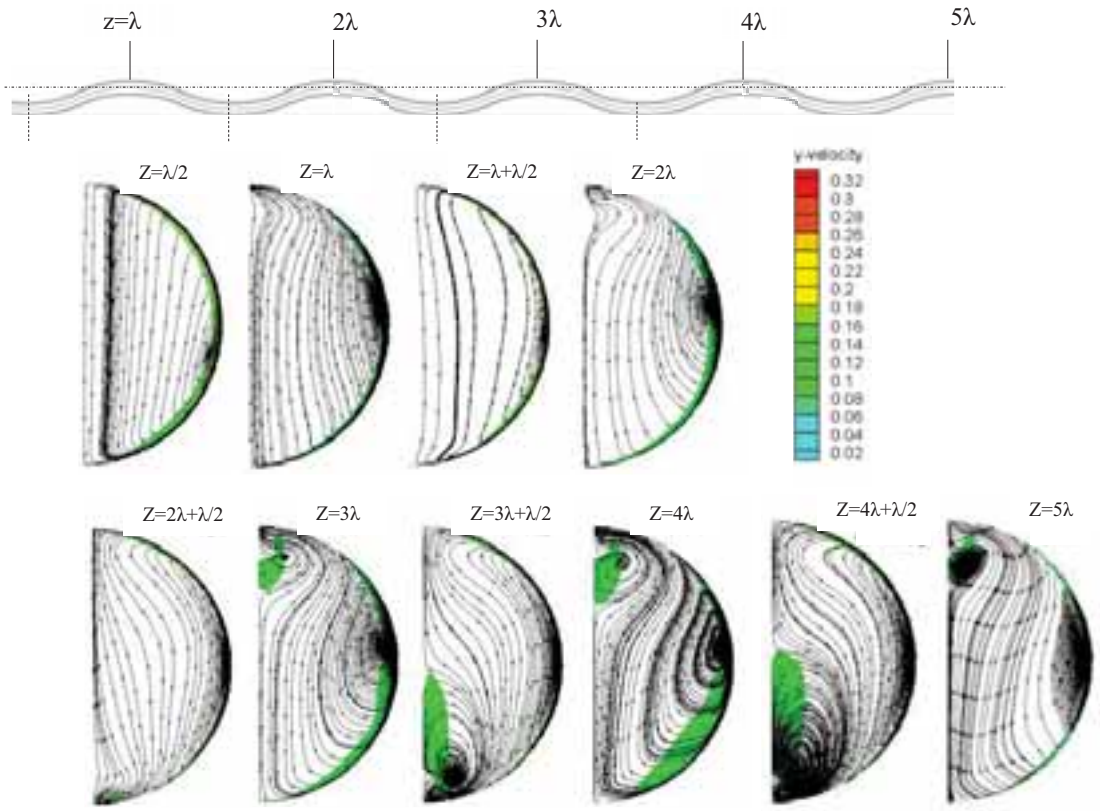

Fig. 6: The Secondary flow configuration. Colours refer to y-velocity magnitude [m/s].

The curve possesses a sinusoidal shape, the local Nusselt number increases up to a location at midway between the uppermost and bottommost bends. From this location, it starts decreasing, exceeding the bottommost bend, up to next midway location of the next periodic segment and increases again, and so on periodically along the entire length of the absorber.

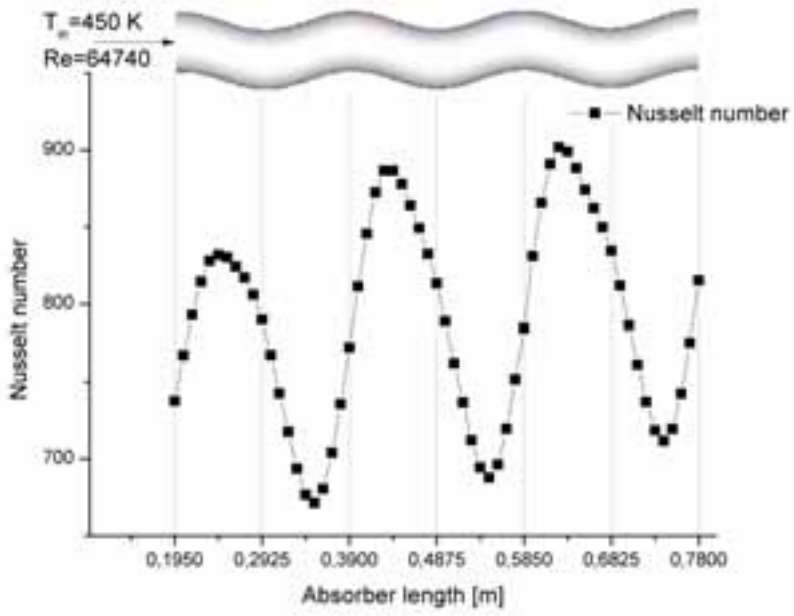

Fig. 8: Change of the local Nusselt number along the absorber length.

All rising branches of the curve occur on the upper half of the absorber pipe where the heat flux density distribution and wall temperature are moderate, see Figs 4 and 6. The HTF temperature will approximates the wall temperature, which it is not heated by the concentrated solar radiation and the local Nusselt number increases. On the other half of the absorber pipe, it's quite the opposite phenomenon, the Nusselt number decreases given that the temperature gap between the HTF and wall increases due to the concentrated solar radiation on this half (Fig. 4) heating the wall of the tube (see Fig. 6). It should be emphasized here that the local Nusselt number seems to respond to the heat flux density distribution to the flow dynamics (acceleration or deceleration in various branches or even the vortex in bends). The general trend of the local Nusselt number is increasing due to the mixture of fluid with each pass through the bends where the vortices occur.

3. Conclusion

For the range of Reynolds numbers, the inlet HTF temperatures and the geometrical parameters considered, it is established that the heat transfer rate may be increased by up to 63% compared with a straight pipe, while the pressure drop increased by less than 60%; the secondary streaming (reversed flow) contribute considerably to the overall heat transfer enhancement. The circumferential temperature difference of the absorber was decreased below 40 K for almost all the range of the mass flow rates and will significantly reduce the thermal stress on the absorber pipe. The local Nusselt number possesses a sinusoidal shape along the pipe absorber, and seems to respond to the heat flux density distribution to the flow dynamics (acceleration or deceleration in various branches or even the vortex in bends). With the 2.547 % increase of the straight length of the pipe absorber, the improvement of heat transfer is mainly due to the existence of secondary flows rather than the increase of the heat exchange surface. The final conclusion is that to achieve the same HTF temperature rise that the conventional straight absorber the length of the undulated absorber would be reduced due to the improvement in the heat transfer rate.

Abstract

One of the main options to drive the cost of parabolic trough collectors (PTCs) technology down is to reduce the size of the solar field. This work proposes a novel receiver longitudinally undulated as a replacement for the conventional straight tube and investigates the effects on the size of absorbers, PTC modules and entire solar field. For this purpose, the developed method based on the similitude analysis should provide tools for drawing a comparison between the various designs of the absorber and should give useful measures of the scenario of their commissioning. Undulated absorber in service and without added supplementary mechanical components; the size of a solar collector field should reduce about ~29.5% consequence of the reduced size of the solar collector module and the absorber. The increase of the pressure drops through the novel absorber pipe should be re-balanced by the reduction in its size.

Keywords: Parabolic trough, undulated receiver, similitude analysis, size reduction of the solar field.

1. Introduction

The PTC large scale technology has proved its capacity to produce power with the lower cost as possible. PTC plants consist mainly of four loops, a large solar collector field, a steam generation system, a turbine/generator cycle and an optional thermal storage. One of the main options to drive the cost of PTC technology down is to reduce the size of the solar field (Price et al. 2002). The first way of reaching this purpose is to increase the parabolic mirrors reflectance and/or the absorber absorptance of the direct solar irradiance. The latter can be achieved through adding a secondary non-imaging reflector on the receiver (McIntire, 1980, Gee et al. 2002).

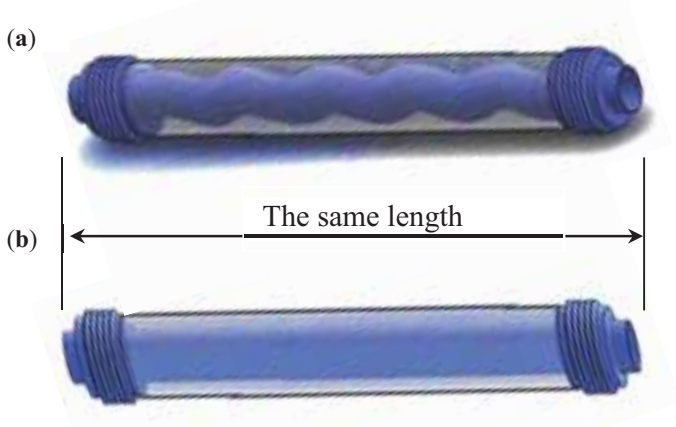

Fig. 1: (a) The novel PTC undulated absorber. (b) The conventional PTC absorber.

The second way is to improve thermal performances with a minimum pressure loss penalty as possible, which cannot be achieved by the passive techniques that add supplementary mechanical components to the absorber,

doi:10.18086/swc.2017.04.03 Available at http://proceedings.ises.org

the increase of the pressure losses is too important and the cost rise dramatically. In 2015, (Demagh et al. , 2015) introduce the possible use of longitudinal curved receiver in PTCs. The novel design (Fig. 1(a)) allows better characteristics of the outer heat flux due to its 3D distribution, with regard to the 2D nature of the conventional straight one (Fig. 1(b)). The focus of this study is to set up a general-purpose methodology to quantify effects of any heat exchanger enhancement technique on the reduction in the size of devices. The particular case of the newly designed undulated PTC absorber pipe will be the subject evaluation of the method.

2. Similitude analysis

It would be very interesting to be able to quantify the advantages of the heat transfer improvement on the reduction in the size of such exchangers. In a general-purpose, the methodology leads to develop expressions that could set up a comparison between two different pipe exchangers. Assuming steady-state conditions, the mean heat flow rate $\dot{Q}$ throughout the pipe can be defined as,

$$\dot{Q} = \rho \bar{c} u_{in} \left(\pi D_i^2 / 4 \right) \left(\bar{T}_{out} - \bar{T}_{in} \right) = h \left(\pi D_i L \right) \left(\bar{T}_w - \bar{T}_m \right) \quad \text{(eq. 1)}$$

u_{in}, ρ and $\bar{c}$ being the convective heat transfer fluid (HTF) inlet velocity, density and specific heat at the HTF mean temperature $\bar{T}_m$, respectively. D_i, h and L being the inner diameter, inner heat transfer coefficient and equivalent length, respectively. $\bar{T}_{in}$ and $\bar{T}_{out}$ being the inlet and outlet HTF bulk temperatures, respectively.

The ratio of equations resulting from the expression (1) when it is applied to a first configuration (subscript 1) and to a second configuration (subscript 2) leads to, after the rearrangement,

$$\left(\frac{L_1}{L_2} \right) = \frac{St_2}{St_1} \frac{\left(\bar{T}_{out} - \bar{T}_{in} \right)_1}{\left(\bar{T}_{out} - \bar{T}_{in} \right)_2} \frac{\left(\bar{T}_w - \bar{T}_m \right)_2}{\left(\bar{T}_w - \bar{T}_m \right)_1} \frac{(D_i)_1}{(D_i)_2} \quad \text{(eq. 2)}$$

$St = h / \rho u_{in} \bar{c}$ being the Stanton number. This result is extremely useful; it suggests that the comparison between the heat exchange rates of various exchangers may be modelled by an equality that introduces dimensionless groups which quantifying the dynamic and thermal behaviour

2.1. The novel undulated absorber: Thermal enhancement

3D steady-turbulent simulations are carried out to predict the flow fields using the CFD code (FLUENT 6.3). The k–ω based Shear-Stress-Transport (SST) model was used in the simulations. Exploiting the established 3D heat flux density distribution on the outer wall of the undulated PTC absorber pipe (Fig. 1(a)) (Demagh et al., 2015), a UDF was established and compiled in the commercial code Fluent. Numerical results for the turbulent heat transfer coefficient and the pressure drop obtained with Syltherm 800 flowing through the undulated PTC absorber are reported in Fig. 2. It is obvious that the average heat transfer coefficient of the undulated absorber is greater than that of the conventional straight absorber obtained by Gnielinski's correlation (Incropera et al., 2007), up to 63% increase, in addition to an increasing of the pressure drops, less than 60%.

2.2. The novel undulated absorber: Dimensional analysis and size reduction

- Without any enhancements, assuming the same pipe diameters and the similar operating conditions, it follows from expressions (2) that $L_2 / L_1 = 1$.
- In the particular case of this study, exchangers would be the conventional PTC straight absorber pipe and the novel undulated PTC absorber, respectively subscript 1 and 2, with the same inner diameter. To reach the similar rise of the HTF temperature (i.e. $\left(\bar{T}_{out} - \bar{T}_{in} \right)_2 = \left(\bar{T}_{out} - \bar{T}_{in} \right)_1$), when it is assumed the similar HTF inlet temperature (i.e., the similar HTF properties), the $\left(\bar{T}_w - \bar{T}_m \right)_1 = \left(\bar{T}_w - \bar{T}_m \right)_2$, the same flow regime (i.e., $\left(u_{in} D_i \right)_2 = \left(u_{in} D_i \right)_1$) and since $h_2 \geq h_1$, equation (2) becomes $L_1 / L_2 = h_2 / h_1 \geq 1$. Taking into account the results of Fig. 2, the trend of the equation (2) while varying the flow regime is

shown in Fig. 3. Until $\mathrm{Re} = 71000$ the trend is decreasing from $L_1/L_2 \cong 1.63$ to $\cong 1.41$; from this location it increases a little and becomes relatively flat, about $\cong 1.45$. To achieve the same HTF temperature increase of the classic straight absorber, the equivalent length of the novel absorber will be significantly reduced, consequence of the heat transfer improvement. With a mean equivalent length of $L_2 = L_1/1.63$, the area size of the solar collector field should reduce about $\cong 0.39\ \%$, consequence of the reduction in the size of solar PTC units. It is clear that the cost will be lower.

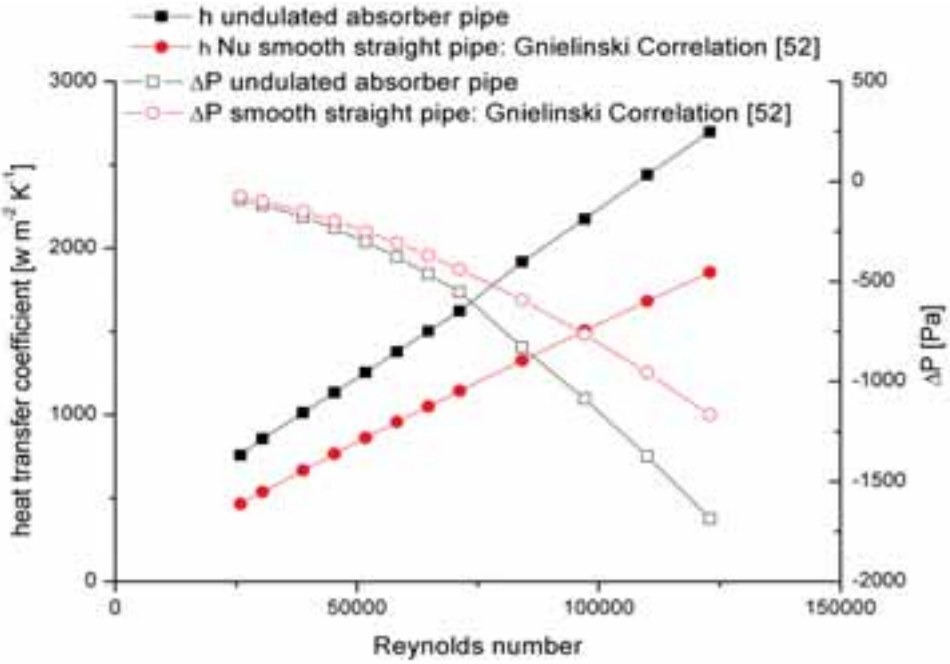

Fig. 2: The convective heat transfer coefficient and the pressure drops through the undulated pipe against Re, for $\bar{T}_m = 450\ \mathrm{K}$. Correlations refer to (Incropera et al., 2007)

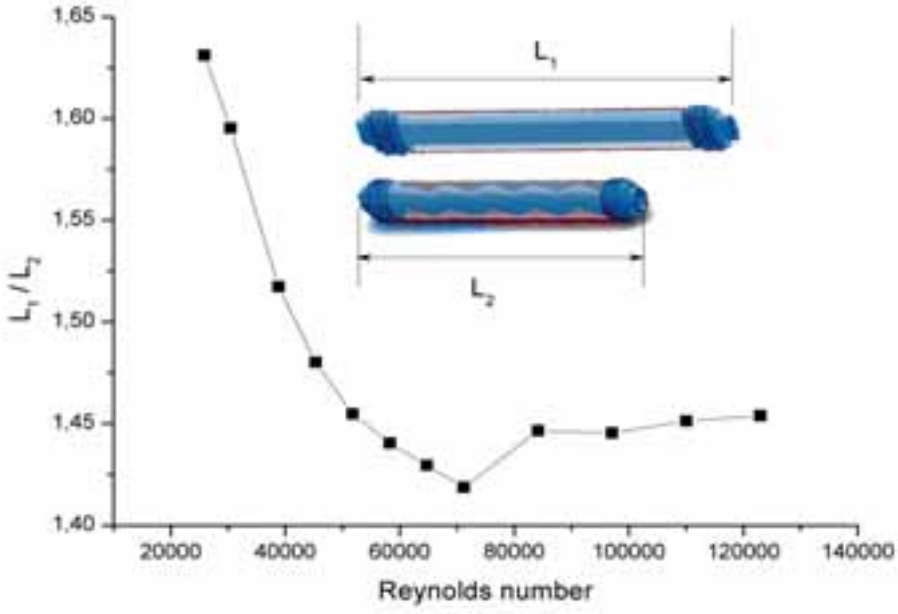

Fig. 3: The reduction in the size of the newly designed undulated PTC absorber

- Taking into account the reduction in the size of the novel absorber (with the length L_2), the pressure drop penalty $\Delta P|_{L1}$, shown in Fig. 2, for the length L_1, should be reconsidered as $\Delta P|_{L2} = \Delta P|_{L1} \cdot (L_2 / L_1)$, and decreases as shown in Fig. 4.

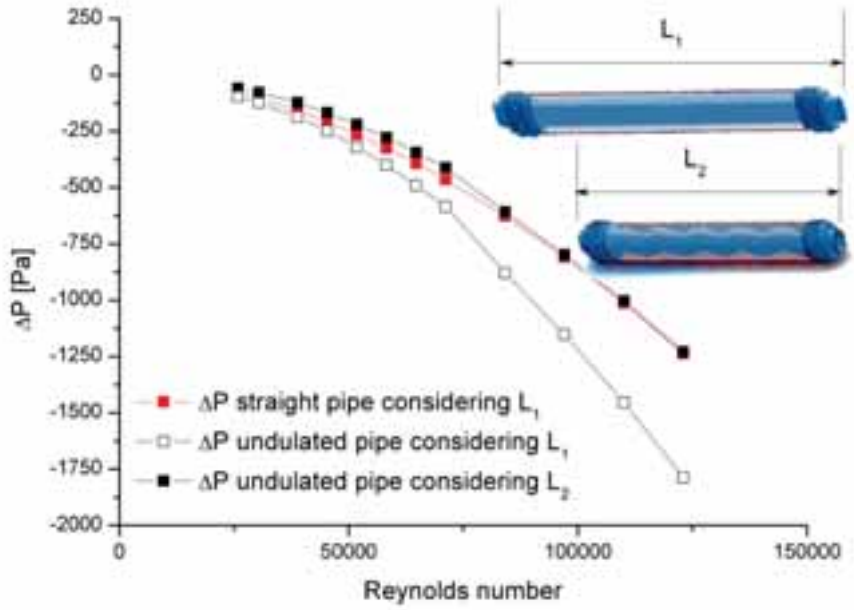

Fig. 4: The re-balancing of the pressure drops.

3. Conclusion

Following a similitude analysis developed in this study, the sizes of the absorber, solar collector modules and solar collector field should reduce about $\simeq 0.39\%$ by using of the novel undulated absorber. The increase of the pressure drop penalty of the novel solar absorber pipe is shown to be re-balanced by the reduction in its length. The manufacturing cost diminishes and the know-how remains unchanged with regard to the conventional absorbers, while the performance increases; the (performance/cost) ratio should be higher, what reduces drastically the kWh cost of the solar power.

Long-Term Variability of Aerosol Optical Depth, Dust Episodes, and Direct Normal Irradiance over Kuwait for CSP Applications

Christian A. Gueymard[1], Majed Al-Rasheedi[2], Alaa Ismail[2] and Tahani Hussain[2]

[1] Solar Consulting Services, Colebrook, NH (USA)

[2] Kuwait Institute for Scientific Research, Shuwaikh (Kuwait)

Abstract

Two sources of aerosol data (from ground-based sunphotometry and long-term reanalysis), as well as irradiance data (from ground-based radiometric measurements) are investigated here. The daily, seasonal and interannual variability of aerosol optical depth is evaluated over Kuwait. Based on the MERRA-2 reanalysis, long-term aerosol trends are also established over the period 1980–2016, showing a slight increase in aerosol optical depth (AOD) since about 2000. This is conducive to a concomitant decrease in the direct normal irradiance (DNI) resource of ≈2% per decade, which can affect concentrating solar power (CSP) projects over the long-term. When compared with sunphotometer data from two AERONET stations located at a distance of only 90 km, but in somewhat differing environments, shortcomings are found in the aerosol data from the MERRA-2 reanalysis. Both bias and scatter are found in the hourly and daily AOD data, as well as occasional mismatch in the prediction of the more-or-less frequent AOD spikes caused by dust storm episodes. The use of MERRA-2 aerosol data for the prediction of clear-sky DNI with a high-performance irradiance model results in underestimation (of ≈13% on average) and substantial scatter on a 1-min basis, based on a comparison with co-located, high-quality DNI data.

Keywords: Aerosol optical depth (AOD), direct normal irradiance (DNI), CSP, dust storms, MERRA2.

1. Introduction

Many large solar projects involving various kinds of Concentrating Solar Power (CSP) technologies are being built in regions such as the Middle East. These arid or desert regions benefit from a low overall cloudiness, and thus overall high solar resource, but are also impacted by significant background aerosol loads and somewhat frequent dust episodes. These can be detrimental to the operation and yield of CSP plants for various reasons: (i) Intense atmospheric attenuation, leading to significant loss in incident direct normal irradiance (DNI); (ii) Increased slant atmospheric attenuation between mirrors and central receiver of solar tower power plants; (iii) Concomitant strong winds that may force an emergency shutdown of the plant; and (iv) Extreme dust soiling on concentrators or mirrors. The present study focuses on the first topic. A related study (López et al., 2017) explores the second one.

Ideally, dust storm episodes should be forecasted a few days early so that the plant and electric utility operators can take all necessary measures to prepare the plant and the electric grid for any potential disruption. Research has now started toward the development of an integrated forecasting system to help the development of CSP and other renewable energy technologies in Kuwait, where significant solar power is being built or projected. Solar forecasts need to focus on both clouds and dust episodes at various time scales.

Before construction, the solar resource needs to be well established in terms of both magnitude and temporal variability. Under arid conditions, DNI's variability directly depends on that in aerosol optical depth (AOD), as discussed elsewhere (Gueymard, 2012b; Polo et al., 2016). DNI also depends on the quantity of atmospheric water vapor, measured in the form of precipitable water (PW), albeit to a much lesser extent than AOD (Gueymard, 2014). More generally, the quality of the AOD data is a major factor that directly affects the accuracy of derived DNI predictions using current modeling techniques (Cebecauer et al., 2011), which in turn can negatively impact the bankability of the solar resource data used by the solar industry (Gueymard, 2011).

doi:10.18086/swc.2017.04.04 Available at http://proceedings.ises.org

Multi-site measurements conducted over Kuwait during the last five years have confirmed that DNI's solar resource is indeed highly variable on a daily and seasonal basis (Al-Rasheedi et al., 2014). This is particularly true during summer when the potential for solar electricity generation reaches its peak, thanks to virtually permanent cloud-free conditions during longer days and high-sun conditions. Until now, the specific link between the magnitude and variability of DNI and of its AOD counterpart had not been precisely defined over Kuwait. In the present contribution, various sources of DNI and AOD data are used to establish (i) the long-term variability in both quantities over Kuwait; (ii) the modeled effects of high-AOD conditions on DNI; and (iii) possible long-term trends in those two quantities.

2. Data sources

The present analysis focuses on both modeled and observed aerosol data, and on observed solar irradiance data. NASA's MERRA-2 reanalysis model provides historical estimates of the hourly AOD at 550 nm (hereafter, AOD550), Ångström exponent (AEX), and total scattering AOD (SAOD) since 1980, among many other atmospheric variables (such as PW), at a spatial resolution of 0.5x0.625°. Although this resolution is relatively coarse, it is not a serious limitation here because of the absence of strong topographic features over Kuwait. Moreover, MERRA-2's consistent evaluation of AOD550, SAOD, and AEX at hourly resolution over more than three decades is a highly desirable feature, which is unique among all reanalysis models currently available.

In parallel, shorter-term ground observations of spectral AOD and AEX from two AERONET sunphotometric stations are also available. The older one is located at the Kuwait University campus in the coastal urban area of the capital, Kuwait City, and has reported Level-2 (L2) data for 2006–2010 and Level-1.5 (L1.5) since 2006, albeit with many long data breaks in both datasets. The newer station is located in the Shagaya solar park, where PV, CSP and wind installations already exist. Shagaya is located 90 km to the west from the capital, in a remote and drier desert area. This AERONET station was commissioned in August 2015, after its installation alongside the existing radiometric station (whose data are also used in this study, see below). Thus far, this station has provided L2 aerosol data for the period August 2015 to July 2016, as well as L1.5 data since February 2017.

The L1.5 data record is much longer than the L2 record at both sites. It is therefore worthwhile to examine the difference in AOD when retrieved with version 2 (V2) of the algorithm applied to L2 data (V2L2) relative to the more elaborate version 3 applied to L1.5 data (V3L1.5). Based on 5000 instantaneous data points at Kuwait University, the distribution of differences shown in Fig. 1 reveals that all older AOD values (from V2L2) are slightly larger than those produced by the newer algorithm. Nevertheless, the difference virtually never exceeds 0.01, which is the typical uncertainty of AOD at that wavelength (Holben et al., 1998). This agreement is remarkable, which confirms information found on AERONET's website (https://aeronet.gsfc.nasa.gov/new_web/Documents/AERONET_V3_AOD.pdf) to the effect that V3L1.5 offers similar results to V2L2. Since V3L1.5 has a more complete historical record than V2L2, the former is exclusively used here in all what follows.

In any case, these observation periods, being relatively short, cannot be used for a long-term analysis of variability or trend, but can still be helpful to validate other sources of aerosol data (such as MERRA-2) and to provide the necessary inputs for short-term irradiance predictions with radiative-transfer models. These applications are discussed below.

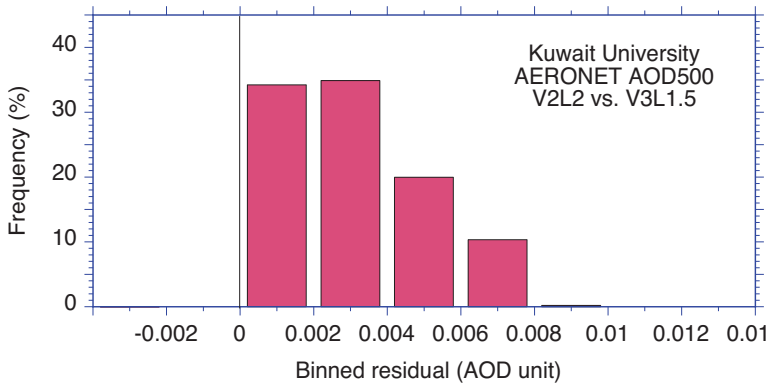

Fig. 1: Binned frequencies of difference between AOD at 500 nm retrieved from AERONET's V2L2 vs. V3L1.5 algorithms at Kuwait University.

The Shagaya sunphotometer is collocated with a well-maintained radiometric station. It monitors all irradiance components (including DNI) with both thermopile and photodiode instruments, thus providing redundancy. Details on the instrumentation, data quality control, early results, and comparisons between measured and satellite-derived modeled data were provided in a previous report (Al-Rasheedi et al., 2014). The Shagaya station has provided high-quality irradiance data since September 2012. Another radiometric station, Kabed, also provides redundant observations of DNI. The DNI resource of Kabed is similar to that of Shagaya, due to the short distance between them (≈65 km), so will not be discussed further here.

3. Results

3.1 Aerosol optical depth: MERRA-2 vs. AERONET

It is desirable to compare the AOD550 data predicted by MERRA-2 to those observed at AERONET stations. This constitutes the conventional way of validating modeled AOD data, and is also important in the context of discriminating high-AOD periods caused by dust storms of various strengths, or evaluating the historical frequency and seasonal variability of such events. This kind of study also prepares for the longer-term goal of qualifying the suitability of NASA's GEOS-5 research forecasting model (from which MERRA-2 is derived) to correctly forecast future dust-storm events over Kuwait.

A first comparison is done for daily-mean AOD data. Since AOD550 is not observed directly by AERONET sunphotometers, it is calculated here from Ångström's law using AOD at 500 nm and AEX evaluated between 440 and 870 nm. The daily-mean AOD550 is then obtained for all days that produce at least 3 instantaneous measurements (per standard AERONET procedures). This removes only a limited number of days (or periods during any day) since cloudiness is generally low or absent, particularly in summer. Observations, however, are only done for a sun zenith angle lower than 82°. To make things as comparable as possible, the MERRA-2 daily means are thus calculated for all hours for which the mid point corresponds to a zenith angle less than 80°.

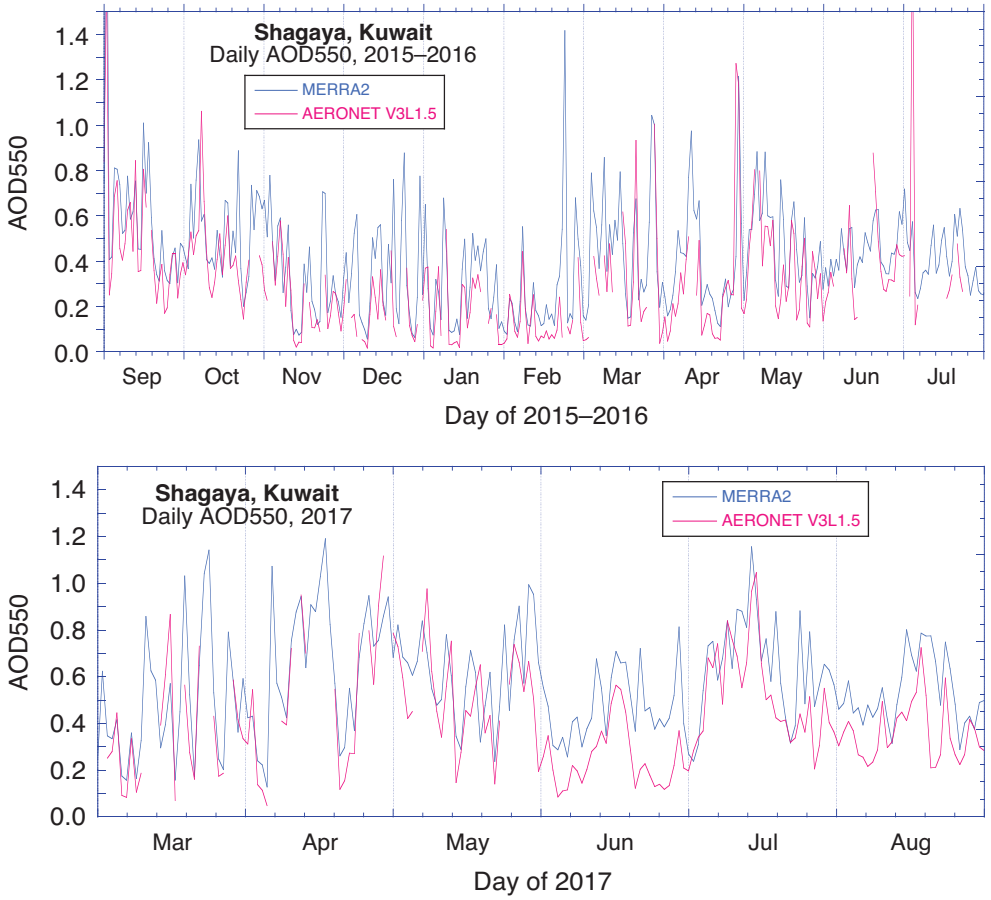

Fig. 2: Time series of daily AOD550 from both modeling by the MERRA-2 reanalysis and ground observations at the Shagaya AERONET station during 9/2015–7/2016 (top) and 3/2017–8/2017 (bottom).

Figure 2 shows the time series of daily-mean AOD550 obtained from MERRA2 and the Shagaya AERONET station during the 12-month period when the latter was operational before it was sent back for repair and calibration, and also for a more recent 6-month period of 2017. The MERRA-2 and AERONET sources of data show similar high daily and seasonal variability, with however occasional differences in magnitude or phase. It is clear that MERRA-2 tends to predict higher AOD than the ground observations. This is confirmed in Fig. 3a, which compares the *hourly* AOD550 data from MERRA2 and the corresponding *instantaneous* data from AERONET's V3L1.5. An additional characteristic is that MERRA2's overestimation is accompanied by significant scatter. A similar scatterplot appears in Fig. 3b, but for AEX. It shows large scatter too, but also a lack of similitude, due to generally too low predictions at high AEX. Figure 4 shows the frequency distributions of the differences between MERRA-2 estimates of AOD550 or AEX and matching AERONET observations. Interestingly, the two distributions of MERRA-2 deviations are skewed in opposite ways. The mean and median errors are ≈0.1 for AOD550. Hence, it can be expected that DNI simulations based on MERRA-2 AOD data should be too low by ≈10%.

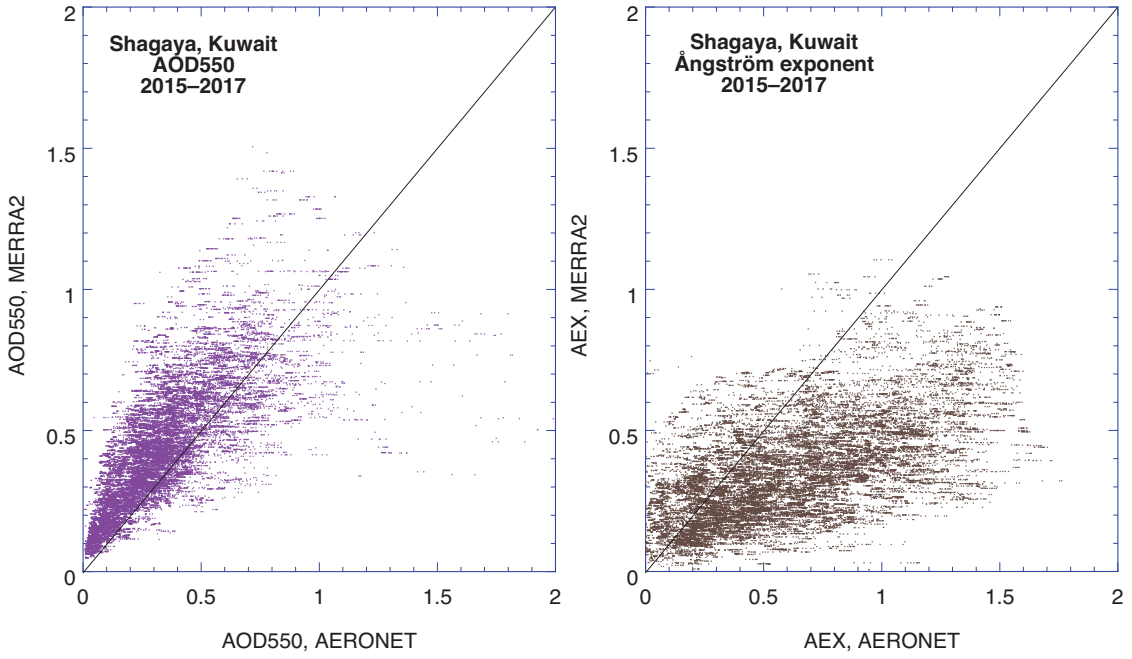

Fig. 3: Scatterplots of AOD550 (left) and AEX (right) comparing MERRA-2's predictions to ground observations from the Shagaya AERONET station.

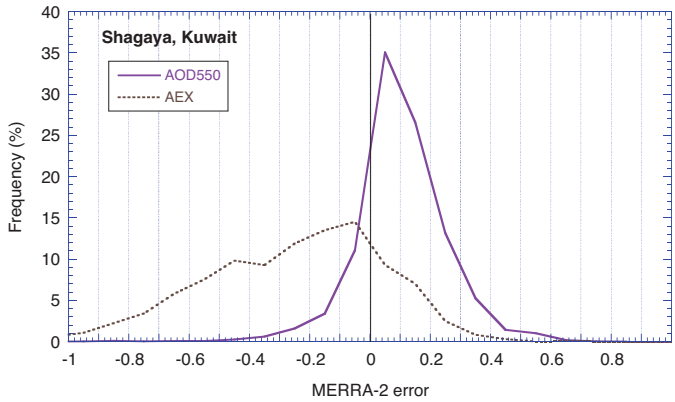

Fig. 4: Frequency distributions of MERRA-2's errors in AOD550 and AEX (compared to AERONET reference data) at Shagaya.

The difference between the predicted and observed AOD550 is reflected in their temporal frequency distribution over the period of record, as illustrated in Fig. 5. It is found that the daily AOD550 frequency distribution obtained from MERRA-2 better match that of AERONET at Kuwait University than at Shagaya. This can be ex-

plained, at least in part, by a statistical artifact caused by the lower number of days in the latter case. It is also possible that the variability of the aerosol loading is more difficult to predict in a pure desert environment such as Shagaya's, or that the (older) Kuwait University data points are assimilated into the GEOS-5 forecasting model, which would improve the aerosol modeling there.

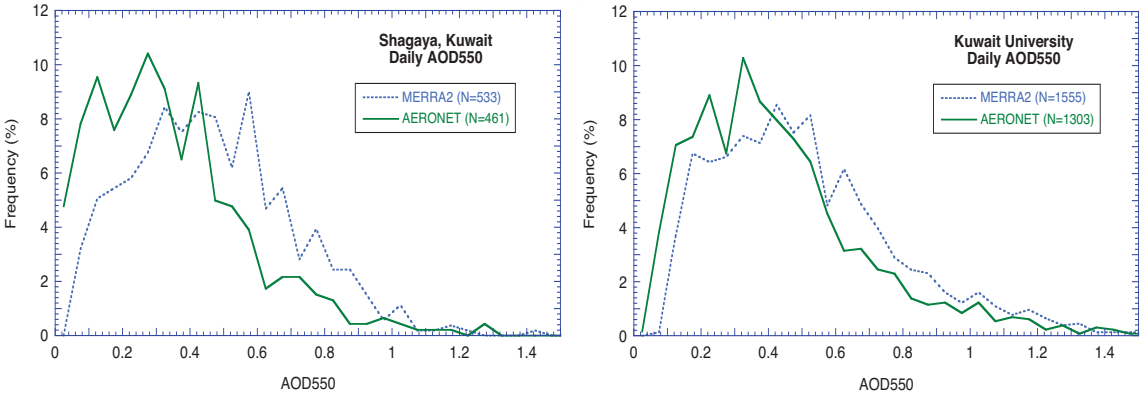

Fig. 5: Frequency distribution of daily AOD550 from MERRA-2 and AERONET for Shagaya (left) and Kuwait University (right). N is the number of days. Periods with 7 or more consecutive days of missing AERONET data were eliminated from the analysis.

Figure 5 also suggests that very hazy days (AOD550 > 0.6) are more frequent in Kuwait City than over Shagaya. For instance, the probability of days with a mean AOD550 higher than 1.0 is ≈2% at Shagaya and ≈5% in Kuwait City, based on AERONET data. At Shagaya, the maximum daily-mean AOD550 of 1.86 was observed on 2016-07-04 according to the 461-day record of AERONET V3L1.5 until end of 8/2017. In comparison, the daily mean for that day was much lower (1.17) at Kuwait University. At the latter site, the record maximum daily-mean value (2.39) was reached on 2017-04-29, while Shagaya simultaneously experienced only less than half of that value (1.06). These differences in peak AOD values and frequency distribution are remarkable, considering the relatively short distance between the two locations. Spatial variability in AOD is thus to be considered in addition to its temporal variability, which will require further study.

3.2 Aerosol optical depth: Historical time series

Based on MERRA2's 1980–2016 time series, the annual average AOD550 remained in the range 0.35–0.50 during that period, with significant interannual variability and possible decadal cycles (Fig. 6). Linear trends are evaluated separately over two distinct periods of similar duration: 1980–1996 and 1997–2016. The former is considered less certain than the latter because of the lack of satellite or AERONET data to constrain the aerosol transport model before 1997. The two last decades experienced an increasing trend in AOD, at the rate of 0.0024 AOD unit per year. This in turn translates into a likely decrease in the DNI resource of ≈2% per decade, based on the analysis of Gueymard (2012b). This positive trend in AOD is consistent with results from Hsu et al. (2012), which were based on AERONET and satellite data, and with the solar radiation dimming experimentally observed over Iran (Jahani et al., 2017; Rahimzadeh et al., 2015). Since a negative trend in DNI is likely to have a notable impact on the performance of CSP plants (many of which being built or planned in the region), more studies will be needed to better quantify this trend, and delineate its geographical extent.

Still using the whole 37-year MERRA-2 dataset currently available, the frequency distribution of AOD550 at Shagaya is shown in Fig. 7. Results are displayed for three important time scales: Hourly, daily, and monthly. The hourly and daily results are remarkably similar, much smoother than the short-term daily distribution in Fig. 5 (as could be expected, considering the much longer period), and show the characteristics of the anticipated log-normal distribution (Ruiz-Arias et al., 2016a). The monthly frequency distribution is substantially different in shape, which results in a lower median than the two other distributions. This statistical feature, in turn, has consequence on the modeling of DNI, and, ultimately, on the bankability of the DNI resource for CSP applications if monthly-mean AOD data are used as input of solar radiation models (Ruiz-Arias et al., 2016b, 2016c).

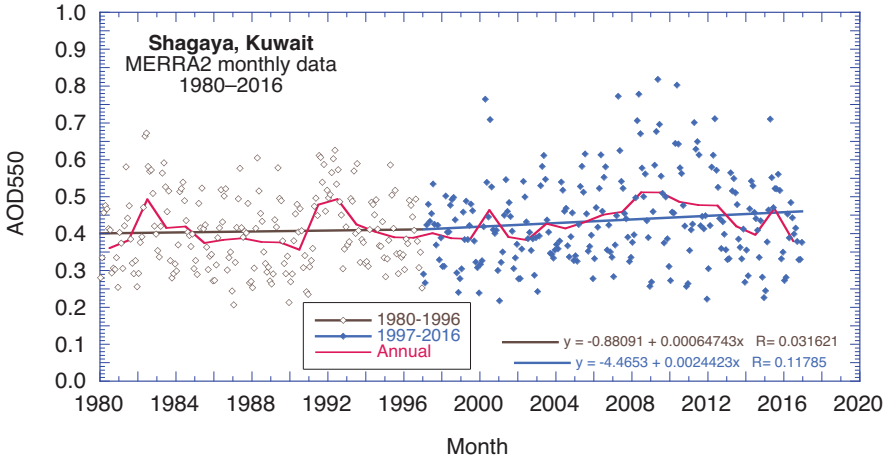

Fig. 6: Time series and trends of mean monthly and annual MERRA2's AOD550 separated into two periods.

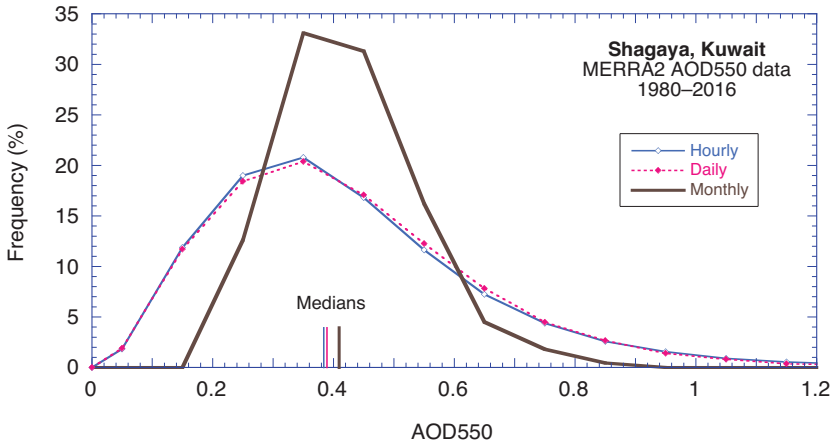

Fig. 7: Hourly, daily, and monthly frequency distributions of MERRA2's AOD550 over the period 1980–2016.

Figure 8 compares the daily variability in MERRA-2's AOD550 and in the measured DNI at Shagaya during summer 2015. Such a period being virtually cloudless (except in early May), the temporal variability in DNI is expected to be essentially due to that in AOD. Nevertheless, the two signals are not exactly in phase due to the shortcomings in the MERRA-2 AOD data discussed above. The daily-integrated DNI reached its maximum of ≈10 kWh/m^2 during a few days only, when the AOD was relatively low for the season at that location. Conversely, the strong aerosol-induced extinction makes DNI reach only 4–5 kWh/m^2 during high-AOD days.

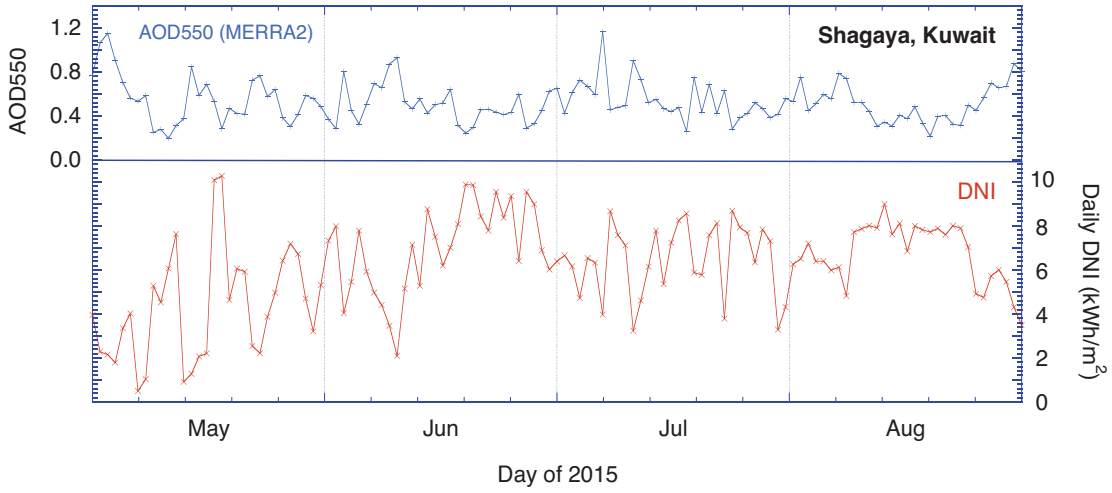

Fig. 8: Daily variability in MERRA2 AOD (top) and in DNI measured at Shagaya (bottom) during summer 2015.

3.3 Direct normal irradiance prediction

Solar irradiance is sensitive to the amount and optical characteristics of aerosols at any instant. This is most particularly true for DNI, which decreases substantially when AOD increases (e.g., Gueymard, 2005, 2012b). This also means that potential errors in AOD data used as input to a radiative transfer model necessarily result in errors (of opposite sign) in DNI. This, in turn, is important for the simulation of the power production of CSP systems before construction, since typically no long-term local DNI observations are then available. CSP systems are strongly non-linear, which makes their energy output sensitive to the quality and representativeness of the DNI resource data. The latter is actually the major source of uncertainty in the modeling of CSP plants (Ho et al., 2011). Even the use of conventional hourly Typical Meteorological Years (TMYs) may result in seasonal and annual errors (Polo et al., 2017). Simulations performed by Hirsch et al. (2010) showed that non-linearity impacts can be avoided, but this requires that calculations be done at high temporal resolution, with irradiance data time steps in the order of 1–10 minutes, which is highly demanding.

Evaluating clear-sky DNI can be done accurately if collocated instruments (e.g., sunphotometers) provide the most important aerosol and water vapor inputs at the required high temporal resolution (Gueymard, 2012a; Gueymard and Ruiz-Arias, 2015). The specialized stations reporting such data are still very scarce, which constitutes a serious limitation. Other sources of aerosol data do exist and are more readily available on a global scale (e.g., on a gridded basis), but their lower quality typically results in substantially biased or distorted DNI time series (Polo and Estalayo, 2015).

In this context, it is important to evaluate whether the MERRA-2 reanalysis data can provide accurate DNI estimates over Kuwait at sub-hourly resolution. To that effect, the latest version of the high-performance REST2 model (Gueymard, 2008) is used to simulate DNI at Shagaya. The best possible modeling of DNI is obtained when using observations of the main inputs (AOD550, AEX and PW) from AERONET V3L1.5. Secondary inputs (hourly ozone amount and station pressure) are obtained from MERRA-2. The (low) columnar amount of nitrogen dioxide is provided by spaceborne observations from the Ozone Monitoring Instrument (OMI) radiometer. The observational DNI dataset comes from a thermopile pyrheliometer and a silicon-based rotating shadowband irradiometer (RSI) that are installed side-by-side at Shagaya. The pyrheliometer observations are used preferably, but are replaced by RSI data in case of tracker malfunction or data not passing the tests of an elaborate quality control procedure, itself based on the method described by (Long and Shi, 2008). A related study has shown that the DNI observations from RSI and thermopile are in close agreement (Al-Rasheedi et al., 2017).

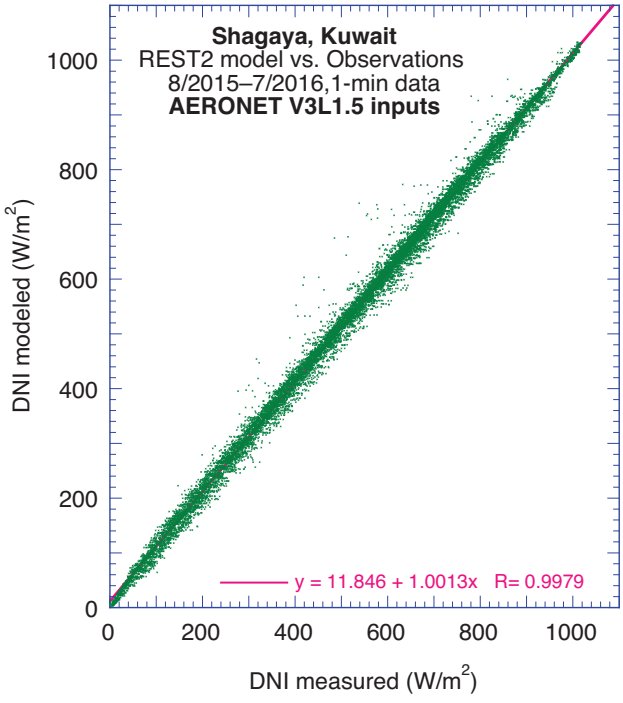

Fig. 9: Scatterplot of REST2-predicted DNI vs. ground observations using aerosol and water vapor input data from AERONET V3L1.5.

Figure 9 shows a scatterplot of the AERONET-based modeled DNI in comparison with its measured counterpart. As expected, the match is excellent, with only a few outliers caused by the passage of clouds during the irradiance observation. (Irradiance is integrated over a 1-min period, whereas AERONET observations are instantaneous, and are allowed to be as much as one minute away from the center of the 1-min period.) In comparison, this simulation is repeated with the main inputs (AOD550, AEX and PW) alternatively provided by MERRA-2 for the matching hour. The comparison of the modeled DNI thus obtained with the same measured data as in Fig. 9 shows a strong underestimation of DNI (≈13% on average) and large scatter (Fig. 10). These results can be directly traced back to the large bias and scatter in AOD (and possibly AEX) shown in Figs. 3 and 4. The difficulties of using the MERRA-2 reanalysis to simulate DNI corroborate previous findings (Polo and Estalayo, 2015), even though those were obtained with a different reanalysis model.

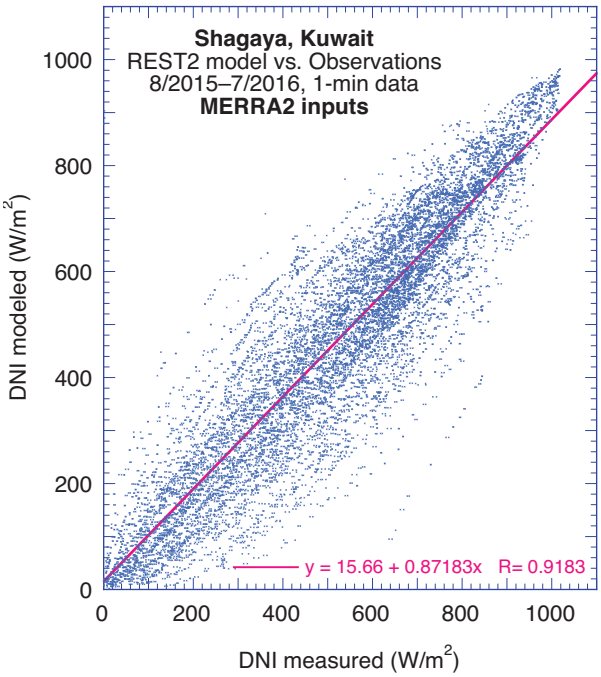

Fig. 10: Scatterplot of REST2-predicted DNI vs. ground observations using aerosol and water vapor input data from MERRA-2.

4. Conclusion

This investigation brings new information on the temporal variability in aerosol optical depth (AOD) and direct normal irradiance (DNI) under the arid conditions of Kuwait. Using data from two AERONET stations and from the MERRA-2 reanalysis, it is found that AOD is highly variable on a daily basis, and can reach very high values during any season, due to the incidence of dust storms. Some spatial variability is also apparent, even over relatively short distances. This significantly impacts the DNI solar resource in particular, and may limit the performance of CSP installations. Further investigation is needed to better characterize the spatio-temporal variability in AOD over Kuwait.

The MERRA-2 reanalysis predictions show a slight positive trend in AOD during the last two decades, signaling that a concomitant downward trend in DNI was likely. A continuation of this trend is possible in the near future, which would impact CSP projects in the region. The long-term MERRA-2 historical data has great value for, such trend analyses, but is found not accurate enough for the unbiased DNI resource evaluation required for the computerized simulation of CSP systems at high temporal resolution. Clear-sky modeled DNI predictions using MERRA-2 aerosol and water vapor data as inputs to a high-performance solar irradiance model are found noisy and too low by ≈13% on average, in comparison with actual high-quality irradiance observations with a 1-min time step.

Although the MERRA-2 aerosol transport-modeling module is still far from perfect, its main features (long time series at hourly frequency) are still unique among all other reanalysis models currently available. It is suggested that further research be carried out to compare the historical estimates of AOD from MERRA-2 or the forecasts

from its parent model, GEOS-5, to those from other similar sources, in an effort to evaluate and improve the uncertainty of modeled DNI over arid areas.

An Organic Rankine Cycle as Technology for Smaller Concentrated Solar Powered Systems

Louis Karsten[1], Dr Jaap Hoffmann[2] and Prof Frank Dinter[3]

[1, 2,] Solar Thermal Energy Research Group (STERG), Stellenbosch University, (South Africa)

[3] Fraunhofer Institute, (Chile)

Abstract

This paper analyses and simulates an organic Rankine cycle (ORC) specifically for smaller concentrated solar powered (CSP) systems to produce solar thermal electricity (STE) in the range from 500 kW to 5 MW. The plant efficiency is optimized with the evaporating and condensing temperatures as optimizing variables. A thorough process for selecting the working fluid is presented to help the designer with this monumental task. After considering various aspects n-Pentane is chosen as working fluid for the ORC. It is also the only organic working fluid that has been successfully used in conjunction with CSP on the scale from 500kW to 5MW. The power block is simulated by modelling each component and combining them to form a complete simulation model. The results of the simulation is document and a plant efficiency of about 14.2% is achieved across the power range. The output if the ORC simulation is then compared to a steam Rankine cycle under the same operating conditions and the ORC proved to be more efficient for a power output up to 3000kW.

Keywords: Organic Rankine Cycle (ORC), concentrated solar power (CSP)

1. Introduction

Even though steam Rankine cycles are more commonly used, the usage of organic fluids as working fluid is not a new concept. In 1826, Thomas Howard patented the first concept of an engine using ether as a working fluid (Casati, 2014), and the first operational solar ORC was built by Frank Shuman in Philadelphia USA in 1907 and was rated at 2.5 kW thermal output. With the 100 m^2 collector area, direct vapour of Ether at 115°C was used to drive an irrigation pump (Shuman, 1907). Currently ORC technology is used in a variety of industries mostly because of the modularity and versatility of the technology. Industries developed around the heat sources used for the ORC where the largest by far is the geothermal energy (76.5%), secondly the heat recovery industry (12.7%), thirdly the biomass industry (10.7%) whilst the solar industry only accounts for 0.1% of the total ORC industry (Tartiere, 2016).

Various micro-scale (1 kW – 10 kW) solar ORC test facilities exist and are well documented in literature but the lack of optimized technology in the ORC solar scale up to 5 MW, leads to industry lacking confidence in this technology. A resurgence of interest in the research and development of ORC as a viable small-scale solution for electrical production has developed after the successful completion of the 1 MW APS Saguaro PT plant in Arizona, USA in 2006. The plant has 10 340 m^2 of PT collectors using thermal oil at 300°C as heat transfer fluid in the solar field. The ORC module uses n-pentane as working fluid with a 1 MW_e turbine supplied by ORMAT. A major increase in efficiency was seen with an overall solar to electrical efficiency of 12.1% at design point. To date this is still the largest operating solar ORC plant in the world and a pioneer in solar ORC as it proved the simplicity of an ORC compared to that of a conventional steam Rankine cycle and this plant even allows for unattended operation. All of which are important factors in the economic considerations and commercial acceptance of this technology (Canada et al., 2005), (Quoilin et al., 2013).

CSP plants operating with traditional steam Rankine cycles tend to become unfeasible in the small scale power range (<5 MW) and ORC's might be able to fill that gap. For lower temperature thermodynamic cycles, the ORC have advantages over the steam Rankine cycle. The most promising advantage of ORC's is that less and cheaper components are needed due to lower temperatures and cycle simplicity. Another technical advantage is that typical working fluids used in ORC cycles have higher molecular weight than water which leads to the fact that a higher mass flow rate can be achieved with an ORC for the same size of turbine. This can lead to higher turbine work output with less turbine losses (Drescher & Bruggemann, 2007). This is a major advantage seeing that the turbine is a key component in an ORC having the largest effect on cycle efficiency.

doi:10.18086/swc.2017.04.05 Available at http://proceedings.ises.org

The benefits of successfully deploying small-scale CSP goes far beyond just the climate and environmental benefits. In South Africa the mining, construction, the auto and metals and engineering sectors contribute about 20% of South Africa's gross domestic product, hence it is important to sustain these industries (SEIFSA, 2016). The ORC technology might form part of the energy solutions to these industries once an optimised small-scale CSP technology is proven hence the proposed future output of electricity generating Rankine cycle plants are shown in figure 1.

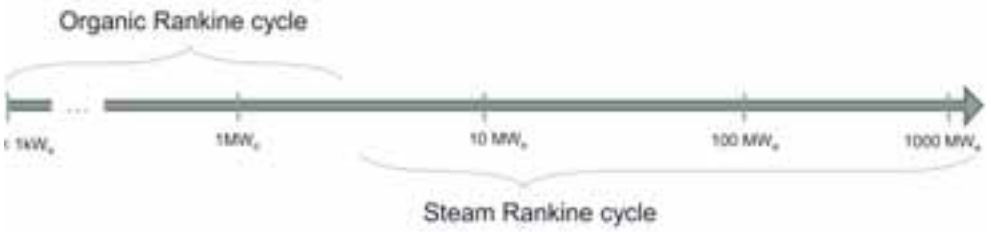

Figure 1: Proposed Thermal range of Rankine Cycles, adapted from (Dickes, 2016)

In this paper a Techno-thermodynamic design optimization is presented for an ORC using CSP as heat source across the gross electrical power output of 500 kW – 5 MW using the MATLAB environment. A specific focus is put on the working fluid selection whilst the paper elaborates on the methodology behind the design optimization, a technical analysis of the plant and components are presented and where after the design optimization results are discussed and conclusions are drawn on the feasibility of such a plant. The exact same simulation is run for a steam Rankine cycle to determine which is better suited for the current conditions.

2. Methodology

A holistic approach is taken on the power plant and its functional units namely the solar field, storage and power block. The main reasons for including storage is to prolong the operating hours of power plant and to eliminate spikes in the ORC caused by solar variations. A technological analysis is done in section 4 in order to model the whole plant consisting out of the various components in each functioning unit. By modelling each component a complete cycle simulation is achieved. For the solar field evacuated tube parabolic trough collectors are considered and Therminol 66 is used as heat transfer fluid. Therminol 66 has been developed especially for solar ORC applications by Eastman Chemicals in Italy. A Thermocline energy storage system will be incorporated in the solar field to balance out the solar variations. Regarding the power block components, it proved to be best to use an axial flow turbine for the wanted power range of 500 kW to 5 MW. A multistage centrifugal pump are commonly used in ORC's and is chosen for the current application (Macchi & Astolfi, 2017). A Plate type heat exchanger is taken for the evaporator due to their compactness and high heat transfer area. The lack of water resources in areas where CSP is implemented necessitates the use of an air cooled condenser. The final proposed ORC power plant that is used for the simulation is shown in figure 2 with the ORC T-S diagram produced by the simulation in figure 3.

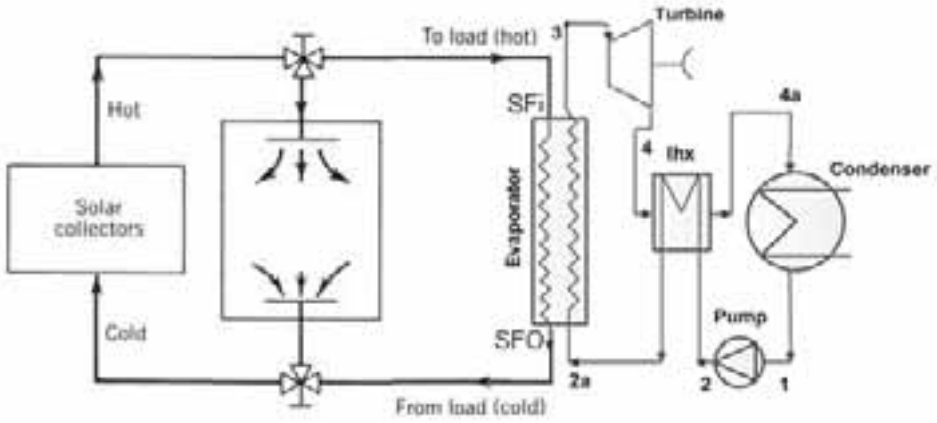

Figure 2: Final plant schematic, adapted form (Stine & Michael, 2001), (Li, G. 2016)

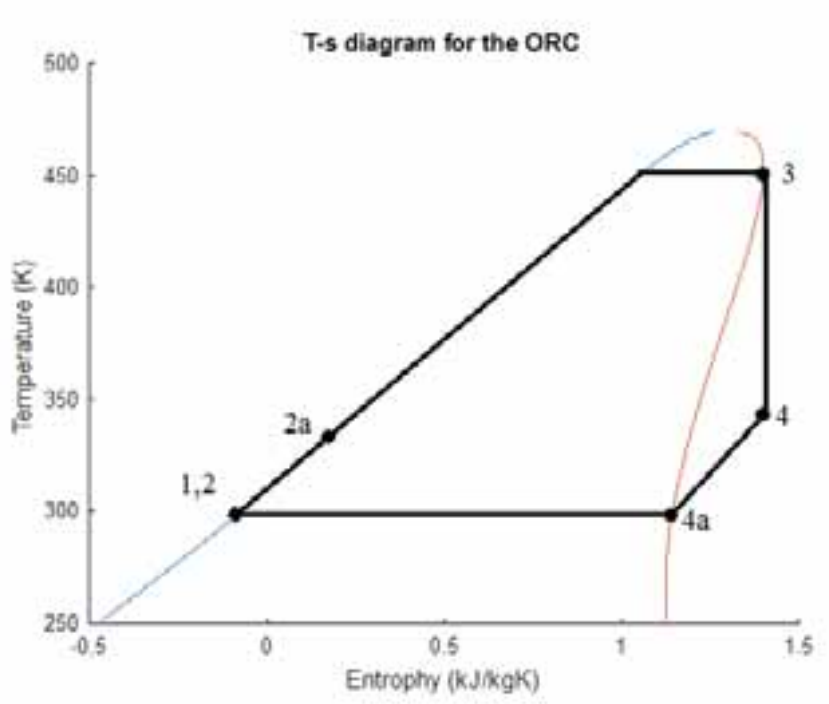

Figure 3: T-S diagram for the simulated ORC plant

A techno-thermodynamic optimization is conducted on the power plant where the total plant efficiency is used as objective function and defined as the ratio between the net power output and the maximum received thermal heat:

$$\eta_{plant} = \frac{W_{net}}{Q_{in}} \quad \text{(eq. 1)}$$

The independent decision variables that are used as optimizing variables are the condensing and evaporating temperatures. The optimization constraints are due to the working fluid property constraints. Looking at a subcritical cycle, the chosen working fluid's critical temperature is 470K which serves as the upper limit for the cycle evaporating temperature. The maximum condensing temperature is constraint at the boiling temperature at the condensing pressure. Due to the air-cooled condenser the minimum temperature to which the working fluid can be cooled down to during condensation is limited. The incorporation of a recuperator or also referred to as an internal heat exchanger as depicted in figures 2 and 3, enables the working fluid to be cooled down to a lower temperature as the working fluid now enter the condenser at a much lower temperature. A design choice is made for the lower limit of condensation temperature and it is set at 7°C above the average ambient temperature of 20°C to compensate for condenser ineffectiveness.

For each iteration of condensing and evaporating temperatures, all model equations are solved sequentially and with the black-box optimization approach the most efficient plant design with the corresponding temperatures, is determined. The flow chart of the calculation procedure is shown in figure 4:

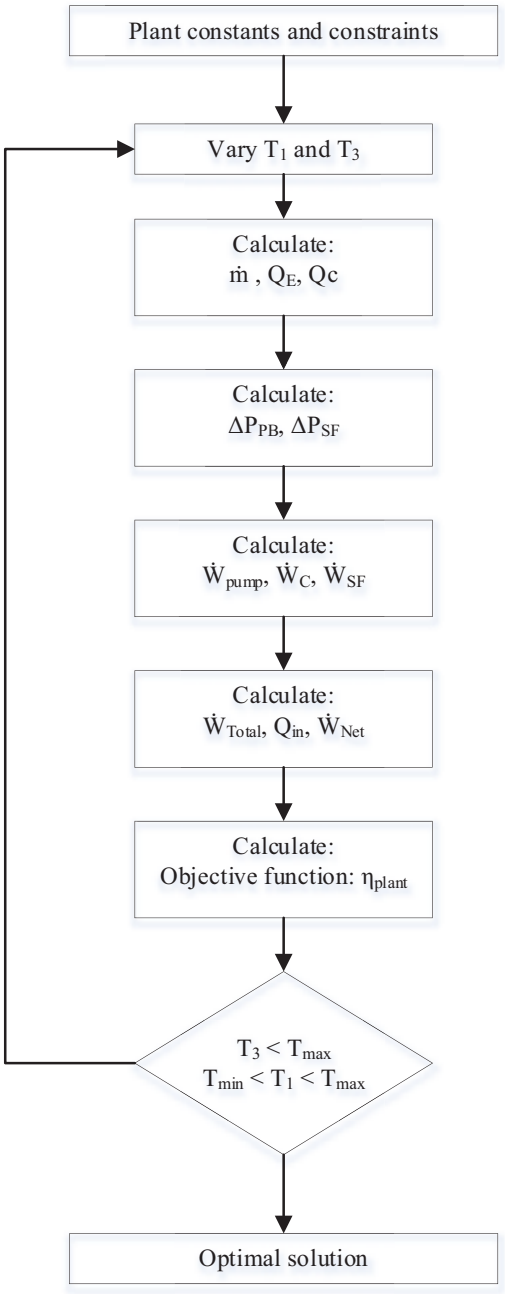

Figure 4: Simulation flow diagram

3. Choice of working fluids

The theory for an ORC is the same as to steam Rankine cycle with only the working fluid properties differing. The selection of the working fluid not only affects the efficiency of the system but also the design and sizes of the system components, stability, safety and environmental concerns and ultimately the cost of the system (Bao & Zhao, 2013). Hence, it is a very important degree of freedom for any ORC design process. Bao and Zhao continues by saying that the selection of an ORC working fluid is more complex than other thermodynamic cycles mainly due to two reasons:

- The heat type sources for ORC varies widely from 80 ^{0}C to 500 ^{0}C
- Excluding a few organic fluids whose critical temperatures are too high or too low, hundreds of fluids are available for usage including hydrocarbons, aromatic hydrocarbons, perfluorocarbons, alcohols, CFS's, siloxanes, ethers etc.

Due to the working fluid selection being so important, many researchers have carried on the fluid screening method and this method is by far the most used method for working fluid selection in scientific literature (Bao & Zhao, 2013). The method consists of building a steady state simulation model of the proposed ORC plant and run it with different working fluids to determine the most effective fluid for the current application.

Another fluid selection guideline has been developed by (Macchi & Astolfi, 2017) to help ORC designers with this monumental task of screening hundreds of working fluids. The number of applicable fluids can be drastically decreased by considering and comparing different fluids. The obvious requirements a fluid must meet is the fluid should be:

- *Commercially available at a reasonable cost*: with the intended MW range of the proposed system, a large fluid inventory is needed and the fluid cost can mount up to a significant portion of the total plant cost.
- *Non-flammable*: Hydrocarbons are flammable working fluids.
- *Nontoxic:* ammonia is toxic but is still sometimes adopted.
- *Compatible with materials*: the working fluid must be compatible with the lubricating oils, elastomers, metals etc.
- *Environmental benign*: the two main indexes that account for fluid acceptance is the Ozone Depletion Potential (ODP) and the Global Warming Potential (GWP).

Macchi & Astolfi continues to say that it is practically impossible to fulfil all these requirements with a working fluid that is suitable for ORC applications hence ORC manufacturers must overlook some of the qualities listed above but they are still aimed for. The second list of considerations in selection a suitable working fluid regards the thermodynamic considerations. The thermodynamic and physical properties of working fluids are what differentiate working fluids the most. The relationship between working fluid properties and thermodynamic cycle performance are discussed below:

- *Thermal stability:* The thermal stability of the fluid used can limit the temperature of the heat source as fluids can chemically brake down at certain temperatures hence a high thermal stability is desired.
- *Vaporization latent heat:* In terms of work output it has been found that for the same defined temperatures, a larger unit work output is produced with working fluids with a higher vaporization latent heat (Chen et al., 2010).
- *Density:* Bao and Zhao states that a high vapour density is of key importance especially for working fluids with a low condensing pressure. A low density leads to higher volume flow rates which in turn lead to larger pressure drops in the heat exchangers and the bigger turbine sizes.
- *Specific heat:* There is no direct recorded effect of specific heat and total system power output.
- *Critical temperature:* High critical temperature has a beneficial effect on cycle performance but has the adverse effect of lower vapour densities which has a benign effect on cycle performance.
- *Boiling temperature:* When comparing fluids of the same family a higher boiling temperature leads to an increase in cycle efficiency but it is by no means an absolute criteria.
- *Freezing temperature:* It serves as a constraint but has no effect on cycle efficiency.
- *Molecular weight:* Bao and Zhao concluded that high molecular weight has a positive impact on turbine efficiency but it must be noted that fluids with a high critical pressure and high molecular weight require higher heat transfer area which increases the total plant cost.
- *Molecular complexity:* A direct link between molecular complexity and cycle performance is not possible as most properties are affected by the molecular complexity and different properties have different effects on cycle performance.
- *Viscosity:* In order to maintain low friction losses in the pipes and heat exchangers, low viscosity is desired in both the liquid and vapour phase (Bao & Zhao, 2013).

- *Conductivity:* In order to obtain a high heat transfer coefficient in the heat exchangers, a high conductivity is required (Bao & Zhao, 2013).

In the case of varying heat source temperatures, it can be more advantageous to use mixtures of working fluids rather than pure working fluids. In such a system heat is supplied to or rejected at variable temperature but at constant pressure because the boiling temperature varies during phase change and the binary mixture evaporates over a large range of temperatures (Bao & Zhao, 2013). The storage incorporated in this analysis allows the heat addition to the power block at constant temperature and only pure working fluids are considered henceforward.

Working fluids are also categorised according to their saturation curve and the categorisation disregarded the structural point of view and type of atoms. When looking at the latter two, the possible ORC working fluids can be categorised in seven main classes and Bao and Zhao pointed out typical characteristics of each after screening the fluids over a range of applications:

1. Hydrocarbons including linear (n-butane, n-pentane), branched (Isobutane, Isopentane) and aromatic hydrocarbons (Toluene, Benzene)
    - Flammability issues
    - Desirable thermodynamic properties
2. Perfluorocarbons
    - Thermodynamically undesirable
    - Extremely inert and stable
    - Extreme molecular complexity
3. Siloxanes
    - Mostly used as mixtures rather than pure fluids
    - Isobaric condensation and evaporation are not isothermal and exhibit a certain glide
4. Partially flouro-substituted straight chain hydrocarbons
    - Several zero ODP fluids exists which are of interest
5. Ethers and fluorinated ether
    - Thermodynamically undesirable
    - Flammability and toxicity issues
6. Alcohols
    - Thermodynamically undesirable
    - Soluble in water
    - Flammability issues
7. Inorganics
    - Operational problems
    - Small environmental impact
    - Inexpensive

Even though the screening process covers a large number of fluids, only a few fluids are actually used in commercial plants. Hydrocarbons are the fluids with the most desirable thermodynamic properties and the flammability issues are often carefully managed in practice by restricting the operating conditions. One of the

hydrocarbon fluids, namely n-pentane, is the working fluid that is used in the 1 MW APS Saguaro PT plant in Arizona. According to Bao and Zhao no other working fluid has been used for commercial solar power plants (>500 kW) before 2013 and no new information has been published according to the author's knowledge since then. This serves as a very strong argument for the acceptance of n-Pentane as working fluid. The screening process further concluded that R134a and R245fa are also possibilities for a solar application and these fluids have been used as working fluids on micro scale (<10 kW) solar applications. Table 1 gives a summary of how n-pentane relates to the selection criteria when compared with R134a and R245fa:

Table 1: n-Pentane regarding the selection considerations

Initial selection	Availability and cost	Locally and affordably available.
	Non-flammable	NFPA 704 rating: 4; readily dispersed in air and will burn readily (Chemistry Reference, 2017).
	Non-toxic	NFPA 704 rating: 1; can cause human irritation (Chemistry Reference, 2017) .
	Compatible with materials	Compatible with all materials
	Environmental benign	Quickly evaporates and biodegrades in soil (National Refrigerants Inc., 2015)
Selection according to thermodynamic properties, (all properties are evaluated at 25°C)	Thermal stability	NFPA 704 rating: 0; very stable
	Vaporization latent heat	n-Pentane: 365 kJ/Kg R134a: 178 kJ/Kg R245fa: 197 kJ/Kg
	Density	n-Pentane: 620 kg/m^3 R134a: 1210 kg/m^3 R245fa:1339 kg/m^3
	Critical temperature	n-Pentane: 197°C R134a: 122°C R245fa: 154°C
	Molecular weight	n-Pentane: 72 R134a: 102 R245fa: 134
	Viscosity	n-Pentane: 0.217 mPa.s R134a: 12.06 mPa.s R245fa: 402.7 mPa.s
	Conductivity	n-Pentane: 0.1112 W/mK R134a: 0.013 W/mK R245fa: 0.0125 W/mK

From table 1 it can be seen that n-Pentane is the best option regarding the vaporization latent heat, viscosity and conductivity. The beneficial higher critical temperature of n-Pentane and the adverse effect thereof can be seen with the lower density. The much higher conductivity of n-Pentane caries a lot of weight as the total heat transfer area is greatly reduced resulting in smaller heat exchangers. Heat exchangers are large contributors to the total power plant cost hence smaller heat exchangers are desired. As a result n-Pentane is the best option for working fluid considering the preceding criteria hence n-Pentane is the working fluid of choice for this analysis.

4. Technical analysis

The numerical calculations were carried out for the gross power output range of 500 kW – 5 MW. Following the procedure of figure 4, the fluid properties at each state point as depicted in figures 2 and 3, are retrieved using compressed liquid, saturated liquid, saturated vapor and superheated vapor property tables for n-Pentane, (NIST, 2017). The heat and mass balance across the devices are used and the procedure follows:

The mass flow rate of the working fluid in the power block is given by:

$$\dot{m}_{PB} = \frac{W_{gross}}{(h_3 - h_4)\eta_T \eta_{gen}} \quad \text{(eq. 2)}$$

The heat supplied to the evaporator and the heat rejected by the condenser is given by:

$$Q_{PB,E} = \dot{m}_{PB}(h_3 - h_{2a}) \quad \text{(eq. 3)}$$

$$Q_{PB,C} = \dot{m}_{PB}(h_{4a} - h_1) \quad \text{(eq. 4)}$$

To calculate the pumping power of the power block pump, the pressure drops in the turbine, condenser and evaporator needs to be accounted for. They are calculated as such:

The pressure increase over the pump to overcome the turbine losses can be calculated by:

$$\Delta P_T = P_2 - P_1 \quad \text{(eq. 5)}$$

The total heat transfer area of the evaporator is given by:

$$A_e = \frac{Q_{PBe}}{U_e \Delta T_{m,E}} \quad \text{(eq. 6)}$$

Where the log mean temperature difference over the evaporator is defined as:

$$\Delta T_{m,E} = \frac{(T_{SFi} - T_3) - (T_{SFo} - T_2)}{\ln\left(\frac{T_{SFi} - T_3}{T_{SFo} - T_2}\right)} \quad \text{(eq. 7)}$$

The size of the evaporator is then determined by determining the number of plates to the upper integer:

$$n_E = \frac{A_E}{w_E \times l_E} \quad \text{(eq. 8)}$$

Due to the phase change in the evaporator the pressure drop across the core part of the evaporator can be a tedious procedure to calculate. By taking the pressure drop equation for single phase flow and incorporating the two phase flow effect in the multiplication factor ϑ^2, a satisfying result can be obtained with this equation (Shah & Sekulić, 2003):

$$\Delta P_{core,E} = \left(\frac{dp}{dz}\right) = f_E \left(\frac{4}{D_{h,}}\right)\left(\frac{G^2}{2\rho_E}\right)\vartheta^2 \quad \text{(eq. 9)}$$

Where:

$$\vartheta^2 = (1-x)^2 + x^2 \frac{\rho_l}{\rho_g}\frac{f_g}{f_l} + \frac{3.24(x^{0.78}(1-x)^{0.24})\left(\left(\frac{\rho_l}{\rho_g}\right)^{0.91}\left(\frac{\mu_g}{\mu_l}\right)^{0.19}\left(1-\frac{\mu_g}{\mu_l}\right)^{0.7}\right)}{\left(\frac{G^2}{gD_h\rho_{avg}}\right)^{0.045}\left(\frac{G^2 D_h}{\rho_{avg}}\right)^{0.035}} \quad \text{(eq. 10)}$$

The pressure losses due to the intake and outlet manifolds are evaluated by the following equation (Shah & Sekulić, 2003):

$$\Delta P_{M,E} = \frac{1{,}5 G_E^2 n_{p,E}}{2\rho_2} \quad \text{(eq. 11)}$$

The total pressure loss over the evaporator for the working fluid side is then after neglecting the gravitational effects due to fact that the tubes are horizontal:

$$\Delta P_E = \Delta P_{core,E} + \Delta P_{M,E} \quad \text{(eq. 12)}$$

The total pressure loss over the condenser, ΔP_c , is evaluated exactly the same way as that for the evaporator taking note that the geometrical features of the air-cooled condenser differs.

The work required for the power block pump is then:

$$W_{PB,pump} = \dot{V}(\Delta P_T + \Delta P_E + \Delta P_c) \quad \text{(eq. 13)}$$

To avoid the integrate and iterative design process of an air-cooled condenser in the scope of cycle optimization such as this, a general relationship between the work required by the air-cooled condenser fan and the turbine power output where (O'Donovan, 2013):

$$W_{c,F} = 0.02 \times W_{gross} \quad \text{(eq. 14)}$$

This relationship was confirmed by taking a typical air-cooled condenser fan that is used in a similar application with similar heat rejection requirements than the 5 MW case. The fan curve was available and by submitting the data in the power block simulation a relationship of about 4% was calculated between fan work and turbine power output. The relationship will be used with the more conservative relationship of 4% and by using a relationship the simulation can be used in a modular way across the power output range.

The next step is to calculate the work required by the solar field pump. After calculating the mass flow rate in the solar field with the following equation, the pressure drop in the evaporator, $\Delta P_{SF,e}$ can be calculated as in the case of the evaporator working fluid side.

$$\dot{m}_{SF} = \frac{Q_{PB,E}}{Cp_{SF}(T_{SFi} - T_{SFo})} \quad \text{(eq. 15)}$$

Neglecting minor losses, the frictional pressure drop of the rest of the solar field can be calculated with the following:

$$\Delta P_{SF,fr} = f \frac{L}{D_{SF,p}} \frac{\rho V_{SF}^2}{2} \quad \text{(eq. 16)}$$

The total pressure drop and maximum required work (during day time) of the solar field pump is given below:

$$\Delta P_{SF} = \Delta P_{SF,e} + \Delta P_{SF,fr} \quad \text{(eq. 17)}$$

$$W_{SF,pump} = \dot{V}_{SF}(\Delta P_{SF}) \quad \text{(eq. 18)}$$

The net power output of the plant is then calculated as given below:

$$W_{Net} = W_{gross} - (W_{PB,pump} + W_{C,F} + W_{SF,pump}) \quad \text{(eq. 19)}$$

Following the objective function can be calculated as described previously given that:

$$Q_{in} = \frac{Q_{PB,E}}{\eta_{trough}} \quad \text{(eq. 20)}$$

5. Results and discussion

A techno-thermodynamic optimization was set up for a solar ORC plant where the plant efficiency was used as the objective function. For the 1 MW gross power output case, the power plant reached an optimal objective function at a condensing temperature, T_C = 300K and evaporating temperature T_E = 450K. These values fall within the constraints set by the simulation which necessitated the evaporating temperature below the critical temperature of 470K of n-Pentane, and keeping the condenser outlet temperature above an ambient temperature of 298K. The evaporating pressure reached a value of 2.45 MPa and the condensing pressure reached a value of 67 kPa. The exact same simulation was run under the same conditions for steam Rankine cycle for comparison sake. The resulting plant efficiencies from the objective function for the whole simulated power range can be seen in table 2:

Table 2: Resulting optimized plant efficiencies with net power output

Turbine power output (kW)	Net ORC plant power output (kW)	Optimized ORC plant efficiency (%)	Optimized steam plant efficiency (%)
500	458	14.26	11.10
1000	916	14.26	11.82
2000	1 831	14.25	13.77
3000	2762	14.25	14.17
4000	3660	14.24	14.76
5000	4598	14.24	15.75

As can be seen from table 2, the ORC performs much better at the lower temperature range. The main reason is that steam turbines are very inefficient at low power outputs leading to the whole cycle efficiency being lower. As the turbine output increases above 4000kW, it can be concluded that a steam Rankine cycle would be a better choice. Furthermore the ORC turbine efficiencies remain relatively constant for different power outputs, hence the whole plant efficiency remains more or less constant with change in power output. The turbine and working fluid has the largest effect of all the components on the cycle efficiency. Typically the average temperature at which heat is added in the evaporator must be increased and the average temperature at which heat is being rejected in the condenser needs to be decreased in order to increase cycle efficiency. The first mentioned is directly linked to the turbine inlet temperature and the effect of the turbine inlet temperature on cycle efficiency can be seen in figure 5.

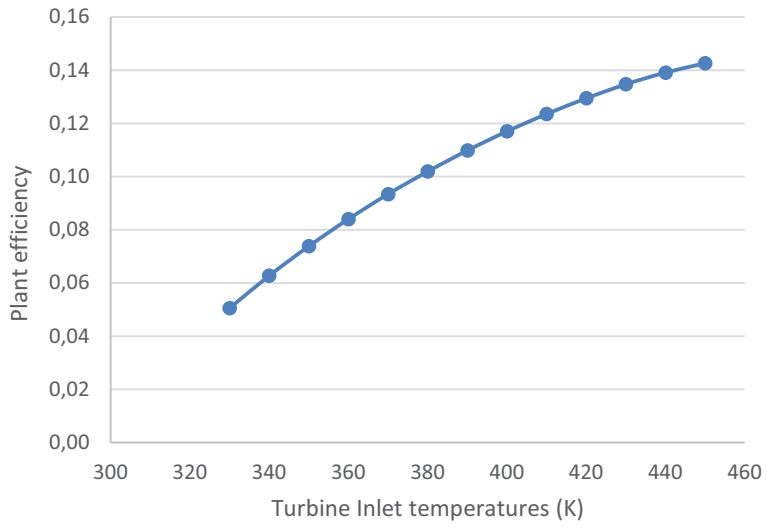

Figure 5: The influence of turbine Inlet temperature on plant efficiency for the 1 MW case

6. Conclusion

The paper optimized an ORC coupled with CSP and obtained a plant efficiency of about 14.2% across the power range of 500 kW – 5 MW. The efficiency correlates with an existing plant. The simulated plant operated at a maximum temperature and pressure of 450K and 2.45 MPa respectively. This is significantly lower than that of traditional Rankine cycles resulting in components needing to have less resilience. This in effect has a

great decreasing effect on plant cost and if accurate cost relations can be found one can conclude on the economical competiveness of an ORC. When the steam Rankine cycle was simulated under the same conditions and temperatures than the ORC, the ORC proved to be more efficient up to 3000kW power output. However the lack of optimized technology in the solar ORC field leads to industry not widely accepting the technology as a feasible solution yet but this paper concludes that further research in this topic is justified and that the solar ORC technology is deemed to reach maturity in the future.

[2] Assistant Professor, Centre for Energy Studies, Indian Institute of Technology Delhi, New Delhi (India)

Abstract

In this article, heat transfer characteristics of various heat transfer fluids (HTF's) such as water, therminol oil, molten salt and liquid metals are studied for parabolic trough solar collector. A three dimensional (3-D) numerical simulation of absorber for parabolic trough solar collector is carried out using commercial computational fluid dynamics software Fluent 16.0. The numerical model is solved based on K-ε turbulent model with standard wall function. The influence of thermo-physical properties of HTF's on heat transfer rate from the absorber wall surface to the fluid is studied for various mass flow rates ranging from 0.5 kg/s to 1.5 kg/s insteps of 0.25 kg/s. The analysis is carried out for both uniform and non-uniform heat flux at the absorber wall surface. For both uniform and non-uniform heat flux configuration, liquid sodium offers better heat transfer characteristics among all the heat transfer fluids. Among all the heat transfer fluids, liquid sodium offers less temperature gradient (8.58 K) and therminol oil offers high temperature gradient (42.74 K) around the circumference of the absorber for the mass flow rate of 1 kg/s. Hence, liquid sodium offers significant benefits in terms of performance enhancement compared to other heat transfer fluids.

Key Words: Parabolic trough solar collector, Receiver, Variable heat flux, Heat transfer fluid, Liquid sodium

1. Introduction

A concentrated solar thermal collector concentrates solar radiation on the receiver that converts solar radiation in to useful high temperature heat. There are four concentrated solar thermal power (CSTP) technologies namely linear Fresnel reflector (LFR), parabolic trough collector (PTC), power tower (PT) and parabolic dish collector (PDC) that have reached reasonably high state of maturity. Globally ~ 4.8 GW CSTP plants are in operation and ~1.6 GW capacity of power plants are under construction as on March 2017 (NREL, 2017). Among the CSTP technologies, PTC is most proven technology and commercially available for power generation with potential of high dispatchability. The parabolic trough collector consists of parabolic shaped concentrator, receiver and supporting structure. Receiver is the most important component of the CSTP system. The PTC receiver consists of an absorber tube surrounded by glass envelope with annulus space evacuated. Heat transfer fluid is circulated through the receiver to collect the heat from the receiver. Typically organic or synthetic oils are used as a heat transfer fluid (HTF) in the PTC system. Synthetic oil has poor heat transfer characteristics and it has limitation of maximum operating temperature (< 400^{o}C). Design of receiver and heat losses from the receiver plays an important role on the performance of PTC. Heat losses from the receiver is the function of absorber temperature, ambient temperature, absorber type, wind velocity, etc. The temperature of the absorber may be reduced by increasing the heat transfer rate between inner wall surface of the absorber to the fluid.

There are few studies exist on enhancement of heat transfer rate from the absorber wall surface to the fluid. Almanza et al., (1997) conducted the experiments to study the deflection of absorber tubes due to temperature gradient in circumferential direction for direct steam generation in parabolic collector. Odeh et al., (1998) studied the performance of parabolic trough solar collector with synthetic oil and water as HTF. Kumar and Reddy (2009, 2012) studied the porous disc receiver for parabolic trough collector with therminol-55 and water as HTF and developed the empirical correlations for Nusselt number and friction factor. Cheng et al., (2010) performed the coupled flux distribution and heat transfer model for parabolic trough solar collector to analyze the heat distribution in the receiver. In recent days, liquid metals gaining much attention for CSTP applications as HTF. Boerema et al. (2012) studied liquid sodium and Hitec (a ternary molten salt 53% KNO_3 + 40% $NaNO_2$ + 7%

doi:10.18086/swc.2017.04.06 Available at http://proceedings.ises.org

$NaNO_3$) as heat transfer fluids and reported that both fluids are alternative for molten salts in PT systems for power generation. Kotze et al. (2012) compares the strengths and limitations of various HTF's for CSTP applications and proposed NaK may be the primary HTF for performance improvement. Pacioa et al. (2013) proposed liquid metals such as liquid sodium and lead-bismuth eutectic as efficient heat transfer fluids for PT systems. The recent development in HTF's for low, medium and high temperature solar thermal systems has been reviewed by Srivastva et al. (2015). Overall, liquid metals gaining momentum for CSTP applications to improve the performance of the receiver. In this paper, heat transfer ability of various HTF's and temperature gradient around the circumference of the absorber tubes are explored. The characteristics of HTF's such as stability at higher temperature, decomposition due to continuous heating and cooling, corrosion issues will be studied in future as continuation of this work.

2. Modeling of Absorber for Parabolic Trough Solar Collector

A 3-D numerical modeling is carried out to investigate the heat transfer rate from the absorber wall inner surface to the various working fluids such as water, therminol oil, molten salt, liquid sodium and eutectic NaK (77.8 % potassium and 22.2 % sodium by weight). The eutectic NaK hereafter referred as NaK78. The thermo-physical properties of various heat transfer fluids are given in Table 1. The schematic of absorber of parabolic trough solar collector is shown in Figure 1. The absorber of 4 m length is considered for the analysis with internal and external diameter of 66 mm and 70 mm respectively. The mass flow inlet and pressure outlet boundary condition is considered. The analysis is carried out for various mass flow rate ranging from 0.5 kg/s to 1.5 kg/s insteps on 0.25 kg/s. Constant and variable heat flux boundary conditions are considered for the analysis. For constant heat flux boundary condition, the absorber wall is subjected to 21000W/m^2 and for variable heat flux boundary conditions, the flux profile is given in Figure 2 (Khanna and Sharma, 2016).

Tab. 1: Thermo-physical properties of various heat transfer fluids (Kotze, 2012)

S. No.	Heat Transfer Fluid	Density (kg/m^3)	Specific Heat (kJ/kg K)	Thermal Conductivity (W/m K)
1	Water	995.7	4.178	0.60
2	Therminol Oil	1056	2.5	0.09
3	Molten salt	1794	1.21	0.55
4	Liquid Sodium	820	1.25	119.3
5	NaK78	749	0.94	26.2

Fig. 1 Schematic of absorber of a parabolic trough solar collector

The governing equations for steady, incompressible, forced convection in the absorber are given as (FLUENT, 2016):

Continuity equation:

$$\nabla \vec{V} = 0 \qquad \text{(eq. 1)}$$

Momentum equation:

$$\vec{V}\nabla\left(\vec{V}\right) = -\frac{\nabla P}{\rho} + \left(\frac{\mu + \mu_t}{\rho}\right)\nabla^2\left(\vec{V} + \vec{V}^T\right) + \overrightarrow{F_B} \qquad \text{(eq. 2)}$$

Energy equation:

$$\rho C_p \nabla\left(\vec{V}T\right) = \lambda \nabla^2 T \qquad \text{(eq.3)}$$

A steady state, 3-D model with incompressible and turbulent flow is solved using K- ε turbulent model. Reynolds Averaged Navier Stokes (RANS) model is used to solve the momentum equation with turbulent stresses. The RANS equations for incompressible flow is:

$$\frac{\partial}{\partial x_j}\overline{(u_i u_j)} = -\frac{1}{\rho_f}\frac{\partial \bar{p}}{\partial x_j} + \frac{\partial}{\partial x_j}\left[\vartheta_{eddy}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)\right] \quad \text{(eq. 3)}$$

where, $\vartheta_{eddy} = C_\mu \frac{k^2}{\varepsilon}, C_\mu = 0.0845, k = 0.71\varepsilon^{2/3}L^{2/3}$

k and ε are the values of turbulent kinetic energy and turbulent dissipation rate.

The heat transfer coefficient from the absorber tube to the fluid may be given as:

$$h_f = \frac{q^{"}}{T_w - T_{ref}} \quad \text{(eq. 4)}$$

Where, $q^{"}$ is heat flux, T_w is the wall temperature and T_{ref} is reference temperature.

3. Boundary Conditions for Receiver

The following boundary conditions are applied for modeling of the absorber of the parabolic trough solar collector:

a) Inlet boundary condition

Mass flow inlet boundary condition is used at the absorber inlet with different temperature depends on the working fluid.

$$u = u_{in}; T_f = T_{in} \; at \; L = 0$$

$$0 \le r \le \frac{d_i}{2}, \; -180^o \le \theta \le 180^o \quad \text{(eq. 5)}$$

Since the melting temperature of molten salt and liquid metals are higher than the ambient temperature, the inlet temperature for various HTF's are considered as 300 K for water, therminol oil and NaK 78, 371 K for liquid sodium and 498 K for molten salt.

b) Wall boundary condition
Absorber inner wall:

No slip boundary condition is given to the inner and outer side of the wall.

$$u = 0 \; at \; 0 \le L \le 4, \; r = \frac{d_i}{2}, \; -180^o \le \theta \le 180^o \quad \text{(eq. 6)}$$

Absorber outer wall is subjected to heat flux boundary condition. Two boundary conditions are applied to study the performance of the absorber (a) Uniform (constant) heat flux boundary condition: the absorber wall is subjected to uniform heat flux of 21000W/m^2 and (b) Non-Uniform heat flux boundary conditions: the heat flux profile applied on the absorber wall surface is given in Figure 2 (Khanna and Sharma, 2016). In figure 2, zero degree corresponds to bottom of the absorber tube and ± 180^o corresponds to top of the absorber.

c) Pressure outlet boundary condition is employed across the outlet of the receiver.

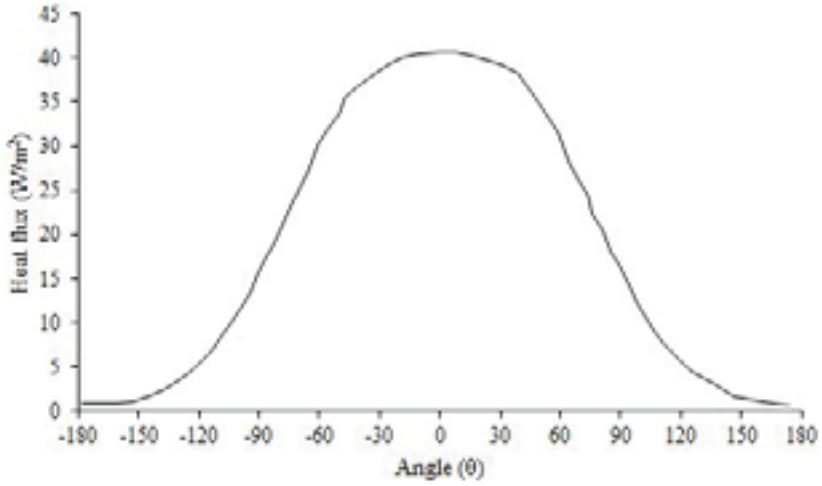

Fig. 2: Heat flux profile applied on the absorber surface (Khanna and Sharma, 2016)

4. Numerical Procedure

The governing equations are solved by finite volume method using CFD commercial software ANSYS Fluent 16.0 with segregated implicit solver and first order formulation (FLUENT, 2016). The first order discretization technique is used in pressure based solver. The velocity and pressure coupling is done by using SIMPLE algorithm. A convergence criteria of 10^{-3} is applied for velocity and momentum equations and 10^{-7} is applied for energy equation. The computational model is created in ANSYS 16.0 geometry module. The model is discretized into quadrilateral elements using ANSYS meshing module. Grid independence study is carried out and the number of mesh element is identified as 688539 cells. The variation of results are insignificant beyond the above mentioned element size. The geometric parameters of the absorber consists of a cylindrical tube with 4 m length having an inner diameter of 0.066 m and an outer diameter of 0.07 m. The computational domain consists of two zones such as solid and fluid. The wall is a solid zone where uniform and non-uniform heat flux is applied in two separate cases as discussed earlier. The fluid zone is the heat transfer fluid flowing the through the cylinder from inlet to outlet.

5. Validation

The model is validated by comparing the Nusselt number of present numerical model with Dittus-Boelter correlation. The result shows that the present model deviates from Dittus-Boelter correlation is around 9%.

The Dittus-Boelter equation is given as:

$$Nu = 0.023 Re^{0.8} Pr^{0.4} \qquad \text{(eq. 7)}$$

for $Re \geq 10,000$ *and* $0.7 \leq Pr \leq 160$

6. Results and Discussion

The numerical simulation of the absorber of a parabolic trough solar collector is carried out to analysis the influence of thermo-physical properties of various HTF's on heat transfer rate from absorber inner wall surface to the fluid with different mass flow rates. The HTF's mass flow rate varies from 0.5 kg/s to 1.5 kg/s insteps of 0.25 kg/s. In first case, simulations are carried out for the constant heat flux boundary condition to compare the heat transfer coefficients and temperature difference (ΔT) between the absorber wall surface and mean fluid temperature. The heat transfer coefficient increases with mass flow rate for all the HTF's. As shown in Figure 3 that the maximum heat transfer coefficient as 1268 W/m^{2}K at 1.5 kg/s is achieved for liquid sodium. For mass flow rate of 1 kg/s, the minimum ΔT is observed for liquid sodium as 1.38 K and maximum ΔT is observed for therminol oil as 31 K (Figure 4). It shows clearly that thermal conductivity of the HTF plays an important role in

heat transfer from absorber wall to the fluid. Also, it helps to reduce the absorber wall temperature that results in reduced heat losses from the absorber.

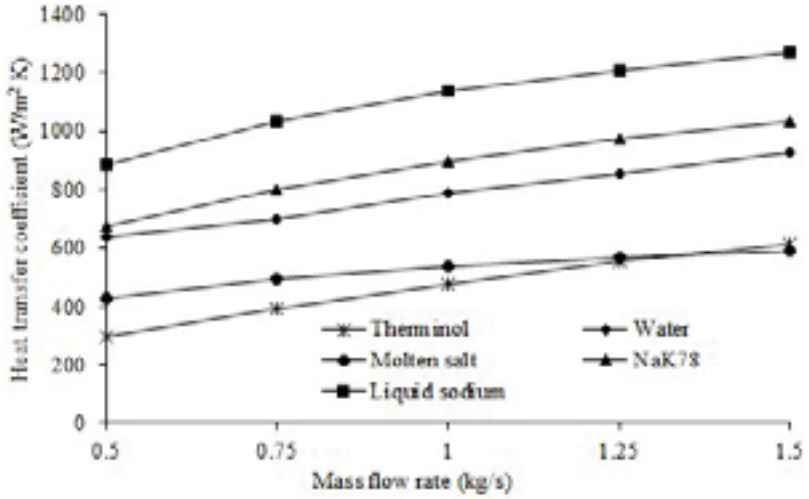

Fig. 3: Heat transfer coefficient for the absorber tube of parabolic trough solar collector for various HTF's with uniform heat flux boundary condition

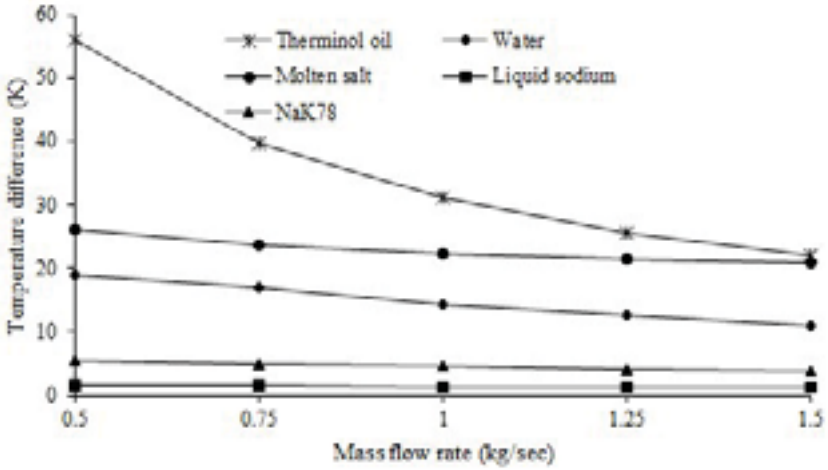

Fig. 4: Temperature difference between the absorber wall surafce and mean fluid temperature for various HTF's with uniform heat flux boundary condition

In second case, non-uniform heat flux boundary condition is applied around the absorber circumference to evaluate the heat transfer coefficient from wall to the fluid, temperature difference between the absorber inner wall surface to the mean fluid temperature and variation of temperature around the absorber circumference. Figure 5 shows that the surface heat transfer coefficient increases with flow rate. For 1.5 kg/s of mass flow rate, the maximum heat transfer coefficient of 1100 W/m^2 K is observed for liquid sodium and minimum of 600 W/m^2 K is observed for therminol oil. It is observed that the temperature difference between the inner wall surface to the mean fluid temperature (ΔT) is gradually decreases with increase in mass flow rate. Among all the HTF's, the maximum and minimum temperature difference occurs for therminol oil and liquid sodium respectively for the given mass flow rate.

Temperature of the absorber around the circumference for 0.5 kg/s and 1.5 kg/s is shown in Figure 7 and 8 respectively. Since the inlet temperature of liquid sodium and molten salt is higher than the other HTF's, the

absorber wall temperature also higher for liquid sodium and molten salt. At bottom of the absorber wall is subjected to higher heat flux (figure 2) and it decreases around the circumference while moving to top of the absorber. For most of the HTF's, higher wall temperature is observed at bottom of the absorber tube (0^o). Absorber wall temperature around the circumference is almost constant for liquid sodium. The temperature difference around the circumference of the wall in descending is observed as therminol oil followed by molten salt, water, NaK78 and liquid sodium for the given mass flow rate (Table 2).

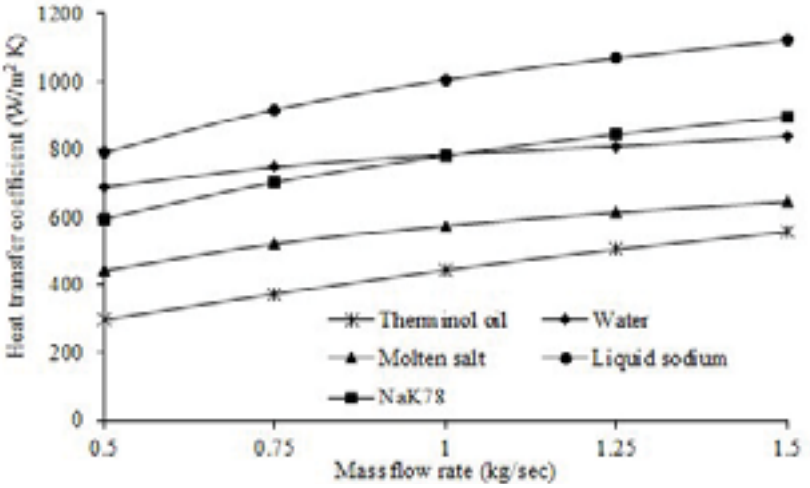

Fig. 5: Heat transfer coefficient for the absorber of PTC with non-uniform heat flux boundary condition

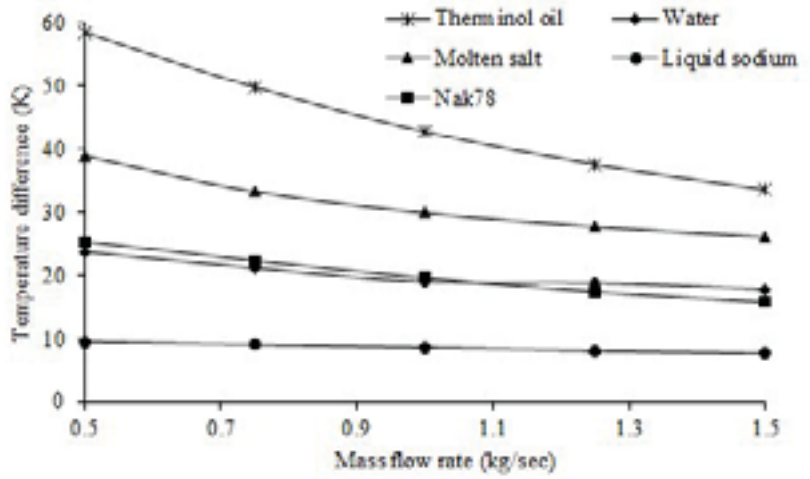

Fig. 6: Temperature difference between absorber wall and mean fluid temperature for various HTF's with non-uniform heat flux boundary condition

The temperature difference around the circumference of the absorber wall is maximum for lower mass flow rate and decreases with increase in mass flow rate. The temperature difference around the circumference is maximum for therminol oil at 0.5 kg/s of mass flow rate and minimum for liquid sodium at 1.5 kg/s. Higher the temperature difference results in thermal stress in the absorber wall. It leads to deflection of the absorber, results in poor optical efficiency. Hence, it is clear that thermo-physical properties of HTF's play an important role in performance of the receiver.

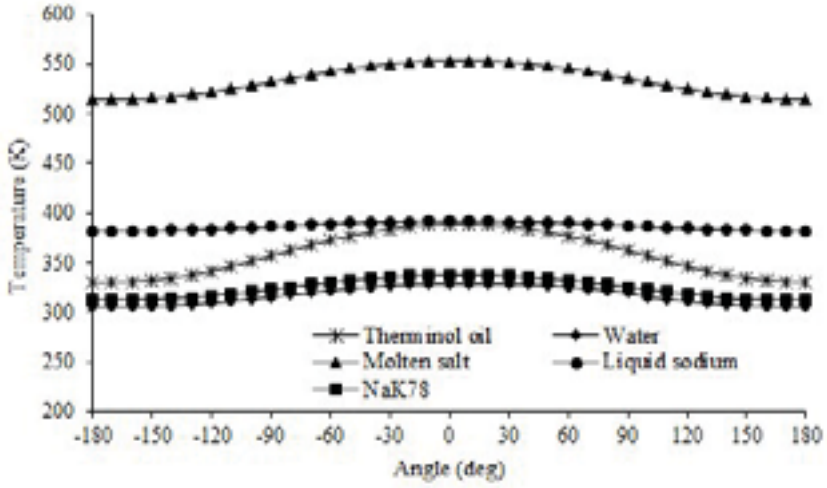

Fig. 7: Temperature of the absorber tube around the circumference for mass flow rate of 0.5 kg/s

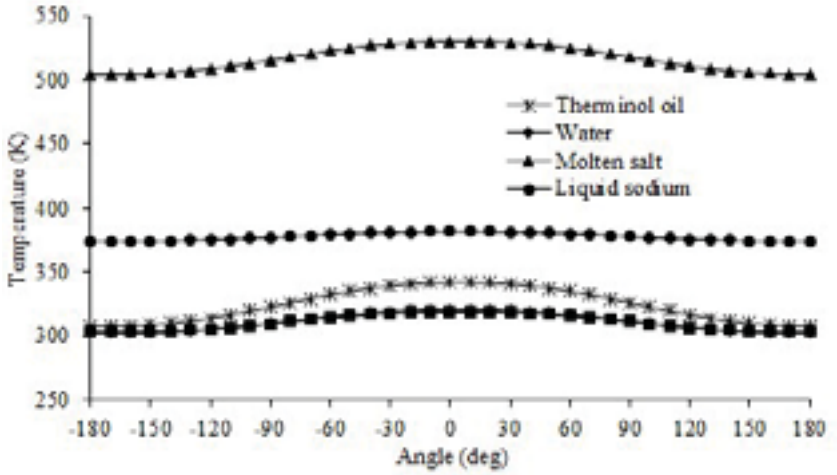

Fig. 8: Temperature of the absorber tube around the circumference for mass flow rate of 1.5 kg/s

Tab. 2: Temperature difference around the absorber circumference for different working fluids

Heat Transfer Fluids	**Temperature (K)**				
Mass flow rate (kg/s)	**0.5**	**0.75**	**1**	**1.25**	**1.5**
Therminol oil	58.45	49.79	42.74	37.56	33.59
Water	23.67	21.12	18.94	18.8	17.79
Molten salt	38.89	33.22	29.84	27.68	26.09
Liquid sodium	9.49	9.01	8.58	8.09	7.65
Nak78	25.37	22.27	19.55	17.4	15.8

The temperature contours along the length for therminol oil, water and Nak78 are sown in Fig.9 at 0.5 kg/s. The temperature increases gradually along the length from inlet temperature of 300 K. Temperature contours of molten salt and liquid sodium is shown in Figure 10 and 11 respectively.

Fig. 9: Temperature contours for (a) Therminol, (b) Water, (c) NaK78 at 0.5 kg/sec mass flow rate with non-uniform heat flux

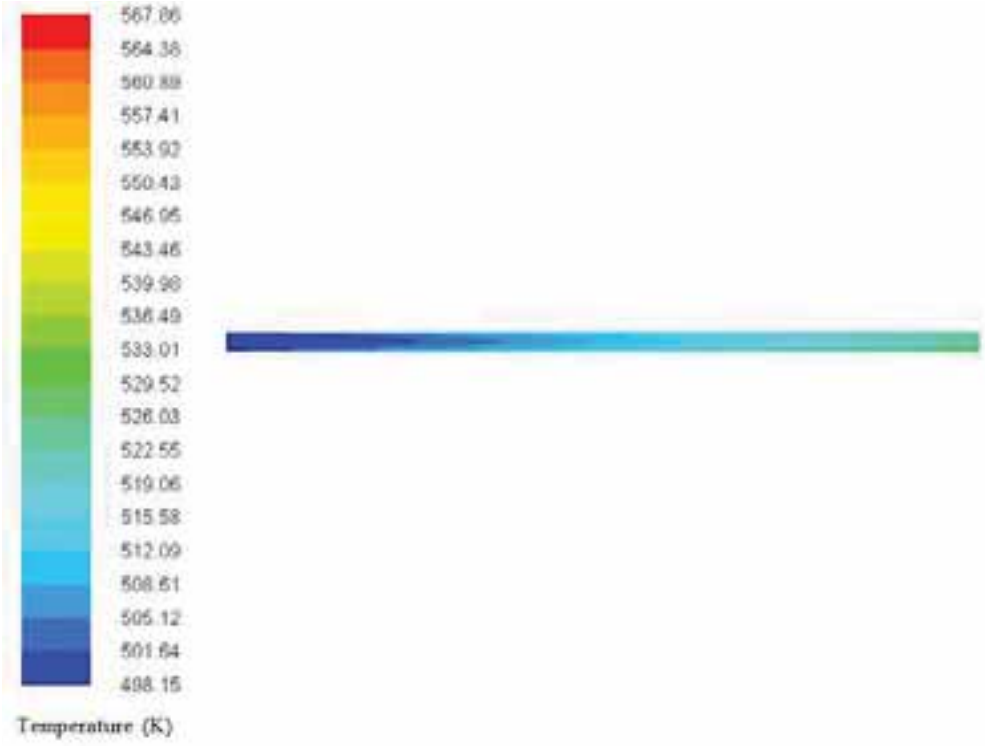

Fig. 10: Temperature contours for molten salt at 0.5 kg/sec mass flow rate with non-uniform heat flux

The temperature contours at the outlet of the absorber tube for therminol oil, water and NaK78 are shown in Figure 12. NaK78 achieves higher outlet temperature due to low specific heat and higher thermal conductivity. The temperature at outlet of absorber tube for various HTF's such as therminol oil, water and NaK78 at 0.5 kg/s are found as 314.3 K, 308.57 K and 337.3 K respectively. Figure 13 and 14 shows the temperature contours at the outlet of absorber for molten salt and liquid sodium respectively. The outlet temperature of the molten salt and liquid sodium is calculated as 527.6 K and 398.8 K respectively for 0.5 kg/s.

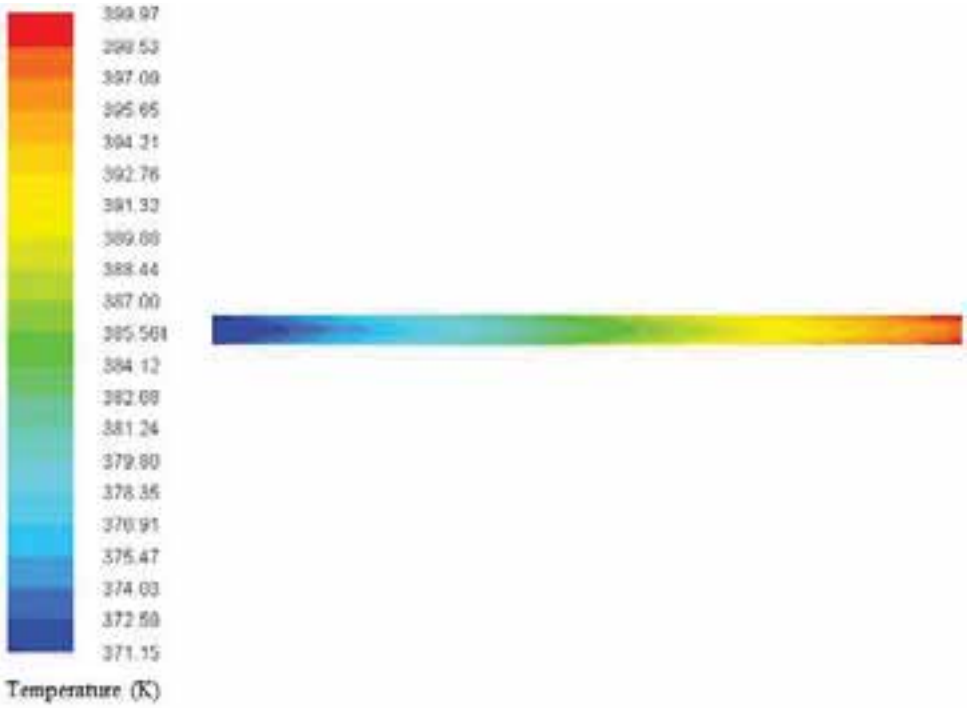

Fig. 11: Temperature contours for liquid sodium at 0.5 kg/sec mass flow rate with non-uniform heat flux

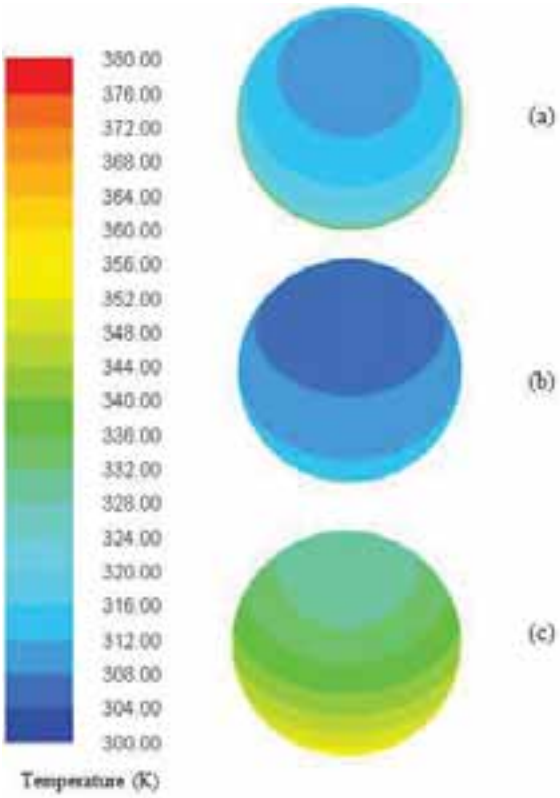

Fig. 12: Temperature contours at outlet of the absorber for (a) Therminol oil (b) water and (c) NaK78 at 0.5 kg/s with non-uniform heat flux distribution

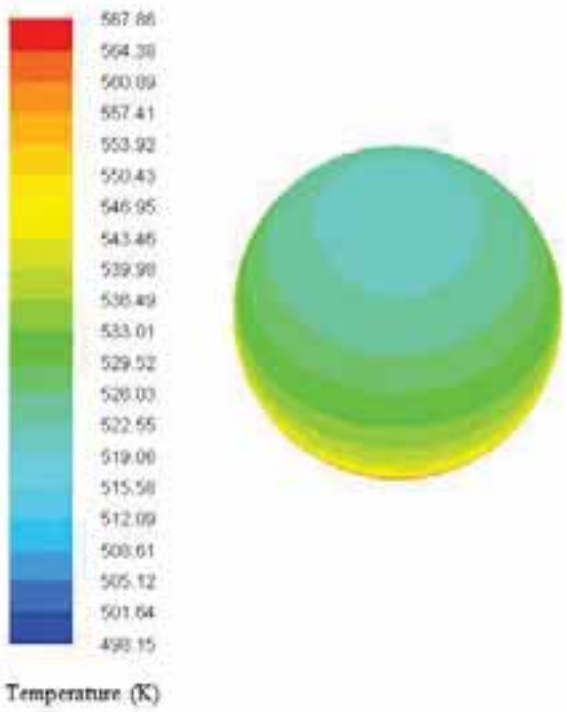

Fig. 13: Temperature contour at outlet of the absorber for molten salt at mass flow rate of 0.5 kg/s

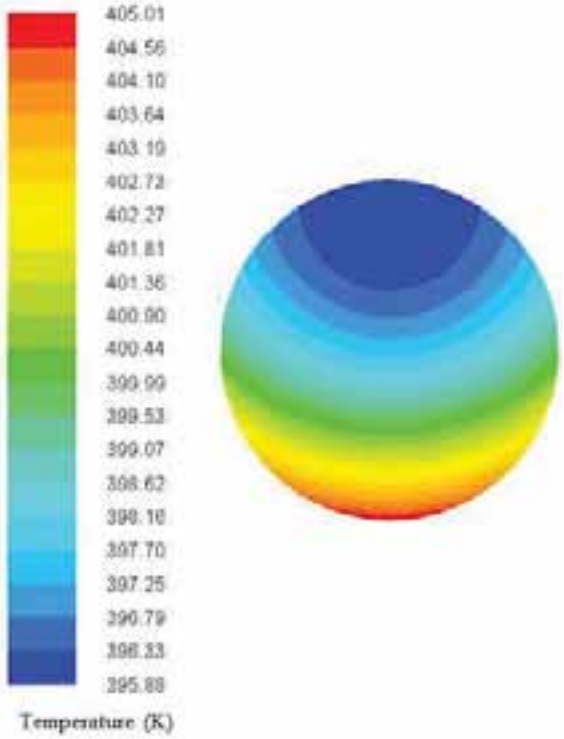

Fig.14: Temperature contour at outlet of the absorber for liquid sodium at mass flow rate of 0.5 kg/s

Based on the analysis, it is found that liquid sodium and NaK78 offers less temperature difference around the circumference of the absorber as well as temperature difference between the inner wall of the absorber to the mean temperature of the fluid as compared to other heat transfer fluids. Since melting temperature of the liquid sodium (97.82^{o}C) is higher than the ambient, it requires either option for draining of liquid sodium from the receiver or trace heating during plant startup. It increases plant operating cost which is not desirable. The melting point of NaK78 is12.6^{o}C which is less than the ambient temperature for most of the climatic conditions. It is desirable to use Nak78 as heat transfer fluid for parabolic trough solar collector to improve the performance of the absorber significantly.

7. Conclusions

The numerical simulation of absorber for a parabolic trough solar collector has been carried out for different HTF's and observed that the liquid sodium and NaK78 performs better than other HTF's due to its high thermal conductivity. It also reduces the temperature gradient between the absorber wall surface to the mean fluid temperature as well as around the absorber circumference. Hence it helps to reduce the heat losses from the absorber of the parabolic trough solar collector. By reducing the circumferential temperature difference, thermal stress in the absorber tube can be minimized which results in no / minimum deflection of the absorber in turn it improves the intercept factor / optical efficiency of the parabolic trough solar collector. Overall, using liquid metal as heat transfer fluid improves the overall performance of the parabolic trough solar collector. Since liquid sodium and NaK78 violently reacts with water and air, special precautions should be taken care to avoid the safety related issues.

Abstract

Ni-Co/Nanoporous Al_2O_3/Aluminum spectrally selective structures are grown using electrochemical anodization of alumina, followed by electrochemical pigmentation of Ni and Co metallic particles simultaneously. The pigmentation of Ni and Co particles into nanoporous anodized alumina (AA) is achieved using the reduction of metal ions in the aqueous electrolyte. The measured absorptivity and emittance are ~ 0.90 ± 0.05 and 0.14 ± 0.04, respectively. These structures are subjected to the ten identical thermal cycling upto 300 °C in inert N_2 and air ambient conditions. The optical performance suggests that absorptivity is nearly same with slight enhancement in the emittance values as compared to the structure without any heat treatment. The accelerated corrosion studies suggest that Ni-Co co-pigmented AA structures are relatively corrosion robust as compared to that of the AA structure.

Keywords: Corrosion, spectrally selective coatings, emittance, absorptance,

Introduction

The energy crisis during 1970-1980 implied the consequences of fossil fuel depletion, greenhouse gases and subsequently the climate change and obligated to look for alternate energy resources. Thus, renewable energy sources are gaining attention continuously and their fractions are increasing slowly. Solar energy is one of the most abundant environmentally safe renewable energy resources. The simplest and direct method of harnessing solar energy is the solar thermal conversion, where thermal energy can be utilized for possible applications later or simultaneously including power generation. The spectrally selective solar absorbers are used to convert the incident solar radiation into thermal energy by employing on receiver tube of the solar collector, which is integrated into a solar thermal systems and sub-systems for different applications including solar thermal power plants [Granqvist 1991, Behar et al. 2013]. Solar collectors can be classified into two category in general: (i) non-concentrating and (ii) concentrating. The concentration ratio for nonconcentrating solar collector is one, which is greater than one (> 1) for concentrating collectors. Non-concentrating collector such as flat plate collectors and evacuated tube collectors are mainly used for relatively lower temperatures based applications including solar hot water and drying of agricultural products, whereas concentrating collectors are used for high-temperature application such as solar thermal power and industrial applications. The initial spectrally selective coatings are mostly electrodeposited black chrome, black nickel, Nis-ZnS composites and were integrated successfully in flat plate collectors. These coatings are useful for moderate temperature applications under vacuum/inert or corrosion free ambients. The performance of a solar absorber depends on optical properties of absorber surface, employed to intercept the incoming solar radiation. For an effective solar energy collection, the spectral selective coatings are used, which are capable of absorbing the maximum of solar spectrum without emitting large thermal radiations. Thus, spectrally selective absorbers should exhibit high absorptance ≥0.95 in the solar spectral range 0.3 - 2.5 μm and low thermal emittance ≤ 0.05 in the infrared spectral range 2.5-25 μm [Barshilia et al. 2006]. Ideally, a spectral selective coating (SSC) should have low reflectance (ρ) ~ 0 for wavelengths (λ) ≤ 2.5 μm and high reflectance ~1 for $\lambda \geq$ 2.5 μm. The cutoff wavelength may be higher or lower as the wavelength distribution of radiation emitted by a black body depends on the temeperature [Duffie 1980]. Concentrated solar thermal power systems(CSP) operate at high temperature (≥ 400 °C). For such application, SSCs should be chemically and thermally stable in the working environment under elevated temperature and thus, high thermal and structural stabilities are essential for both the combined and individual layers of the coating structures [Kennedy 2005]. The SSC performance may degrade at high-temperature not only because of oxidation in a residual environment in a vacuum or in air ambient but also

doi:10.18086/swc.2017.04.07 Available at http://proceedings.ises.org

due to the thermal cycling, causing periodic thermal stresses. In addition, this may also cause interlayer diffusion and chemical reactions, leading to the poor interlayer adhesion and thus deteriorating the solar performance. The chemical reactions, especially in open ambient and moist conditions, may corrode and thus damage the coating structure. Further, the challenge is to keep the emiittance (ε) low at high temperatures as the thermal radiative losses are proportional to the fourth power of the temperature in conjunction with high absorptance. Thus, there is a tradeoff between emittance and absorptance as these are mutually exclusive properties for SSCs [Kennedy 2002].

Among numerous SSCs, **cer**amic-**met**al (**cermet**) based spectrally selective absorber structures are extensively investigated and are still extensively under consideration due to their potential for solar thermal applications. Their high solar absorptance, low IR emittance and good thermal stability for mid and high temperature range make them very attractive for concentrated solar power applications [Cao et al. 2014]. The coating thickness and metal volume fraction in the ceramic matrix as well as particle size, shape and orientation can affect the spectral selectivity. For example, thicker cermet structures with smaller particle size are desired for high solar absorptance, whereas with increased thickness leads to the higher thermal emittance. Electrodeposited black chrome coatings are widely studied and used for solar hot water applications [Niklasson and Granqvist 1983, Craighead et al. 1981]. However, these are not very useful for high-temperature applications. Alumina (Al_2O_3) based cermet coating exhibit desired optical properties and thermal stabilities, showing relatively better solar thermal performance with enhanced thermal stability.The metal pigmented dielectric nanoporous structures such as anodized alumina may provide suitable cermet type spectrally selective absorber structures [Graqvist and Hunderi 1979]. The porous alumina layers with inclusion of transition metals like Fe, Co, Ni, Cu, Au, Ag, Mo, Cr, and W are widely studied [Galione et al. 2010,Salmi et al. 2000, Wackelgard 1996] for solar absorbers showing a high solar absorptance (α) of 0.93 and low thermal emittances (ε) ranging 0.04– 0.10 [Andersson et al. 1980]. In addition to the solar absorbers, metal pigmented anodized alumina is also used in nanostructured electronic devices [Sellmyer et al. 2001, Paulus et al. 2001].

Various physical and chemical deposition techniques are employed for synthesizing cermet structutre [Kennedy 2002].Among them electrochemical deposition is promising because of its easy synthesis process and the scalability for depositing coating structures on desired surfaces. This also provides the good control on synthesis parameters such as current density, electrolyte concentration, deposition time or combination of these as well to realize the optimized coating structures for possible applications. Thus, relatively good quality spectrally selective structures can be realized using electrodeposition with optimal solar thermal properties. The double anodization process is proposed by Masuda and Fukada [Masuda and Fukuda 1995] to obtain the ordered pore arrays and pores with straight side walls. The ordered pore arrays are useful when the porous alumina is used as a template, for example, in the electrodeposition of metallic or semiconducting nano-particles, wires and nanorods to achieve the metal-alumina composite matrix structure and also the specific structures for electronic device applications [Gerein and Haber 2005, Shin et al. 2009]. However, the requirement of straight pores is not so stringent for spectrally selective cermet coating structures and single step anodization process is used is followed to generate the porous alumina structure [Graqvist and Hunderi 1979, Salmi et al. 2000, Andersson et al. 1980, Cuevas et al. 2014]. These structures are obtained by anodizing aluminum in dilute phosphoric acid and electrolytically colored using nickel pigmentation. However, the stability of such structure is limited upto 250-300°C. Nahar et al and Cuevas et al also used cobalt pigmentation instead of nickel because of stronger oxidation resistance as compared to nickel [Cuevas et al. 2014, Nahar et al. 1986]. There are studies on Ni pigmented AA and Co pigmented AA spectrally selective coating structures as mentioned in Table 1 [Cuevas et al. 2014, Nahar et al. 1986, Niklasson and Granqvist 1984, Nahar et al. 1989]. However, very few studies are available on simultaneous Ni-Co pigmentation of anodized alumina for solar thermal applications in conjunction with their thermal and corrosion stabilities.

This work reports the development of Ni-Co/Nanoporous Al_2O_3/Aluminum structures. These structures are synthesized electrochemically. The anodization process has been optimized to get the desired pore size (~ 50 nm), followed by Ni and Co co-pigmentation into the nanoporous alumina structures. The detailed structural, microstructural and optical studies will be discussed in conjunction with their thermal and corrosion stabilities. The theoretical estimations are carried out to understand the impact of the metal fraction in a dielectric matrix on optical properties.

2.Experimental detail

The development of Ni-Co co-pigmented anodized alumina as the spectral selective coatings involve the three successive steps: (i) pre-treatment of substrate surface, (ii) electrochemical anodization for porous alumina structure and (iii) electrochemical co-pigmentation of nickel-cobalt in anodized alumina. The process is explained schematically in Fig 1. The pretreated degreased 80 mm × 40 mm × 1 mm aluminum 'Al' sheets are used as working electrodes and a 7 mm x 10 mm x 3 mm graphite plate as the counter electrode [Bostrom et al. 2003, Green et al. 2007]. The anodization is carried out at constant voltage 15 V_{DC} for about 15 minutes at room temperature (~ 25℃) in 2M phosphoric acid electrolyte solution. This led to the porous aluminum oxide structure with 50 ± 10 nm diameter pores. Further, aqueous electrolytic bath, containing 0.11M $CoSO_4$, 0.11 M $NiSO_4$, 0.2 M H_3BO_3 and 0.1 M ascorbic acid, is used for co-electrodeposition of Ni-Co metallic nanoparticulates inside the porous alumina structure. This is achieved under AC electrodeposition conditions at ~10 V_{AC} (frequency ~50 Hz) for 10 minutes [Foyet et al. 2008]. The solar thermal properties of these structures are investigated using UV-Vis and IR spectroscopic measurements. The accelerated corrosion tests are carried out in 3.5 wt% NaCl electrolyte solution at room temperature. The thermal treatments are carried out under ambient and inert N_2 gas environments. The microstructural and surface properties are investigated using Carl Zeiss EVO 18 especial edition scanning electron microscope (SEM). The elemental compositions are measured using the energy dispersive X-ray (EDX) instrument (OXFORD make); equipped with SEM system. The optical reflectance is measured using UV–Vis-NIR spectrophotometer (Carry 5000) in 0.2-25 μm wavelength range to understand the spectral response. These reflectance measurements are used to calculate the room temperature solar absorptance α(λ) in 0.2 - 2.5 μm wavelength range and thermal emittance ε(λ) in 2.5-25 μm respectively.

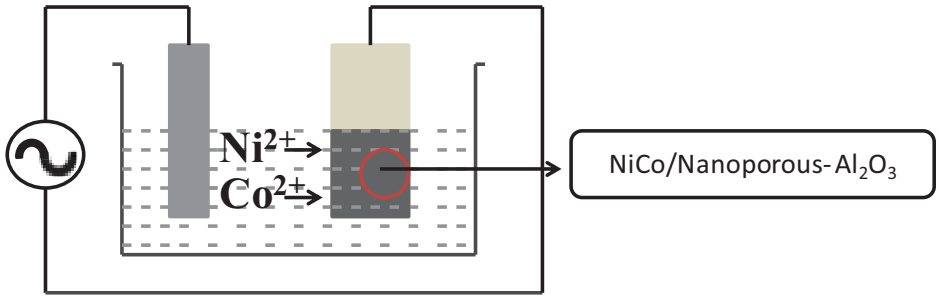

Fig.1: The schematic diagram explaining electrodeposition setup for Ni-Co pigmentation into the nanoporous Al_2O_3 structure.

3. Results and discussion

The SEM micrographs are shown in Fig. 2 (a) and 2(b) for anodized alumina and Ni-Co co-electrodeposited anodized alumina, respectively. The respective schematic structures are shown as the insets. The pore size of the anodized alumina is estimated using higher magnification image of anodized alumina, as shown in inset, in Fig. 3 (a)). We observed pore size ~ 40 ± 10 nm. For elemental composition determination, EDX measurement was performed and estimated results are shown as the insets in respective figures. The introduction of Ni and Co can be observed in anodized alumina structures, as shown in Fig. 2 (b). In spite of equimolar ratios for Ni and Co precursors, the electrodeposition of Co is preferred and larger Co fraction is deposited as compared to that of Ni in these Ni-Co co-pigmented anodized alumina structures.

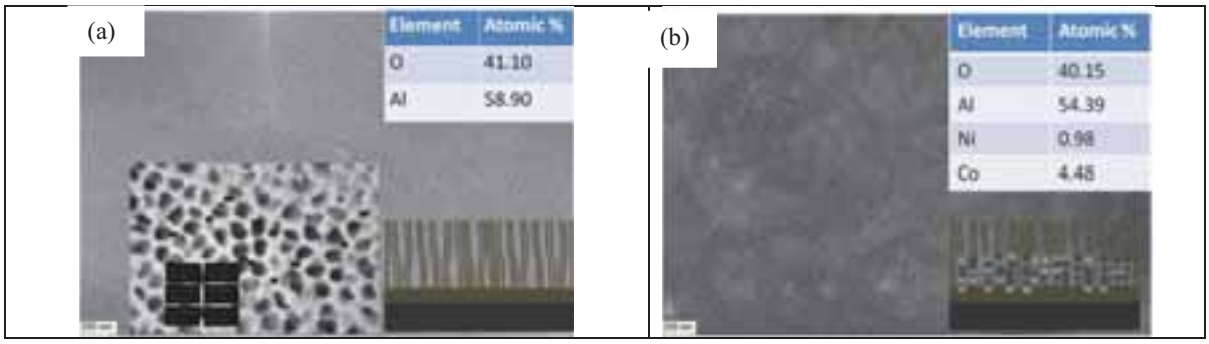

Fig. 2: SEM micrograph of the anodized alumina (a) and Ni-Co co-electrodeposition in anodized alumina (b)

The representative UV-Vis-NIR reflectance measurement is shown in Fig 3(a) for Ni-Co/Nanoporous Al_2O_3/Aluminum spectrally selective coatings ~ 0.2 – 25 μm wavelength range. The effective medium approach is used to simulate the reflectance for these structures [Niklasson et al. 2007] and is shown in Fig 3(a) in conjunction with experimentally measured reflectance. The materials parameters such as dielectric and optical constants are borrowed from references [Andersson et al. 1980, Palik 1998]. The metallic fraction is varied to achieve the best fit for the experimentally recorded reflectance, as shown in Fig. 3(a).

The simulated reflectance trend is similar to the experimentally measured reflectance and is in good agreement towards higher wavelength region. However, the simulated and measured reflectances are not showing good agreements and the difference is attributed to ignorance of the surface irregularities and lack of reliable materials parameters in the desired wavelength regions. The measured absorptance and emittance values are 0.95 and 0.14, respectively for the pristine spectrally selective structures. The measured absorptance is in close agreement with the simulated absorptance whereas the emittance value is slightly higher as compared that of the simulated emittance for optimal 25% metallic fraction in anodized alumina ceramic matrix. Further, these coating structures are thermally heat-treated at 300°C for 50 hours and respective reflectance results are summarized in Fig. 3(b) & (c). The emissivity value increased from 0.14 for as prepared structure to 0.20 and 0.22 for thermally treated structures in inert N_2 and air ambient conditions, suggesting that these structures are relatively thermally stable with a small increase in their emissivity values.

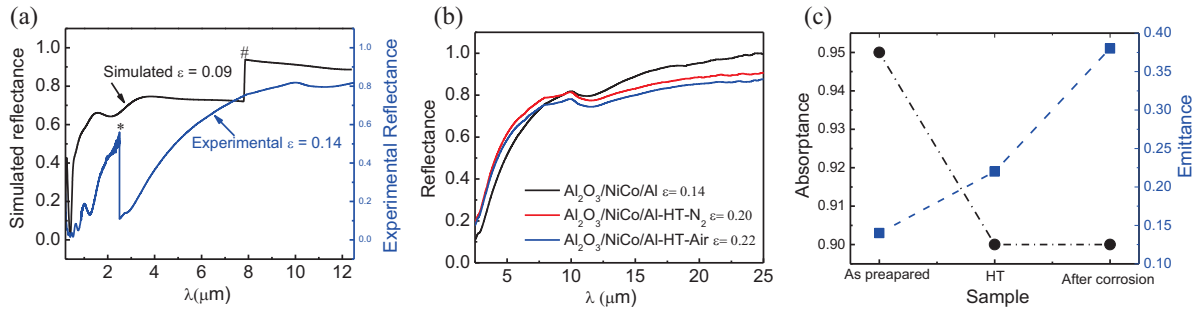

Fig. 3: Reflectance curves for (a) pristine Ni-Co/Nanoporous Al_2O_3/Aluminum coating, experimentally measured one with blue color and simulated one with black color (* glitch at 2.5 μm is the instrumental error, while changing the wavelength range near NIR region and # glitch in data taken from references at 7.8 μm); (b) high temperature (HT) thermally treated Ni-Co/Nanoporous Al_2O_3/Aluminum coatings, with respective emissivity values and (c) absorptance and emittance for as prepared, HT and after corrosion treatment of Ni-Co pigmented Ni-Co/Nanoporous Al_2O_3/Aluminum coatings.

For corrosion studies, potentiodynamic polarization measurements are carried out in 3.5 wt% NaCl electrolyte solutions for anodized alumina and fabricated SSCs structure at room temperature. The corrosion experiments were performed using Autolab (Metrohm) workstation in three electrode configuration, where platinum is used as counter electrode, Ag/AgCl as reference electrode and sample as working electrode. In both the corrosion measurements, sample was immersed in 3.5% NaCl solution for half an hour to establish open circuit potential (OCP). The OCP for anodized alumina was ~0.56 mV and -0.65 for fabricated SSC sample. So, measurement were performed in -1.5mV to 0 to cover the OCP range. The measured voltage versus logarithmic of current measurement is summarized as Tafel plots in Fig. 4(a). The respective corrosion parameters are calculated using Nova software, provided with Autolab (Metrohm) workstation and are summarized in Table 1. The polarization

resistance is measured using Stern-Geary relation, $R_p = \frac{b_c \times b_a}{2.3 \times i_{corr}\,(b_c + b_a)} (K\Omega cm^2)$, where b_a and b_c are anodic and cathodic curve slope. The corrosion current (i_{corr}) is lower ~0.182μA cm^{-2} for Ni-Co/Nanoporous Al_2O_3/Aluminum structure as compared to that of ~ 0.936μA cm^{-2} for anodized alumina at a scan rate of 10 mVs^{-1}, suggesting that corrosion resistance has increased for pigmented structure. The corrosion potential and polarization resistance (R_p) also showed higher values for fabricated SSCs with respect to that of anodized alumina. The corrosion rate after metal pigmentation is observed much lower as compared to that of anodized alumina. These results suggest that the Ni-Co/Nanoporous Al_2O_3/Aluminum structure is better corrosion resistant with respect to the anodized alumina. This is desirable for a SSC structure for longer lifetime in open environmental condition. After corrosion measurement, the optical characterization was performed to estimate the absorptance and thermal emittance. The observed absorptance of these corrosion treated samples remains nearly unaffected, whereas the emittance values showed enhancement upto 0.38 as shown in Fig. 4(b). This is mainly attributed to the increased surface roughness due to microstructure evolution, introduced during the accelerated corrosion testing.

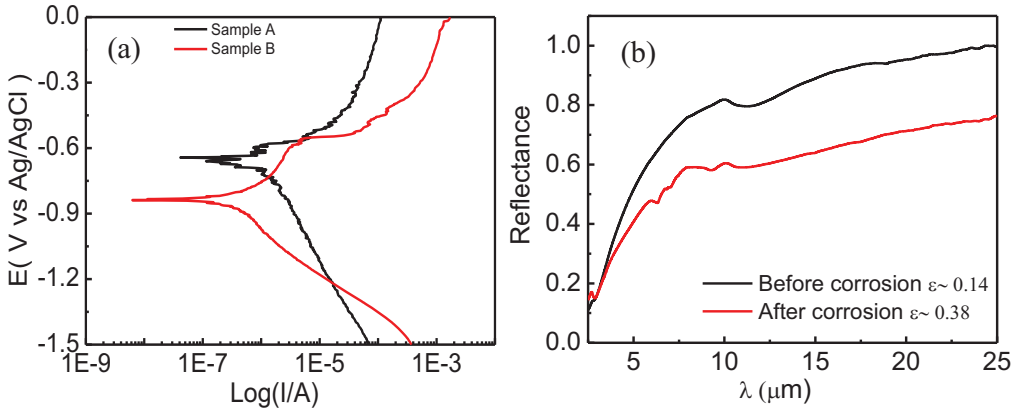

Fig. 4: (a) Potentiodynamic polarization curves and (b) respective reflectance curves for anodized alumina (black) and Ni-Co/Nanoporous Al_2O_3/Aluminum SSCs (red).

Table 2.The estimated corrosion parameter of anodized Al and Ni-Co/Nanoporous Al_2O_3/Aluminum SSCs

Sample	**E_{corr} (V)**	**i_{corr} (μA/ cm^{-2})**	**R_p (KΩ)**	**C. Rate (mm/y)**	**b_a (V/dec)**	**b_c (V/dec)**
Sample A	-0.6589	0.936	40.66	0.0108	0.100	0.359
Sample B	-0.837	0.182	135.03	0.0021	0.049	0.050

4. Conclusion

We demonstrated successful deposition of Ni-Co/Nanoporous Al_2O_3/Aluminum SSCs using simple electrodeposition process. These structures showed optimal absorptivity ~ 0.95 and emissivity ~ 0.14. Further, these structures showed enhanced thermal resistance without degrading their optical properties significantly. The corrosion studies suggest that Ni-Co co-pigmented SSCs structures are relatively corrosion resistant as compared to that of the bare anodized alumina substrate. The observed absorptance is nearly unaffected whereas the emittance values enhanced to ~ 0.38 for corrosion treated SSC structures. Thus Ni-Co co-pigmentation in anodized alumina structures may provide a thermally stable and corrosion resistant spectrally selective structure.

Abstract

The failure of receiver tube is the primary ongoing issue in the parabolic trough power system. In this study, the stress field of the receiver is studied by numerical simulation and the field measurements. The three-dimensional numerical simulation on the whole receiver is conducted firstly by combining the Monte-Carlo Ray Tracing method and the Finite Volume Method. The temperature, the heat loss and the expansion length of the receiver were tested on a heat loss test bench. The simulated concentrated heat flux on the absorber tube and the glass envelope have good agreement with Jeter's results. The temperature field of the entire receiver then was used to analyze the thermal stress and the deformation of the receiver. Finally, the effects of the DNI, the fluid temperature and flow rate on the temperature gradients and the thermal stress fields of the whole receiver were studied. The absorber tube bending and glass to metal seals failure were also analyzed. The Von-Misses stress and allowable strain of 316L stainless steel were used to analyze the deformation and the fatigue failure of the receiver.

Keywords: parabolic trough receiver, thermal stress, DNI, temperature distribution

1. Introduction

Solar thermal electricity generation is one of the feasible renewable technologies to reduce the consumption of conventional fossil fuels and CO_2 emissions. At present, large-scale solar thermal electricity generation mainly has four types of systems: parabolic trough, solar tower, solar dish and linear Fresnel, among them parabolic trough technology is the most proven and widespread solar thermal power technology today.

In a parabolic trough system, the mirrors concentrate the sun rays on the receivers. The heat transfer fluid (HTF) passes through the receivers and transfers heat from the receiver tubes to a heat exchanger in a power station. The receiver is one of the most important elements in the system for converting the solar energy into thermal energy of HTF. The parabolic trough receiver consists of an absorber tube with a selective coating and a glass envelope surrounding the absorber tube to form a vacuum annular space between the glass envelope and the absorber tube. A glass to metal sealing element is arranged on each free end of the glass envelope, wherein the central absorber tube and the glass to metal sealing element are connected with each other by means of bellows, as shown in Fig. 1 (Price et al. 2002). In order to decrease the sealing residual stress, a thermal coefficient matched material combination that composed of the Kovar alloy and the 5.0 borosilicate glass was applied in the receiver studied in this paper (Lei et al. 2012).

doi:10.18086/swc.2017.04.08 Available at http://proceedings.ises.org

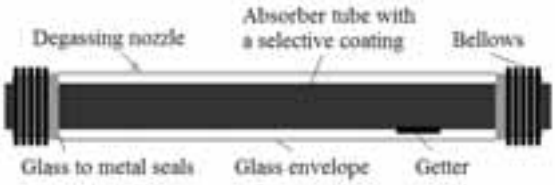

Fig.1 Typical parabolic trough receiver

The receiver's structural reliability has a significant influence on the safety and economic operation of the parabolic trough system (Cheng et. 2010, Glenn, 2012). Data from existing commercial parabolic trough power stations show that receiver failure is the primary ongoing issue. The first nine solar energy generation system plants (SEGS) have experienced very high receiver failure (about 5.5% per year) in the first few years (Price, 2002,). The most recent data for SEGS pants indicated that receiver failures had decreased to 3.4% of the total field receivers per year, which still seems unacceptably high. These failures involved vacuum loss, glass envelope breakage and degradation of the coating. Of these failures, 55% were reported to involve broken glass and 29% involved loss of vacuum, in most cases due to the failure of glass to metal seals, but also due to bowing tubes (Mills, 2004). The receivers themselves represent 30% of the solar field material cost and would require additional labor to replace (Charles, 2010).

In order to investigate the failure mechanisms, some researchers have focused on the temperature gradients and stress fields on the absorber tube due to the non-uniform heat flux (Cheng et al. 2010; Wu et al. 2014b; Abedini et al. 2015). The literature survey shows that most of their models mentioned above ignored the end parts of the receiver (without bellows and glass to metal sealing element). There are few researchers to study the detailed heat transfer and thermal stress of whole receiver under non-uniform concentrated solar heat flux in a parabolic trough system. They did not consider the temperature and stress distribution of the bellows and the glass to metal seals which could result in the glass envelope breakage or vacuum loss. Especially, their models ignored the effect of the bellows and glass envelope on the temperature and stress distribution of the absorber tube. Actually, the bellows and glass envelope will also affect or constrain the axial expansion of the absorber tube.

In this paper, the stress distribution of the whole receiver is further studied by numerical simulation and the experimental measurements. The three-dimensional numerical simulation on the whole receiver is conducted firstly by combining the MCRT method and the FVM. The non-uniform concentrated heat flux on the absorber tube and the glass envelope was obtained through the coordinate transformations (CT) and Monte-Carlo ray tracing (MCRT) method. The heat flux verified by comparing with Jeter's results was used as a boundary condition of the coupled heat transfer modeling. The processes of fluid dynamics and coupled heat transfer of the receiver was analyzed by FVM. Then the temperature, the heat loss and the expansion length of the receiver were tested on a heat loss test stand. After validation, the temperature field of the entire receiver was used to analyze the thermal stress and the deformation of the receiver. Finally, the effects of the DNI, the fluid temperature and flow rate on the temperature gradients and the thermal stress fields of the whole receiver were studied. The absorber tube bending and glass to metal seals failure were also analyzed. The Von-Misses stress and allowable strain of 316L stainless steel were used to analyze the deformation and the fatigue failure of the receiver.

2. Methodology

There are three steps for the methodology in this study. Firstly, the solar energy flux distribution on the selective coating and glass envelope is calculated and validated. Secondly, three dimensional temperature distribution of the whole parabolic trough receiver tube is analyzed based on the previous step as a boundary condition. At the third step, the temperature distribution data are used to calculate the thermal stress and deformation of the receiver tube.

2.1. Simulation of solar energy flux distribution

The coordinate transformations (CT) and Monte-Carlo ray tracing (MCRT) method were combined to simulate the solar energy flux distribution on the receiver tube. In the simulation process, non-parallelism of solar rays with a 9.3mrad optics cone, rim angle, transmittance of the glass tube, absorptance of the coating, reflectance of the glass tube and reflectance of the parabolic trough mirror were considered (Zhao et al. 2015). The detail calculating process was presented in the Ref. Zhao et al. 2015. The heat distributions on the selective coating and the glass tube were calculated under the same parameters as Jeter's (Jeter, 1986). The simulation results in this paper show that the heat flux distribution has a very good agreement with Jeter's results as shown in Fig.2. The heat flux on the absorber tube is low near angle of 0° due to the radiation shadow of the absorber, and then increases very fast up to

the maximum value. After that, the heat flux decreases down rapidly with the angel and then it keeps the minimum value due to the one sun radiation. The heat flux distributions on absorber tube and glass envelope were treated as the heat flux boundary for the heat transfer simulation model.

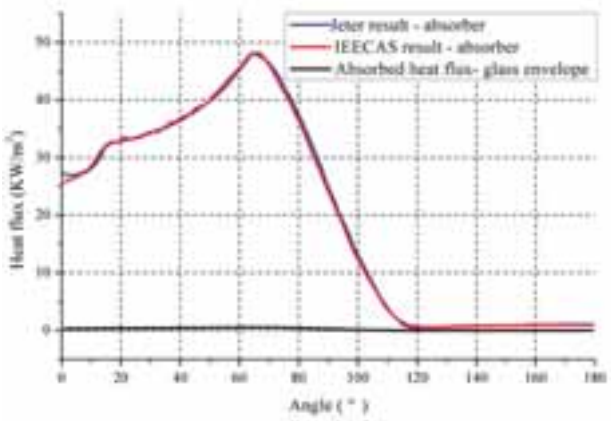

Fig. 2 Simulated heat flux distribution result compared with Jeter's result

2.2. Simulation of temperature distribution

In typical parabolic trough solar system, the solar radiation is reflected and concentrated on the glass envelope, and then it transmits the glass envelope and finally arrives on the coating of the absorber tube. The coating converts the solar energy into the heat energy, and then the heat energy is conducted to the absorber inner surface. The heat transfer fluid (HTF) passes through the absorber tube then obtains the heat energy by convection. Meanwhile, a part of heat energy (heat loss) passes through the glass thickness and by radiation and convection to the environment from the outer surface of the glass envelope.

2.2.1 Assumptions in the simulation

A three-dimensional computational fluid dynamics and heat transfer simulation of whole receiver was established. Fig. 3 shows the three dimensional mesh of the receiver tube used in this study. All of the meshes were generated with O-grid method by Ansys ICEM. After performing a grid independent, the study based on the variation of frictional pressure drop and temperature increase within the absorber tube, a grid of 3,000,000 cells was chosen for the simulation of the temperature and the stress distribution.

In order to investigate the temperature gradient in the glass-to-metal seals and the bellows, finer grids were generated near the glass-to-metal seals where large temperature gradient exists.

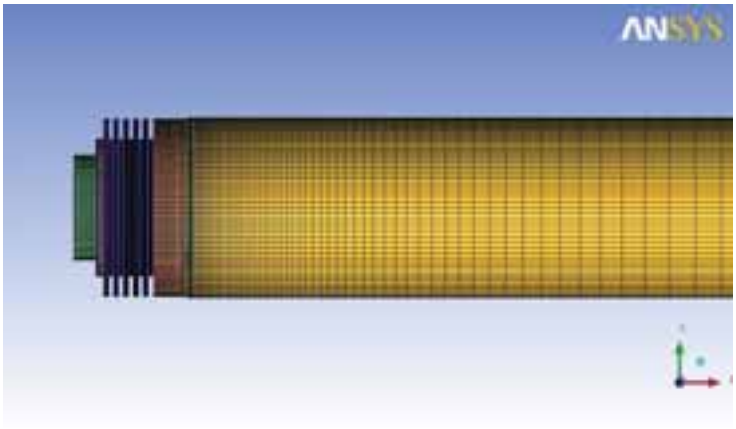

Fig. 3 Three-dimensional mesh of the receiver tube

The three dimensional heat transfer problem was solved using FVM model. Some assumptions in the simulation are listed as follow:

1) The vacuum level between the absorber tube and the glass envelope is so good that the convection can be ignored.

2) The fluid flow is in steady state conditions. The calculated Reynolds number ($Re=\rho ud/\mu$) of HTF flow in the absorber tube is much higher than 2300, and the flow is turbulent. Therefore, standard k-ε model, a turbulence model, was used in this study.

2.2.2 The governing equations

The governing equations include continuity equation, momentum equation, energy equation and standard k-ε two-equation turbulence model equation.

Continuity equation:

$$\frac{\partial}{\partial X_i}(\rho u_i) = 0 \qquad \text{(eq.1)}$$

Momentum equation:

$$\frac{\partial p}{\partial x_i} = \rho g_i + \frac{\partial}{\partial x_j}[(\mu+\mu_t)(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}) - \frac{2}{3}(\mu+\mu_t)\frac{\partial u_l}{\partial x_l}\delta_{ij}] - \frac{\partial}{\partial x_i}(\rho u_i u_j) \qquad \text{(eq.2)}$$

Energy equation:

$$\frac{\partial}{\partial x_i}(\rho c_p u_i T) = -\lambda\frac{\partial T}{\partial x_i} \qquad \text{(eq.3)}$$

κ equation:

$$\frac{\partial(\rho u_i \kappa)}{\partial x_i} = G_k - \rho\varepsilon + \frac{\partial}{\partial x_i}[(\mu+\frac{\mu_t}{\sigma_k})\frac{\partial \kappa}{\partial x_i}] \qquad \text{(eq.4)}$$

ε equation:

$$\frac{\partial(\rho u_i \varepsilon)}{\partial x_i} = C_1 G_k\frac{\varepsilon}{\kappa} - C_2\rho\frac{\varepsilon^2}{\kappa} + \frac{\partial}{\partial x_i}[(\mu+\frac{\mu_t}{\sigma_\varepsilon})\frac{\partial \varepsilon}{\partial x_i}] \qquad \text{(eq.5)}$$

With

$$\mu_t = C_\mu\rho\frac{\kappa^2}{\varepsilon}, \quad G_k = \mu_t\frac{\partial u_i}{\partial x_j}(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}) \qquad \text{(eq.6)}$$

The model constants $C_1, C_2, C_\mu, \sigma_\kappa, \sigma_\varepsilon$ have the following default values:

$$C_1 = 1.44, C_2 = 1.92, C_\mu = 0.09, \sigma_K = 1, \sigma_\varepsilon = 1.3$$

2.2.3 Boundary conditions

(1) The following boundary conditions are applied to the inlet and outlet:

Inlet: $u_x = u_{in}, u_y = u_z = 0, T = T_{in}$

$\kappa_{in} = 0.005u_x^2, \varepsilon_{in} = c_\mu \cdot \rho(T)\cdot\kappa_{in}^2/\mu_t$, where $c_\mu = 0.09, \mu_t = 100$

Outlet: fully-developed conditions.

(2) The selective coating is defined as a wall with the heat flux distribution calculated by the CT and MCRT Method.

(3) Surface-to-surface (S2S) radiation model is used between the selective coating and inner surfaces of the glass envelope, the Kovar rings and the bellows. The participating surfaces were assumed to be gray and diffuse.

(4) The outer surface of the glass envelope was defined with the equivalent coefficient of convective heat transfer for convection and radiation.

2.3. Simulation of thermal stress

The ANSYS software was used in the thermal stress analysis. Except the temperature distribution data of HTF, the temperature distribution data of the receiver obtained in the CFD analysis were imported into the nodes of thermal-stress analysis model with the same grids as the temperature analysis model. According to the materials used in the receiver, thermo-elastic equations of hollow cylinder were solved by using finite element analysis (FEA) with the aim of calculating thermal stress field and deformation for the receiver in this study.

In the parabolic trough collectors, the receiver tubes of the triples are generally straight and the mounting arms can compensate the axial heat expansion of the absorber tubes. In the study, one end of the absorber tube was fixed in X axial direction however the other end was allowed to move along the X axis freely and rotate around the X axis freely. The gravity of the receiver tube was considered and its direction was assumed the negative Z axial direction.

In the parabolic trough receiver, although the bellows are used to compensate the axial and radial expansion differences between the glass envelope and the absorber tube, the bellows are mainly subject to the axial force and affect the deformation of the absorber tube in actual operation. Therefore, the bellows axial stiffness was considered and input into the Ansys software.

In this study, the analysis of thermal stress field considers the combined effects of temperature gradients, support constraints, internal constraints and gravity. According to the Von-Mises theory, the equivalent stress equation is expressed as follows:

$$\sigma_{eff} = \sqrt{\sigma_x^2 + \sigma_y^2 + \sigma_z^2 - (\sigma_x\sigma_y + \sigma_x\sigma_z + \sigma_z\sigma_y)} \quad \text{(eq.7)}$$

The Von-Misses stress and allowable strain of 316L stainless steel were used to analyzed the deformation and the failure of the receiver

3. Experimental system description

A heat loss test stand was built in Institute of Electrical Engineering, Chinese Academy of Sciences (IEECAS). This test bench was used to test the temperature of the glass envelope and the heat loss of the receiver. In order to get the real thermal emittance of the coating, the heat losses depended on temperature were used to calculate the thermal emittance (Lei et al. 2013).

Fig. 3 Receiver heat loss test stand at IEECAS

4. Results and discussion

4.1. Validations of numerical simulation results

4.1.1 Comparison between FVM model and experiment

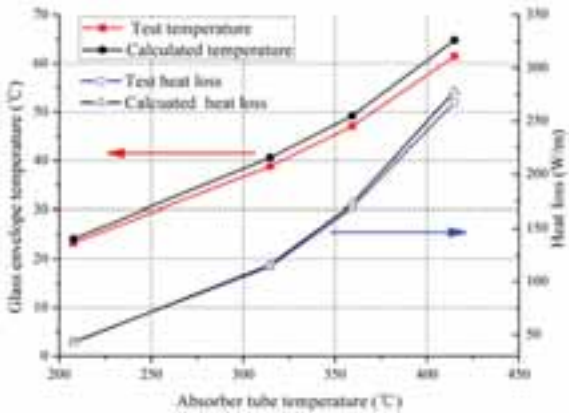

Fig. 4 Compared results between the test and the simulation

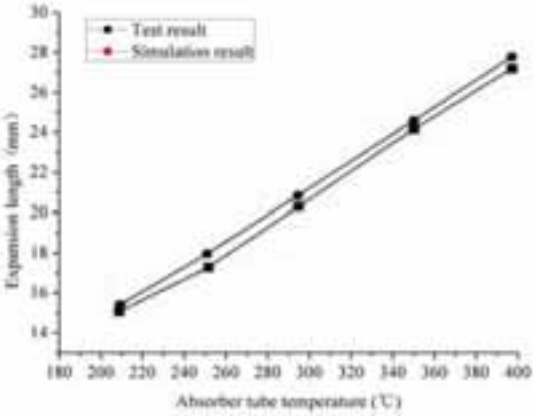

Fig. 5 Simulated result compared with test result

The FVM model generally can be validated by comparing the heat loss test results (Wu et al. 2014a; Chenget al. 2010). A heat loss test bench of the receiver was built in IEECAS in 2012. The heat loss test method, procedure, test conditions and results were described in Ref.12 in detail. In this paper, the same test conditions as the Ref.12 were used to calculate the temperature and the heat loss of the receiver. In the simulation, the inner surface temperature of the absorber tube was assumed to be constant, and no HTF was in the absorber tube. The average temperature of the glass envelope was calculated by the same method in the heat loss test. The heat loss was obtained by calculating the heat flux from the inner surface of the absorber tube in the simulation. Fig. 4 shows the compared results between the test and the simulation. The heat loss difference between the simulation results and the test results were between 1.6 and 10.3W/m with a relative error range of 1.4%-3.8%. The calculated glass envelope temperature had a maximum 5.4% relative error with the test results. Considering the uncertainty associated in both simulation and test, the agreement is very good. The uncertainty in the simulation contains the uncertainty of the equivalent convective heat transfer coefficient used between the glass envelope and the ambient and the thermal emittance of the coating. Especially, the thermal emittance of the coating is a very important parameter for the simulation and can remarkably affect the simulated results. If the thermal emittance increases only 1%, the heat loss will increase about 10%. Therefore, the thermal emittance of the coating should be tested at different temperature because it is temperature-dependent. In this paper, the thermal emittance of the coating has been tested in IEECAS heat loss test bench. Therefore, the numerical simulation methodology is valid in this study.

4.1.2 Comparison between FEA model and experiment

The validation of FEA model with real field test results is very difficult because the complicated external environment, such as the real concentrated heat flux, the changeable wind speed, the installation error, the end support condition of the receiver and the mirror shape error. In addition, the internal mechanical stress and residual stress on the receiver tube also affect the test results.

Fig. 5 indicates the expansion length curves of the absorber tube with temperature. The expansion length of the absorber tube was tested when the heat loss test was carried out. It shows that the simulation results agree with the test results very well. The maximum HTF temperature is generally less than 400℃ in parabolic trough system, the material of the absorber tube is within the elastic range. Therefore, if the two end supports do not constrain the axial expansion of the absorber tube, the stress is caused only by temperature and is linear functional relation with the thermal strain in the absorber tube. The FEA methodology is valid and reliable for the stress analysis on the absorber tube.

4.2. Temperature distribution of receiver tube

In order to calculate thermal stress field, the temperature distributions of the whole receiver and the key components were shown in Fig.6.

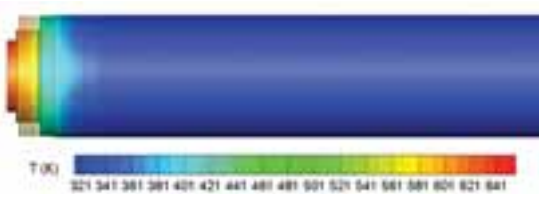

Fig.6 Temperature distributions of the whole receiver tube and the key components

In Fig. 6, DNI is 1000W/m^2. HTF inlet temperature is 350℃ and the flow rate is 2 m/s which is a typical condition in system operation. Fig.10 a) shows the temperature distribution on the out surface of the whole receiver tube. The temperature varies considerably at the end of the receiver tube, which decreases from 641K to 321K from the end of the absorber to the middle of the glass envelope. Therefore, the receiver is subject to very large temperature gradients in operation. In order to obtain the temperature information of the key components in detail, Fig. 6 clearly exhibits the temperature distribution of the absorber tube, the Kovar ring and the bellows. It shows that the temperature distribution is very nonuniform along both the axial and the circumferential direction of the absorber tube. The larger temperature gradient occurred on the end part of the absorber tube due to the shield of the bellows and the glass to metal sealing element. This nonuniform temperature along the axial direction of the absorber tube can also cause thermal stress and the deformation of the absorber tube. Therefore, it is not reasonable to ignore the bellows and the glass metal sealing elements when the temperature and stress are simulated for the receiver. The temperature distribution of cross section of the absorber tube and HTF is symmetrical approximately, which is very similar to the heat flux distribution on the surface (see Fig. 2). This temperature difference creates variable expansion and nonuniform deformation of the absorber tube. The above temperature data are very important and helpful for the structure design, optimization and the reliable operation of the receiver.

4.3. Stress distribution and deformation of receiver tube

The temperature information was further used to analyze the thermal stress distribution on the whole receiver tube. Fig. 7 shows the stress distributions on the absorber tube, the glass envelope, the bellows and the Kovar ring. The stress distribution on the absorber tube is nonuniform and similar to the temperature distribution and the heat flux distribution. The maximum equivalent tensile stress is a bout 34MPa at the place of the maximum heat flux density. It also shows that the absorber tube has a little deflection of 4.2mm, as shown in Fig 7 a). In the field test, although the absorber bending has been seen, the deflections of the absorber tubes are no any rule when HTF velocity is higher than 1m/s. When HTF velocity is lower than 1m/s, the absorber tube can easily bend and the bending generally is permanent. The absorber tube bending can cause part of solar radiation out of the absorber tube and decreases the thermal efficiency of the collector.

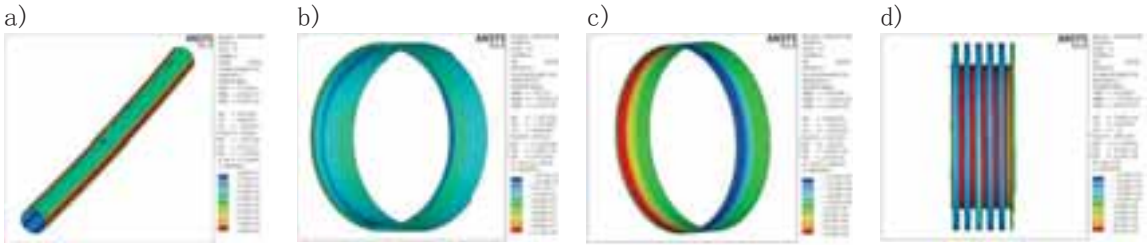

Fig. 7 stress distributions on the absorber tube, the glass envelope, the bellows and the Kovar ring

Fig. 7 b) and c) illustrate the axial stress distribution on the end of glass envelope and the Kovar ring. The two figures present that the bigger stress concentration occurs at the junction between the Kovar ring and the glass envelope. The maximum tensile stress of 11MPa locates at the end of the glass envelope. The reason may be that the expansion difference between the absorber tube and the glass envelope causes the tensile force on the end of the glass envelope, and the expansion difference between the Kovar ring and the glass also causes the tensile stress on the end of the glass envelope. If the coefficient of thermal expansion (CTE) of the Kovar ring is much bigger than CTE of the glass envelope, the larger tensile stress may exceed the tensile strength of the glass and cause the glass break. Therefore, the difference of CTEs between the glass and the metal is an important factor affecting the magnitude of stress.

The stress distributions on the bellows are also very nonuniform, as shown in Fig.7 d). The maximum axial stress is at the third trough of the bellows. The bellows are subject to the larger axial stress due to the expansion difference between the glass envelope and the absorber tube. While the maximum equivalent stress of 757 MPa is at the wield

junction between the bellows and the Kovar ring, which the magnitude may be too big. The authors contribute the large equivalent stress to the difference of CTEs between the Kovar ring and the bellows, and the unsuitable elastic modulus or axial stiffness used in simulation. Because the thickness of the bellows is generally 0.2-0.3mm and the bellows cyclically expand and compress every day, the bellows with large stress are easy to fatigue or crack, and then lead to the vacuum failure of the receiver. Therefore, the bellows, as the key component, should have enough fatigue strength and be protected from any concentrated solar radiation.

5. Conclusions

In this study, the distributions of the temperature and the stress were studied by numerical simulation and the experimental measurements. The three-dimensional numerical simulation on the whole receiver was conducted successfully by combining the MCRT method, the FVM and the FEA. The distributions of the temperature and the stress were analyzed for the whole receiver including the bellows, the Kovar ring, the glass envelope and the absorber tube in detail. After validating the numerical model, the effects of the fluid temperature and flow rate on the temperature gradients and the thermal stress fields of the whole receiver were studied. The results show that：

1） Thermal emittance of the coating should be tested at different temperature because it is a very important parameter in the simulation and can remarkably affect the simulated temperature results.

2） The stress distribution is nonuniform along both the axial and the circumferential direction on the absorber tube, which is similar to the temperature distribution and the solar flux distribution.

3） The bigger stress concentration occurs at the junction between the Kovar ring and the glass envelope. The difference of CTEs between the glass and the metal is an important factor affecting the magnitude of stress.

4） The bellows are subject to the larger axial stress due to the expansion difference between the glass envelope and the absorber tube.

Abstract

A thermoeconomic analysis of a solar polygeneration plant for the joint production of electricity, fresh water, cooling, and process heat is carried out, in order to analyze in depth the process of exergy cost formation and comparing with standalone systems. The solar polygeneration plant consists of a concentrated solar power as prime mover, and a multi-effect desalination, a refrigeration absorption, and a process heat plants. Results show that the main components that contribute to the costs formation are: solar collectors, evaporator, re-heater, economizer, turbine, and super-heater. Also, a solar polygeneration plant is more cost effective than stand-alone systems, which produces the lower unit exergy cost of electricity, water, cooling and heat.

Keywords: polygeneration, symbolic thermoeconomic, exergy cost theory, concentrated solar power, multi-effect distillation, refrigeration.

1. Introduction

Polygeneration is the integration of multiple utility outputs with one or more inputs for better performance. The better performance may be assessed from different aspects, such as, thermodynamic, economic, environmental, and social, in which the main advantages are in terms of the improvement of energy efficiency and cost-effectiveness, use of alternative fuels and energy carriers, and reduction of emissions. Its advantages make polygeneration competitive technologies [1]. In a topping cycle polygeneration system [2], fuel is used in the prime mover, typically in a power cycle such as Rankine, Brayton or Diesel cycles, that generates electricity, and the prime mover's hot exhaust is used to supply thermal energy to other technologies driven by heat, like thermal distillation, process heat (industrial heating, production of synthetic fuels, and other), and absorption cooling. The concentrated solar power (CSP) as a prime mover is an interesting alternative to analyze the operation of a polygeneration scheme since it produces electricity fueled by solar energy, and could be helped by a thermal energy storage or the hybridization with a fossil fuel or a biofuel. This allows continuous operation, with a capacity factor similar to a conventional plant to better match supply with demand, and additionally, rejects thermal energy from the power cycle that it is feasible to couple it with technologies driven by thermal energy. In order to evaluate the integration in a polygeneration scheme there are several methods [1], [3], [4], however the thermoeconomic (or exergoeconomic) method [5] is recommended because provides compact matrix-based formulation for the detailed analysis of complex systems such as polygeneration systems, where the Second Law of Thermodynamics provides its physical roots [6]. Exergy indicates the maximum work that a flow or a system might produce while interacting with the environment, and it is very useful for the analysis of this system because it allows measuring in the same physical unit resources of very different nature, for instance electricity, energy, water, cooling, heat, resources, and waste. The exergy cost of mass and/or energy flow represents the units of exergy used to produce it, i.e. the exergy cost of a flow is the amount of resources expressed in exergy consumed for producing this flow [7]. The unit exergy cost allows analyzing and identifying integrations because it is possible to determine the potential for resources savings. Exergy cost is a conservative magnitude that increases in every process according to the irreversibility involved in that process. So, in an integrated process, it is interesting to study in depth how exergy costs are being formed, therefore the process of cost formation

doi:10.18086/swc.2017.04.09 Available at http://proceedings.ises.org

provides vital information for the designer and evaluator that allows a better design and performance analysis, respectively.

CSP could be integrated into polygeneration schemes [8] and different studies have focused mainly on the final cost of each product [9]–[12]. However, such those studies do not consider the evaluation of the process of exergy cost formation and the decomposition of each cost. For the reasons mentioned above, a solar polygeneration system is analyzed by applying the symbolic exergoeconomic method to study the process of exergy cost formation and to determine the main components that contribute to the cost formation of each product, so that find out new opportunities for savings. The solar polygeneration scheme considered in this work is composed of a concentrated solar power, a multi-effect desalination plant, a single-effect refrigeration absorption module, and a process heat module.

2. Methodology

The methodology consists first of the modeling of a solar polygeneration plant and stand-alone plants. Secondly symbolic exergoeconomic methodology [6], [13], [14], which is a technique based on the exergy cost theory [15], was then applied.

The solar polygeneration plant is depicted in Figure 1, this consists of a concentrated solar power [16], [17] type parabolic trough with thermal energy storage (TES) and backup system (BS), a multi-effect desalination (MED) plant [18], a single-effect refrigeration absorption (REF) plant [19], and a process heat (PH) module. The configuration and validation of the solar polygeneration plant and the stand-alone systems are described as Poly 1 and stand-alone plants in a previous study of the authors [11].

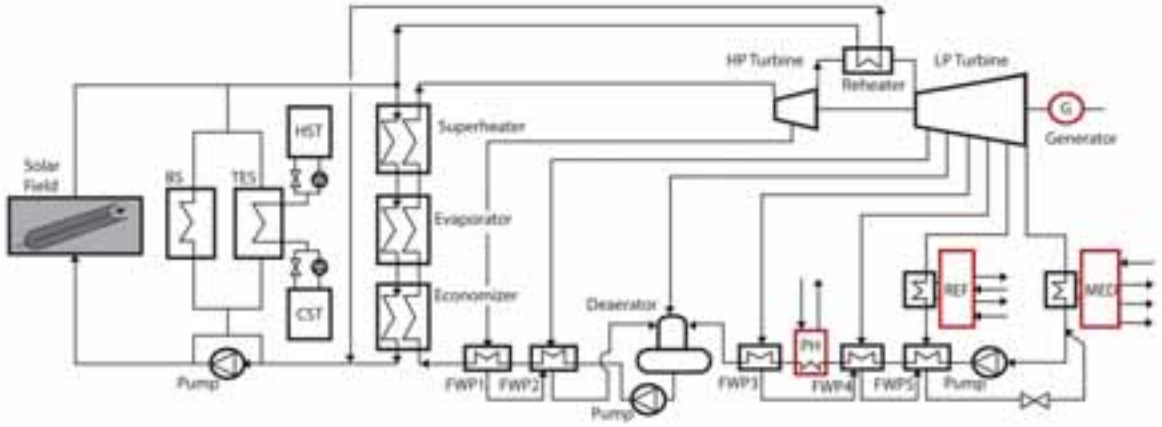

Fig.1. Configuration solar polygeneration plant. CST: cold storage tank, FWP: feed water preheater, G: generator, HP: high pressure, HST: hot storage tank, LP: low pressure.

The main characteristics of those plants are shown in the Table 1.

Tab. 1: Main characteristics of the polygeneration plant and the stand-alone plants.

Property	Polygeneration	Stand-alone
CSP		
TES, storage fluid	Two tank, molten salt	
Tank temperature (cold/hot), °C	292 / 386	
Full load hours of TES, h	12	
Parabolic trough collector model	EuroTrough	
Absorber tube	Schott PTR-70	
Heat transfer fluid	DowTherm A	
Collector optical efficiency, %	72.073	
Irradiance at design day, W/m^2	1 010	
Solar Field inlet temperature (inlet/outlet), °C	293 / 393	
Aperture area, m^2	616 650	510 520

Solar Multiple	2.56	
BS efficiency	90 %	
Capacity factor	96 %	
Gross power production, MW_e	55.0	
HP turbine inlet pressure, bar	100.0	
LP turbine back pressure, bar	0.37	0.06
MED		
Feed seawater intake temperature, °C	25	
Feed seawater intake salinity, kg/kg	0.042	
Feed seawater after down condenser temperature, °C	35	
Maximum salinity in each effect, kg/kg	0.072	
Top brine temperature, °C	65	
Gained Output Ratio, kg/kg	9.07	
Fresh water production, m^3/day	37 168	
Concentration factor	1.7	
Specific heat consumption, kJ/kg	245.2	
Specific electricity consumption, kWh/m^3	1.5	
REF (single stage absorption chiller)		
Cooling capacity, MW_{th}	5	
Chilled water temperature (inlet/outlet), °C	10 / 6	
Cooling water temperature (inlet /outlet), °C	25 / 35	
Inlet temperature desorber, °C	108.49	
Coefficient of Performance (COP)	0.70	
PH (countercurrent heat exchanger)		
Process heat capacity, MW_{th}	7	
Heat exchanger temperature (inlet/outlet), °C	63 / 90	

The solar systems were simulated at the design point by considering an hourly meteorological year [20]. The software IPSEpro [21] and MATLAB were used for the simulation of the different systems. The exergoeconomic evaluation was conducted using MATLAB, and the ExIO module [22] as a complement of the Microsoft Excel.

The exergy cost theory (ECT) provides a general criterion that enables to assess the efficiency of energy systems and rationally explains the process of cost formation of products. Thus, it is a cost accounting methodology that propose methods to determine the number of resources required for getting a product. As a numerical technique, cost values could be assessed. And with the help of the symbolic exergoeconomic method, the causes of the cost formation process can be easily obtained by using matrix algebra. The ECT requires that the system be described by a physical structure and a productive structure, the last structure is built according to the purpose of each component, and shows the origin of the resources of each component and its product. Each plant has only one physical structure to describe the physical relations between the process units, but various productive structures can be defined depending on the fuel and product definitions as well as the disaggregation level selected. The disaggregation level is interpreted as the degree of accuracy of the analysis. Each subsystem can be a part of an equipment, an equipment, or a group of equipment. The productive diagram is a graphic representation of the thermoeconomic model of the plant, in which the inputs of a component are its resources, and the outputs of a component are its products. This structure is composed of n components connected by flows characterized by its exergy. Each component consumes resources from other components or from an environment (those resources are named Fuel), to produce useful effects for other components or for the environment (those useful effects are named Product). Fuel (F) is partially transformed into product (P) and partially destroyed as irreversibility (I). A flow from component i to component j is represented by the exergy flow, then, the Fuel and Product is defined as

$$F_i = P_i + I_i = \sum_{j=0}^{n} E_{ji} \quad \text{(eq. 1)}$$

$$P_i = F_i - I_i = \sum_{j=0}^{n} E_{ij} \quad \text{(eq. 2)}$$

where E_{ij} is the exergy flow, the subscripts i and j are generic components.

The fuel-product presentation is the adjacency matrix of the productive graph, that allows getting all flows within the productive structure, and is based on distribution coefficients y_{ij} which indicate the proportion of the production of the j-th component used as resource for the i-th component: it shows how the product of a component is distributed among the other components and the environment.

$$y_{ij} = \frac{E_{ij}}{P_j} \quad \text{(eq. 3)}$$

Expressing the Equation 1 as function of y_{ij}, it yields:

$$F_i = E_{0i} + \sum_{j=1}^{n} E_{ji} = E_{0i} + \sum_{j=1}^{n} y_{ij} \cdot P_j \quad \text{(eq. 4)}$$

The previous equation in matrix notation is:

$$\boldsymbol{F} = \boldsymbol{F}_e + \langle \boldsymbol{FP} \rangle \cdot \boldsymbol{P} \quad \text{(eq. 5)}$$

where $\boldsymbol{F}$ and $\boldsymbol{P}$ are vectors of all fuels and products, $\boldsymbol{F}_e$ is the vector of external resources, and $\langle \boldsymbol{FP} \rangle$ is a matrix composed of elements y_{ij}.

Similarly, with the same procedure, it is obtained:

$$\boldsymbol{P} = (\boldsymbol{K}_D - \langle \boldsymbol{FP} \rangle)^{-1} \cdot \boldsymbol{F}_e \quad \text{(eq. 6)}$$

where $\boldsymbol{K}_D$ is a diagonal matrix containing the unit exergy consumptions of all components (k_i), defined as

$$k_i = \frac{1}{\psi_i} = \frac{F_i}{P_i} \quad \text{(eq. 7)}$$

where ψ_i is the exergy efficiency.

Equation 6 allows to calculate the products of all components starting from the external resources consumed by the plant ($\boldsymbol{F}_e$) and using the parameters that define the components (unit exergy consumptions and distribution coefficients).

The thermoeconomic analysis of energy systems, such as a polygeneration plant, has productive and dissipative components. The productive components provide functional products, fuel (resources) to other processes, and residues and waste disposals. Likewise, the dissipative components are required to reduce or eliminate the environment impact of residues and waste, to maintain the operation conditions of the system, and to improve the efficiency of the system.

According to the cost model, the exergy cost of the product is defined as

$$C_{P,i} = C_{F,i} + C_{R,i} \quad \text{(eq. 8)}$$

where C is the exergy cost, and the subscripts P, F, and R mean product, fuel, and residues, respectively.

The costs of the external resources are known values as

$$C_{e,i} = E_{0i} \quad \text{(eq. 9)}$$

and the cost of each flow making up the product is proportional to its exergy

$$C_{ij} = c_{P,i} \cdot E_{ij} \quad \text{(eq. 10)}$$

where $c_{P,i}$ is the unit exergy cost of the product of i-th component.

The exergy cost of residues allocated to each productive unit is

$$C_{R,i} = \sum_{r \epsilon V_D} C_{ri} = \sum_{r \epsilon V_D} \beta_{ir} \cdot C_{P,r} \quad \text{(eq. 11)}$$

where C_{ri} is the exergy cost of the residues dissipated in the r-th component that has been generated by the i-th productive component, β_{ir} is the residue cost distribution ratio, V_D is the set of the dissipative system components. The residue cost distribution ratios represent the portion of the cost of the residue dissipated in the r-th component which has been generated in the i-th productive component.

The exergy cost of the product is decomposed into two parts

$$\boldsymbol{C}_P = (\boldsymbol{C}_e + \boldsymbol{C}_R) \cdot (\boldsymbol{U}_D - \langle \boldsymbol{FP} \rangle)^{-1} = \boldsymbol{C}_P^e + \boldsymbol{C}_P^r \quad \text{(eq. 12)}$$

where $\boldsymbol{C}_P^e$ is the exergy cost due to irreversibilities of the components, $\boldsymbol{C}_P^r$ is the exergy cost due to the residues allocation, and $\boldsymbol{U}_D$ is the identity matrix.

In the same form, the unit exergy cost of the product is decomposed into two parts

$$c_p = c_P^e + c_P^r \quad \text{(eq. 13)}$$

where c_P^e is the unit production cost due to irreversibilities of the components, c_P^r is the unit production cost due to the residues, they are calculated by

$$c_P^e = (\boldsymbol{U}_D - \langle \boldsymbol{FP} \rangle)^{-1} \cdot \boldsymbol{c}_e \quad \text{(eq. 14)}$$

$$c_P^r = (\boldsymbol{U}_D - \langle \boldsymbol{FP} \rangle)^{-1} \cdot \boldsymbol{c}_R \quad \text{(eq. 15)}$$

where $\boldsymbol{c}_e$ is the unit exergy cost of the external resources, $\boldsymbol{c}_R$ is the unit exergy cost of the residues.

In summary, the process to assess the cost of the flow streams and processes in a polygeneration plant helps to understand the process of cost formation, from the input resources to the final products.

Note that in this analysis different levels of disaggregation were taken: in the case of the CSP plant, is considered at the level of components, but in the case of the systems to provide the other products, there are considered at the level of a unique subsystem. Finally, nominal conditions of both alternatives have been used estimates this exergy cost analysis.

3. Results and discussion

3.1. Stand-alone plants

The results about the costs decomposition for the stand-alone CSP plant are depicted in Figure 2 and shows how the unit cost of product is obtained as the sum of the irreversibility contributions of the other devices which are preceeding this product. The main components that contribute to the costs formation of electricity cost (in the generator), in descending order of importance, are: solar collectors, evaporator, condenser, reheater, low-pressure turbine, economizer, and superheater. In the solar collectors is produced the most significant exergy destruction, that it is attributable to the irreversibilities associated with the large temperature difference between the sun and the heat transfer fluid. Furthermore, it can be seen that this exergy cost is charged to the rest of components according to a topping cycle scheme. On the other hand, the condenser is a dissipative component, that is allocated to all productive units. It interacts with other components, in the sense is that the device allowing to close a thermodynamic power cycle. As its operating temperature is quite low, from the point of view of the Second-Law of Thermodynamic, its contribution to exergy costs is not so high, being the steam generator (or solar collectors in this case) the main inefficient components.

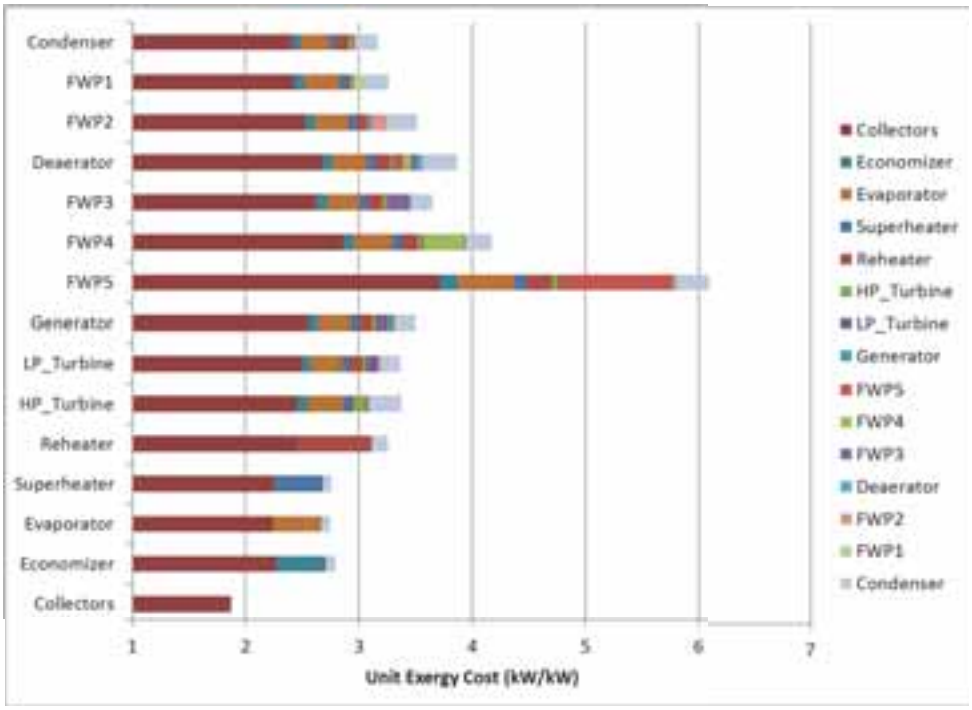

Fig. 2: Cost decomposition in stand-alone CSP plant.

In the case of other stand-alone plants, the main contribution in the cost of each product comes from the boiler, being the higher heat source and then having the higher exergy destruction. Note that since both the MED plant and the REF plant include a dissipative component to operate, they participate in the costs formation. Figures 3, 4 and 5 show the costs decomposition in the other stand-alone plants. In the case of the PH major exergy costs comes from the boiler and a residual additional cost comes from the heat exchanger to accommodate the heat supply.

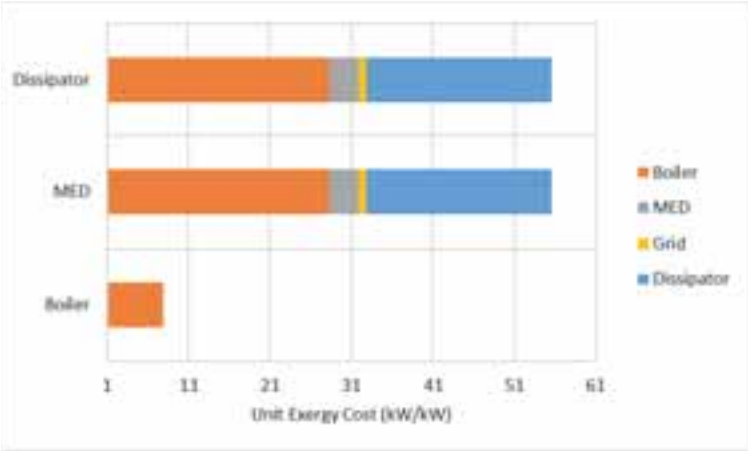

Fig. 3: Cost decomposition in stand-alone MED plant.

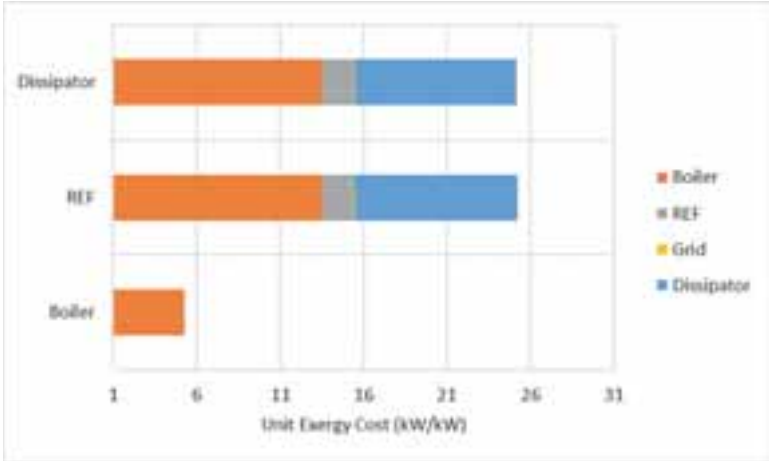

Fig. 4: Cost decomposition in stand-alone REF plant.

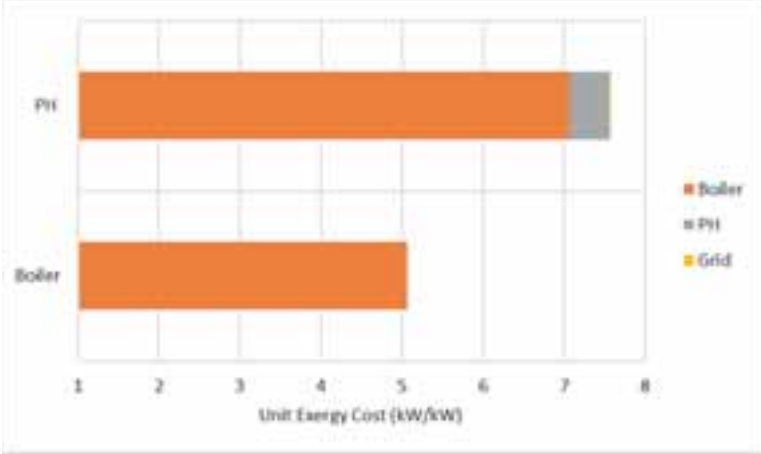

Fig. 5: Cost decomposition in stand-alone PH plant.

3.2. Polygeneration plant

The costs decomposition in the solar polygeneration plant is depicted in Figure 6. The products such as electricity, fresh water, cooling, and head are produced in Generator, MED, REF and PH, respectively. The main components that contribute to the costs formation of electricity are: solar collectors, evaporator, reheater, economizer, low-pressure turbine, and superheater. In the case of water, these components are: MED's dissipative, solar collectors, MED, evaporator, reheater, economizer, and superheater. In the case of cooling, the devices are: REF's dissipative, solar collectors, REF, evaporator, reheater, economizer, and superheater. Finally, in the case of process heat, they are: solar collectors, PH, evaporator, reheater, feed water preheater (FWP4), economizer, and superheater. In order to reduce the costs of products, it is necessary to first consider these components in an in-depth process of analysis and optimization.

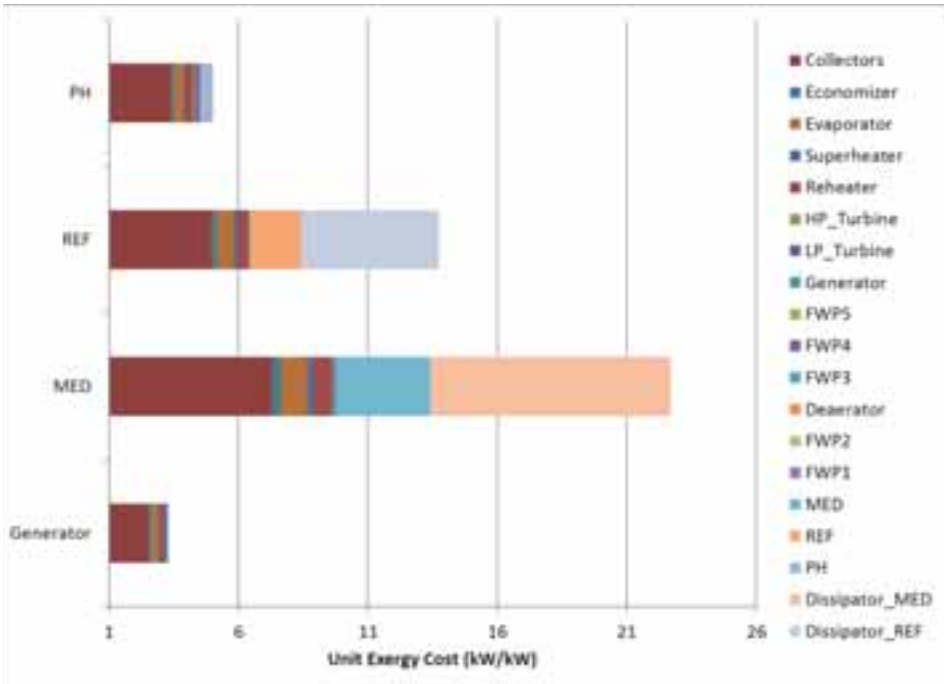

Fig. 6: Cost decomposition in polygeneration plant.

3.3. Comparison between polygeneration plant and stand-alone systems

Regarding the comparison between polygeneration plant and standalone systems, the results are presented in Figure 7. According to these results, a solar polygeneration plant is more cost-effective than stand-alone systems, since a lower unit exergy costs of electricity, water, cooling and process heat has found with respect to the stand-alone scheme. Remember that the unit exergy cost represents the amount of exergy required to get a unit of exergy of the product, i.e. the resources required to carry out the production. For instance, a unit of exergy cost of electricity of 3.3 kW means that 3.3 kW of exergy of resources is needed for producing 1 kW of electricity. The unit exergy cost is possible to express in USD/kWh also, but in this case, is necessary to consider the investment and operation costs. Anyway, this analysis was already done in a previous study conducted by the authors [11].

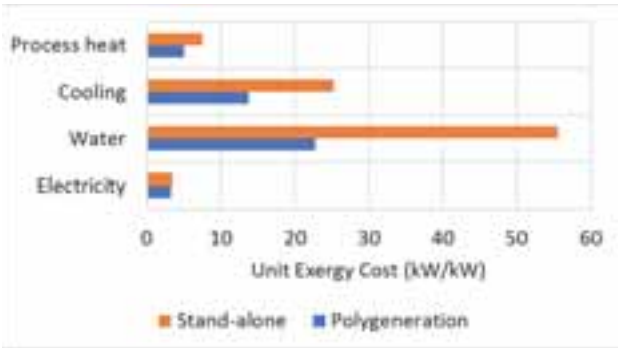

Fig. 7: Unit exergy cost of each product.

4. Conclusions

The exergy cost theory was applied to a solar polygeneration plant and stand-alone plant to analyze the process of exergy cost formation in this complex and integrated scheme, as it is a solar polygeneration plant using a concentrated solar power as prime mover, a multi-effect desalination, a refrigeration absorption, and a process heat plants. The solar polygeneration plant was simulated in a location with high direct normal irradiations.

Symbolic thermoeconomic provides a method to decompose the production costs into the contributions of the components irreversibilities and residues cost, thus it determines the cost formation process in a solar polygeneration scheme. This method delivers information that is crucial to the design and optimization process of those complex schemes.

Results show that the main components that contribute to the costs formation of electricity in a solar polygeneration plant are: solar collectors, evaporator, reheater, economizer, low-pressure turbine, and superheater. In the case of stand-alone CSP plant is similar, but includes the condenser, the order is: solar collectors, evaporator, condenser, reheater, low-pressure turbine, economizer, and superheater. On the other hand, the main components that contribute to the costs formation of water are: MED's dissipative, solar collectors, MED, evaporator, reheater, economizer, and superheater. In the cooling are: REF's dissipative, solar collectors, REF, evaporator, reheater, economizer, and superheater. Finally, in the process heat are: solar collectors, PH, evaporator, reheater, feed water preheater (FWP4), economizer, and superheater. To sum up, it is noted that ECT allows finding some interactions between different plant components that are not necessarily very close one from the other.

The analysis shows that the integrated solar polygeneration plant is more cost-effective than stand-alone systems since it produces the lower unit exergy cost of electricity, water, cooling and heat.

Nevertheless, the ECT applied here should be enlarged in future studies to different configurations of solar multi-generation plants (cogeneration, trigeneration, and polygeneration schemes) through different coupling points in a concentrated solar power plant. Also, it might be considered other alternative technologies to provide desalted water and cooling.

Design of a Calorimetric Facility to Asses Volumetric Receivers Employing a 42 kW High Flux Solar Simulator

Salvador Luque, José González-Aguilar and Manuel Romero

IMDEA Energy Institute, Avda. Ramón de la Sagra 3, 28935 Móstoles, Spain

Abstract

This paper presents the design of a new calorimetric facility for the experimental aerothermal assessment of volumetric receivers. The facility employs a 42 kW_e high flux solar simulator composed of 7 Xenon-arc lamps associated to as many ellipsoidal reflectors. An incident concentrated radiative power in excess of 14 kW_{th} is achieved at its focal point, with peak fluxes in excess of 3600 suns. A radiation homogenizer of square cross section is utilized upstream of the working section to uniformly heat the receiver aperture. Measured irradiance levels are discussed, and it is shown that the flow field non-dimensional governing parameters are highly representative of on-sun experiments at larger scales. The facility allows for the acquisition of comprehensive measurements to validate the design point operation of volumetric solar receivers, including absorber wall temperatures, air inlet and outlet temperatures, pressure drop, incident heat flux and thermal efficiency.

1. Introduction

Solar receivers absorb incident concentrated sunlight and convert it to thermal energy at the temperature required by the downstream conversion process: mechanical, thermal, or chemical (Becker and Vant-Hull, 1991). To make them feasible for large-scale industrial deployment, it is expected that working fluid temperatures at receiver exit in excess of 720 ºC, thermal conversion efficiencies over 90%, minimum service life of 10,000 cycles, and overall costs below 150 USD per kilowatt of thermal power delivered ought to be achieved (Mehos et al, 2016). Operating temperatures play a conflicting role because receiver thermal losses typically become significant at the very high levels that are required for efficient downstream conversion processes.

Four heat transfer fluids have been researched in the development of solar power plants with central receiver systems: water (or steam, either saturated or subcritical), molten salts, sodium and air (Romero et al., 2002). The use of air has advantages in terms of abundance, availability, low environmental impact, and the ability to achieve very high temperatures without thermal degradation. In this context, volumetric receivers constitute a good alternative due to their functionality and geometric configuration. They operate as radiative-convective heat exchangers, generally at irradiance levels which can be approximately five times higher than those of tubular receivers (Romero et al., 2016). The goal is to achieve the so-called volumetric effect: a situation where the hottest part of the receiver is located deep inside its structure so that thermal emission losses from its outer surfaces (particularly the front face) are minimized (Boehmer et al., 1991).

Volumetric receivers are made of generally porous structures that enable concentrated sunlight to be absorbed and conducted within their solid volume, from where it is gradually transferred by forced convection to a heat transfer fluid that flows within (Ávila-Marín, 2011; Ho, 2017). Current design trends towards higher thermal efficiencies have led to the use of complex intricate geometries to maximize temperatures deep inside the structure and thus minimize frontal thermal emissions (Gómez-García et al., 2016). High (or selective) solar absorptance, high internal convective heat transfer, high (or directional) thermal conductivity, low radiative and convective thermal losses, mechanical durability at severe operating conditions, and, where possible,

doi:10.18086/swc.2017.04.10 Available at http://proceedings.ises.org

inexpensiveness of manufacturing, operation and maintenance are all desired features for volumetric receivers.

There exists, to the authors' knowledge, scarce experimental evidence of solar receivers achieving a significant volumetric effect, the exception being a double-layer selective receiver composed of an external silica square-channel monolithic honeycomb (transparent in the solar spectrum and absorbent in the infrared band) and an internal layer of solar absorbent silicon carbide particles (Menigault et al., 1991). It is thus possible that selective reflectance and absorptance technologies (Kribus et al., 2014) or pressurized systems (Pozivil et al., 2015) are thus required.

This paper describes the design of a new calorimetric facility for the measurement of steady-state thermal conversion efficiency in volumetric receivers. The facility and its associated techniques are expected to serve as an experimental platform for the evaluation and validation of such radiative-convective heat exchangers in highly operation-representative conditions. Absorber samples up to a maximum aperture area of 300 cm^2 can be tested in it, at an incident power of 14 kW_{th}, typical air mass flow rates of 10 g/s, and maximum air outlet temperatures of approximately 1200 ºC. The facility allows for fully-integrated evaluations of performance and thermal conversion efficiency in solar receivers. Measurements acquired in it can thus be placed at technology readiness levels of 5 to 6 (technology validated and demonstrated in relevant environment).

2. The 42 kW High Flux Solar Simulator

High-flux solar simulators allow for the possibility of conducting high temperature solar thermal and thermochemical research under controlled, stable and adjustable laboratory conditions. The solar simulator employed in this study consists of 7 Xenon arc lamps, arranged in a compact hexagonal layout (Li et al., 2014). Cathodes and anodes are mounted on electrode rods, and contained within quartz glass bulbs. Each lamp is connected to a 6 kW electrical power supply and associated to an ellipsoidal reflector that also acts as a radiation concentrator. Reflectors are made from polished aluminum in order to have a very high reflectivity surface, in turn protected by a transparent polymeric coating. The ellipsoids have semi-major and semi-minor axes of 1374 mm and 569 mm, respectively, and their truncation diameter is 750 mm. The working section aperture plane is situated at a distance of 2314 mm from the reflector. The focal length is 2500 mm. The solar simulator has been illustrated in Fig. 1. Axisymmetric radiation flux profiles are achieved with this configuration, with peak flux in excess of 3600 kW/m^2 and a total incident power of approximately 14 kW_{th} at the working section aperture.

Fig. 1: Left, frontal photograph of the high flux solar simulator. Right, attenuated photograph of the Xenon lamps in operation

High flux solar simulators have the advantages of stable and adjustable radiation intensity and heat flux. They have been employed in research on high-temperature solar thermal applications, including solar thermo-chemistry, in the temperature range between 250 and 2250 ºC. Artificial radiation sources with spectral distributions that are close to that of actual sunlight are typically employed, such as metal halide lamps (Codd et al., 2010) and Xenon arc lamps (Petrasch et al., 2007; Krueger et al., 2011; Li et al., 2015). They are commonly employed in conjunction with ellipsoidal reflectors that concentrate radiation onto their secondary focal plane. Light sources and reflector surfaces are the main factors affecting the optical performance of high-flux solar simulators. The electric arc size has a notable influence on the optical performance of solar simulators. Smaller arcs allow for reflectors that are more effective at redirecting radiation toward the target focus. For this reason, Xenon arc lamps are typically preferred in the design and development of high-flux solar simulators.

3. Experimental Facility

A schematic diagram of experimental facility is given in Fig. 2. The facility is composed of the following elements: a fluid inlet module which also acts as a radiation homogenizer, a working section which houses the heavily thermally insulated receiver, an air-water heat exchanger to lower the air temperature to 50 °C, a thermal mass flow meter, a secondary air inlet for volumetric flow control, an air filter, and a high mass flow rate high pressure blower (operated by means of a frequency converter) that supplies the necessary pressure difference to circulate air through the system. Orifice plates of various sizes are employed to adjust the volumetric flow rate through the absorber between 5 and 20 g/s. They are installed in both primary and secondary air flow inlets in order to allow for adjustable pressure drops in both channels, which operate hydrodynamically in parallel. The facility is modular in design to allow for a rapid interchangeability of the test components, instrumentation, and experimental configurations.

The nominal operating mass flow rate through the absorber is 10 g/s, which leads to an average flow velocity in its flow channels of 2.8 m/s. The resultant Reynolds number is approximately 80, well inside de laminar flow regime. The pressure loss is thus, to first order, directly proportional to the mean flow velocity (and thus mass flow rates) in each flow channel. As non-uniform heating of volumetric absorbers can cause a reduction in their thermal conversion efficiency due to the dependence of air properties on temperature (which causes the air stream to flow preferentially through colder channels, where viscosity is lower), a radiation homogenizer is used to generate a uniform incident radiative heat flux on the absorber aperture. A 10 kW nominal shell-and-tube heat exchanger, operating in a counter-flow configuration, is utilized to lower the air temperatures from 1227 °C (achieved at the receiver outlet) to and 50 °C (suitable for operation of the downstream blower).

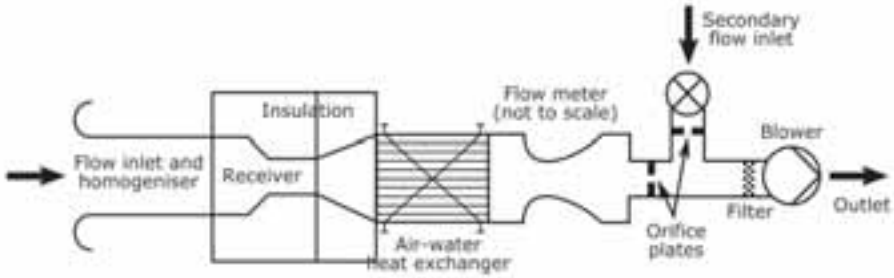

Fig. 2: Schematic diagram of the calorimetric experimental facility, with its main constitutive blocks labelled

Fig. 3: Left, frontal photograph of the absorber aperture plane (square lateral size is 125 mm). Right, three-dimensional view of the complete receiver, composed of the absorber plus a cup-shaped air collecting manifold

Two photographs of the baseline volumetric absorber experimentally characterized in this work are given in Fig. 3. It consists of a square-cell monolithic honeycomb module, manufactured from siliconized silicon carbide by Saint-Gobain High Performance Refractories[1], coupled to a cup that ducts the heated air towards the back of the facility. There are various experimental and numerical studies already conducted on this absorber (Téllez, 2003; Palero et al., 2008; Fend et al., 2013; Cagnoli et al., 2017), which therefore constitutes an adequate platform for the operational validation of new experimental facilities. The absorber has a 125 mm × 125 mm aperture and a

[1] Saint-Gobain IndustrieKeramik Rodental GmbH, Postfach 1144 D-96466 Rodental, Germany.

62.5 mm length. Absorber walls are 0.8 mm thick (nominal) and each flow channel is approximately 1.84 mm × 1.84 mm wide. The cross-sectional porosity of the absorber is thus 48.6%. Figure 4 illustrates the absorber assembly within the working section of the calorimetric facility. Sealing O-rings are distributed throughout the facility to prevent air leaks between the absorber aperture plane and the mass flow meter (such leaks would introduce unacceptably high uncertainties in the calculation of the absorber thermal conversion efficiency). During installation, the working section is placed on a highly accurate computer-controlled positioning table that moves along three axes. Careful alignment of the absorber aperture with the optical axis of the high flux solar simulator is achieved by employing a high precision cross level laser pointer. The inlet of the radiation homogenizer is situated exactly at focal point of the high flux solar simulator.

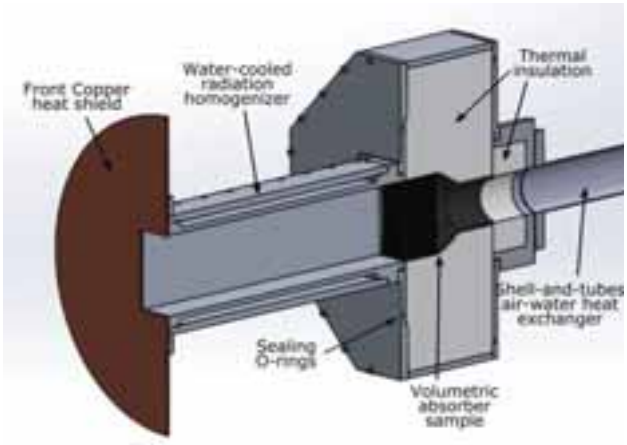

Fig. 4: CAD schematic diagram of the working section of the new experimental facility, with its main constitutive blocks labelled

4. Operating Conditions

A list of the operating conditions that can be achieved in the experimental facility is presented in Tab. 1, where comparisons to other experimental datasets at both smaller and larger scales are also given. Reynolds numbers have been calculated at the absorber aperture plane. Nusselt numbers and convective heat transfer coefficients have been obtained from correlations for thermal entry length solutions of the energy equation for internal laminar flows in square channels (Kays and Crawford, 2004). Averages have been taken along channel lengths.

Tab. 1: Typical operating conditions in the new experimental facility (at a scale of 42 kW_e) and comparison to values in the SolAir 200 on-sun experiments, from Téllez (2003), and to values achieved at a scale of 7 kW_e in a smaller solar simulator also at the Institute IMDEA Energy, reproduced from Luque et al. (2017)

Variable, units	7 kW_e scale	42 kW_e scale	SolAir 200
Absorber aperture, cm^2	4.5 – 9	156.3	2579
Total incident radiative power, kW	0.4 – 0.8	6.72	389
Maximum average radiation flux density, kW/m^2	1016	397.9	640
Mass flow rate, g/s	0.5 – 5	5 – 20	345
Mass flow rate per unit aperture area, $kg/(s\ m^2)$	1.3 – 2.1	0.7 – 2.6	~1.3
Maximum radiation per unit mass flow rate, kJ/kg	2500	1344	1128
Reynolds number (at inlet conditions)	50 – 250	62 – 248	~124
Average Nusselt number	3.0 – 3.24	3.02 – 3.15	~3.1
Average Biot number	0.52 – 2.92	0.57 – 2.27	~2.3
Technology readiness level (EU definition)	3 – 4	5 – 6	7 – 8

As shown in Tab. 1, the facility has been designed such that on-sun representative values of incident power per unit mass flow rate, Reynolds, Nusselt and Biot numbers can be achieved. Operating conditions that are highly representative of central receiver systems in actual solar towers are thus reproduced, whilst maintaining the advantages of operational flexibility and inexpensiveness of maintenance. The last row on the table shows technology readiness levels for the three experimental scales, based on the scale defined by the European Commission. The new experimental facility places itself between a smaller scale test bed for the aerothermal assessment of volumetric receivers already developed at the Institute IMDEA Energy (Luque et al., 2017), and actual on-sun central receiver experiments. It is thus expected that the flexibility and cost-effectiveness of the technique will allow for the validation of novel solar absorbers that show promise at the smaller scale, and prior to conducting on-sun tests, in order to de-risk the latter, typically resource-intensive, experimental campaign.

5. Instrumentation and Data Acquisition

The facility employs a dedicated instrumentation system based on an 8-slot National Instruments[1] CompactRIO platform. A total of 32 K-type thermocouples with 1 mm diameter Inconel sheaths have been placed throughout the facility, including measurement points on the radiation homogenizer walls and cooling water channels, on the intake module, on the absorber walls inner and outer walls, and in the exhaust module. Arrays of thermocouples were also placed at various position on the thermal insulating material in order to aid the calculation of heat conduction losses in it. The pressure drop across the absorber channels is measured by calibrated differential pressure transducers, and a thermal mass flow meter provides reliable mass measurement for the air flow.

Two radiation-shielded suction pyrometers are employed to accurately measure air inlet and outlet temperatures, immediately upstream and downstream of the absorber aperture and outlet planes, respectively. Their use is justified by the environment in which they operate and the fact that these measurements are key to the calculation of absorber thermal efficiency. Large amounts of radiation could affect unshielded thermocouples at those measurement planes: the radiation homogenizer outlet plane, where radiation from the high flux solar simulator is redirected and collimated, and the absorber exit plane, which is affected by intense thermal emissions from the hot inner walls of the facility.

A supervisory control and data acquisition system has been developed in National Instruments' LabVIEW for operation, hardware monitoring and data-logging in the experimental facility. Its main control window is shown in Fig. 5. It is divided in three main parts: on the left hand side, the user is presented with all control, monitoring and adjustment options for the 7 lamps of the high flux solar simulator. All information related to the facility instrumentation is displayed on the top right of the screen. Finally, the right lower part contains all options for the control and automated motion of the high precision three-axis positioning table. Safety operation interlocks have been included in the program to prevent hardware damage through user error.

6. Radiation Conditioning on Absorber Aperture

Non-uniform heating of volumetric absorbers can cause a reduction in their thermal conversion efficiency (Pitz-Paal et al. 1997). The dependence of air properties on temperature causes the air stream to flow preferentially through colder channels, where viscosity is lower. Hotter flow channels then remain relatively uncooled, and the temperature imbalance can lead to a runaway effect that originates flow instabilities and hot spots on the absorber aperture. Orifice plates can be used to balance the flow by creating additional pressure loss in colder flow channels. When designing an experimental facility, a well-conditioned set-up requires the use of radiation homogenizers to produce a uniform incident heat flux on the absorber aperture.

Numerical ray-tracing simulations were then conducted during the design of the radiation homogenizer with the objective of maximizing the uniformity of the radiation profile at its outlet plane. The 7-lamp high flux solar simulator and the homogenizer were modelled in Tracepro[1]. The homogenizer was assumed to be a square cross-sectioned tube with a length of 500 mm and height and width both equal to 125 mm in this analysis. The mirrors were defined as perfect reflectors as the main goal was to assess the uniformity of radiation profiles rather than obtain actual values. In the ray-tracing simulation 100,000 rays per lamp were calculated, assumed to be emitted by a surface source located at the first focal point of each ellipsoidal reflector. The homogenizer inlet plane is situated exactly at the second focal point of the ellipsoidal reflectors.

Figure 6 shows the irradiance distribution on the outlet plane of the homogenizer, normalized with respect to the peak flux. The graph on the left hand side have been smoothed and averaged in groups of 8×8 pixels. The graphs in the middle show normalized heat flux profiles in the horizontal and vertical directions. On the right hand side the simulated rays are displayed in the setup. The analysis was conducted for all seven lamps both individually and in conjunction, but only selected results are shown for brevity. The simulations showed that moving the homogenizer closer to the ellipsoidal reflectors (i.e., ahead of the solar simulator focal point) results in a slightly smoother profile in horizontal direction, but a lower radiation level in the vertical direction. Moving the homogenizer away from the reflectors leads to an inverse horizontal profile, i.e., one where regions of maximum heat flux are found near the corners rather than in the center.

Single lamp analyses showed small areas in the center of the homogenizer outlet plane where irradiance was relatively lower than in their surroundings. This can be explained by the existence of a hole in the center of each the ellipsoidal reflector through which the lamp bulb electrical connections pass through. Simulations showed that these troughs could be reduced by moving the homogenizer away from the solar simulator focal point, but this led, again, to inverse radiation profiles. On the basis of this study, the final decision was to operate the radiation homogenizer with its inlet plane located exactly on the solar simulator focal plane. Numerical results showed that this configuration provided the best balance between homogeneity of the heat flux profiles and overall incident power on the absorber aperture.

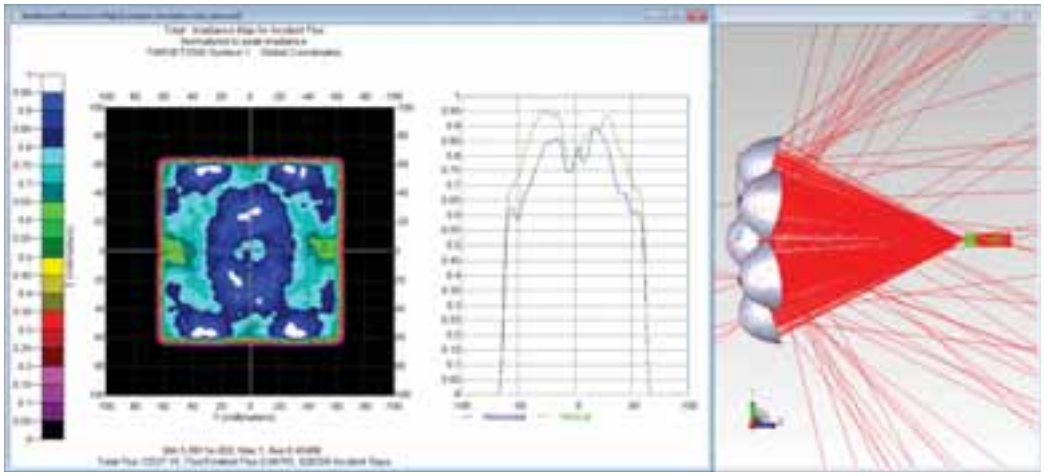

Fig. 6: Left, normalized heat flux map at the homogenizer outlet plane, for all seven lamps of the solar simulator. Center, normalized radiation profiles along the horizontal and vertical directions. Right, image of the simulated rays.

7. Incident Radiation Flux Distribution

The radiative flux density distribution at the outlet plane of the radiation homogenizer was acquired by direct measurements conducted with a Gardon radiometer (Gardon, 1953). The gauge traverses the measurement plane by means of an automated motion control mechanism that allows for high-spatial measurement resolution. At the homogenizer inlet plane, on the contrary, heat flux measurements were acquired by employing a water-cooled Lambertian target, in a procedure which was described in detail by Li et al. (2014). Radiation intensity on the Lambertian target was recorded by employing a high resolution CCD camera, which was calibrated against the Gardon radiometer.

Irradiance maps at the inlet and outlet of the radiation homogenizer are shown in Fig. 7. The white line in the right hand side figure indicates the actual size and relative location of the volumetric absorber aperture plane. It can be observed that the highly non-uniform and approximately Lorentzian radiation profile produced by the high-flux solar simulator is transformed to a square and relatively flat profile at the homogenizer outlet. The uniformity of the irradiance map at the homogenizer outlet was characterized by an average of 397.9 kW/m^2 and a standard deviation of 136.4 kW/m^2, both measured over a surface area of 125 mm × 125 mm (equal to the absorber aperture). The peak flux is 607.6 kW/m^2. Integration leads to an overall incident radiative power on the homogenizer outlet of 6.72 kW_{th}. This plane is approximately 2 mm upstream of the absorber aperture, so uniform heating of its front face is considered to be achieved.

There are, nonetheless, slight discrepancies with respect to results from the numerical ray-tracing simulations, especially noticeable in the region of high heat flux near the geometric center of the homogenizer outlet and the radiation trough that is found in the upper region of the channel (Fig. 7, right). This is attributed to two main effects: first, having a less reflective homogenizer than simulated, which leads to a lower level of homogenization of the outlet heat flux, and, second, to slight misalignments in the solar simulator with respect to the perfectly aligned numerically simulated configuration. Measurements showed that the points of maximum heat flux of all seven lamps where contained within a circular area of 18 mm diameter, whereas the simulation assumed perfect concentric alignment.

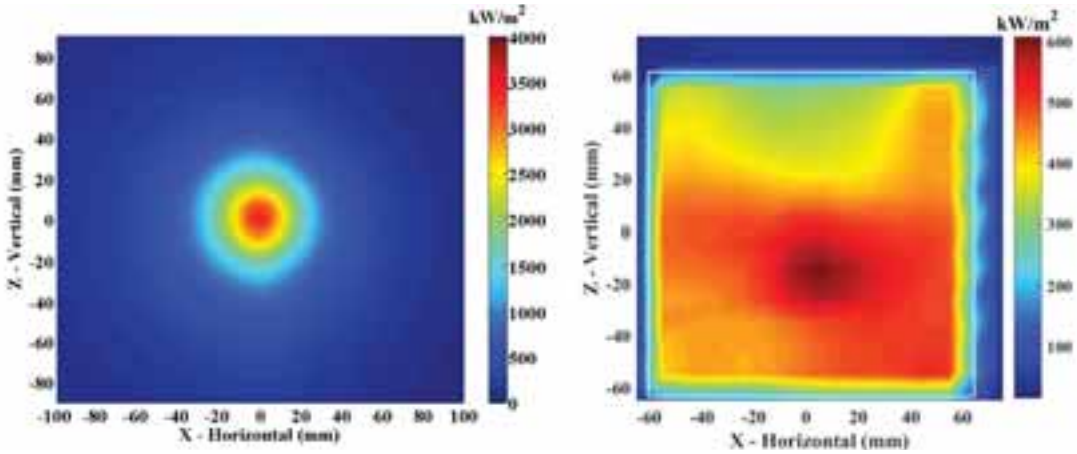

Fig. 7: Left, measurements of irradiance at the homogenizer inlet plane, reproduced from Li et al. (2014). Right, measurements of irradiance at the homogenizer outlet plane, conducted by traversing a Gardon radiometer

Laterally averaged irradiance distributions at the homogenizer inlet and outlet planes are shown in Fig. 8. Two curves are shown in the figure, one for Z-averaged data (in which averages have been taken along the vertical direction), and one for X-averaged data (in which averages have been taken along the horizontal direction). The edges of the absorber aperture are located at -62.5 mm and 62.5 mm. It can be observed that the X-averaged data shows the region of high heat flux that is close to the center of the absorber aperture, as well as the trough on the upper part. Z-averaged measurements presented in Fig. 8 also show a somewhat higher irradiance towards the right hand side of the absorber aperture.

In assessing whether or not the heat flux distribution on the absorber aperture can lead to the unstable operation of volumetric receivers, the receiver thermal conductivity was also shown to be an important factor to consider by Becker et al. (2006). In a theoretical and numerical study, it was demonstrated that sufficiently conductive

volumetric receivers could altogether avoid flow instabilities by allowing for an enhanced redistribution of heat within the absorber solid volume. As a result, the temperature difference between hot and cold flow channels is not sufficient for instabilities to occur. Considering that the volumetric absorber to be tested is made out of highly conductive siliconized silicon carbide, the heat flux profile at the homogenizer outlet was thus considered sufficient for the stable operation of the experimental facility in this initial aerothermal characterization test campaign.

8. Conclusions

A new calorimetric facility has been designed to investigate volumetric absorbers by employing a seven-lamp 42 kW high flux solar simulator, and is described in this paper. A modular design has been sought to allow for the quick interchangeability of components and experimental configurations. Incident radiation levels and internal flow field variables have been shown to be highly representative of central receiver systems in actual solar towers. Together with its associated techniques, the facility allows for fully integrated assessments of absorber radiative-to-convective heat conversion efficiencies, whilst maintaining the advantages of operational flexibility and inexpensiveness of maintenance.

It is envisaged that the facility will be used in investigations of novel volumetric absorbers that include gradual variations of convective heat transfer coefficients (implemented, for instance, by variable porosity configurations), gradual variations of thermal conductivity through the sample, or selective absorptance and reflectance profiles. Transient measurements are possible too. The technique is expected to allow for a more rapid experimental validation of such innovative concepts than has previously been possible. Experimental data will also be used for the validation of both high-fidelity numerical simulations and simplified analytical models of air solar receivers in high-irradiance high-temperature operation. Besides, the new facility can also serve as a platform for the validation of other type of central receiver systems for concentrated solar power applications, (for instance directly or indirectly heated tube and particle receivers) with minimal changes to the experimental apparatus.

9. Acknowledgements

Research leading to these results has received funding from the regional government of Comunidad de Madrid through project ALCCONES (S2013/MAE-2985), and from the European Union FP7 Programme through grant agreements 609837 and REA 291803 (Marie Curie Actions). Lena Bühre is thanked for substantial contributions relating to the radiation homogenizer numerical ray-tracing simulations. All are gratefully acknowledged.

To beam or not to beam down

Sarah A. Miller[1]

[1] CSIRO Energy, Newcastle (Australia)

Abstract

Concentrating solar thermal (CST) technologies can be employed for high-temperature applications such as electricity generation, industrial process heat and solar thermochemistry. There has been on-going interest in tower reflectors or beam-down systems without any commercial systems in operation yet. This paper reviews the geometry of beam-down central receiver tower systems along with the resultant receiver flux distributions to develop an understanding of the opportunities for beam-down systems. It includes a qualitative analysis in terms of the field, tower, secondary reflector and receiver, as well other CST beam-down systems.

Although beam-down systems will have a lower optical efficiency than an equivalent tower system, there is also a trade-off between either power or energy collection and concentration, although there are design options to improve these. The application of beam-down systems may be suited to applications, such as solar thermochemistry, where the cost of the additional plant is warranted by the value of the products.

Keywords: Concentrating, solar, thermal, CST, beam-down tower, secondary, reflector, CPC, flux, power

1. Introduction

Concentrating solar thermal (CST) technologies can be employed for electricity generation, industrial process heat and solar thermochemistry (Blanco and Miller, 2016) and the choice of technology depends on a range of details required to meet the end-use specifications or overall cost envelope. One critical detail is the temperature requirements of the end-use, and point focus technologies provide the higher concentration ratios required for high-temperatures. While one limitation of dish CST technologies is the mass of the receiver in the focal point, the optical efficiency is better than central receiver systems. However central receiver tower systems are being increasing deployed for electricity generation because they are often more cost effective than other CST technologies.

While secondary reflectors can be employed in close proximity to linear receivers to improve the capture of reflected rays, they can also be used to achieve further concentration in point receivers, such as in a solar furnace, but with an overall loss in optical efficiency. There is growing interest in beam-down central receiver systems, where the rays reflected onto a tower mounted secondary reflector are further reflected down to the ground.

The beam-down concept is attributed to Rabl (1976) who proposed a tower reflector as an alternative to the tower boiler concept for a central receiver solar thermal electric conversion plant. He expected this could be accomplished without excessive optical losses and his preliminary estimates appeared favourable. He recommend that a detailed systems analysis be performed comparing the tower reflector with the power tower.

In 1991, Vant-Hull considered the beam-down concept as based on a Cassegrain reflector system. While he felt there may be obvious benefits in simplifying the tower and saving on pumping power and piping, there were also penalties and difficulties. The obvious loss of added reflection is that of the primary heliostat reflector, ~5%, although at higher flux densities on the secondary reflectors, this might more likely be 10%. If this 10% optical energy loss represents thermal energy absorbed by the secondary reflector, active cooling might be required to dissipate this heat. Vant-Hull assumed the secondary reflector area must be smaller than the primary reflector area, except “where cost is secondary to performance”, as for a solar furnace.

Vant-Hull (1991) considered 3 secondary reflectors shapes based on geometrical optics, finding:

- An elliptical (concave) reflector would need to be placed beyond the focal point of the heliostats, requiring a taller tower to reflect a more diffuse cone of rays (image) created by a longer optical path without any advantage
- A hyperboloidal (convex) reflector would need to be placed before of the focal point of the heliostats, requiring a shorter tower. The smaller the secondary reflector, the larger the reflected secondary sunshape image and lower the concentration. A further concentrator could be placed at the receiver, adding to the cost

doi:10.18086/swc.2017.04.11 Available at http://proceedings.ises.org

- A flat reflector would need to be placed anywhere up to the focal point of the heliostats, so long as the total optical path length does not change. The flat reflector system would have small, 5-10%, reflection losses but require a moderately large mirror.

In reference to beam-down system, he stated that "Although often recommended, when subjected to a comprehensive design and costing analysis, all such concepts have failed to date".

In 2000, Segal and Epstein considered both concave (ellipsoidal) and convex (hyperboloidal) tower reflectors for electricity generation system. They identified that elliptical reflectors require both higher tower, perhaps twice as high, and also a larger secondary reflector and directed their attention to hyperboloidal reflectors. In 2011, Segal stated that appropriately placed hyperboloidal and ellipsoidal tower reflectors can provide comparable results, although the hyperboloidal surface is definitely more effective. Although a "quadratic surface mirror always magnifies the sun image" and they highlight the importance of its linear magnification, it is noted that the flux density and concentration decrease as the beam area increases by the square of the linear magnification.

There has been on-going interest in beam-down systems for both electricity generation and solar thermochemistry. The purpose of this paper is to review work since 2000 with a view to understanding the opportunities for beam-down systems. This paper will focus on simple ray geometry of beam-down systems as well as receiver flux distributions that affect the resultant black-body temperature limit.

2. Simple ray geometry

In CST technologies, determination of receiver flux distributions requires ray-tracing involving the position of the sun and the properties of any reflectors, including consideration of the conical magnification of the sun upon reflection and the imperfections of the reflector structure and tracking. An example of the initial system design using simple ray geometry is shown in Figure 1 for a hyperboloidal secondary reflector. This geometry considers the rays from the edges and centre of the heliostat that is furthest from the tower (R_{max}). The heliostat is flat, although a curved heliostat can also be considered. The sun position and annual DNI intensity for Alice Springs, Australia, shown in Figure 2 highlights the range of zenith and azimuth angles that need to be considered in the design of CST systems.

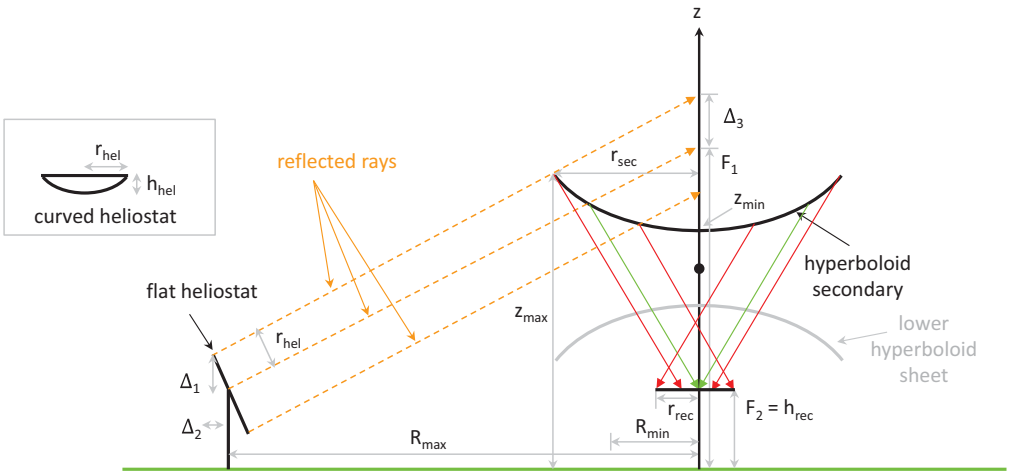

Fig 1: Geometry of beam-down tower system with hyperboloidal secondary reflector

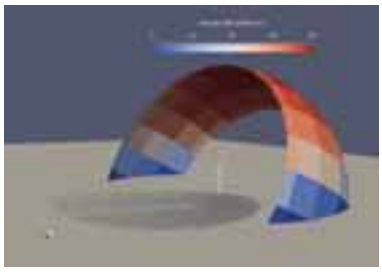

Fig. 2: Sun position diagram for Alice Springs, Australia (Potter et al., 2017)

The effect of eccentricity on the hyperbola size and shape is shown in Figure 3 for an upper focal height (F_1) of 75m for a heliostat radius of (a) 5m and (b) 1m, both at R_{max} = 150m. The vertex of the hyperbola changes with eccentricity but not heliostat radius. The radius of the hyperbola increases with increasing eccentricity and increasing heliostat radius. The linear magnification of the rays with the smaller heliostat will be less since the outer edge of the hyperbola is slightly closer to both the heliostat and the receiver.

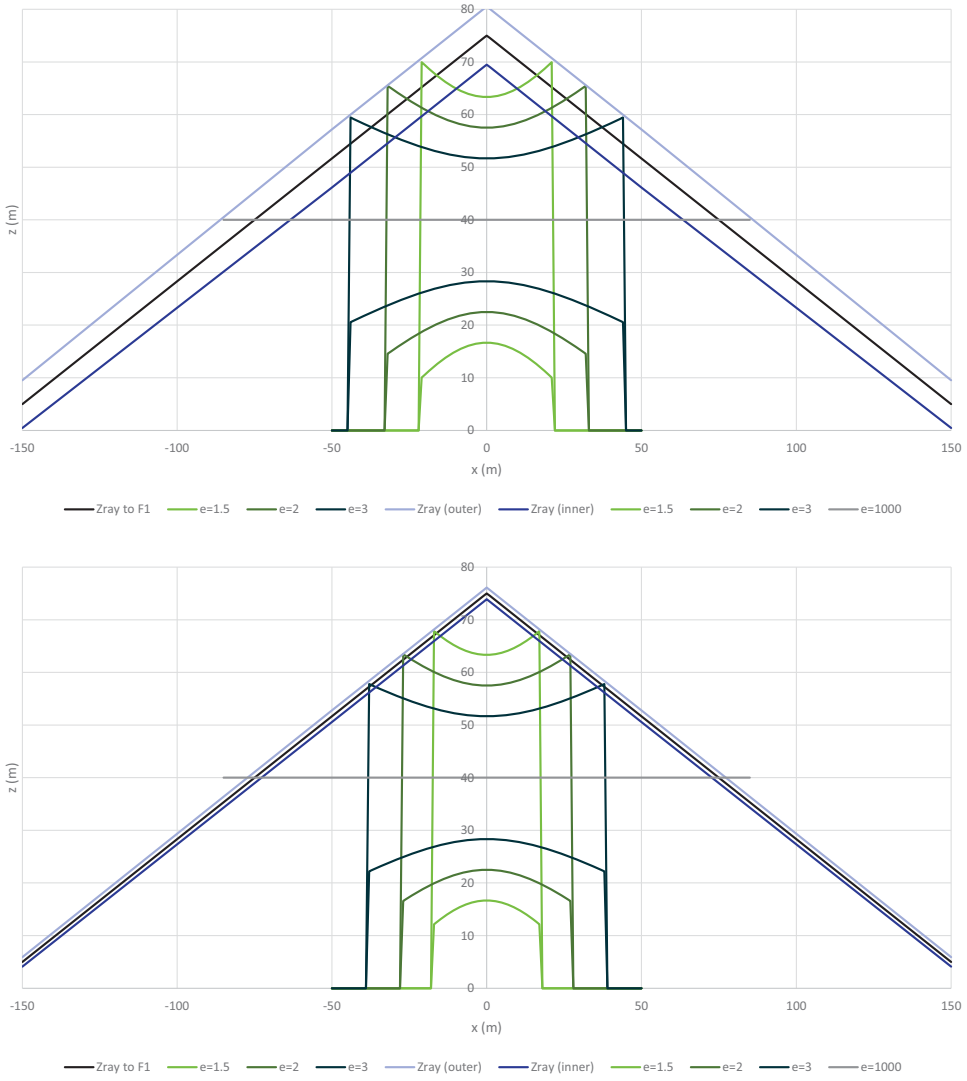

Fig. 3: Effect of eccentricity on hyperbola size and shape for heliostats of (top) 5m and (bottom) 1m (F1=75m, Rmax=150m)

3. Receiver flux distribution

In 2012, Vant-Hull stated there are 3 basic configurations for central tower concentrating solar power (CSP) systems defined essentially by the receiver; these being an external cylinder receiver, with a cavity receiver as principal alternative, and a beam-down concept as the third alternative. In 2014, he stated that "However there are substantial disadvantages which make the beam-down concept impractical except in a few very special situations", without clearly articulating the special situations. The tabulated results for a Gemasolar type system show the beam-down system has a receiver power of 124 MW_t, which is 91% of the original 137 MW_t. More dramatically, the concentration of the beam-down system without a compound parabolic concentrator (CPC) on the receiver is only 28. Adding a CPC gives a concentration of 390, which is still much lower than the original 736. The concentration of the beam-down system can be further increased by reducing the rim angle, which reduces the field size but the power is also significantly reduced. The effect of decreasing the field radius on decreasing the receiver incident power whilst increasing the concentration, and black-body temperature are shown in Figure 4.

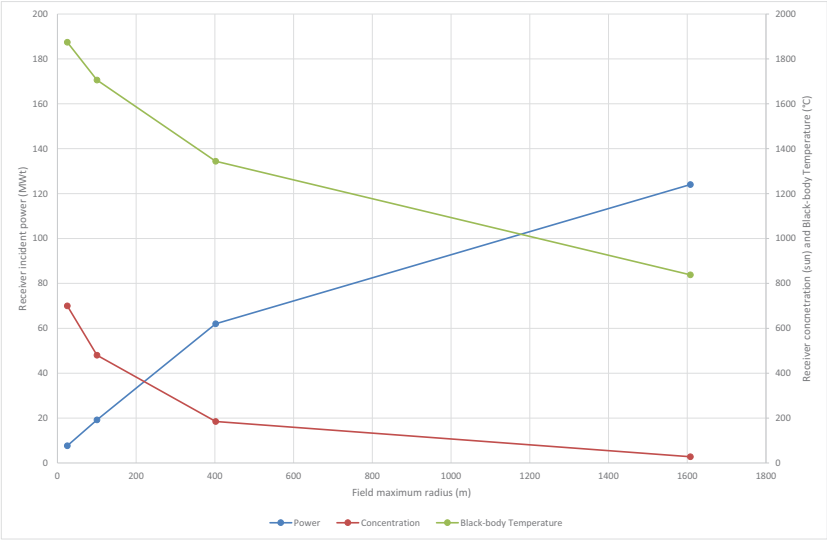

Fig. 4: Effect of field maximum radius on receiver incident power, concentration and black-body temperature (data from Vant Hull, 2014)

Circa 2000, the Weizmann Institute (Israel) built a 700kW experimental system with a secondary hyperboloidal reflector of 75m² and claims to use a CPC, with a magnification of 25, to attain average concentration of ~4000. Segal and Epstein (2003) published a concept for a 50MW ground reformer, involving an asymmetric surround field, hyperboloidal secondary reflector and a packed array of CPCs. The geometric concentration ratio of CPC aperture to heliostat mirror area is 12909. The pattern of rays arriving at the CPC aperture shows a high power density (25 MW or 3400 kW/m²) at the central CPC and low density (~4.8 MW or 653 kW/m²) in each of the outer 6 CPCs (see Figure 5).

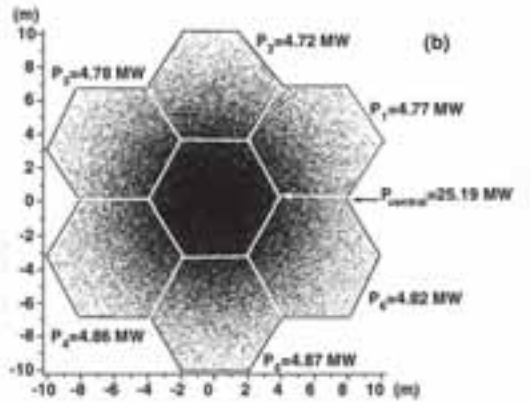

Fig. 5: Pattern of rays arriving at the CPC aperture for a 50MW ground reformer (Segal and Epstein, 2003)

Blackmon (2008) reports some details about a 10MW$_t$ "High Concentration Solar Central Receiver Demonstration Plant" for Zaafarana (Egypt) based on ideas from the Weizmann Institute. The system involves a tower-mounted reflector and CPC on the ground passing to volumetric air receivers, with quartz windows, coupled to a Brayton turbine system. This type of volumetric receiver is capable of operation at high concentrations of 2,000 to 10,000 suns. They determined that smaller heliostats were needed and selected 9.2 m² to achieve the required high concentrations at the receiver. Appendix C (Blackmon 2008) has the power from the solar field as 12.1 MW having 10.0 MW at the secondary reflector and 9.6 MW at the collector (presumably the CPC inlet). The equivalent concentration is 58.7 kW/m² at the secondary reflector and 1,013 kW/m² at the collector. Appendix E (Blackmon 2008) reported flux density at the aperture of the real CPC of 54 kW/m² (0.054 MW$_t$/m²), ranging from peak of 95 to edge of 30 kW/m². Blackmon designed and patented a number of features including the tripod-tower, the secondary reflector frame with heat recovery.

Circa 2007, Masdar Institute built 100 kW pilot plant based on a design from the Tokyo Institute of Technology (Hasuike et al., 2009). The total heliostat field aperture is 280.7 m², using small flat heliostats of 8.5 m² each, a hyperboloidal tower reflector composed of 45 flat mirrors mounted on a 19m tower. The original receiver was a

4.88mx4.88m (16'x16') near-lambertian ceramic tiled surface located 2.3m above ground to allow performance measurement (Mokhtar et al., 2014).

Mokhtar et al. (2014) report experimental analysis of the original Masdar system. They measure the optical performance in terms of flux, then compute the optical efficiency as well as both the receiver intercept factor (spillage) and thermal efficiency based on a model to determine optimum receiver aperture for a desired temperature. For a large receiver aperture of 1.71m (9.186m²), the peak optical efficiency appears ~48%, with the daily average over ~10 hours of sunshine given as 37%. The daily average mean flux density was given as 9.422 kW/m², corresponding to power of 86.55 kW, presumably at 300°C.

For a small receiver aperture of 1.06m (3.53m²), the peak optical efficiency appears circa 42%, with the daily average given as 32%. The daily average mean flux density was given as 20.9 kW/m², corresponding to power of 73.77 kW, presumably at 600°C. The higher temperature, at 2.2 times the concentration, results in a 15% loss of power.

Moktar (2011) calculated both the flux density and accumulative power with radius at the receiver plane. The peak flux density was 110 kW/m², decreasing to about 50 kW/m² at a radius ~0.75 m and decreasing to about 20 kW/m² at a radius ~1 m (Figure 6). The accumulative power is 80 kW at 0.75m and 105 kW at 1 m, reaching 130 kW at 3 m (Figure 7). However the large the receiver aperture, the greater the heat loss, so the useful radius is likely to be 1 m.

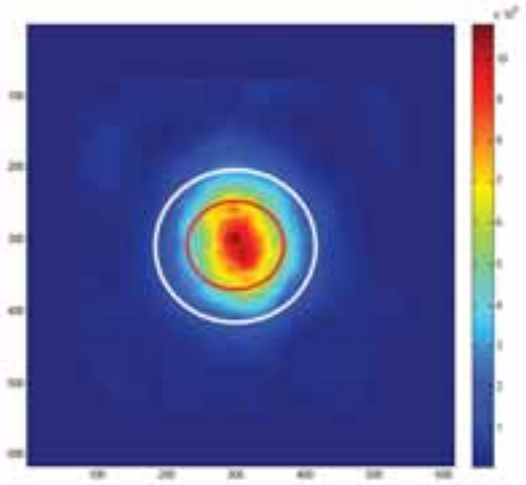

Fig. 6: Typical flux distribution [W/m²] at the receiver plane [distance in cm] (Moktar, 2011)

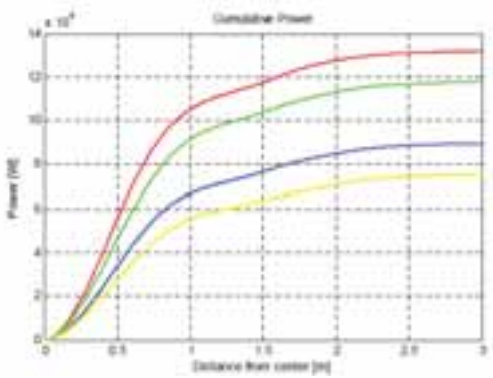

Fig. 7: Accumulative power [W] with radius at receiver plane at different times of the day (Moktar, 2011)

Grange at al. (2015) simulated the system giving an efficiency, from 77 % to 22 % depending on the solar zenith angle, appearing to be circa 68% at 40°. The simulated concentration was stated as ~150 suns at zenith angles of <40°. To improve the concentration, both a CPC and a cone were considered as a third-stage non-imaging concentrator. The power at the inlet to this final optical element was 143.2 kW at midday and 104.1 kW at 10am, being 71 and 52 kW/m² respectively. The 0.385 m² CPC led to a power loss of 5.2% at midday and 6.4% at 10am, but increased the concentration to 353 kW/m² and 253 kW/m² respectively. The 0.636 m² cone led to a power loss of 4.5% at midday and 5.5% at 10am, but increased the concentration to 215 kW/m² and 155 kW/m² respectively. Thus the CPC gave higher concentration, but also increased the power loss.

In 2012 Magaldi built a 100 kW thermal experimental system at Buccino (SA), Italy. CSP Today (2014) described the system concept being multiple 500 kWe modules. A photograph shows a hyperboloid type secondary reflector, being a 4-sided inverter pyramid on 4-legged tower system, with the receiver being directly underneath. The heliostats appear flat, but there are no optical details.

In 2016 Magaldi started operating a 2MW thermal system at S. Filippo Del Mela (ME), Italy. This is designed to produce 20.5 tons of steam daily, using 786 heliostats on a site of 2.25 hectares. The website says each module can store 8.2 MWh of thermal energy. Several modules can be combines to produce superheated steam at circa 500°. It indicates the 270 ton sand receiver-fluidised bed operates at 550-650°C.

Each module has 390 heliostats of 7m² each, or 2,730 m² (on a site of 12,000 m²), giving a thermal input of 1.05 MW, which equates to 0.384 kW_t/m^2.

Circa 2012, the University of Miyazaki (Japan) built a 100 kW experimental system (Kodama et al., 2014). The system has an elliptical secondary reflector, 4.6m diameter, mounted on a 16m tower. The heliostat field is a half circle around the tower. Each of the 88 heliostats units consists of 10 small mirrors with 50 cm diameters, giving a total area of mirrors is 176 m². The sunlight being beamed-up to the elliptical secondary reflector pass through the first focal point at 14 m height and returns to a second focal point plane 10 m above ground level (Figure 8).

Kodama et al. (2014) report using 78 of 88 heliostats, DNI was about 0.9 kW/m², 113 kW_t solar power was concentrated within an area of 1.3m × 1.3m at the second focal spot, being ~59 kW/m². Of this, 70 kW_t was concentrated within area of 0.6m × 0.6m, or 194 kW/m² (Figure 9). However, laboratory results suggest that a flux >1000 kW/m² is required to get 1400°C. Thus a CPC was proposed with a 0.75m inlet and 0.44m outlet, length of 1.525m, to achieve this. Kodama et al. (2016) reported testing this system on a fluidised bed of sand that had been pre-heated to 600°C. They achieved central bed temperatures of 1100°C, albeit with a non-uniform flux distribution (Figure 10a). They subsequently proposed that canting the CPC by an angle of 6-12 ° will provide a more even flux distribution (Figure 10b) and, with smaller particles, higher temperatures can be achieved.

Fig. 8: University of Miyazaki (Japan) tower with elliptical secondary reflector (Kodama et al., 2014)

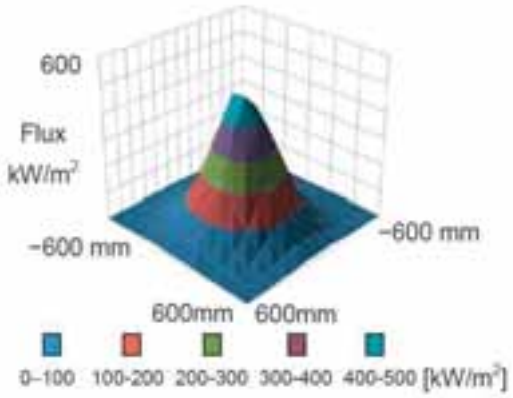

Fig. 9: Flux density from elliptical secondary reflector at CPC inlet (Kodama et al., 2014)

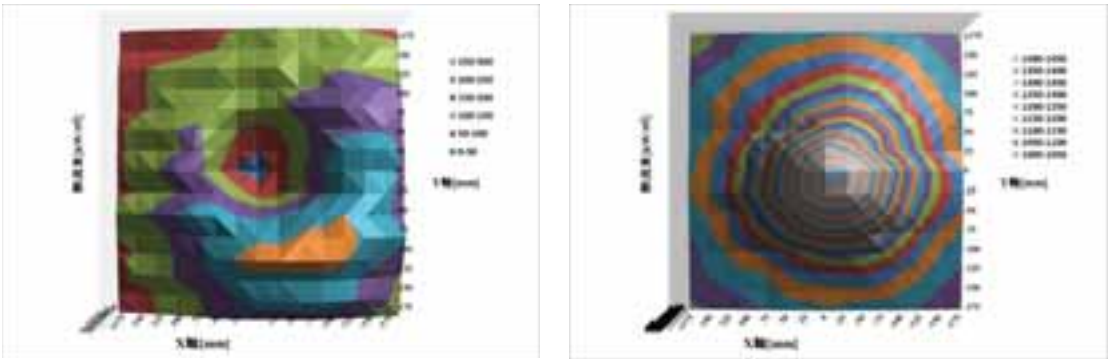

Fig. 10: Flux density 25 cm below CPC outlet (a) uncanted (b) canted (Kodama et al., 2016)

In 2013, Seigel and Ermanoski proposed a thermochemical water splitting system using a flat secondary reflector. This system places the particle-based receiver-reactor close to the flat secondary reflector to minimise image magnification and not need a terminal (CPC) concentrator for high concentration. In considering a 3MW thermal system capable of temperatures of 1500°C, they propose that the annual average collection efficiency can be 43% or more. They note the secondary reflector design will need to consider non-uniform incident flux of 20-140 kW/m². They emphasise the need for accurate, and possibly individually focused mirrors, choosing small heliostats of 1m².

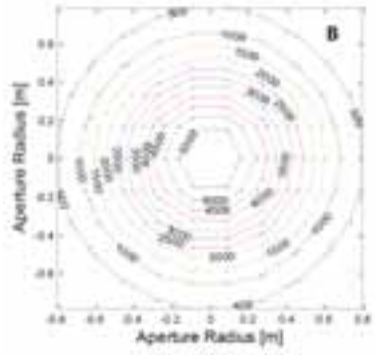

Fig. 11: Flux density from flat secondary reflector at receiver reactor inlet (Seigel and Ermanoski, 2013)

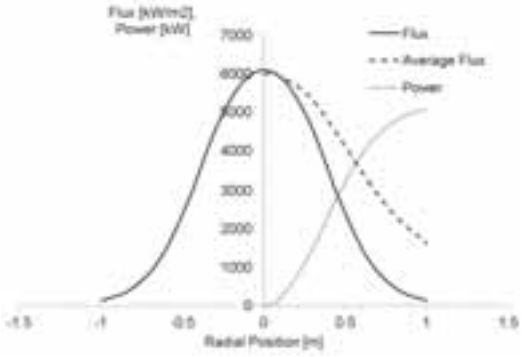

Fig. 12: Flux density, average flux and power with receiver reactor radius (Seigel and Ermanoski, 2013)

Hoffman (2011) also considered a flat secondary reflector and concave converging heliostats for a 1 MW, 1000 suns concentration, showing 2 MW and 4,000 suns concentration is achievable. He considers performance details for 4 days of the year, being solstice and equinox. The peak power output ranges from 1-2 MW, with peak concentrations of 2,000-4,000 and peak optical efficiencies of 39-50%.

In 2012, Leonardi undertook a detailed analysis of a beam-down central receiver system. The system has a symmetrical surround field, flat heliostats of either 5m or 1m radius, hyperboloidal secondary reflectors with eccentricities 1.5, 2.0 or 3.0 as well as considerations of a CPC. Ray-tracing to examine the sunshape at the upper and lower focus, she considers a conic bundle of perfectly rays reflected from the heliostat centre to the aim point (F_1). At low eccentricity, the sunshape is most spherical and the magnification is largest, resulting in the lowest concentration. At high eccentricity, as the secondary reflector becomes more flat, the sunshape is more elliptical and the magnification is unity, resulting in little concentration. Leonardi (2012) found that simplifying the optical analysis to only one conic bundle per heliostat results can lead to drastic approximations; with errors up to 35%.

Leonardi (2016) compares the use of flat and concave heliostat in beam-down systems, considering the secondary reflectors as hyperbolas with significant concavity (eccentricity, e=3), or flat (e=∞). The system has a symmetrical surround field with heliostats of 5m radius. The design point is solar noon at equinox, but also considers the annual efficiency. She finds that concave heliostats are beneficial, even when a hyperbola of small eccentricity (e=3) is considered. Concave heliostats provide a higher concentration, ~ 10 times, over a smaller receiver area, offering the possibility of avoiding a CPC. She deems that it may not be practical to have each heliostat with its own concavity in large solar fields (Figure 13).

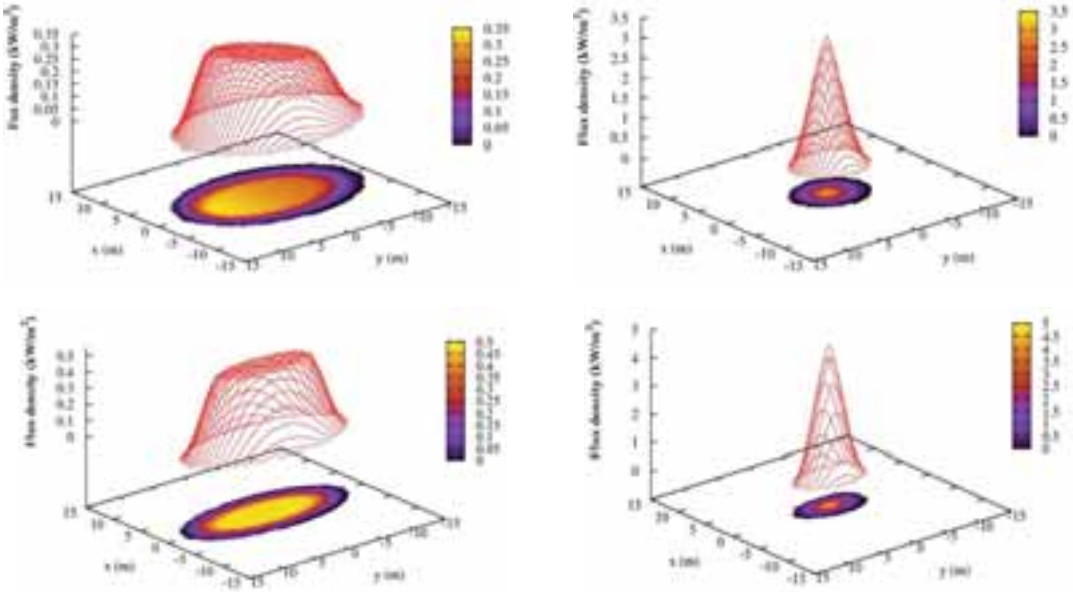

Fig. 13: Receiver flux density for (a) Flat heliostat, hyperbola eccentricity = 3 (b) Concave heliostat, hyperbola eccentricity = 3 (c) Flat heliostat, hyperbola eccentricity = ∞ (b) Concave heliostat, hyperbola eccentricity = ∞ (Leonardi, 2016)

A convex or hyperboloidal secondary receiver provides a higher annual energy collection than a flat secondary, particularly at low receiver radius (Figure 14). The relationship between concentration, black-body temperature and annual energy collection is shown in Figure 15. In this system, at the low receiver radius and high concentration, the field efficiency based on annual energy is 66.37 % in the case of concave heliostats and only 19.30 % in the case of flat heliostats. The field efficiency at the design point is 80.1 % for concave heliostats and 15.8 % for flat heliostats.

4. Discussion

CST systems are often simple in concept and complex in detail, with subsystems that integrate to optimise power, energy, concentration and ultimately cost. CST beam-down systems have the added complexity of a secondary reflector. This paper has focused on central receiver tower systems and the following analysis considers the field, tower, secondary reflector and receiver, as well other CST beam-down systems.

Field

The literature reviewed in this paper suggests heliostat size plays an important role the design of CST beam-down systems with small heliostats giving less beam magnification. Reducing the size of the heliostats implies increasing the number of individually controllable heliostats in a heliostat field. While the number of heliostats may be

decreased by having different sized heliostats in the field, it is noted the greatest linear magnification occurs from the most distant heliostats.

The style or concavity of heliostats has been explicitly considered by Leonardi (2016). Concave heliostats provide a higher concentration over a smaller receiver area, offering the possibility of avoiding a CPC. She deems that it may not be practical to have each heliostat with its own concavity in large solar fields. . While increasing the number and concavity of heliostats increases the total cost, this may be offset by a system cost benefit.

Heliostat pedestal height has not been considered in this paper but it is noted that it is normally the minimum height to match the heliostat size. It is further noted that the heliostat height might need to be considered in terms of the height of the receiver.

The size of the heliostat field is normally dictated by the power sizing of the system. Where an application involves heating particles to heat a heat transfer fluid, it is possible to design multi-tower systems where a number of small fields are closely packed. This packing may be to (1) keep the size of each system small, (2) have the heat transfer fluid from each system accumulate to produce a large system and/or (3) have heat from one system pass to one or more systems to increase the temperature of the system.

In addition to the outer size of the heliostat field, a zone around the tower will be void of heliostats. While this zone will house the receiver, it may also need to house ancillary equipment such as pumps, heat exchangers and turbine, although these may also be sited underground.

The literature reviewed in this paper considers a range of heliostat field styles, being asymmetric surround, symmetric surround or polar wedge. While asymmetric surround fields are common for large solar thermal electricity plants, it is likely this will remain the case for large single-tower beam-down systems, while the other options remain under consideration for small multi-tower systems.

Tower

The tower height relative to the outer size of the heliostat field gives a rim angle, with a small rim angle having a relatively tall tower to field radius. This may also be considered in terms of the optical *f*-Number, which is the focal length divided by twice the field radius. Thus decreasing the field radius, whist keeping then focal length constant, decreases the rim angle and increases the *f*-Number. As shown by Vant Hull (2014, decreasing the field radius decreases the receiver incident power whilst increasing the concentration (Figure 4).

This paper has not considered the tower design options but notes that the tower may need to be a significant structure to support the secondary reflector to prevent imparting wind loads onto the mirror, thereby increasing aberration errors. Consideration should also be given to preventing soiling of the secondary mirrors as well as potentially needing to capture and/or dissipate heat to cool the secondary reflector.

Tower Reflector

The literature reviewed in this paper covers hyperboloidal, flat and ellipsoidal secondary reflectors. It is most common for researchers to consider the hyperbola. Leonardi (2012) compared different eccentricities and found that at low eccentricity, the sunshape is most spherical and the magnification is largest, resulting in the lowest concentration. At high eccentricity, as the secondary reflector becomes more flat, the sunshape is more elliptical and the magnification is unity, resulting in little concentration. In 2016 she found a convex or hyperboloidal secondary reflector provides higher annual energy collection than a flat secondary, particularly at low receiver radius.

Thus Leonardi and Vant Hull are both clear that there is a trade-off between either power or energy collection and concentration.

Seigel and Ermanoski (2013) considered flat secondary but located the receiver close “up the tower” close to the secondary. While this avoids losses due to magnification, it negates some of the common drivers for beam-don to have the receiver close to the ground. In this case the receiver aperture is the entrance to a reactor and having a CST particle reactor facing upwards has some advantages over a particle reactor facing downwards.

Kodama et al (2014) considered an elliptical secondary reflector but did not achieve the desired flux density. They added a CPC to increase the concentration by ~4-5 and then found they needed to cant the CPC 6-12° to provide more uniform flux distribution. Since they are using a semi-circular field, further consideration is required to determine whether canting the secondary reflector, more concentrating heliostats or a surround field provide alternative solutions.

Receiver

In this paper, the receiver is taken to be the focal or aperture plane. It is noted that CPCs are often considered as part of the receiver to increase the concentration. CPC may also provide a means of minimizing heat losses from the receiver by shielding the cavity from aperture wind and/or reducing convection currents.

It is noted that Leonardi (2012) proposes that concave heliostats offer the possibility of avoiding a CPC. Seigel and Ermanoski (2013) propose to locate the receiver close "up the tower" close to the secondary to avoid needing a CPC. The height of the receiver is an important consideration to avoid introducing additional shading of the solar field.

Other CST beam-down systems

Although this paper focuses on central receiver tower beam-down systems, the general concepts can also be applied to

- linear Fresnel systems, where a longitudinal receiver might be fixed and located near the ground
- parabolic trough systems, where longitudinal receiver might be integrated into or onto a torque bar at the vertex
- parabolic dish systems, where a cavity receiver might be integrated into or onto the structure at the vertex

A brochure in 2009 describes the CNRS solar furnace in Ordellio, France. This furnace has a more horizontal beam-redirection and is intended for research purposes. The heliostat field reflective area is given as 2136 m², with the elliptical secondary reflector area as 1830 m² and the receiver area as 0.29 m². This equates to a heliostat-to-secondary geometric concentration ratio of 1.17 and heliostat-to-receiver geometric concentration ratio of 7321. The thermal output is stated as 600 kW, equating to an average flux of 2026 kW/m². This flux equates to a black-body radiation temperature of 3371 K. Assuming a peak insolation of 1 kW/m², the thermal output relative to the heliostat area is 28.1%.

The peak and annual optical efficiency of a "conventional" CST collectors in large solar thermal electricity plants are

- parabolic dish: peak 94%, annual 87%
- central receiver tower: peak 63%, annual 51%
- parabolic trough: peak 72%, annual 59%
- linear Fresnel: peak 64%, annual 41%.

It is noted that the most significant proportion of the cost for large solar thermal electricity plants is for the CST collectors (Fernandez-García et al., 2016). The beam-down system increases this cost by adding the secondary reflector whilst reducing the overall optical efficiency. The beam-down system also either (1) reduces power and concentration or (2) requires more complex concentrating heliostats and/or more complex receiver by including a CPC. Thus the potential applications for beam-down systems must be able to tolerate thermal energy costs that are higher than equivalent large solar thermal electricity plants. These applications are likely to include solar thermochemistry where the additional cost is warranted by the value of the products.

5. Conclusion

Although beam-down systems will have a lower optical efficiency than an equivalent tower system, there is also a trade-off between either power or energy collection and concentration. The power or energy collection and concentration can be improved by using small, individually controlled heliostats, and keeping the rim angle and heliostat field outer radius small, with options of asymmetric surround, symmetric surround or polar wedge fields being options for small multi-tower systems. Convex or hyperboloidal secondary reflectors provides higher annual energy collection than a flat secondary, particularly at a low receiver radius. CPCs are often considered as part of the receiver to increase the concentration.

The beam down concept may be applied to CST systems other than central receiver tower systems. . The application of beam-down systems may be suited to applications, such as solar thermochemistry, where the cost of the additional plant is warranted by the value of the products.

Experimental validation of a novel light-splitting technique for retrofitting CSP plants by hybridizing with CPV

Matthew Orosz[1], John Dale[1], and Todd Otanicar[1]
The University of Tulsa, Tulsa (USA)

Abstract

Photovoltaic (PV) solar power generation is expanding rapidly relative to Concentrating Solar Power (CSP) due to a faster decline in solar PV panel costs after manufacturing commenced in east Asia in the 1990s. One remaining advantage of CSP is thermal energy storage (TES) which allows for smoothing output and timed dispatch of power at utility scales, whereas PV power, which currently has lower investment and levelized costs, is dependent on battery storage that has not yet matured at a large scale. There are potential advantages in hybridizing the two technologies if the low investment cost and higher areal basis yield of PV can be combined with CSP's robust and scalable storage. Under the Advanced Research Projects Agency-Energy (ARPA-E) FOCUS program, our team developed a novel approach to achieve CSP-PV hybridization through an add-on package that can retrofit existing parabolic trough collector (PTC) plants with secondary spectrum-splitting optics and a concentrating PV (CPV) receiver. The dichroic filter transmits UV and IR solar irradiance to the standard evacuated tube heat collection element (HCE) while wavelengths that are optimally utilized by PV are reflected down to an actively cooled flow through CPV receiver. The fraction of solar energy remaining available for storage can be tuned between 20-100% through configuration of the extension and optical properties of the filter. An experimental section of a standard RP3 mirror parabolic trough and HCE outfitted with the upgrade demonstrates the proof-of-concept for the approach and validates key technical and economic performance targets. The results of these experiments are relevant to operators of CSP plants as a means of enhancing output and return on investment.

1. Introduction

Solar thermal, also known as concentrating solar power (CSP), and solar photovoltaic (PV) generation are competing approaches to viably and economically supply utility scale energy converted from sunlight. In the past decade market forces, technology and volume manufacturing in east Asia have resulted in PV power surpassing CSP in installed capacity and bankability, with PV projects competing for power purchase agreements (PPAs) at prices competitive with traditional sources (Bleich & Guimaraes, 2016). As penetration of grid-scale solar generation has increased since the 1980s, the phasing of daytime supply against 24-hour demand has led to an increased awareness of the value of energy storage in promoting and maintaining grid stability (Castillo & Gayme, 2014). CSP historically has been coupled with an economical grid-scale storage solution by capturing solar energy as heat, pre-conversion to electricity, in thermal energy storage (TES) typically using molten

doi:10.18086/swc.2017.04.12 Available at http://proceedings.ises.org

salts and other phase change materials (PCMs). Photovoltaics directly convert sunlight to electricity and therefore require batteries for energy storage. Due to nascence of technology for grid-scale battery deployment both the absolute and relative capacity of battery storage to solar generation lags for PV in comparison with CSP (Orosz, 2015). Whereas PV and CSP generation are technologically disparate conversion methods, there is a means of fusing the technologies to pair the advantages of PV's low investment costs with CSP's mature and scaleable thermal batteries. This paper describes an approach for separating the solar spectrum via the addition of an optical filter to the standard parabolic trough collector (PTC) CSP architecture and equipping the PTC with a secondary, linear, actively-cooled concentrating photovoltaic (CPV) receiver.

2. Spectrum Splitting Secondary Optics

Under the Advanced Research Projects Agency-Energy (ARPA-E) FOCUS program, several concepts for spectrum-splitting hybrid solar thermal and photovoltaic power are under investigation with the rationale of coupling with TES to promote grid stability. The conversion of photons into electricity is only marginally wavelength dependent for CSP technology; to a first order approximation the spectral response of optical and thermal elements in solar thermal conversion is flat. Approximately 70% of a photon's energy can be expected to be concentrated and captured as heat and from there conversion to electricity by endoreversible thermodynamic means is typically around 30% for a 390ºC steam Rankine cycle, for a combined efficiency of around 22% for a well matched solar field and power block (Lovegrove & Stein, 2012). Photovoltaics conversely have a distinctive spectral response due to the bandgap of the semi-conductor junction: longer wavelength photons below the bandgap energy (E_g) threshold fail to promote an electron into the conduction band, while high energy photons excite electrons into overshooting and relaxing back towards the band gap. Over 70% of the solar spectrum in a single junction PV cell is lost in heating up the device, however the quantum efficiency of conversion at the band gap approaches 90% and falls off from there towards higher wavelengths (Green, 1982). This suggests a simple logical framework for comparison of PV and CSP efficiency on the basis of spectral determinants: for any wavelength a photon would be optimally directed to PV where the quantum efficiency of the PV cell exceeds a baseline of 22%, and elsewhere directed to CSP. Calculating this in turn specifies the band edges for a dichroic filter interposed in the flux line of a PTC with transmission and reflection bands capable of splitting sunlight and directing photons of differing energies to their respective optimal targets. Following this procedure we specify a spectral response for an optical coating on borosilicate glass facets for reflecting (mainly visible and near IR) light downwards to a CPV receiver using single junction c-Si cells (E_g of 1.1 eV). The as-built performance of the filter at normal incidence is shown in Figure 1.

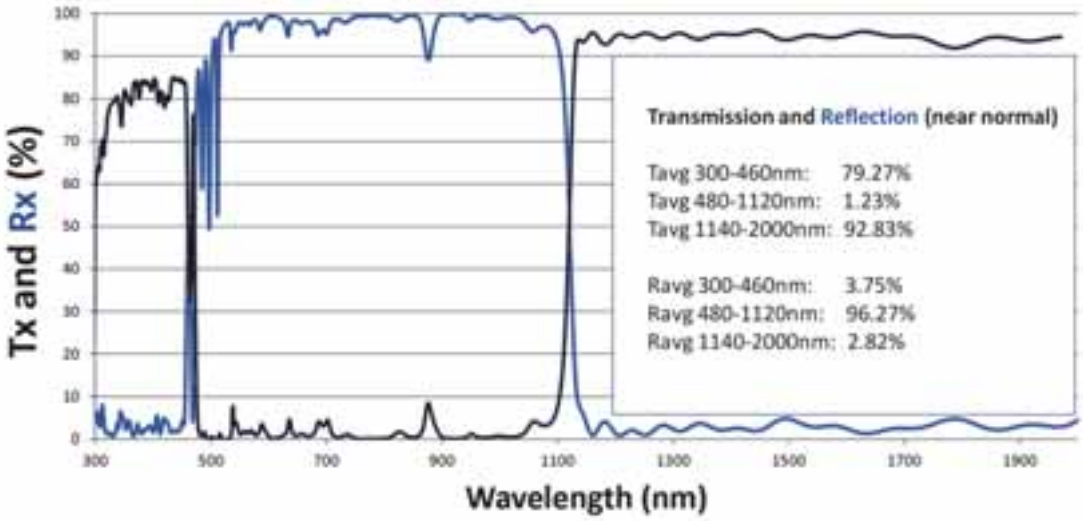

Figure 1. Spectral response of a dichroic filter for separating light into bands optimized for PV (blue) and CSP (black) receivers

It should be noted that efficiency is not necessarily the only determinant of the filter design. The selection of the band edges for reflection to the CPV receiver is subject to tuning as part of an optimization strategy considering component and system level efficiency and economic impacts - which may be site specific relating to the Rankine power cycle specifications and the physical properties of any connected thermal energy storage (TES) system. The retrofit can be flexibly adapted, by means of the dichroic filter spectral response and physical placement, to redirect design specific amounts and wavelengths of the solar spectrum within wide ranges.

3. CSP-CPV Retrofit Prototype

3.1. Design approach and component performance validation

To evaluate the potential for solar thermal and photovoltaic hybridization ("Retrosol") our team modelled and considered both ground-up designs and approaches that add filter and CPV components to an existing CSP platform (Matthew Orosz, Zweibaum, Lance, Ruiz, & Morad, 2016). The latter strategy has the economic advantage of requiring minimal investment since the primary optical and thermal infrastructure is already present, and the deployment of specialized concentrating PV panels is minor in extent relative to the solar field aperture due to the 50-100 concentration factor. Techno-economic dynamic modelling of a retrofit to a case study CSP plant in Bythe, CA indicates a potential increase in power output of 30% (O'Hern, et. al., 2017). To validate the concept and the previously developed performance models we designed a prototype for on-sun testing consisting of a standard inner set of RP3 mirrors (featured in many parabolic trough plant designs) focusing on a standard 70mm evacuated heat collection element (HCE) at a characteristic focal length of 1.7m – essentially a copy of the typical parabolic trough collector (PTC). The main components and design features are illustrated in Figure 2.

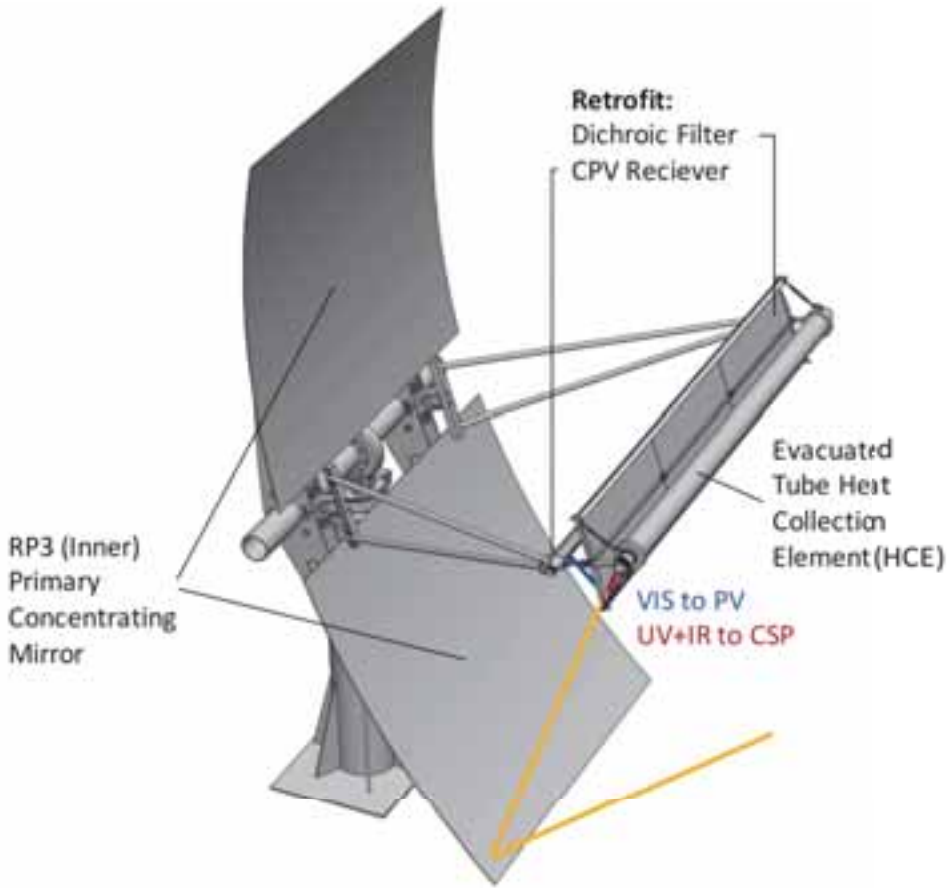

Figure 2. Prototype hybrid CSP-CPV collector using standard PTC architecture and adding dichroic filter and PV receiver as a bolt-on retrofit.

The rationale behind the design of the prototype for Retrosol is to combine the ability to experiment and collect research data with a platform that is reasonably similar to the operational Parabolic Trough Collector (PTC) power plants that would be candidates to retrofit with CPV. While PTCs are linear concentrators, there are some losses associated with walk off at the edge of the collectors that are insignificant at the length scales of 100m or longer assemblies common in CSP plants. For a single set of RP3 inner mirrors, this effect is significant and we therefore mount the PTC on an Azimuth-Zenith two-axis tracking platform such that the aperture is always normal to the sun. The use of RP3 mirrors as a primary reflector is consistent with the standard practice in PTC plants and the prototype features inner RP3 segments, a typical Schott-like Heat Collection Element (HCE), and a torque tube and arm design which is a combination of support structure that is in use in commercial plants (alongside space frame support structures). Whereas the typical PTC plant uses both inner and outer mirror segments and a single axis tracking layout, in order to operate at a reasonable scale for experimentation the prototype features only inner mirrors and uses a dual axis slewing drive for Azimuth-Zenith tracking to avoid dealing with walk-off effects on a small aperture of ~5m^2. This approach enables the project to achieve its R&D goals while demonstrating the appearance and geometry familiar to the CSP industry which can be leveraged during technology-to-market outreach. Conceptual design of the prototype following these principles has resulted in detailed part and assembly design and fabrication with installation at the North Campus facility of the University of

Tulsa, Oklahoma, USA.

Testing is achieved through I-V measurement of CPV receiver output and heat gain the HCE is measured as mass flow times heat capacity and temperature difference across the focal line.

3.2 Wind Load Analysis

In order to take appropriate steps towards a prototype design that would be compliant with relevant standards regarding safety and wind loading the team developed specifications using IEC 62817: Design Qualifications for Solar Trackers as a reference (IEC 2014). These included that the prototype structure should survive a 40 m/s (90 mph) wind and be operable in a 10m/s (22mph) wind. For this purpose a deflection of 1mm and 5mm are applied for operable and survival respectively. Wind loading is estimated using CFD flow simulation and deformation of the structure under the calculated static load is performed using finite element analysis.

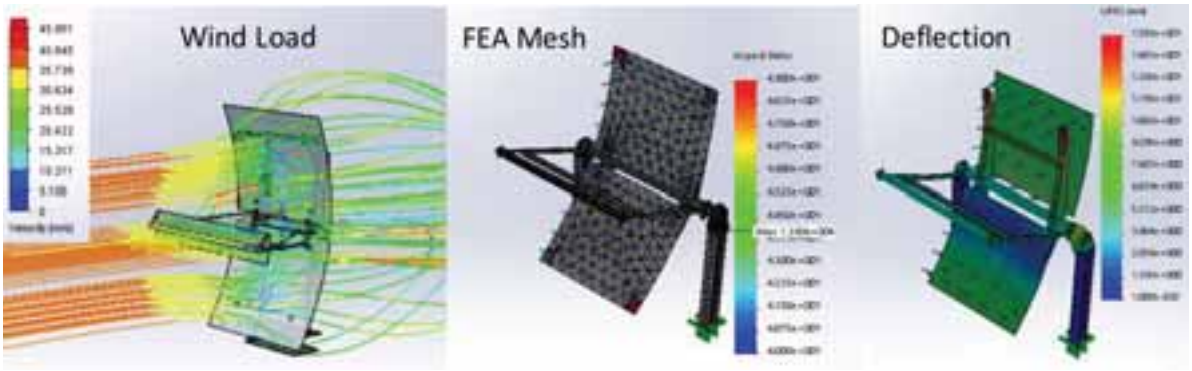

Figure 3 Design structural integrity and compliance with IEC 62817 uses simulated wind loading and finite element modeling

These analyses were used to investigate different mounting configurations and evaluate various design configurations for the mounting of the CPV receiver and dichroic filter. As a result of this process several changes were made to improve structural support of the receivers while also enabling them to be readily serviced and replaced in the field (an important consideration for operation and maintenance). This was a challenge due to the fact that there is a tradeoff between adding structure and shading the primary, and the fact that while the CPV receiver is intermediate between the torque tube and the HCE, a support that extends up from the torque tube supporting both CPV and HCE should be able to function while either one is removed. The updated configuration for mounting the CPV receiver meeting these requirements is shown below.

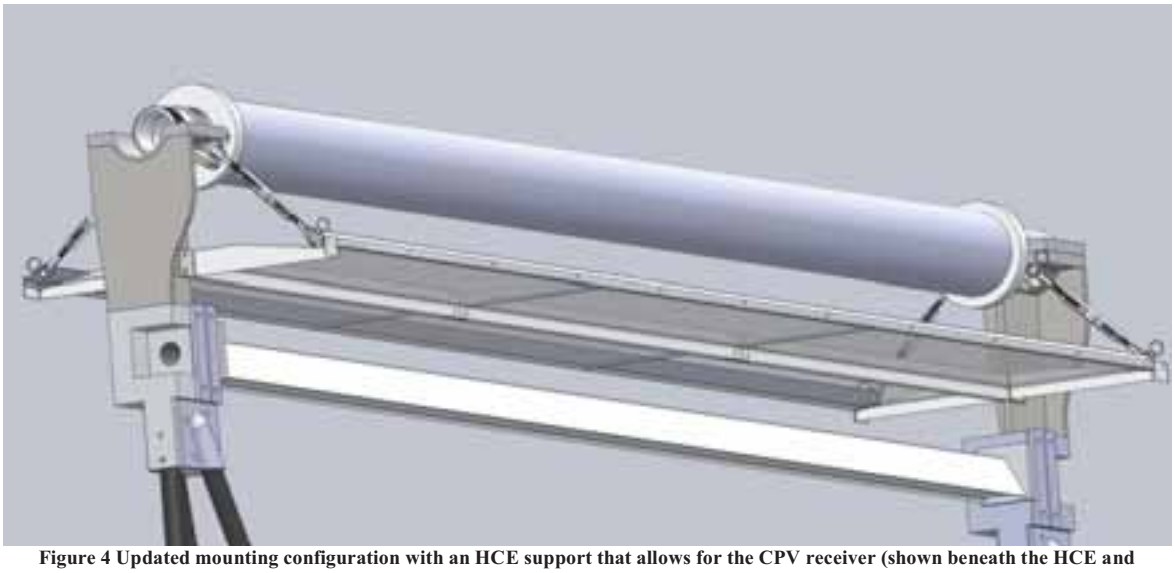

Figure 4 Updated mounting configuration with an HCE support that allows for the CPV receiver (shown beneath the HCE and dichroic secondary) to be removed for servicing from the side

3.3 CPV Receiver design

SunPower Maxeon back contact cells are deployed in the Retrosol CPV receiver as a low cost option that avoids the shading losses from dense front contacts (needed to convey increased current at concentration) of specialized concentrator cells. The solid copper substrate is suitable for managing the current generated at concentration. Because current increases nearly linearly with concentration and SunPower panels are nominally fused at 15A, the ~5A I_{mp} Maxeon cell nominally remains within its specifications if operated up to 10 suns and possibly can be operated at even higher concentration when e.g. the 125mm semi-square cell is sliced into 1/6th sections (Nesterenkov et. al., 2016).

The Retrosol prototype under development uses a 50mm width CPV receiver but to facilitate testing in parallel with construction, a version using the form factor of a Cogenra Solar T14 concentrator receiver was manufactured using 64 SunPower 1/6th form factor cells in series with customized interconnects made of bus wire and encapsulated using liquid silicones (Figure 5).

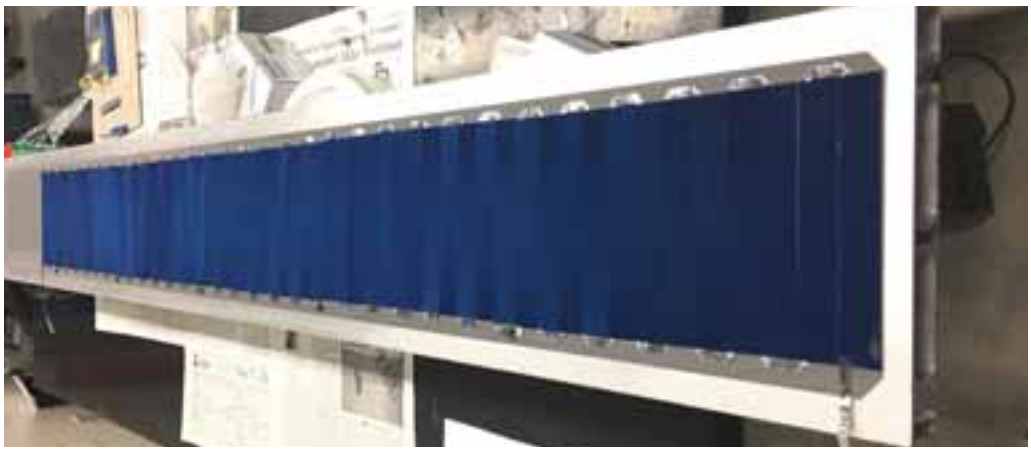

Figure 5. T14-type CPV receiver fabricated at TU using 1/6th SPWR Maxeon cells in series

Vopen (V)	39.59		Area:	0.17	m^2
Ishort (A)	0.985		Irradiance:	1031	W/m^2
Vmaxp (V)	31.41		Efficiency:	15.98%	

Imaxp (A)	0.891
Pmax (W)	28.01

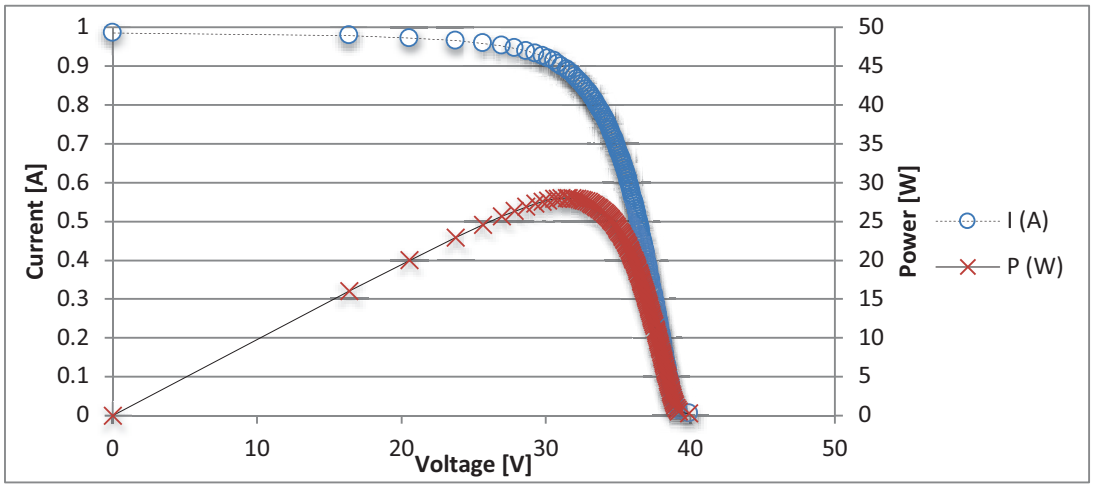

Figure 6. 64 cell SPWR Receiver benchmarked at 1-sun and ambient temperature (electrical data in table above)

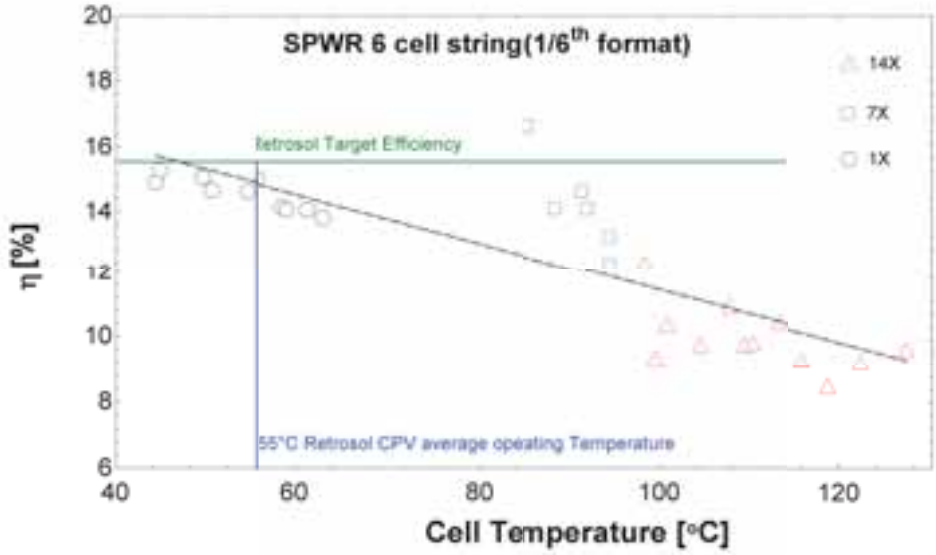

Figure 7. Test data for a 6-cell SPWR CPV Reciever at 1, 7 and 14X and a range of temperatures

Test sections of the SunPower T14 type CPV receiver were tested at 1, 7 and 14X (Figure 7) in a T14 concentrator (Morad, 2014), and the data indicates that concentration (at least up to 14X) is not significantly impairing receiver performance whereas temperature plays a driving role in CPV receiver efficiency. Further testing is underway but extrapolation of this dataset indicates that operational efficiencies at an average receiver temperature of 55°C will be approximately 95% of the targeted 15.8% efficiency.

3.4 Retrofit mounting considerations

The prototype provides an example of a design that uses a torque tube as the foundation for the attachment of mounting struts for the HCE. Torque tubes are a common design feature in parabolic trough collectors, beginning with the LS-2 design used at SEGS I-VII in California as well as troughs designed by Sener (Extrasol and Valle plants in Spain, Genesis in the US) and ENEA. Similar to these collectors, the prototype mounts the primary mirror

on cantilevered arms. The prototype is compatible with torque tube designs with the only modification being the U-bolt clamp to accommodate variation in torque tube diameters, which are generally standard pipe cross sections so only a few variants would be needed. Alternative designs in the market would require more modification to the attachment format. These include Flabeg's torque box design (Andasol plants in Spain and Kuraymat in Egypt) and Acciona (Nevada Solar One) and Abengoa (Solana, Mojave in the US) space frame mirror support structures. For these formats the prototype mounting structure would require additional modification to adjust the mode and orientation of the fixture to the frame elements, as well as variation in the length of the support. These aspects are considered to be relatively straightforward mechanical engineering challenges that could be addressed quickly with access (via partnership) to the relevant structural design drawings and documentation.

4. Prototype Evaluation

Figure 8 Prototype hybrid CSP-CPV system in on sun operation

Initial on-sun testing of the Retrosol prototype (Figure 8) has been dedicated to experiments that have benchmarked the durability of the ~65W 0.5m length CPV receiver section installed (no degradation of maximum power point output after daily use at operating temperatures) under conditions of 45x concentrated sunlight (reflected in the 500-1000nm band) and evaluating various power evacuation techniques. The remaining (~23%) of concentrated sunlight not utilized by the CPV receiver passes through the dichroic filter and is absorbed by the HCE. Because radiative and convective heat losses to the ambient are a function of operating

temperature (averaging around 300°C in the collector field) , the diversion of a significant portion of the solar spectrum to the CPV receiver results in a corresponding reduction in the efficiency of the HCE due to constant losses and less heat gain per unit length under lower incident irradiance (Figure 9). The dichroic filter effectively increases thermal losses by up to 30% at operating temperatures, however, this thermal efficiency penalty is compensated by the increased in-band quantum efficiency of the CPV receiver.

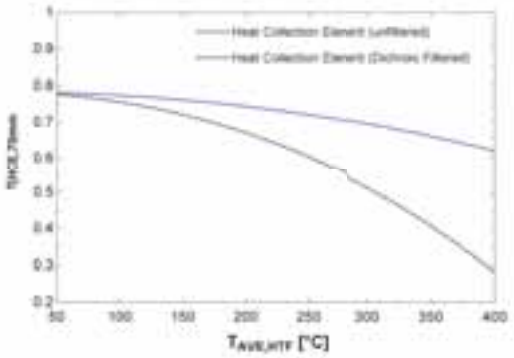

Figure 9 HCE performance pre (solid blue line) and post (dashed black line) retrofit

5. Summary and future work

This work describes technical aspects of an approach for modifying CSP power plants using linear PTC solar fields with the addition of hybrid CPV receivers for increased power output using spectrum-splitting secondary optics. A practical motivation for this exists as evidenced by the example of a CSP plant (SEGS II) which was decommissioned and redeveloped with PV. Retrofitting the existing solar field with a CPV receiver represents an alternative means to achieve PV conversion and increased capacity. The output improvement compared to investment requirement possible with this retrofit is comparatively advantageous as described in (O'Hern et al., 2017) and the validation of the performance simulation is carried out by component and system level validations, including those described in this work: spectral selectivity of the dichroic filter secondary optic and the CPV receiver efficiency at various concentrations and temperatures. The remaining components (standard HCE and CSP primary optics) are modelled using validated and well understood energy balance models based on (Forristall, 2003).

Future work includes translating the learnings from the proof of concept prototype to a full scale pilot on a collector assembly at an operating parabolic trough plant in partnership with a CSP operator to demonstrate the feasibility and benefits of retrofitting PTC plants with CPV receivers.

Abstract

In this work, mathematical model of molten carbonates electrolyzer (MCEC) has been developed for its integration into concentrating solar power (CSP) plant. MCEC modeling has been based on electrochemical and thermodynamics approach using experimental information from a testing device. Despite the high temperature requirements for MCEC operation (above 500 ºC), heat generation during the electrolysis process reduces the requirement of external heat addition. Energy optimization approach using ASPEN HYSYS pointed out that MCEC stable operation could be achieved for a wide temperature range of the feeding steam by using smart heat recovery diagram. Temperature conditions that are covering from exothermal to thermoneutral working conditions have been explored depending on the input thermal and electrical requirements. MCEC model described in this work has been encoded into TRNSYS platform for transient performance evaluation. Optimal integration scheme of MCEC coupled to linear-Fresnel solar plant has been proposed and sized for the hydrogen production of a refueling station.

Keywords: High Temperature Electrolysis, Molten Carbonates, CSP Modeling, Hydrogen Production

1. Introduction

Concentrating Solar Power (CSP) consists in producing electricity through thermo-mechanical transformation by heating a working fluid using concentrating solar technologies (parabolic through, solar tower, parabolic dish or linear Fresnel (Lovegrove and Stein, 2012)). Later this fluid is expanded inside the turbine of a power cycle converting the thermal energy into mechanical power and electricity by its self-mounted generator. CSP deployment has been growing over the last few years as it is seen as one of the most promising energy options for the upcoming years. This is mainly due to its high flexibility on energy dispatch thanks to use of thermal energy storage (TES).

Apart from the wide variety of TES systems mainly focused on short- medium term thermal storage, an alternative way is considered based on production of energy carriers like hydrogen. In this case, hydrogen can be used either for compressed storage, transportation, electricity production using a fuel cell (Carrette et al., 2001), engine powering (Dimitriou and Tsujimura, 2017) or as a valuable product for chemical and oil companies. Despite the high interest and number of applications for hydrogen, its production is still considered a costly and high greenhouse gas emission process since most of hydrogen is still produced from fossil fuel sources. However, for becoming a true zero-emission energy carrier, hydrogen should be produced from renewable energy sources such as wind, solar energy (Sanz-Bermejo et al., 2014b) or biomass (Dincer and Acar, 2015). Several technologies can be used for hydrogen production from renewable energy sources such as biomass gasification, solar-driven direct water splitting, solar-driven high-temperature thermochemical water splitting, bio-derived liquids reforming or water electrolysis using renewable electricity (Ibrahim Dincer, 2012). Water electrolysis is based on water splitting into its components (hydrogen and oxygen) inside an electrochemical device (electrolyzer) by applying an electrical current. Low temperature water electrolysis is a mature technology and hydrogen plants based on alkaline or proton exchange membrane (PEM) electrolyzers are very common. Nevertheless, power consumption is relatively high (Zeng and Zhang, 2009). Therefore high temperature steam electrolysis is being developed as an alternative because it shows a decrease on the electrical power requirements in spite of an increase of thermal energy demands as steam temperature increases (Laurencin and Mougin, 2015). This is explained from kinetics point of view, since higher temperature is promoting electrode activity while reducing cell overvoltage what is translated into lower energy losses and

doi:10.18086/swc.2017.04.13 Available at http://proceedings.ises.org

more efficient process (Schiller et al., 2009). Two main electrolyzer technologies can be distinguished for high temperature electrolysis; these are Solid Oxide Electrolytic Cell (SOEC) and Molten Carbonates Electrolytic Cell (MCEC). These devices operate at temperatures above 500 ºC at higher power density than conventional low temperature electrolyzers. These characteristics allow more compact components and less number of units. SOEC and MCEC can work either as electrolyzer or as fuel cells improving grid stabilization in a near and likely future with high penetration of renewable energy sources.

In this work, an electrochemical and thermodynamic model for molten carbonates electrolyzer (MCEC) has been developed and validated with experiments from small lab demo prototype (Frangini et al., 2014). Due to the small size prototype, scaling-up design has been proposed and applied for larger power plants corresponding to commercial application of 400 kg/day for hydrogen production. This scenario corresponds to hydrogen requirements for municipality refueling station (Sanz-Bermejo et al., 2014a). Proposed model has been used to investigate the effect of working operative conditions (current density, steam temperature, conversion ratio…) on MCEC performance. Trends and limits found from that analysis will help choosing best operative conditions. Later, proposed model has been encoded as a TRNSYS component (Trnsys, 2007) for the dynamic analysis. Integration scheme for MCEC coupling to the solar plant has been proposed and energy recovery network optimized for system efficiency maximizing. Finally, solar plant requirements have been discussed for linear Fresnel coupling assessment.

2. Molten carbonates electrolyzer (MCEC) description

One of the main differences between SOEC electrolyzers and MCEC is the requirements of the second one on CO_2 feeding together with water steam. Water and carbon dioxide molecules decompose into H_2 and carbonate ion (CO^{3-}) at electrolyzer cathode. Simultaneously CO_3^{2-} diffusion occurs through the alkaline electrolyte made of lithium, sodium and potassium towards the anode resulting into CO_2 and O_2 (Hu et al., 2014). Chemical reactions occurring inside the MCEC are summarized in Table 1.

Table 1 MCEC involved reactions

Cathode	$H_2O + CO_2 + 2e^- \leftrightarrow H_2 + CO_3^{2-}$
Anode	$CO_3^{2-} \leftrightarrow CO_2 + ½\ O_2 + 2e^-$
Full conversion	$H_2O + O_2 \leftrightarrow H_2 + CO_2 + ½\ O_2$
ΔH_r (298 K)	285,8 kJ/mol

Nickel-based alloy with chromium and aluminum rate between 2-10 % is employed for the cathode due to its sintering resistance and mechanical properties (Bodén, 2007). The anode is made of NiO with lithium and MgO intercalated (Antolini, 2011; Hu et al., 2014) in order to avoid short-circuits into the cathode. Ceramic matrix made of $LiAlO_2$ (Hu et al., 2014) separates the cathode from the anode and supports the electrolyte LiNaK, which is a ternary eutectic mixture of molten carbonates Li_2CO_3-Na_2CO_3-K_2CO_3 (Frangini et al., 2014; Hu et al., 2014).

MCE concept is quite flexible and apart from H_2 and O_2 production as it is discussed in this work, it could operate for oxy-fuel combustion processes or methanation as it can be observed from Figure 1.

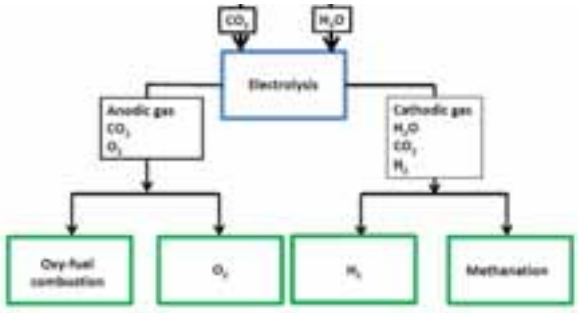

Figure 1 Applications of MCEC electrolyzer

2.1 Experimental device

Small lab-scale MCE was designed, developed and tested by ENEA (Frangini et al., 2014). This electrolyzer was made of a gold electrode with surface area of 0.2 cm^2 and a standard oxygen electrode of gold immersed in molten electrolyte and hold by alumina tube with a small hole at the bottom part. CO_2 and O_2 mixture in a relation of 2:1 with gold sheet of 1cm^2 surface was employed as counter-electrode. A mixture composed of alkaline molten carbonates Li_2CO_3-Na_2CO_3-K_2CO_3 with 43.5-31.5-25.0% molar ratio was used. This mixture has its melting point at 397 ºC. Several steady-state galvanostatic and cyclic voltammetric tests were performed for a temperature range between 500 ºC and 600 ºC as it can be seen on Figure 2. Experiments were performed by introducing different gas compositions of dry CO_2 and wet mixture in a 50:50 composition (p_{CO2}=0.5 atm; p_{H2O} =0.5 atm) at 120 ºC with a flow rate of 60 mL/min (Frangini et al., 2014).

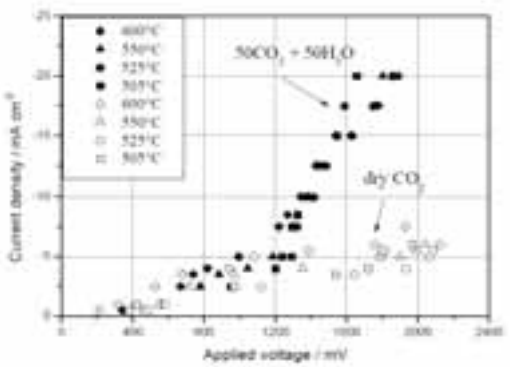

Figure 2 Applied voltage dependency according to experimental results at different temperatures (Frangini et al., 2014)

3. Mathematical model

MCE model was based on the electrochemical equations shown below.

3.1 Potential calculation: Nerst, reversible and thermoneutral

Reversible potential exchanged in a cell (eq. 1) depends on Gibbs free energy that changes with cell temperature *T* according to (eq. 2) (Brouwer et al., 2006; Petipas et al., 2013)

$$E_{REV} = \frac{\Delta_r G_T^0}{2 \cdot F} \quad \text{(eq. 1)}$$

Where *F* is the Faraday's constant equal to 96485.33 C mol^{-1}.

$$\Delta_r G_T^0 = 244800 - 49.18 \cdot T - 2.72 \cdot 10^{-3} \cdot T^2 \quad \text{(eq. 2)}$$

Nernst potential (eq. 3) depends on gases partial pressure in cathode and anode, according to electrolyzer operating pressure and spices composition (Brouwer et al., 2006).

$$E_N = E_{REV} + \frac{R \cdot T}{2 \cdot F} ln \left[\frac{p_{H_2,cat} \cdot p_{O_2,an}^{1/2} \cdot p_{CO_2,an}}{p_{H_2O,cat} \cdot p_{CO_2,cat}} \right] \quad \text{(eq. 3)}$$

Thermoneutral potential can be derived from (eq. 4)

$$E_{TN} = \frac{\Delta_r H_T}{2 \cdot F} \quad \text{(eq. 4)}$$

Where $\Delta_r H_T$ is the reaction enthalpy (eq. 5) given by (Petipas et al., 2013).

$$\Delta_r H_T = 238200 + 13.12 \cdot T - 3.53 \cdot 10^{-3} \cdot T^2 \quad \text{(eq. 5)}$$

3.2 Mass balance

Streams flow and composition can be determined using the following mass balance equations (eq. 6-10). On the first hand, hydrogen molar flow can be estimated according to Faraday's electrolysis law (eq. 6) (Petipas et al.,

2013).

$$n_{H2} = \frac{j \cdot S}{2 \cdot F} \quad \text{(eq. 6)}$$

Hydrogen production is proportional to current density j (A/cm^2) and electrodes active surface S (cm^2). Once hydrogen molar production has been determined, composition of involved species in the cathode can be determined by taking the standard conversion steam rate of the cell (x_{H2O}). Molar flow for cell feeding (n_{H2O}) can be calculated from (eq. 7).

$$n_{H_2O,cat} = \frac{n_{H_2}}{x_{H_2O}} \quad \text{(eq. 7)}$$

Considering that cell feeding is equimolar (0.5 H_2O + 0.5 CO_2) (eq. 8) can be derived (Frangini et al., 2014).

$$n_{CO_2,cat} = n_{H_2O,cat} \quad \text{(eq. 8)}$$

In a similar way, mass balance applied to electrolyzer anode results into (eq. 9) and (eq. 10).

$$n_{O2,an} = n_{H2} \cdot 0.5 \quad \text{(eq. 9)}$$

$$n_{CO2,an} = n_{H2} \quad \text{(eq. 10)}$$

3.3 Overpotential calculation

Electrolyzer working potential (E) can be determined as the sum of all system irreversibilities (eq. 11) (Brouwer et al., 2006) and includes ohmic losses (E_{ohm}), activation overpotential (η) and Nernst potential (E_N).

$$E = E_N + E_{ohm} + \eta(j) \quad \text{(eq. 11)}$$

Ohmic losses can be determined from Ohm law while the overpotential (η) is determined from Butler-Volmer expression (eq. 12) (Brouwer et al., 2006).

$$\eta = \frac{R \cdot T}{2 \cdot \alpha_A \cdot F} \cdot \sinh^{-1} \cdot \left(\frac{j}{2 \cdot j_{0,an} \cdot S} \right) + \frac{R \cdot T}{2 \cdot \alpha_C \cdot F} \cdot \sinh^{-1} \cdot \left(\frac{j}{2 \cdot j_{0,cat} \cdot S} \right) \quad \text{(eq. 12)}$$

Where j is the exchanged current (A/cm^2), α_c, α_A are transfer coefficients for cathode and anode while $j_{0,an}$ and $j_{0,cat}$ are the exchange currents of anode and cathode respectively. Due to the complexity on parameters fitting from Butler-Volmer equation and its later model programming (Sanz-Bermejo et al., 2015) simplified (eq. 13) has been proposed (Ulleberg, 2003) instead of (eq. 11).

$$E = E_{REV} + r \cdot j + s \cdot \log_{10}(t \cdot j + 1) \quad \text{(eq. 13)}$$

Where r, s and t parameters are referring to the ohmic resistance (r) and electrolyzer overpotential (s, t) that are depending on temperature.

3.4 Applied power

Electrical applied power (P) can be determined multiplying cell voltage (E), current density (j), surface (S) and the number of cells (N).

$$P = j \cdot N \cdot E \cdot S \quad \text{(eq. 14)}$$

3.5 Cell geometry

Cell dimensioning was addressed according to the following equations and considering that cells were arranged in a stack (Petipas et al., 2013; Yu et al., 2007). Unit volume depends on cell length (l), cell thickness (e_{cell}), endplate thickness (e_{plate}) and the number of cells (N) (eq. 15).

$$V = l^2 \cdot (N \cdot e_{cell} + 2 \cdot e_{plate}) \quad \text{(eq. 15)}$$

Number of stacks (eq. 16) are depending on unit volume and length.

$$N_{stack} \approx \left(\frac{\sqrt[3]{V}}{l} \right) \quad \text{(eq. 16)}$$

Number of cells per stack ($N_{cell/stack}$) can be calculated dividing the number of cells (N_{cell}) and stacks (N_{stack}). From abovementioned parameters, unit surface (S_{unit}) can be determined from (eq. 17).

$$S_{unit} = 4 \cdot \left(N_{stack} \right)^{1/2} \cdot l \cdot \left(N_{cell/stack} \cdot e_{cell} + 2 \cdot e_{endplate} \right) + 2 \cdot N_{stack} \cdot l^2 \quad \text{(eq. 17)}$$

3.6 Energy balance

Energy balance for the electrolyzer can be expressed according to (eq. 18).

$$K_s \cdot \frac{dT}{dt} = E \cdot j \cdot S \cdot (1 - \eta) - \frac{(T - 25)}{R} - n_{H_2O} \cdot c_{p\,H_2O} (T - T_{IN}) - n_{CO_2} \cdot c_{p_{CO_2}} (T - T_{IN}) \quad \text{(eq. 18)}$$

Left-hand side of the equation accounts for the temperature variation of the electrolyte whose thermal capacity was already characterized (An et al., 2016). On the right-hand side of the expression, the first term represents the gained thermal energy while the other terms are representing the energy losses. T is referring to the cell temperature while T_{IN} corresponds to the feeding temperature. Cell efficiency is determined as the ratio between thermoneutral potential (E_{TN}) and total potential (E).

3.7 Iterative solving method

MCE electrolyzer model has been derived from standard electrochemical and thermodynamics equations that are solved following the flow diagram presented on Figure 3. Design input parameters such as cell current density and steam conversion are needed for electrolyzer modeling, these parameters can be estimated from lessons learnt during experimental testing device (Frangini et al., 2014). Steam flowrate required for the electrolysis process was determined accordingly to the chosen conversion and desired hydrogen production. Main design criteria for MCE was based on hydrogen production rates for its later application, while from modeling results the number of cells, stack geometry, electricity consumption, production rates (CO_2, H_2, steam), cell temperature and the thermal energy released will be determined by solving material and energy balance equations (Petipas et al., 2013; Ulleberg, 2003).

3.8 Model fitting

Proposed model for MCEC has been calibrated using experimental data shown in Figure 2 what resulted into a series of fitting parameters for *r, s* and *t* (eq. 13). Family of coefficients was obtained due to temperature dependence of *r* and *t.* This allowed temperature-based equations definition shown in Table 2.

Table 2 Fitting coefficients proposal

Parameter	Value
r (Ω cm^2)	$-7.58 \cdot 10^{-5} \cdot T + 8.19 \cdot 10^{-2}$
s (V)	$2{,}18 \cdot 10^{-2}$
t (cm^2/mA)	$-5.69 \cdot 10^{-8} \cdot T + 6.62 \cdot 10^{-5} \cdot T - 1.91 \cdot 10^{-2}$

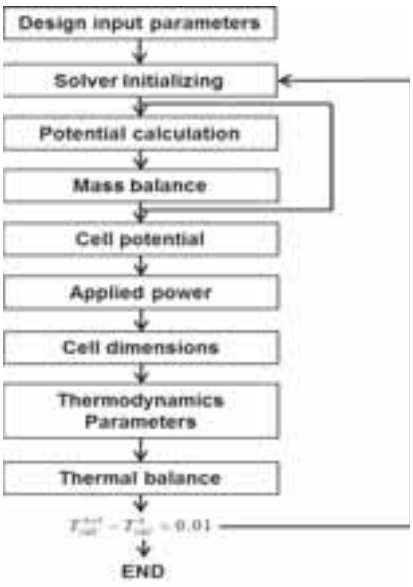

Figure 3 Solving diagram for MCEC characterization

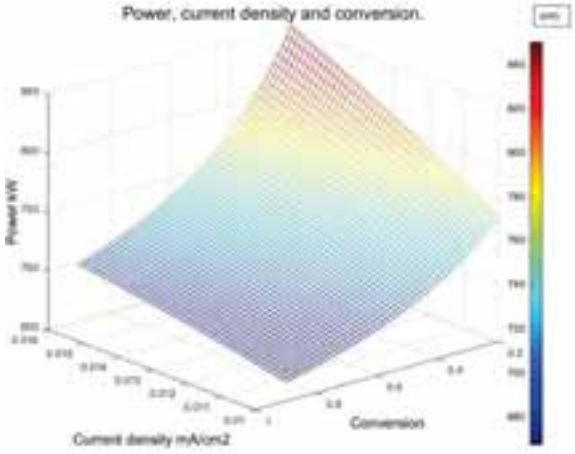
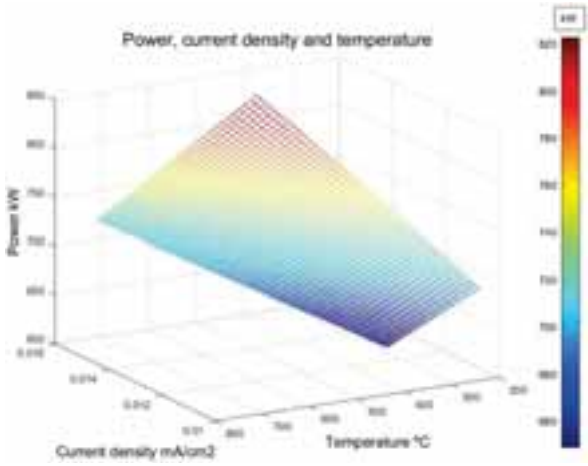
4. Sensitivity analysis

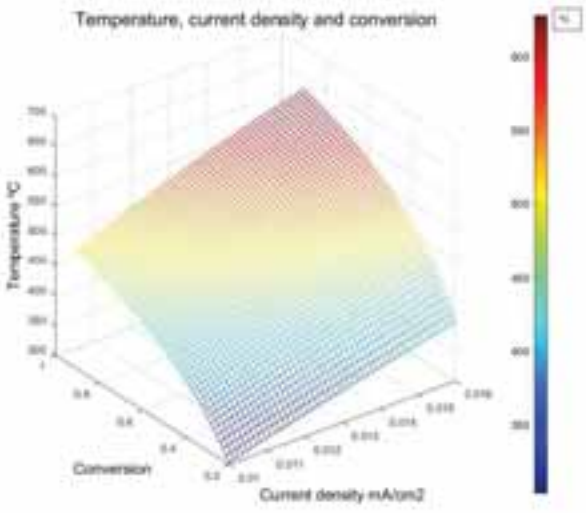
MCEC performance has been explored using the model described above. Effects of conversion ratio, current density and feeding temperature on cell temperature and electrical power have been investigated by means of the sensitivity analysis shown on Figure 4. Data were obtained for 400 kg/day production of H_2 by fixing feeding temperature at 100 ºC (when not modified) and 60% conversion (when not modified).



a. Given feeding temperature (100 ºC)



b. Given conversion rate (60%)



c. Given feeding temperature (100 ºC)

Figure 4 Working conditions effect on MCEC performance. Power consumption (top). Cell temperature (bottom)

As it can be observed from Figure 4-a, higher conversion rates and lower energy density currents would be desired in order to reduce electrical power consumption of the electrolyzer. Those conditions correspond to intermediate cell temperature range (400 ºC – 500 ºC) as it can be observed from Figure 4-c. This figure also gives an idea about the working range for the electrolyzer, since lowest cell temperature is limited to 400 ºC to avoid molten carbonates electrolyte freezing. Figure 4-b shows the effect of MCE feeding temperature (steam and CO_2) into electrical power consumption for a given conversion rate. As it can be observed, the lower is the feeding temperature of streams, the higher is the electrical power consumption for the electrolysis process. In other words, higher thermal input energy will be compensated with lower electrical power consumption of the electrolyzer which is the design target. Optimum working conditions for the electrolyzer should meet low density currents, with high conversion rates and high feeding temperatures.

5. Plant integration

As it was observed on Figure 4-b, high temperatures of the feeding streams to the electrolyzer are desired due to the lower electrical power consumption. In addition, MCE can operate under exothermal conditions which are increasing the temperature of the electrolyte cell. Thermal energy generated during the exothermal process can be mostly recovered using a heat exchangers network; the objective of this regeneration process is two-fold. On the one hand, it would increase the temperature of feeding streams (steam and CO_2) what will reduce electric power consumption of the MCEC. On the other hand, hot streams out of the electrolyzer will be cooled-down what is required for H_2 and O_2 separation processes whether using amines process or membranes.

Figure 5 shows the energy recovery network proposed for MCEC operation, this network was optimized using pinch-point methodology (Das, 2005) on ASPEN Energy Analyzer (AspenTech, 2017). This optimization was based on energy recovery maximizing from hot products streams (electrolyzer output) for input streams preheating (steam and CO_2) by using network of heat exchangers named as E-101, E-103, E-104, E-105 and E-106. Water from the network will be pumped into the system and firstly preheated by low temperature products stream at heat exchanger E-101. Later, water stream will be heated-up using external heat addition at E-102 in case of the electrolyzer operation cannot cover the thermal demand. This thermal power could be provided by external process heat as for example from concentrating solar power (CSP) plant. After external heat addition, heat exchanger network will be used for reaching the operation temperature of the electrolyzer. As it can be observed, membranes separation process (M-101 and M-102) has been proposed for CO_2 separation from products streams (H_2 + CO_2 for stream marked as 7 and O_2 + CO_2 for output stream 8). Separated CO_2 is recirculated back for electrolyzer feeding mixed with pumped water. Demister (component V-101) is considered for downstream cathode line for water droplets separation in those cases where the electrolyzer is operating with a conversion ratio lower than 100%. Condensed water is pumped back and mixed with feeding water stream. As

it can be observed, cathode stream (7) is cooled down while preheating feeding water through heat exchanger E-101; this will favor water droplets separation while reducing external heat addition on heat exchanger E-102. Furthermore, suitable temperature for membranes separation process M-101 will be expected after E-101 cooling down. Additional heat exchanger E-107 has been included as a heat sink for cooling down anode stream (8) to ensure low temperature for CO_2 separation on membrane M-102.

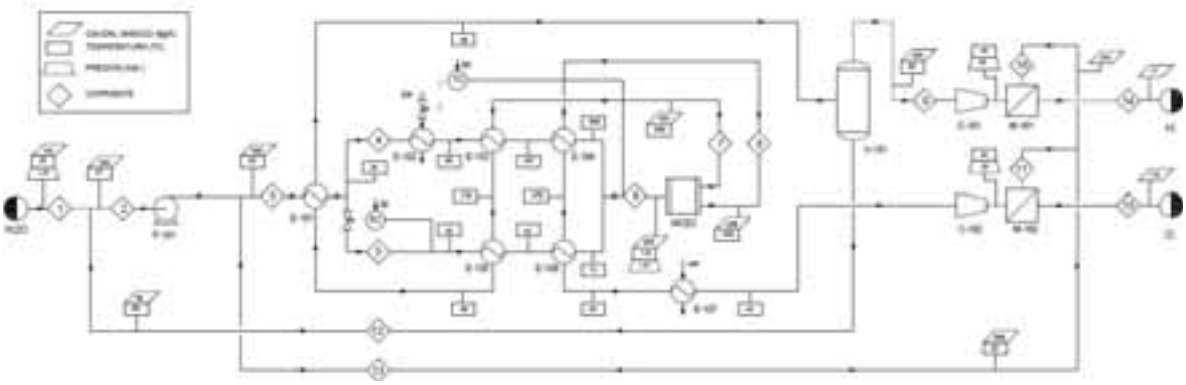


Figure 5 Energy recovery network of the MCEC

As it has can be observed on the diagram from Figure 5, feeding water stream mixed with CO_2 was separated into two streams (4 and 5) for optimizing preheating process what will reduce the external heat addition and optimizing heat exchangers network design. Mass flow splitting factor was optimized according to ASPEN HYSYS Energy Analyzer tool resulting into a ratio of 60% through the branch 4 and 40% trough branch 5 which optimized the annual cost of the system. Later, both streams were mixed again for electrolyzer feeding (branch 6). Electrolyzer feeding using separated branches was considered as well, but this option was discarded due to less efficient energy utilization resource according to pinch-point analysis.

6. TRNSYS integrated model

MCEC model described above has been programmed as a TRNSYS component (own created Type203) which will allow for performance evaluation under transient conditions and its coupling to a solar power plant. Mixer component numbered as Type210 was also developed to precisely account for energy balance when mixing streams with different fluids and with temperature dependent specific heat capacities.

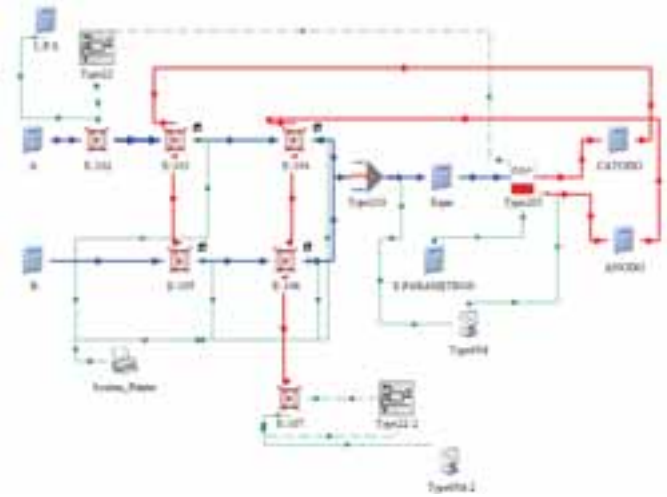

Figure 6 TRNSYS layout for MCEC developed model and auxiliaries

TRNSYS integrated model allowed to investigate the dynamic effect of warming-up the electrolyzer or its response to fluctuating temperature of feeding streams as it can be observed from Figure 7. Warming-up scenario is described on Figure 7-a, in this case the electrolyzer is fed at 1 bar and 100 ºC while molten

carbonates electrolyte are kept at initial temperature of 400 ºC (below that temperature will froze). As it can be observed, cell temperature will increase due to the exothermal electrolysis process till converging to 539 ºC cell temperature. Electrical power reduction as cell temperature is increasing is observed based on kinetics improvement and reversible potential reduction (Mazloomi et al., 2012). Figure 7-b shows electrolyzer time response against a change on feeding temperature according to sinusoidal temperature oscillation. As it can be seen, amplitude signal of 50 ºC on the feeding stream was dumped to less than 10 ºC for the electrolyte due to its thermal capacity. Similar effect on the time delay of temperature signal for the electrolyzer cell was found when varying the feeding temperature.

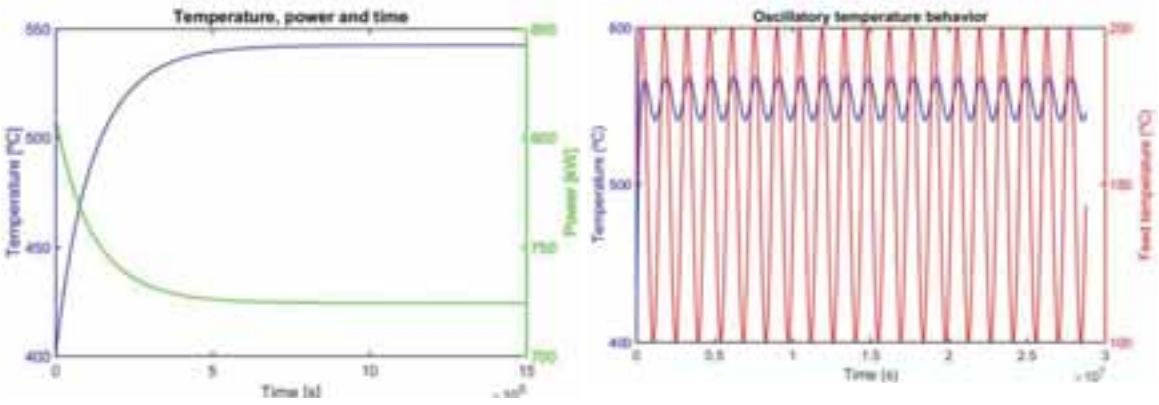

Figure 7 Time response of MCEC model programmed into TRNSYS. Electrolyzer warming-up (a). Fluctuating response (b)

7. Modelling results

Modelling results for commercial application using MCEC concept studied in this paper are presented on Table 3. Two different cases have been modelled, one corresponding to exothermal MCEC behavior with low feeding temperature and another one for thermoneutral working conditions. Working conditions for the exothermal case were taken from lessons learnt from experimental test data (Frangini et al., 2014), considering conversion ratio of 60% for current density of 0.014 A/cm^2 and low feeding temperature. Thermoneutral working conditions were determined from (eq. 4) considering cell temperature of 550 ºC. As it can be seen, the exothermal working mode consumes higher electrical power for the electrolysis process than thermoneutral mode (23% more). However, external thermal power requirements are one fourth of the thermoneutral needs at a lower temperature (40 kW at 110 ºC instead of 160 kW at 550 ºC from thermoneutral mode).

Table 3 Modelling results for commercial application

		Units	Exothermal	Thermoneutral
Assumptions	H_2 production	kg/day	400	400
	Current density	A/cm^2	0.014	0.0073
	Conversion rate	%	60	60
	Feeding temperature	ºC	110	550
Model calculation	Cell temperature	ºC	539	550
	Feeding steam	kg/h	248.2	248.2
	Feeding CO_2	kg/h	606.4	606.4
	Applied voltage	V	1.62	1.34
	Number of cells	-	319000	616000
	Electric power consumed	kW	726	593
	Required external thermal power	kW	40	160

According to results shown on Table 3, exothermal mode is suitable for low temperature applications since small amounts of thermal heat at low temperature are enough for hydrogen production using molten carbonates electrolyzer. For example, it could be coupled to low temperature CSP applications such as linear Fresnel collector according to diagram shown on Figure 8. In that case, dedicated linear Fresnel CSP plant is considered for external heat generation required for increasing temperature of feeding streams to the electrolyzer (heat exchanger named E-102 on Figure 5).

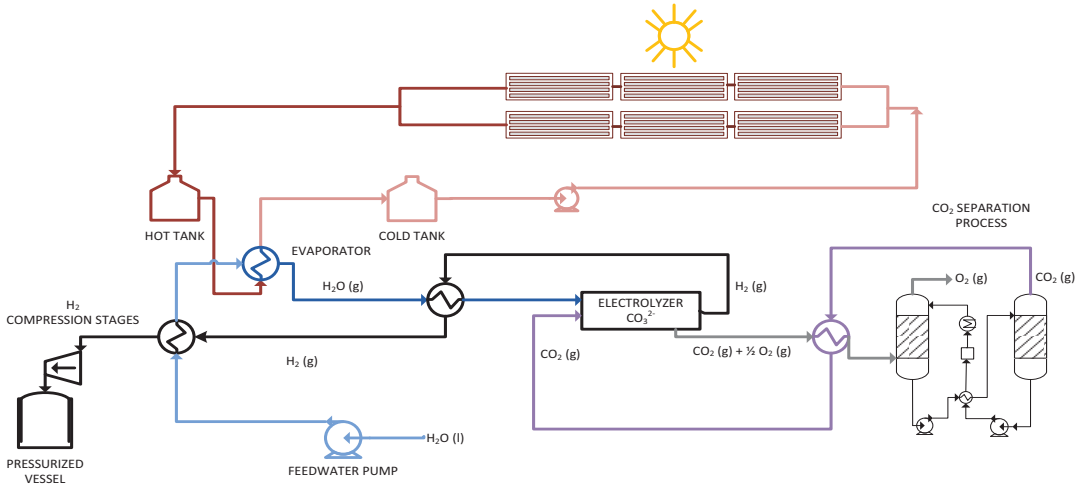

Figure 8 MCEC coupling to dedicated linear Fresnel CSP plant

8. Conclusions

In this paper it has been analyzed the application of molten carbonates electrolyzer cell (MCEC) for hydrogen production. Mathematical model has been developed based on electrochemical and thermodynamics equations and encoded as TRNSYS component for dynamic performance evaluation. MCEC model was completed considering experimental data from lab-scale demonstrator which also contributed to determine model assumptions (conversion ratio and operative cell temperatures). Sensitivity analysis performed on MCEC model demonstrated that operative conditions corresponding to high conversion ratios and low density currents were preferred due to the lower electricity requirements for the electrolysis process. However those conditions were leading to low cell temperatures what could damage the electrolyzer by freezing the electrolyte. It was also found that smart energy recovery network was required for input streams pre-heating for reducing external thermal power requirements, and in this case, splitting the mass flow into two streams (60% and 40%) will be beneficial according to pinch-point methodology. Dynamic response of TRNSYS model simulation showed how the electrolyzer was able to dump temperature fluctuations of the input streams while shifting its response due to molten carbonates thermal inertia.

Detrimental Effects of Dust Deposition in Pores of an Open Volumetric Air Receiver

[1]Indian Institute of Technology Jodhpur, Jodhpur (India)

[#] corresponding author: chandra@iitj.ac.in

Abstract

Recently the novel concept of solar convective furnace based on open volumetric air receiver is proposed and evaluated for metals processing. The use of open volumetric air receiver is motivated by the need of hot air at about 750 K. It is well-accepted that the dust deposition will be a major challenge for implementation of open volumetric air receiver in the arid deserts, worldwide. In this paper, some of its detrimental consequences pertaining to flow instability and absorber temperature are presented. A pressure-drop correlation for straight pore based absorber is developed for analyzing the flow instability. A two-dimensional validated approach is adopted for analyzing the receiver overheating as a result of dust deposition forming a so-called insulation-type layer on the inner surface of absorber pore. The findings show stable flow regime with a uniform thickness of the deposited dust layer (100 μm & 200 μm) on the inner surface of a pore. The thickness of dust layer is more detrimental in view of substantial rise of absorber temperature and thus, the sustainability of the open volumetric air receiver needs to be addressed. The presented details are both encouraging and alarming, addressing some of the gaps and outlining the need of an in-situ cleaning approach for operating such a system in the arid deserts of India and worldwide.

Keywords:open volumetric air receiver, solar convective furnace, dust deposition, heat flux distribution

1 Introduction

Rajasthan and Gujarat in India are prosperous in terms of direct normal irradiance. This can be converted to heat or power using the concentrated solar thermal technologies. As an application, the concept of solar convective furnace system is being developed at IIT Jodhpur (Patidar et al., 2015). A three-dimensional view of this furnace for heat treatment of aluminum is shown in Fig. 1a. Here, the obtained hot air from an open volumetric receiver is introduced limiting the required temperature to 750 K for annealing of aluminium. The open volumetric air receiver based central receiver systems fulfill the same and even beyond 750 K (Romero et al., 2002). The desired volumetric heating effect may be manifested by applying a uniform heat flux throughout the absorber length. In such a case, the absorber temperature at the inlet will be lower than that of the outlet. Achieving such an ideal operating condition on the field condition is not possible. This is referred to non-volumetric heating and is a manifestation of heat flux non-uniformity along the axial and radial direction. For evaluating an open volumetric air receiver, which is open to atmosphere, the solar air tower simulator facility is installed at IIT Jodhpur as depicted in Fig. 1b. The porous absorbers of this receiver are exposed to concentrated solar irradiance with simultaneous cooling basing on the forced convection of air. The installed foot-piece, anchor-plate and nozzle ensure thermal uniformity of hot air at its outlet. The designed receiver aims to provide (a) a uniform outlet air temperature, (b) a stable flow condition and (c) the long-term operation in dusty environment. An open volumetric air receiver comprising of circular straight pore based cylindrical absorber is developed to fulfill these requirements, as far as possible, and is discussed subsequently. A review and challenges in achieving the volumetric effect in such a receiver is presented in e.g. (Gomez-Garcia et al.,2016; Capuano et al., 2015).

Even with volumetric or more so with a non-volumetric heating the desired stable flow limits the targeted high air temperature in an open volumetric air receiver (Kribus et al., 1996; Pitz-paal et al., 1997). The combined effect of high temperature and its non-uniformity leads to flow instability beyond a critical heat

doi:10.18086/swc.2017.04.14 Available at http://proceedings.ises.org

flux level. This is associated with the thermo-physical properties of air and in particular, the offered flow resistance at a high temperature. The concentrated solar irradiance on the open volumetric air receiver aperture is known to be quasi-Gaussian and thus centrally located absorbers are more prone to such an unwanted situation (Becker et al., 2006; Roldán et al., 2014). One way of mitigating the same is the use of an absorber with high thermal conductivity to reduce thermal gradient and the resulting change in fluid properties. Another challenge pertaining to its operation in the arid desert region is the deposition of dust having a low thermal conductivity of about 1-2 W/mK in absorber pores. This is likely to limit its installation in such areas of high potential, worldwide, and in particular the Thar-desert of India and the great desert of Middle-East. The deposition mechanism and a dust removal process were analyzed by Singh et al., (2016). The possible consequences of dust deposition are (a) the flow instability even at a low heat flux concentration, (b) the local or wide-area hot spot and (c) an eventual failure of open volumetric air receiver. Considering these aspects (a) the effect of uniform and non-uniform heat flux distribution on an absorber pore and (b) the detrimental consequences of the dust deposition in an absorber pore are discussed in this paper.

2 Modeling and simulation

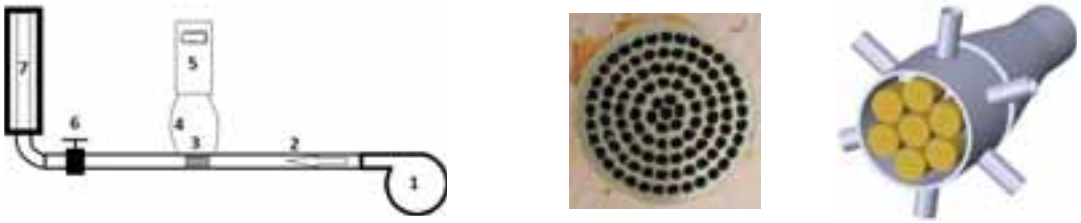
In this section the derived new pressure-drop coefficient based correlation is presented. Subsequently, the validated two-dimensional computational approach is used to address the above-mentioned objectives.

2.1 Pressure-drop Correlation

The porous absorbers in an open volumetric air receiver are made of metals, alloys and ceramics that are of foam or straight pore –type (Avila-Marin, 2011). The straight two-dimensional pore based absorbers offers a lower pressure-drop in comparison to that of a three-dimensional structures, which can be easily inferred in comparison to the Ergun equation. Thus, the straight pore based receiver is attractive for pressure-drop and are also less prone to the dust accumulation. There are a number of correlations to predict the pressure-drop (Δp) across the foam-type absorbers, which may not be applicable for the straight pore based absorber (Edouard et al.,2008). Therefore, several experiments and detailed analysis are performed to deduce a realistic correlation for Δp across the designed circular straight pore based open volumetric air receiver (Sharma et al., 2015a, 2015b). The employed cylindrical absorber and the receiver assembly are shown in Fig. 2b and 2c. The schematic of experimental setup for measuring the pressure-drop across an isolated absorber is shown in Fig. 2a. This consists of a blower, two connecting pipes each of length ~0.83 m, an absorber of length (L) ~0.0254 m, pore hydraulic diameter (d_p) ~0.002 m and porosity (ε) ~52%, a differential pressure transducer (Dwyer 475 mark III with an accuracy of about ±1.5%, a rotameter and a hot-wire anemometer (Fisher scientific make with an accuracy of about ±1%). The detailed analysis is presented in Singh et al. (2018). The authors' have also reported three dimensional numerical analyses with absorbers having porosities of 42, 52 and 62%. The obtained correlation based on these investigations is as follows:

$$\left.\begin{aligned} \Delta p &= k_p \times \frac{\rho_f \mathrm{v}_p^2}{2} \\ k_p &\approx 179.25 Re_p^{-0.588} \end{aligned}\right\} \qquad \text{(eq. 1)}$$

where,k_p is the pressure drop coefficient, ρ_f is the density of air, Re_p is the Reynolds number based on the hydraulic diameter (d_p) of circular straight pore and v_p is the average speed of air inside an absorber pore. The derived correlation is expressed in terms of Re_p, which includes fluid properties. It is well known that $\left(\Delta p/\rho_f v^2\right) \propto f\left(Re_p\right)$ for an incompressible fluid flow in a smooth straight pore (Fox et al., 2011). This can be also be inferred from the fact that a blower of large capacity is required to achieve a high mass flow rate through a given porous geometry. Thus, with the increasing velocity/mass flow rate of air or the corresponding Reynolds number the pressure-drop increases. This is also evident from eq. (1) in which including the proportionality constant k_p (a function of Reynolds number) the pressure drop scale with $v^{1.412}$.



(a) (b) (c)

Fig. 2: (a) Schematic of experimental setup showing 1:blower, 2:pipe, 3:absorber, 4-5:differential pressure transducer with probes, 6:valve, 7:rotameter; (b) a circular straight pore based cylindrical absorber; (c) the receiver assembly.

2.2 Two-dimensional analysis: clean and partially blocked pore

The deposition of dust will enhance the thermal resistance in an absorber pore and as a consequence the temperature difference between solid and air will be higher than that of a clean pore. The thermal resistance between solid and air for a clean and partially blocked pore can be easily estimated as follows:

$$\left.\begin{aligned} R_{th\_cl} &= \frac{1}{h_{cl} A_{ps\_cl}} \\ R_{th\_bl} &= \frac{1}{h_{bl} A_{ps\_bl}} + \frac{\ln\left(d_{cl}/d_{bl}\right)}{2\pi k_d L} \end{aligned}\right\} \qquad \text{(eq. 2)}$$

where, R_{th} is the thermal resistance in the pore, h is the convective heat transfer coefficient in the pore, A_{ps} is the wetted surface area of the pore, d is the hydraulic diameter of the pore, subscripts cl and bl stands for clean and blocked pores, L is the length of the circular straight pore and k_d is the thermal conductivity of dust. In eq. (2) the offered conductive resistance by the absorber solid material is ignored basing on its high thermal conductivity (~ 100 W/mK) in comparison to that of dust (~ 1-2 W/mK). The porosity (ε) of absorber in terms of dust layer thickness can be obtained as

$$\varepsilon = \frac{A_c \times n_c + A_b \times n_b}{A_{cs}}, \text{where } A_c = \frac{\pi d_p^2}{4} \text{ and } A_b = \frac{\pi (d_p - 2t)^2}{4} \qquad \text{(eq. 3)}$$

where, A_c is the cross section area of a clean pore, A_b is the flow cross section area of a partially blocked pore, t is the thickness of dust layer, n_b is the number of partially blocked pores, n_c is the number of clean pores and A_{cs} is the cross section area of absorber. Therefore, if dust deposits then the porosity of absorber will be lower than that of a clean pore. This will offer higher resistance to flow and heat transfer for a given mass flow rate. For a simple analysis the uniform layer of deposited dust along the pore length is assumed. Because of the identical geometry only one pore will suffice to estimate its effect on the heat transfer. This is manifested as the rise of mean temperature difference between absorber material and air with thickness of dust layer as summarized in Table 1. The digits are rounded off to the first decimal point. In these calculations an average convective heat transfer coefficient is used, which ideally should vary along the length. Thus, the numbers are only representative in nature. The Table 1 confirms that the mean temperature difference between absorber solid and air will increase with the dust layer thickness as a result of the enhanced conductive resistance and decrease with

Re_p as a consequence heat transfer coefficient for a given thickness of dust layer. Thus the need for a more detailed analysis is realized. As the next step, a two-dimensional analysis, based on axisymmetry is performed with Ansys-Fluent.

Tab. 1: Mean temperature difference between solid and fluid in a partially blocked pore with a uniform dust layer thickness

Re_p	Dust layer thickness (Porosity in %)		
	100 µm (42%)	200 µm (33%)	300 µm (25%)
100	103.5 K	104.7 K	106.3 K
200	92.8 K	94.8 K	97.2 K
300	84.7 K	87.1 K	89.8 K

Assuming that all the pores are identical and are exposed to the same condition suffices modeling a single pore. The modeled single pore geometry comprises a fluid (air) domain with temperature dependent properties and a solid (brass) domain with constant thermo-physical properties for a clean pore. For a partially blocked pore the dust layer is introduced as a solid domain with thermo-physical properties of sand. This is sandwiched between the absorber and fluid domain (see Fig. 3a). Thus the dust-air and dust-solid interface is suitably modeled with consistent thermal boundary condition. The deposition of dust, in an ideal case, will be uniform along the length, however, in reality, a non-uniform profile is expected. To simulate these different scenarios, uniform dust layer (UDL) and non-uniform dust layer (NDL) distributions are assumed (Fig. 3a). Moreover, both the ideal volumetric and real non-uniform heating effects are modeled with uniform and non-uniform heat flux distribution on the circumference of pore. The solved continuity, momentum and energy equations are given in eq.(4) and the numerical setup is summarized in Table 2. This describes the adopted numerical scheme and the convergence criteria.

Fluid (air)

$$\nabla \cdot \vec{\mathrm{V}} = 0$$

$$(\vec{\mathrm{V}} \cdot \nabla)\,\vec{\mathrm{V}} = -\frac{\nabla p}{\rho_f} + \nu_f\,\nabla^2\,\vec{\mathrm{V}}$$

$$\left(\nabla \cdot \rho_f\,\vec{\mathrm{V}}\mathrm{H}_f\right) = \nabla \cdot \left(\frac{k_f}{c_{pf}}\nabla H_f\right)$$

Solid (absorber material/dust)

$$\nabla \cdot (k_s \nabla T) = 0$$

(eq. 4)

Tab.2: Numerical setup for two dimensional analysis

Mesh-type	**Mesh-size (in mm)**	**Numerical Scheme**	**Convergence**
Structured	0.015 mm -0.05 mm	First-order Upwind with SIMPLE algorithm	10^{-6}

The schematic in Fig. 3c and depicts (a) volumetric heating effect with a uniform heat flux and (b) non-volumetric heating effect or a field condition with a non-uniform heat flux distributions along the axial direction, ignoring the radial variation with a single pore. The latter is adopted from Roldán et al.(2014) as eq. (5) and is implemented as a user-defined function.

$$I(z) = I_0 e^{-\xi z} \text{ with } \xi_{3d} = \frac{3(1-\varepsilon)}{d_p} \qquad \text{(eq. 5)}$$

where, $I(z)$ is the heat flux at a given axial position along the flow direction, I_0 is the irradiance at the front face, ε is the porosity of an absorber, ξ_{3d} is the extinction coefficient (Wang et al, 2013; Wu et al, 2011). Also, the

radiation based heat loss from the front surface of absorber is introduced as a boundary condition using a user defined function. Different cases are analyzed with a dust layer thickness up to 200 µm depicting one to four successive layers of deposition (see Yadav et al., 2014). Each absorber pore is subject to the same Δp inferring the applied same suction by a blower. This assumes that a common blower for suction through a receiver comprise of several porous absorbers. The same is depicted with a schematic of a clean and a partly blocked pore in Fig. 3b. In the two-dimensional simulation, a total pressure of 15.8 Pa corresponding to $\dot{q}/\dot{m}_a$~200 kJ/kg for a power ($\dot{q}$) of 1.03 W is employed as the inlet boundary condition. Zero gage pressure is applied at the outlet. Thus the flow inside a clean and a partially blocked pore is driven by the same pressure-drop as in a real absorber. The resulting Re_p is about 175, 70 and 19 for the clean and partially blocked pores with uniform dust layer thickness of 100 µm (ε ~ 42%) and 200 µm (ε ~ 33%), respectively. The lower value of Re_p is a manifestation of the offered higher resistance to the flow by the blocked pore in comparison to the considered clean pore. Thus, the flow and thermal development length (~0.05 Re_p with Pr ~ 1) will be shorter in the partially blocked pore as compared to its clean counterpart. In realistic conditions, the dust deposition is generally non-uniform. To estimate the effect of such a distribution, the simulations with non-uniform dust layers are also performed. Here, the dust layer thickness is maximum (100 µm or 200 µm) at the inlet and reduces to zero at the outlet as shown in Fig. 3a.The generated coarse and fine meshes in a dust deposited pore are shown in Fig. 3e. The finest mesh having a resolution of 0.05 mm is preferred for further analysis based on a grid independence test.

3 Results and discussion

3.1. Two-dimensional analysis:validation and flow-instability with dust deposition

The employed axisymmetric numerical model is validated with the measured values of air temperature at the absorber outlet (T_{out}) with uniform or volumetric-type heating in laboratory bySharma et al., (2015a, 2015b). The comparative assessment in Fig. 4a shows a variation of less than 5% between the measured and computed values confirming the acceptability and quality of the performed analysis. The pressure-drop correlation as in eq. (1) is derived using experiments/computations under ambient condition and its applicability with heat input remains a question. To answer the same, simulations are performed using the validated numerical setup with uniform heat flux boundary conditions and Re_p < 300. A comparison between the computed and correlation based Δp is shown in Fig. 4b. This depicts that (a) the Δp increases with decreasing T_{out} that corresponds to a high mass flow rate of air or Re_p, (b) the derived correlation compares within 10-25% with the performed simulations for a T_{out} up to 900 K. One of the reasons for this error is the measurement uncertainty of about 2 Pa. This is substantial at a low mass flow rate and thus, differences are observed between experiment and computed values. Furthermore, the measured values will be affected by the curved streamlines at the inlet and outlet. Also, a comparison between the installed- rotameter and hot-wire anemometer based $\dot{m}_a$ values showed an uncertainty of about *5%*. These are some of the possible encountered errors. Also it is noted that a 5% of uncertainty in $\dot{m}_a$ corresponds to 10% uncertainty in pressure drop. Thus, the realistic pressure-drop correlation with its known limitations is used for flow stability analysis.

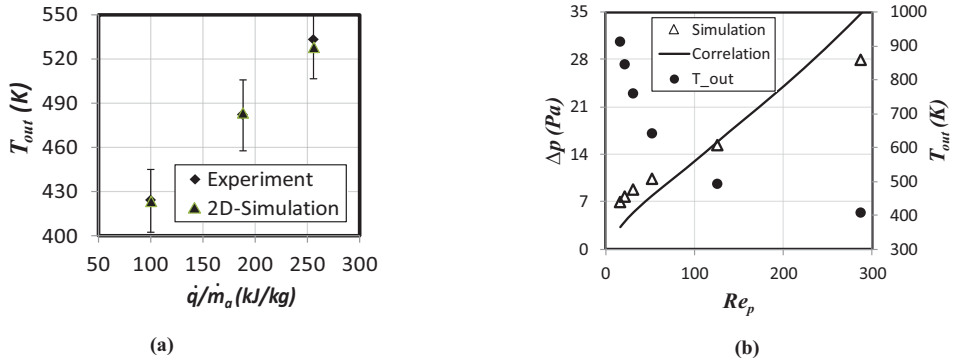

Fig 4: Comparison between (a) computed and measured air temperature at the absorber outlet and (b) computed and correlation (eq. (1)) based pressure-drop with different heat flux condition

For flow stability analysis the well-known quadratic pressure across the absorber is deduced by adopting the approach from Becker et al. (2006) and is presented in eq. (6). The detailed derivation of this expression considering a clean circular straight pore and the underlying assumption are reported in Singh and Chandra (2018). The instability is envisaged by the oscillatory nature of the difference between quadratic pressure-drop at a critical heat flux level. The investigation of the obtained expression clearly show that the non-existence of the same. The effect of dust deposition may be implicitly evaluated by updating the porosity of a partially blocked pore in eqn. (6) at the steady state.

$$\Delta p^2 = p_{inlet}^2 - p_{outlet}^2 = B'.\left(\frac{q_s''/\varepsilon\, T_{out} - \Sigma\beta\sigma T_{out}^5}{(T_{out} - T_0)}\right)^{1.412} \quad \text{where B}'=\left(\frac{179.25R\mu_0^{0.588}}{c_{pf}^{1.412}d_p^{0.588}T_0^{0.412}}\right) \qquad \text{(eq. 6)}$$

A variation of the derived expression for Δp^2 as in eq. (6) with respect to T_{out} and $\dot{m}_a$ is shown in Fig. 5. This illustrates that the pressure-drop decreases with mass flow rate of air or the corresponding Reynolds number for a circular straight pore. As a result, the outlet air temperature increases for the considered temperature dependent thermo-physical properties of air. Unfortunately, the analysis is not performed for the large scale receiver as the absorber design needs to be optimized. The work on the same is in progress. It is also inferred that for a given T_{out} the Δp^2 increases with the dust layer thickness or the decreasing effective absorber porosity

at a given mass flow rate of air. This is indicated by a dotted arrow. It must be emphasized that the estimated value of Δp^2 with eq. (6) compares well with that of the numerically analyzed values. This serves as an alternative validation of the derived expression. The difference between analytically and numerically obtained values of Δp^2 decreases with the mass flow rate of air, which is also inferred with the increasing values T_{out}. This is desirable in view of analyzing the flow instability. Higher values of Δp will lead to an elevated parasitic loss and the reduction in an overall efficiency, which is defined by Boddupalli et al. (2017). Thus, one of the consequences of dust deposition is the reduction of open volumetric air receiver performance or efficiency. Interestingly, with the uniform layer of dust deposition and the manifested volumetric heating effect no signature of flow instability is found, which is encouraging for implementing such a receiver design in desert regions and is a step towards optimization. The effect of non-uniform- dust deposition and heat flux distribution on the same will be investigated at a later date.

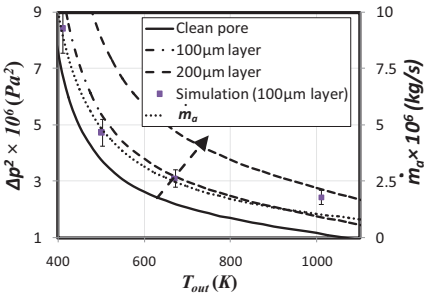

Fig. 5: Computed and eqn. (2) analyzed Δp^2 with clean and partly blocked pores.

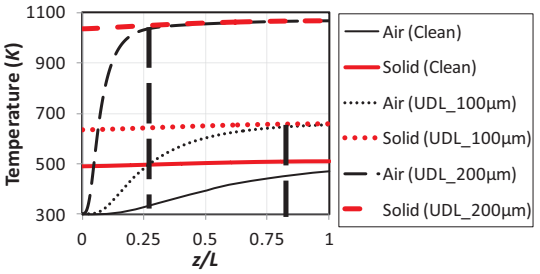
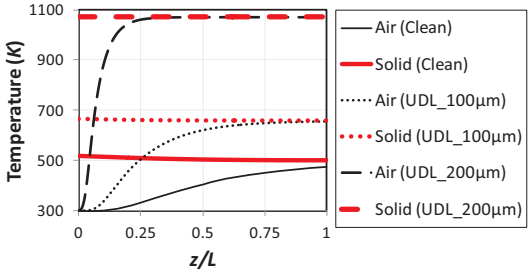
3.2. Effect of dust deposition and heat flux distribution: air and absorber temperature

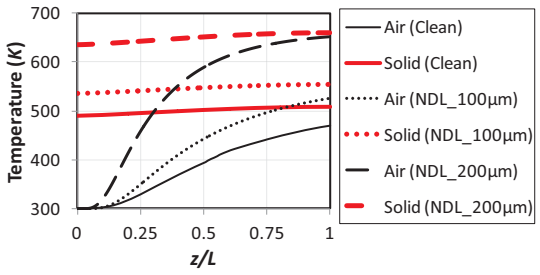
The simulations are performed with the clean and partly blocked absorberpores with an imposed fixed pressure drop across the absorber inlet and outlet (see Fig. 3b). This will allow one-to-one comparison between a clean and a partially blocked pore that are operating under an identical suction. The axial temperature variation of fluid and absorber material is shown in Fig. 6 for the cases with uniform and non-uniform heat flux distributions.



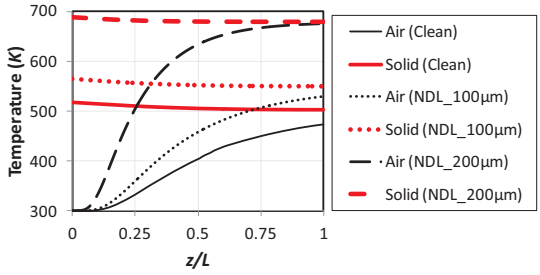
(a) Uniform heat flux(uniform dust layer, UDL)



(b) Non-uniform heat flux(uniform dust layer, UDL)



(c) Uniform heat flux (non-uniform dust layer, NDL)



(d) Non-uniform heat flux (non-uniform dust layer, NDL)

Fig. 6: Axial temperature profile of fluid and solid with uniform and non-uniform dust layer thickness along the absorber pore

With the numerically imposed uniform heat flux along the pore length the desired volumetric heating effect is observed. This is inferred with an increasing solid temperature from the absorber inlet to outlet. Whereas with the employed non-uniform heat flux distribution along the pore length as in eq. (5) the highest absorber temperature is obtained at the inlet. This confirms the non-volumetric heating effect. The partially blocked pore shows a substantial increment in temperature with the applied pressure-drop attributed to the reduced mass flow rate. The temperatures of solid and air increase with the thickness of dust layer as expected. For the uniform dust layer a temperature rise of about 150 K and 580 K is found, which correspond to the thickness of 100 µm and 200 µm, respectively. For the non-uniform thickness of dust layer a temperature rise of about 40 K and 150 K is found, which correspond to 100 µm and 200 µm at the inlet, respectively. This is attributed to the decreasing mass flow rate of air in blocked pore for the applied pressure-drop and is substantiated by a shorter thermal development length (~ 0.05 Re_pPr) in blocked pore compare to its clean counterpart as depicted by the dotted vertical lines in Fig. 6a. Thus, it is concluded that the dust deposition is detrimental to long-term sustainable operation and also increases parasitic losses. Moreover, high surface temperature will lead to an elevated radiation based heat loss, which adds up to the losses. In essence, both the efficiency and durability of an open volumetric air receiver will be a concern in arid deserts.

Fig. 7: Temperature contours for a clean pore and for a partially blocked with uniform dust layer (UDL) thickness of 100 µm and the applied uniform heat flux along the pore length

The numerically analyzed solid and fluid temperature contours for a clean and a partially pore is shown in Fig. 7. The scale is preserved for a better visual comparison. As observed, the contours depict parabolic distribution of fluid temperature and its value increases with the axial position. As explained in Fig. 6a, it is clear that the fluid attains the solid temperature closer to the inlet for the blocked pore case in comparison to that of the clean pore. Thus, it may be inferred that the absorber solid will be exposed to a high temperature over a wider length with the blocked pore in comparison to the clean pore under a given operating condition. Thus, the need of in-situ cleaning is a must for mitigating the failure of such a system in arid deserts.

4 Conclusions

This paper aims at demonstrating the detrimental effect of dust deposition in an absorber pore of an open volumetric air receiver. A validated two-dimensional numerical approach is adopted for this purpose. The analyses reveal the following:

a. The uniform dust deposition may not encourage flow instability in the considered absorber. This is encouraging and allows expecting a stable operation of such a receiver in desert regions.

b. The dust deposition will increase parasitic and radiation based losses that are detrimental to overall efficiency of such a receiver. These can be easily inferred from the reduced pore diameter based Reynolds number and the computed higher temperature with a partially blocked pore in comparison to a clean pore.

c. The dust deposition will lead to an elevated temperature and thus the flow resistance. This will limit the operation of such a receiver in desert regions and confirms the need of an in-situ cleaning device.

Concentrating solar collectors integrated with low CO_2 emissions ultra supercritical power plants

Vittorio Tola, Mario Petrollese, Mario Cascetta and Daniele Cocco

University of Cagliari, Department of Mechanical, Chemical and Material Engineering, Cagliari (Italy)

Abstract

This paper focuses on the evaluation of the potential benefits arising from the integration of concentrating solar systems with coal-based Ultra Supercritical (USC) power plants with post-Combustion CO_2 Capture (PCC). In this study, the USC-PCC plant was integrated with a concentrating solar field with or without a thermal energy storage section. Different collector technologies (parabolic trough and linear Fresnel) and heat transfer fluids (direct steam generation and molten salts) were analyzed and compared. The performance of both solar field and power plant were evaluated by means of specifically developed models, by using data sets of a typical meteorological year for two sites in Italy and Morocco. A preliminary cost analysis was finally carried out.

Keywords: CSP plant, USC, CO_2 capture, parabolic trough, Linear Fresnel

1. Introduction

Worldwide, the Concentrating Solar Power (CSP) plants installed capacity is around 5000 MW, generated using parabolic troughs (83 %), solar towers (13 %), linear Fresnel reflectors (3.4 %) and single dish engines (0.02 %) [1]. Moreover, it is rapidly increasing with about 4000 MW of additional capacity under construction or development. [2]. Nowadays, different technologies and configurations are available for solar field (parabolic trough, linear Fresnel, solar tower and solar dish systems), power block (steam Rankine and ORC, Stirling engines, combined cycles, etc.), heat transfer fluid (thermal oil, molten salts, steam, etc.) and thermal energy storage (TES) systems (active, passive, two-tank, thermocline, etc.) [3,4]. Currently, parabolic trough collectors (PTC) are the most commercially proven technology for the solar field. Linear Fresnel collectors (LFC) are a viable alternative, despite a lower optical efficiency but requiring less land availability and capital costs [5,6]. Thermal oil is usually used as heat transfer fluid (HTF), but the maximum allowable temperature for these fluids is limited to about 400°C. For this reason, one of the main R&D activities in this field aims to overcome this limit by replacing it with Molten Salts (MS) or by using Direct Steam Generation (DSG) solar plants [7,8].

One of the most interesting options is represented by the integration of the solar field with a conventional power plant fed by fossil fuels through hybrid CSP plants [9]. A solar hybrid plant can utilize the existing infrastructure of a conventional power plant, thereby, reducing the investment cost and, consequently, the costs of electricity production. In addition, solar contribution in fossil plants allows to reduce fuel consumption and therefore CO_2 emissions [10]. Hybrid CSP plants can be found in North Africa and Middle East countries, where solar system have been integrated with combined cycles [11,12]. Moreover, with the aim to reduce CO_2 emissions, conventional power plants should require their integration with Carbon Capture and Storage (CCS) systems. In particular, coal-based steam plants require Post-Combustion CO_2 Capture (PCC) processes based on chemical absorption, especially with amine-based solvents, leading to a remarkable net efficiency penalty [13], in the order of 10-11 percentage points for the usual target of most CCS projects (90% CO_2 removal) [14,15]. Since low and medium temperature thermal energy can easily be produced by solar radiation, in recent years, several interesting options for integrating solar energy and CCS technologies have been studied aiming to mitigate the energy penalty generated by the large heat consumption required for solvent regeneration [16]. In particular, two main approaches are proposed: the first is the production of low-pressure steam for the solvent regeneration process (at about 130-140 °C). The advantage of using this approach is that, for a given fossil fuel input, steam production from solar energy reduces the extraction from the low-pressure (LP) turbine increasing its power output. The second

doi:10.18086/swc.2017.04.15 Available at http://proceedings.ises.org

approach is the production of high or intermediate pressure steam for the high-pressure (HP) and intermediate-pressure (IP) turbines. In this case, for a given fossil fuel input, steam production from solar energy raises the mass flow of the steam turbines and therefore increases the overall power output. Obviously, from a thermodynamic point of view, the latter is undoubtedly the preferred approach [17,18], although the best option also depends on climatic conditions and solar collector technology. The integration of solar systems both based on parabolic trough collectors and linear Fresnel collectors with PCC has been studied [18–20], demonstrating that solar integration improves the economic feasibility of CCS, especially for decreasing collector costs and increasing CO_2 emission prices [21,22].

In this framework, the present study evaluates the performance improvements of an Ultra Super Critical (USC) steam power plant with PCC integrated with concentrating solar collectors. USC systems represent the state of the art in the field of coal fired power plants, with conversion efficiencies above 45-46%, more than 5 percentage points greater than those of conventional steam power plants [23]. Firstly, the USC-PCC plant was integrated with a solar field based on LFC or PTC with DSG, without considering a thermal energy storage. Subsequently, the results were compared with those of an USC-PCC plant integrated with PTC using Molten Salts (PTC-MS) as HTF and a two-tank direct TES. The comparative analysis aims to evaluate the increase in USC-PCC energy production and global efficiency due to the solar energy contribution by considering two different locations: Sardinia (Italy) and Morocco. Finally, a preliminary cost analysis was also included, evaluating the levelized cost of energy (LCOE).

2. Configuration and performance of the solar field

As mentioned, a solar field based on parabolic trough (PTC) or linear Fresnel collectors (LFC) is considered in this paper. For both options, PTC and LFC collector line includes several modules connected in series and the different lines of linear collectors are connected in parallel to achieve the required thermal power output. Two different solutions based on direct steam generation or molten salts are compared. Table 1 reports the main geometrical and performance parameters assumed in this study [24].

Table 1 - Main characteristics of solar collectors.

	LFC (DSG)	PTC (DSG)	PTC (MS)
Module length/ width	44.8/16.56 m	100/5 m	100/5 m
Focal length F	7.4 m	1.8 m	1.8 m
Module collecting area A_C	513.6 m^2	470.3 m^2	470.3 m^2
Modules per line	16	8	8
Reference optical efficiency	0.665	0.745	0.745
Cleanliness efficiency	0.98	0.98	0.98
Inlet/outlet steam conditions (p=80bar)	175°C/500°C	175°C/500°C	175°C/500°C
Receiver thermal losses	$0.056\Delta T+2.13E\text{-}4\Delta T^2$ (EVA) $0.013\Delta T+6.251E\text{-}10\Delta T^4$ (SH)	$0.056\Delta T+2.13\ E\text{-}4\Delta T^2$ (EVA) $0.013\Delta T+6.251E\text{-}10\Delta T^4$ (SH)	Forristall model [25]

The performance of PTC and LFC are evaluated on a yearly basis and compared by means of a specifically developed simulation model starting from hourly data of Direct Normal Irradiation (DNI), solar position, air temperature and wind speed. Firstly, the actual thermal power incident into the receiver $\dot{Q}_{INC}$ is calculated according to the following equation:

$$\dot{Q}_{INC} = DNI \cdot A_C \cdot \eta_{OPT,R} \cdot IAM \cdot \eta_{END} \cdot \eta_{SHD} \cdot \eta_{CLN} \quad \text{(eq. 1)}$$

where $\eta_{OPT,R}$ is the reference optical efficiency, IAM the Incidence Angle Modifier, η_{END} the end-loss optical efficiency, η_{SHD} the shadow efficiency and η_{CLN} the surface cleanliness efficiency. Figure 1 shows the two IAM components in function of the longitudinal and transversal components θ_L and θ_T of the solar incidence angle θ. End loss optical efficiency is evaluated in function of collector length, focal height and longitudinal component θ_L. Shadow efficiency is considered only for the PTC cases and is evaluated in function of the distance between module rows and collector width.

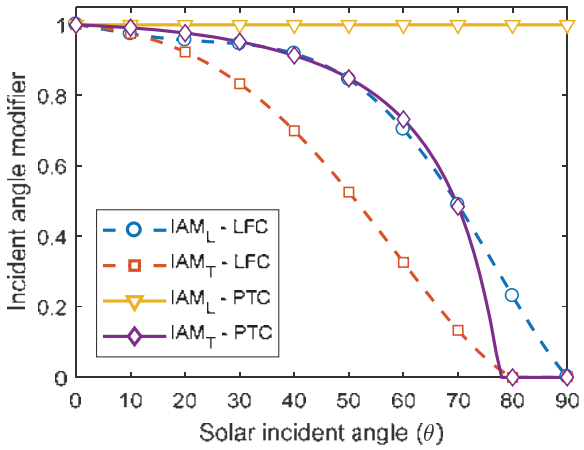

Figure 1 - Longitudinal and transversal IAM components

The thermal power $\dot{Q}_{SF}$ actually transferred to the HTF is calculated by applying the receiver energy balance:

$$m_R \frac{\partial h}{\partial t} + \dot{Q}_{REC,L} - \dot{Q}_{INC} = -\dot{Q}_{SF} = \dot{m}_{HTF}(h_{IN} - h_{OUT}) \quad \text{(eq. 2)}$$

Where the first term considers the thermal capacity of the HTF inside the tube and $\dot{Q}_{REC,L}$ represents the receiver thermal losses evaluated according to the specific correlations reported in Table 1 (ΔT is the temperature difference between the HTF temperature and the ambient temperature). A more detailed description of the simulation model can be found in [26]. Finally, a solar field control is introduced and the mass flow rate $\dot{m}_{HTF}$ is adjusted to meet the design point value of the loop outlet enthalpy. The latter is set to produce steam at 500 °C and 80 bar. For the DSG case, the overall steam production directly feeds the USC plant and the rated steam mass flow rate and the solar field aperture area are determined by setting a desired solar field power output under nominal conditions.

In case of molten salts as HTF, a direct two-tank TES system is considered: one tank stores the hot fluid while the other holds the exhausted cold fluid. The TES system is modelled by considering the mass and energy balance of each tank, as reported in the following equations:

$$\frac{\partial m_{TES}}{\partial t} = \dot{m}_{HTF,IN} - \dot{m}_{HTF,OUT} \quad \text{(eq. 3)}$$

$$m_{TES} \frac{\partial h_{TES}}{\partial t} = \dot{m}_{HTF,IN} h_{HTF,IN} - \dot{m}_{HTF,OUT} h_{TES} - \dot{Q}_{TES,L} \quad \text{(eq. 4)}$$

where m_{TES} is the HTF mass stored in the tank, $\dot{m}_{HTF,IN}$ and $\dot{m}_{HTF,OUT}$ are the inlet and outlet mass flow rate respectively, h_{TES} is the average HTF enthalpy inside the tank, $h_{HTF,IN}$ is the inlet HTF enthalpy and $\dot{Q}_{TES,L}$ are the TES thermal losses due to a not perfect insulation of the tanks. The HTF stored in the hot tank is then used to produce steam in a heat exchanger, simulated by considering a constant pinch point temperature difference (set to 10°C) and by applying a steady-state energy balance:

$$\dot{m}_{HTF}(h_{HTF,IN} - h_{HTF,OUT}) = \dot{m}_S(h_{S,OUT} - h_{S,IN}) \quad \text{(eq. 5)}$$

Where $\dot{m}_S$ is the steam mass flow rate, $h_{S,OUT}$ and $h_{S,IN}$ are the outlet and inlet steam enthalpy respectively. Therefore, thanks to the introduction of a TES system, the PTC-MS configuration slightly differs from the DSG case, as the steam mass flow rate produced is constant and does not depends on the solar energy availability. The thermal storage capacity (C_{TES}) is here expressed in terms of equivalent full-load hour of TES, which indicates the number of hours that the thermal storage section can supply energy to the heat exchanger to produce steam at nominal conditions. Moreover, in order to better exploit the TES storage an increase of solar field aperture area respect to the rated one is often recommended. Solar multiple (SM) is therefore used to represent the actual solar field thermal power as a multiple of the solar field reference thermal power. It is worth noting that the solar

multiple in case of DSG is always equal to one in this study. Two locations characterized by different DNI availability are considered in order to compare the energy performance and the cost-effectiveness of the solar field in different weather conditions. In particular, a site with a high DNI availability (Ouarzazate, Morocco, 2444 kWh/m²y) and one with a lower DNI (Cagliari, Sardinia, Italy, 1720 kWh/m²y) are evaluated. The data set for a typical meteorological year was obtained from the Meteonorm software, including DNI, solar azimuth and elevation, air temperature, relative humidity and wind velocity. Table 2 reports the main meteorological data of the chosen sites and the corresponding design conditions assumed for the solar field.

Table 2 - Meteorological data for the sites of Italy and Morocco and solar field design assumptions.

		Italy	Morocco
Available DNI	kWh/m^{2}y	1720	2444
Average ambient temperature	°C	17.2	18.8
Average wind velocity	m/s	3.96	3.80
Design DNI	W/m^2	800	900
Design elevation/azimuth angles	°	74.2/0.0	82.5/0.0
Design ambient temperature	°C	22.5	30.0

For both sites, Table 3 reports the main performance of a single line in terms of reference thermal power output and reference efficiency, as well as annual thermal energy production and average efficiency (the ratio of annual thermal energy production and annual available DNI), considering both LFC and PTC with DSG and PTC-MS. A decrease of about 9 percentage points in the reference efficiency and 17 percentage points in the average efficiency is observed in the LFC case compared to PTC with DSG. This is mainly due to the lower reference optical efficiency of the linear Fresnel collectors together with the effect of the transversal IAM, which is not present in the parabolic trough collectors. A reduction of about 3 percentage points in the reference efficiency is also detected by using PTC with molten salts instead of DSG, due to the higher HTF average temperature inside the receiver tube and the consequent increase of the receiver thermal losses. A more important decrease is observed in the annual performance due to both the higher receiver thermal losses and the higher thermal inertia of the molten salts. A reduction of 2-3 percentage points from Italy to Morocco cases is finally observed, because of different weather conditions and solar elevation. This difference rises up to 9 percentage points in the PTC-MS case. In fact, this case is characterized by a higher thermal inertia of the molten salts involving in the solar field due to the presence of a TES section. Consequently, a great increase of the energy spent to warm the molten salts in the first morning up to the nominal conditions occurs.

Table 3 - Performance of a single LFC and PTC line.

		LFC		PTC		PTC-MS	
		Ita	Mor	Ita	Mor	Ita	Mor

3. Configuration and performance of the USC plant with PCC

USC power plants are characterized by very hard operating conditions, reaching maximum steam pressures higher than 30 MPa and maximum steam temperatures up to 600-620 °C [27]. In recent years, several R&D studies focused on a further increase of the steam pressure and temperature with the aim of reaching overall plant efficiency as high as 50% [28]. The achievement of higher temperatures and pressures is closely related to the use of suitable advanced materials to withstand the harshest operating conditions [29,30]. A medium size plant (in the order of 450-500 MW_e) has been considered for this study. This size is lower than typical modern USC plant, but better matches with the integration with the solar field. The reference plant configuration is based on a superheated and double reheat steam cycle with ten regenerative steam extractions and four steam turbines: a very high-pressure turbine (VHPT), a high-pressure turbine (HPT), an intermediate pressure turbine (IPT) and a low-pressure turbine (LPT). Figure 2 shows a simplified scheme of the USC power plant.

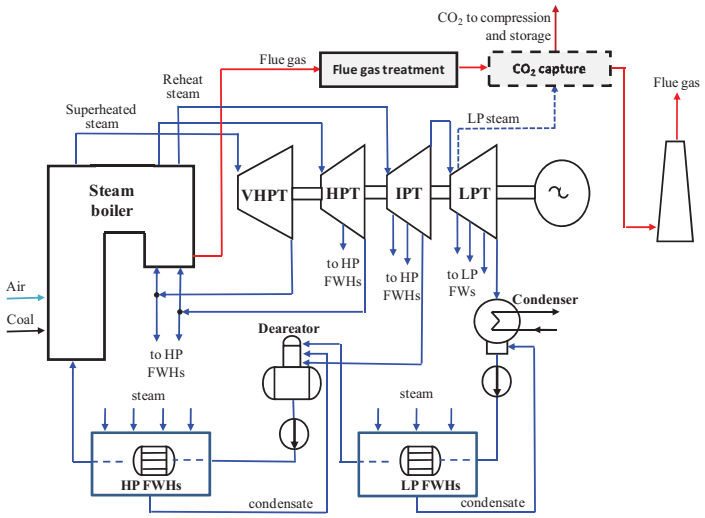

Figure 2 - Simplified scheme of the USC plant.

Performance of the plant have been assessed referring to a commercial coal, characterized by a carbon fraction slightly higher than 0.65 and a lower heating value of 25.03 MJ/kg. A coal power input of 1.0 GW was imposed. The plant is equipped with both a conventional flue gas cleanup (FGC) section (including a selective catalytic reduction denitrification system, baghouse filters and a low temperature flue gas desulphurization system) and a low temperature CO_2 removal section, based on a post-combustion chemical absorption process with amine-based solvents (MEA 30%wt), including an absorption and a regeneration column. To match CO_2 transport and storage requirements, the CO_2 removal section is also integrated with a conditioning and compression section to provide a high pressure (11 MPa) and high purity (99.7% by volume) CO_2 flow.

As in modern USC units, a maximum pressure of 33.5 MPa has been assumed, leading to a superheated (SH) steam pressure at the VHPT inlet of about 30 MPa. A minimum pressure of 4.2 kPa has also been assumed at the condenser. Superheated and reheat (RH) steam temperatures of 600 and 620 °C have been assumed, respectively. High temperature of the steam extraction allows to reduce to -1.5 °C the minimum temperature difference inside the high-pressure feedwater heat exchangers, whereas such a difference increases up to 1.5 °C inside the low-pressure feedwater heat exchangers. A deaerator pressure of 0.8 MPa has been assumed. Table 4 reportes the main characteristics of the plant and Table 5 summarizes its overall performance. The very high pressure of the first steam extraction (slightly lower than 15 MPa) allows to increase water temperature upstream of the economizer above 335 °C. The reference USC plant (without CCS) attains a net power output of about 465 MW with a corresponding net efficiency of 46.64%. The integration with the CO_2 removal section largely reduces the USC performance, mainly due to the large steam extraction (at about 4 bar) for solvent regeneration and to the power required by the CO_2 compression process.

Table 4 - Main characteristics of the USC plant.

Coal chemical power input	MW	1000
SH/RH1/RH2 steam temperatures	°C	600/620/620
SH/RH1/RH2 steam pressures	MPa	30.0/13.5/5.4
Cycle maximum pressure (boiler feedwater pump)	MPa	33.5
Cycle minimum pressure (condenser)	kPa	4.2
Deaerator pressure	MPa	0.8
BOP loss as steam turbine power fraction		0.02
High/low pressure heat exchangers minimum ΔT	°C	-1.5/1.5
MEA mass fraction	%	30
CO_2/MEA molar ratio		0.28
Reboiler specific thermal energy	MJ/kg_{CO2}	3.72

Table 5 - Overall performance of the USC plant.

		NO-CCS	CCS
Coal chemical power input	MW	1000	1000
- Steam turbines	MW	516.4	439.7
- Pumps	MW	16.1	16.1
Steam cycle output	MW	500.0	423.6
- Aux. absorptions and mechanical losses	MW	19.4	16.1
- Generator losses	MW	5.2	4.4
Gross power output	MW	475.4	403.1
- FGC section absorptions	MW	9.0	9.0
- CO_2 capture and compression	MPa	-	32.4
Net power output		466.4	361.7
Net efficiency		46.64	36.17
Plant availability	h/year	8760	8760
Energy production	GWh/year	4085.6	3168.5
CO_2 emissions	Mt/year	3.00	0.300
CO_2 specific emissions	g/kWh	734.3	94.7

In particular, a CO_2 removal efficiency of 90% requires about 320 MW_t, halving the LPT mass flow and reducing the USC power output by about 70 MW. This remarkable penalty combined with the power requirements of the CO_2 capture and compression section causes a noteworthy power output reduction of about 105 MW. Overall, the introduction of the PCC process reduces the energy production by about 25% and the USC efficiency by about 10.5 percentage points (from 46.6% to 36.2%). Obviously, the CO_2 specific emissions greatly benefit from the introduction of the CO_2 capture and compression section (decreasing from about 735 to about 95 g/kWh).

4. Performance of the integrated CSP-USC-PCC plant

To mitigate the energy penalty generated by the large heat consumption required for solvent regeneration, the USC-PCC plant has been integrated with concentrating solar collectors in a CSP-USC-PCC plant. The hybridization occurs through the production of intermediate pressure steam (80 bar and 500°C). The water is extracted downstream of the feedwater pump, it is pre-heated, vaporized and superheated in the solar field and then reintroduced downstream of the high-pressure turbine before entering in the second reheater. In particular, when solar energy is available, the IP steam produced by the solar field increases the mass flow rate of both IP and LP steam turbines allowing a greater power production but leading also to an off-design operation mode of the USC plant with a corresponding efficiency penalty. Moreover, the steam production from solar field causes both an increase of the LP turbine outlet pressure and a rise in the condenser thermal load, therefore, leading to a higher cooling water requirement or higher cooling water outlet temperature. Figure 3(a) shows the pressure and the condenser mass flow rate (the latter in percentage with respect to design conditions) in function of the ratio between solar field power output ($\dot{Q}_{SF}$) and fuel power input ($\dot{Q}_{USC}$). The condenser mass flow greatly increases with solar contribution and, therefore, in order to avoid an excessive increase in the condenser thermal load, a maximum value of the power ratio equal to 0.2 was considered in this study. The increase in steam pressure and mass flow leads to corresponding changes in the turbine power output owing to the sliding pressure operating mode of the steam turbine. Obviously, the USC-PCC-CSP net power output increases with the solar contribution and annual average performance of the power plant are greatly influenced by annual DNI availability. However, the USC power plant operates without solar energy integration for a large share of the annual operating hours, as concentrating solar collectors require a minimum available DNI (100-150 W/m^2). Moreover, during most of the solar field operating hours, the DNI is below its design value. Therefore, in the case of direct steam generation, the USC plant operates at reference conditions when no solar production occurs, while it operates in off-design conditions with the introduction of IP steam from solar field, with a corresponding cycle efficiency penalization. On the other hand, the use of molten salts as heat transfer fluid allows the introduction of a thermal storage at relative low costs. In this case, the steam production from the solar field is constant along the day with an important increase of the operating hours at on-design conditions.

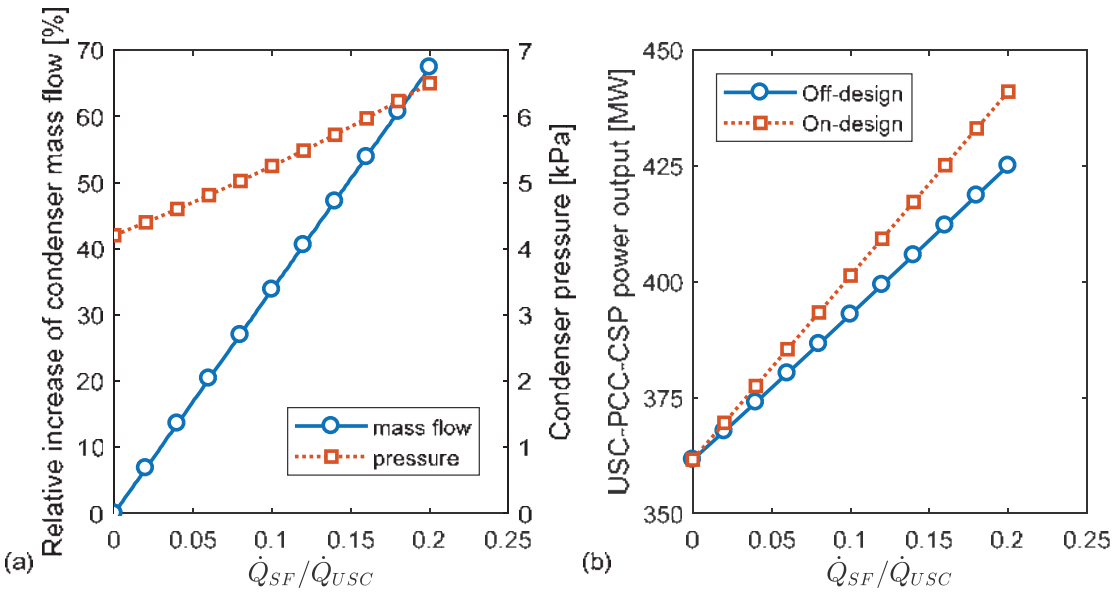

Figure 3 – (a) Relative increase of the condenser mass flow, condenser pressure and (b) power output of the USC-CCS-CSP plan as a function of the ratio between solar field power output and fuel power input.

The advantages in terms of efficiency and, thus, of net power output by working at on-design conditions instead of off-design is shown in Figure 3(b) as a function of the ratio between solar field power output and fuel power input. Figure 4(a) shows the annual performance of the system in terms of USC net energy production as a function of the ratio between the solar field power output and fuel power input in case of direct steam generation or molten salts as HTF (storage capacity equal to 4 hours and solar multiple equal to 1). The USC net energy production linearly increases with the solar contribution for all cases, and, as expected, the highest values are reached by adopting parabolic trough collectors. By referring to the Morocco case, an increase of 0.715 GWh in annual USC energy production for an increase of 1 MW of solar field reference thermal power is detected for PTC with DSG, 0.840 GWh/MW_{CSP} for the PTC-MS case and 0.590 GWh/MW_{CSP} for LFC solar field. Similar trends are observed by referring to the Italian site, although the lower DNI availability results in a lower solar contribution of 0.550 GWh/MW_{CSP}, 0.545 GWh/MW_{CSP} and 0.450 GWh/MW_{CSP} for the PTC-DSG, PTC-MS and LFC configurations, respectively. It is worth noting that for a given value of solar contribution, the overall collecting area increases by using LFCs instead of PTCs and by considering an Italian location instead of a Moroccan one.

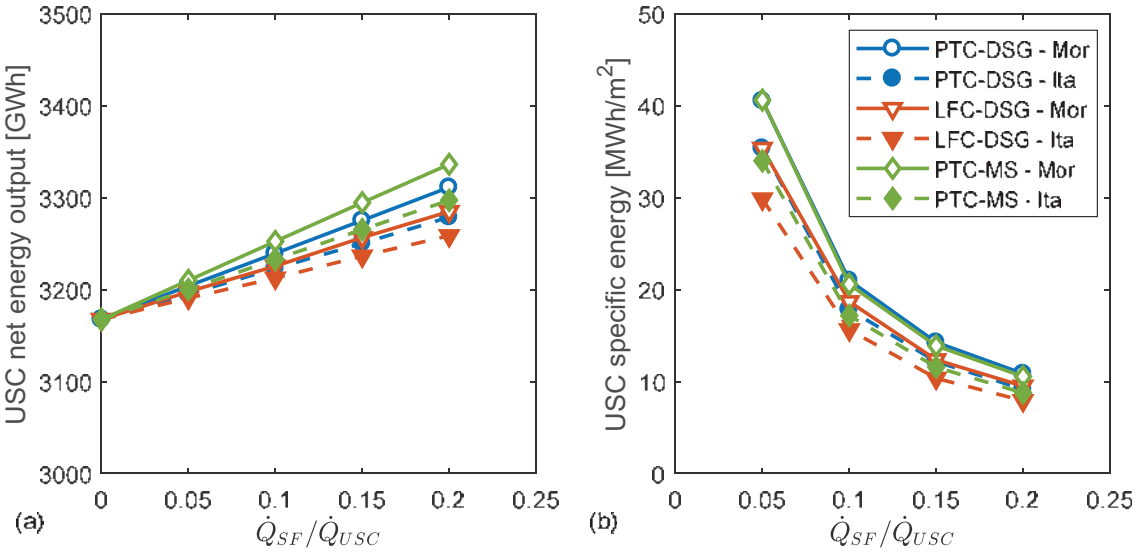

Figure 4 – (a) Annual USC-PCC-CSP energy production and (b) specific energy production as a function of the ratio between solar field power output and fuel power input.

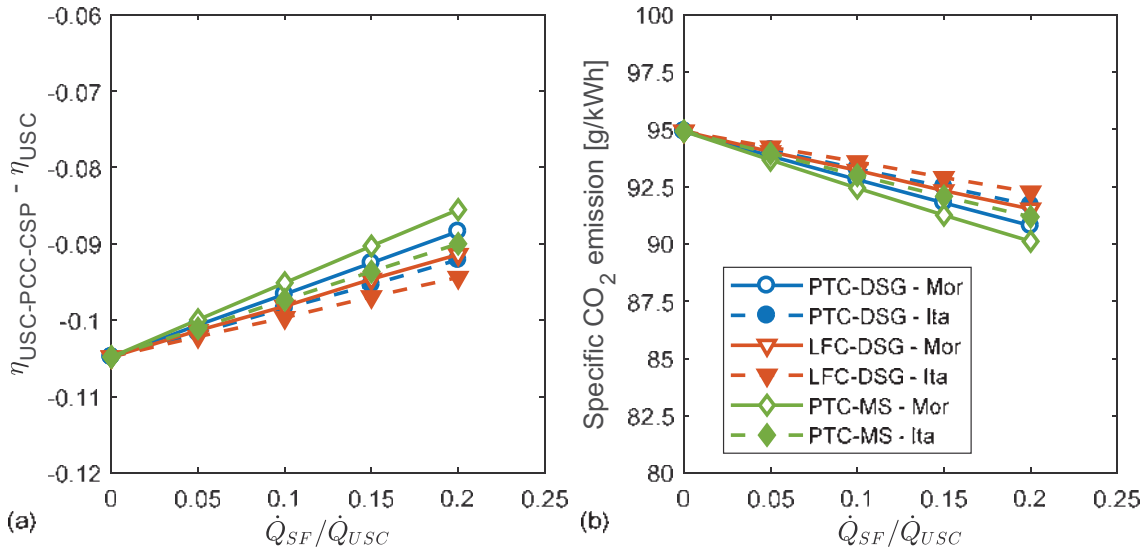

Figure 5 – (a) USC efficiency decrement and (b) specific CO_2 emissions as a function of the ratio between solar field power output and fuel power input.

For instance, for a solar contribution equal to 0.2, the overall collecting areas are about 304750 m^2 (81 loops) and 357430 m^2 (95 loops) for PTC in Morocco and Italy respectively, while the LFC solar field is characterized by a collecting area of 345140 m^2 (43 loops) in Morocco and 410880 m^2 (50 loops) in Italy. For this reason, Figure 4(b) depicts the specific annual energy production in terms of energy produced per unit area of solar field. The figure shows a marginal difference between the use of DSG and molten salts by referring to the Moroccan case. In fact, although as reported in Table 3 the average efficiency of the solar field using molten salts was lower than the use of PTC-DSG, they are substantially balanced by the higher USC efficiency resulting from the constant steam mass flow rate production of the solar field. On the other hand, the drop in solar field performance detected for the Italian case by using molten salts as HTF is predominant and the use of the PTC-DSG achieves the highest specific energy production. The main benefits arising from a solar integration are shown in Figure 5:

- the efficiency penalty due to the CO_2 removal section are partially balanced by the steam generation from the solar field (Figure 5(a));
- a further reduction of the specific CO_2 emissions is achieved thanks to the increase of annual energy production due to solar field without any further production of carbon dioxide (Figure 5(b)).

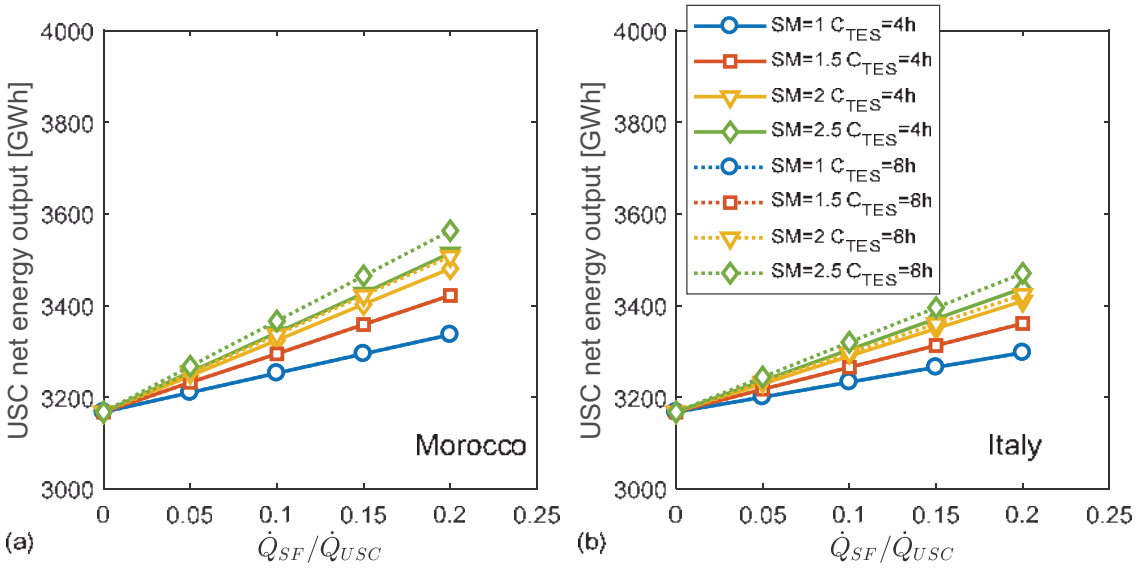

Figure 6 - Annual USC-PCC-CSP energy production as a function of the ratio between solar field power output and fuel power input for the Molten Salts case.

Both these performance indexes follow a linear increment with the increase in the solar field power output.
As mentioned, one of the advantages of introducing a TES system is the possibility to time shift the production of the solar field. In other words, with a TES system it is possible to increase the time of steam feeding to the USC by keeping a constant mass flow rate. As mentioned, other two important design parameters for the molten salts case are the storage capacity and the solar multiple. Figure 6 shows the annual energy production of the USC plant as a function of the solar contribution for different combinations of solar multiple and TES capacity. For solar multiples lower than 2, a TES capacity higher than 4 full-load hours do not introduced any benefits in terms of rising in energy production, independently form the plant location. On the other hand, with the rise in the solar multiple value, a higher storage capacity is required to store the surplus of energy produced by the solar field, especially during summer days. In particular, the increase of the TES capacity from 4 to 8 hours in Morocco results in an increase of about 15% of the annual steam production.

5. Preliminary economic analysis

A preliminary economic analysis was carried out to compare the energy production cost of the reference USC plant (with and without PCC) and the solar assisted configurations. In fact, the increment in the energy production with the solar integration also results in a rise of capital and operating costs. The economic analysis is based on the determination of the levelized cost of electricity (LCOE) for the various configurations considered. The LCOE was calculated by means of the following equation:

$$\mathrm{LCOE} = \frac{\mathrm{TCI_{USC}} + \mathrm{TCI_{PCC}} + \mathrm{TCI_{CSP}} + \sum_{n=1}^{N}\left(\mathrm{C_F} + \mathrm{C_{O\&M,USC}} + \mathrm{C_{O\&M,CSP}}\right)(1+\mathrm{i})^{-n}}{\sum_{n=1}^{N}\mathrm{E_E}(1+\mathrm{i})^{-n}} \qquad \text{(eq. 6)}$$

Where $\mathrm{TCI_{USC}}$, $\mathrm{TCI_{PCC}}$ and $\mathrm{TCI_{CSP}}$ are the total capital cost investment of the USC plant, PCC system and the CSP section (including solar field costs and, if present, TES costs) respectively, $\mathrm{C_F}$ is the annual cost of the fuel, $\mathrm{C_{O\&M,USC}}$ and $\mathrm{C_{O\&M,CSP}}$ are the operating and maintenance costs for the USC-PCC plant and solar section, $\mathrm{E_E}$ is the annual energy production, i is the annual interest rate and N is the expected operating lifetime.

Table 6 - Cost assumptions of the USC-PCC plant, solar field and TES section.

USC specific capital investment	1300 €/kW	Solar field specific cost	100-300 €/m^2
PCC specific capital investment	1170 €/kW	Piping specific cost	30 €/m^2
O&M cost of USC (% of TCI)	3%	Land cost	10 €/m^2
O&M cost of PCC (% of TCI)	2.5%	TES specific cost (only MS case)	625 €/m^3
Coal price	75 €/t	Molten salts cost	0.93 €/kg
Engineering cost (% of direct cost)	20%	O&M cost of solar section (% of TCI)	1.5%
Contingency cost (% of direct cost)	2%	Annual interest rate	7%
Insurance annual cost (% of TCI)	1%	Operating lifetime	20

Table 6 reports the main cost assumptions. In particular, the assumption of specific costs for the USC-PCC plant are taken according to [15], and for the CSP plant according to [31]. The solar field specific cost is not constant but ranges in the interval 100-300 €/m^2. In fact, the present economic analysis aims to evaluate the minimum capital cost of the solar field that allows to produce electricity at a lower LCOE than the reference USC-PCC plant. For a solar integration of 20% (that is the ratio between solar field power output and fuel power input equal to 0.2), Figure 7(a) shows the LCOE for the six different cases analyzed as a function of the solar field specific cost, as well as the LCOE obtained without considering any solar integration. Obviously, a linear increase of the LCOE is observed with the increase of the solar field specific costs. The LFC case always attains higher values of LCOE than PTC and a decrease of the solar field cost of about 60 €/m^2 should occurs to becomes competitive with PTC solar fields. The LCOE with solar integration in the Italian case always exceeds the LCOE of the USC-PCC plant even for the lowest solar field specific costs. On the other hand, the solar integration becomes cost effective for a solar field cost lower than 180 €/m^2 for the PTC-DSG case. The use of molten salts and the introduction of a TES section, despite the enhancement in annual energy production, increase the capital and operating costs and result less profitable than the direct steam generation.

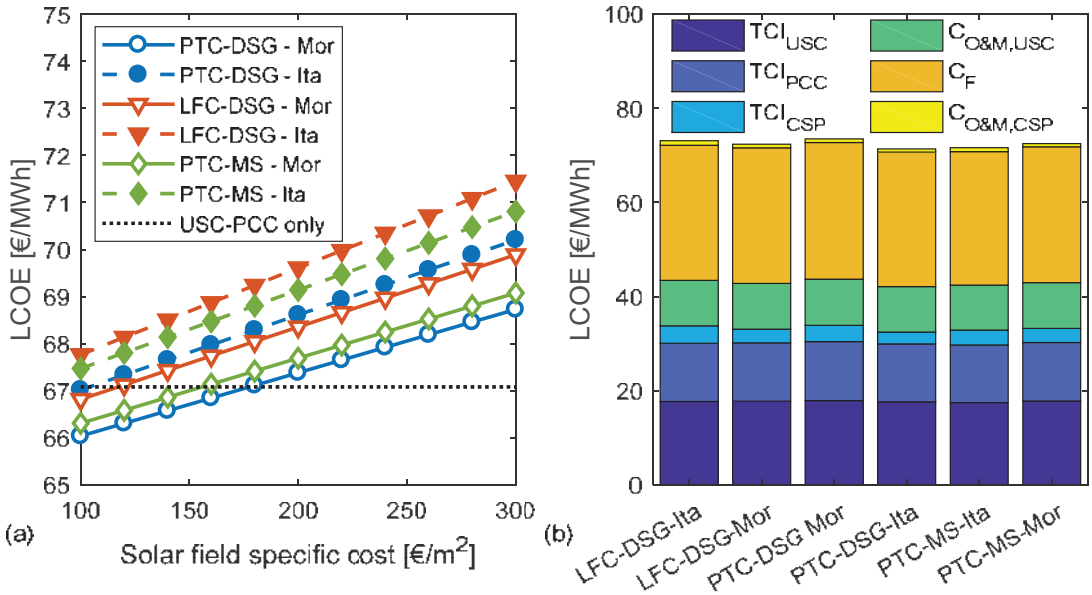

Figure 7 – (a) Levelized cost of electricity as function of the solar field specific cost and (b) influence of capital and operating costs on the determination of the LCOE.

It is worth noting that the influence of the solar field costs on the overall plant costs is marginal. As shown in Figure 7(b), by assuming a solar field specific cost of 200 €/m^2, the capital cost for solar integration contributes for about 5% of the overall LCOE while O&M costs of the solar section are lower than 1%. Finally, Figure 8 shows the levelized cost of energy in case of molten salts as HTF and different values of solar multiple and TES capacity. The figure demonstrates the not profitability to increase the storage capacity beyond 8 hours independently from the location, as the excess energy that cannot be stored due to the complete charge of the TES section is minimal (only for few summer days in case of C_{TES}=4h). Consequently, the rise in capital costs due to higher storage and HTF costs is not properly balanced by the increase in the energy production. On the other hand, an increment of the solar multiple to 1.5 could be a cost-effective solution if the solar field specific cost drops to 160 €/m^2 in the Morocco case. In this case, the benefits arising from a higher energy production becomes preponderant compared to the corresponding increment of the solar field capital costs.

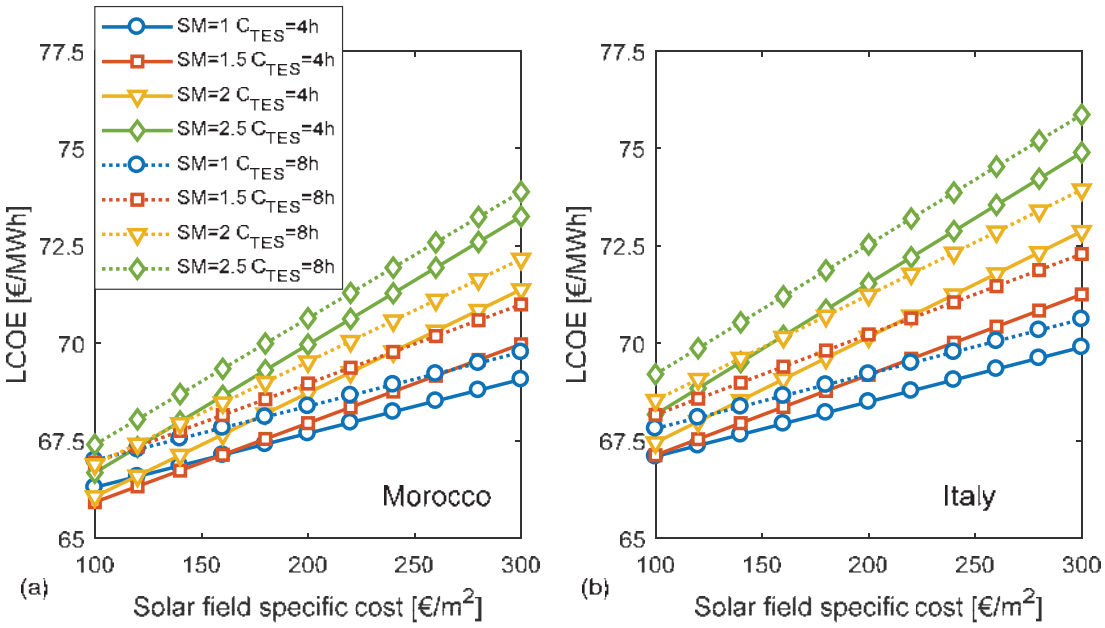

Figure 8 – Levelized cost of energy as function of solar field specific cost using molten salts in case of (a) Moroccan site and (b) Italian site.

6. Conclusions

The paper investigated the benefits arising from the integration of low CO_2 emission steam power plants with concentrating solar systems. Different solar field configurations were studied, varying both collector technology (parabolic trough or linear Fresnel) and heat transfer fluid (direct steam generation or molten salt with thermal energy storage). The achieved results proved that the energy produced by the solar field reduces the efficiency penalty due to CO_2 capture and compression system from about 10.5 percentage point (reference case without solar integration) to a maximum of about 8.5% (ratio between solar energy and fuel chemical energy equal to 0.2). As expected, better performance are achieved in Morocco in comparison to Italian site. The preliminary economic analysis demonstrated as, in Morocco, the solar integration in a USC-PCC plant becomes cost effective for a solar field costs lower than 180 €/m^2 for PTC-DSG case. A reduction of about 60 €/m^2 in solar field cost should occurs for LFC to becomes competitive with PTC solar fields. The use of Molten salts as HTF and the introduction of a TES section enhance the annual energy production but increase the capital and operating costs, resulting less profitable than the direct steam generation.

Daylighting

Calculation of energy performance indices of daylight linked control systems by monitored data

Marco Beccali[1], Marina Bonomolo[1], Valerio Lo Brano[1] and Gaetano Zizzo[1]
[1]Università degli Studi di Palermo, Dipartimento Energia, Ingegneria dell'Informazione e Modelli Matematici, Palermo (Italy)

Abstract

The actual performances of Building Automation systems are often lower than the ideal ones. In order to investigate the actual performance of a Building Automation system for lighting control, a large stock of collected data, including indoor illuminance and absorbed electric power, have been presented and analysed in this paper. The measures have been taken during one year, in a laboratory located at the University of Palermo, where different lighting control systems, produced by two different manufacture companies, have been installed. As demonstrated in literature, many factors affecting energy savings' evaluation in lighting control systems are the position and the typology of the sensors and their configuration. Furthermore, using the collected data, a set of indices has been calculated. It is able to test the performance of the systems in terms of energy efficiency and fulfilment of visual comfort tasks, according to different natural light availability, lighting system configurations and time scenarios. Finally, the performances of the two above lighting control systems have been compared.

Keywords: Daylight control system, Building automation system, lighting, indices, daylight.

1. Introduction

The benefits of Building Automation and Control (BAC) systems are well-known and, for this reason, their application in both residential and commercial buildings and become very common. In several studies, potential energy savings due to BAC systems have been assessed (Ferrari and Beccali, 2017) and calculated by conventional methods sometimes suggested by technical standards, or by using simulation software. Parise and Martirano (Parise and Martirano, 2009) proposed a methodology to calculate energy consumption for lighting systems and the impact of the BAC systems promoting a comprehensive eco-design. In particular, the method mentioned above allows to satisfy in selected subareas lighting and energy performances and to provide design elements with a basic efficient control system suitable for a manual or automatic regulation. Asif ul Haq et al. (2014, a) developed a new method that is easy to apply but comprehensive at the same time and gives a good indication as to the potential of energy saving from daylight utilization. They gave a detailed description for applying it based on a simulated test project as an example. The same authors (Asif ul Haq et al., 2014, b) investigated the various control system types, the development of their associated technologies, the savings obtained from their application and the factors affecting their performance. They also presented a complete literature review, which demonstrated that lighting control systems can ensure important energy savings and reduction in electricity costs. Other researchers are beginning to study

doi:10.18086/swc.2017.05.01 Available at http://proceedings.ises.org

also the problem of an accurate and reliable calculation of these figures. Bellia et al. (2015) investigated the factors that influence the performance of Daylight-linked controls (DLCs) and did a review of the several aspects that must be considered during the design, installation, configuration and operating steps. P. Valíček, et al. (2015) explained the complexity in setting the system due to the usual different position of the task surface and the sensor commanding the system' operation. Chen et al. (2016) carried out a cost-benefit evaluation method for building intelligent systems underlining that the problems, like sensor faults and control strategy flaws, may result in low performance and that high energy consumptions and maintenance costs are needed as well. Doulas et al. (2014) presented a decision-making method capable of estimating the best position of a photosensor on the ceiling and its proper field of view (FOV) based on multiple criteria analysis, using three criteria:

- the correlation of the lighting levels between the working plane and the ceiling;
- the corresponding energy savings and the lighting adequacy (defined as the percentage of occupied time with total illuminance exceeding design illuminance)
- the influence of the control algorithm.

Their work is based on a high number of simulations with variable FOV and position of photosensors, performed to clarify the calculation procedure of the proposed methodology and on the measurement taken from a prototype photosensor with variable FOV through the use of a telescopic cylinder.

In general, since there are no standard rules among manufacturers of BAC systems, a trial-and-error method is often used by the contractors to obtain reliable dimming response. Moreover, commercial BACs, installed in residential or small offices to manage several functions of home services, often include functions of lighting control, acting as DLCSs. Their hardware and software configurations, as well as inaccurate commissioning, could not always allow reaching the desired tasks correctly; therefore, the systems could not work as expected. This lack of metric tools and methods, mainly regarding the assessment of the actual performances of such DLCs, is the object of the present research which presents an application and an extension of an original method carried out by the authors and presented by Bonomolo et al. (2017).

2. Objectives

The method is based on the calculation of a set of indices and has been developed for the assessment of the energy performance of DLC systems, starting from monitored data and aiming to consider both the influence of systems characteristics and the daylight availability in the room. In particular, the index named Over illuminance Avoidance Ratio (OAR) takes into account the excess of light that could be caused by the position of the detector. On the contrary, the index named Under illuminance Avoidance Ratio (UAR) takes into account the defect of light. The Artificial Lighting Demand (ALD) index is defined to evaluate the rate of lack of natural lighting and, therefore, the rate of required artificial lighting to achieve appropriate illuminance values on the working plan. Finally, the Energy Ratio of Illuminance (ERI) index, being the ratio of the electrical consumption for lighting and the ALD as mentioned above, is used to assess how close the performance

of the real DLC system is to the one of an ideal system.

In this paper, the application of the above-described method is presented using a broader set of data, collected during about a one-year-long period and relative to two DLC systems. The original contributions of the present work are: to further validate the method with reliable experimental data, to use the here described indices to make functional and energy performance comparisons between alternative DLCs that could be utilised in the same room even if these have been tested in different time.

3. Lighting system and daylight control systems

The measurement campaign has been carried out at the Solarlab laboratory (Figure 1), located at the third floor of the building hosting the DEIM (Department of Energy, Engineering of the information and Mathematical Models) of the University of Palermo (Italy) and described in detail in a previous work presented by Beccali et al. (2015). The laboratory has been equipped by a measurement instrumentation set. For measuring the indoor illuminance six indoor probes Delta Ohm HD 2021T (measuring range 0.02-20 klx) have been utilized. Two of them have been placed on two different points of the ceiling, two on opposite walls and, finally, two at the height of 0,80 m or 0,6. Furthermore, in order to measure apparent, active and reactive power, current and voltage a SIEMENS SENTRON Power Monitoring Device PAC3200 (Siemens, 2009) has been used. Data have been collected through the platform LabVIEW System Design.

Fig. 1: Some pictures of the laboratory, of the sensors used to measure indoor illuminance and the section with their location.

In order to test the DLC systems, four suspended luminaires equipped with LED (each one with a power of 54 W) have been installed. They are characterized by a power supply unit with DALI interface and are equipped with micro-lens optics in a polycarbonate cover. The nominal luminous is 3600 lm, and the initial LED luminaire efficacy is 92 lm/W. Also, four mono optic LED luminaires have been installed, with an initial luminous flux of 700 lm and with an efficacy of 50 lm/W. Both types of luminaires have a colour temperature of 3000 K and a colour rendering index ≥80. The lighting power density is 1.86 W/m^2 for the whole area and 2.9 W/m^2 for the zone considered in this work (where the three dimmable suspended luminaires are installed). Two different daylight linked control systems, produced by two manufacturers have been tested. The first one ("System A"), has been installed, in a first period, on the ceiling at about 1.60 m away from the window, close to one of the two photosensors Delta Ohm installed on the ceiling utilised for the measurements. This latter is characterized by an angle view of 180° longitudinally and 360° horizontally and, as in most lighting control systems, its positioning was not

optimized with a precise method but was installed simply following the manufacturer's suggestions. It is designed for being easily usable by anyone, also by not skilled personnel; indeed, its interface is very user-friendly. It was composed by a closed loop photosensor, a scenario programmer, a touch dimmer, three manual actuators and four basic controls (current switches). The second system ("System B") is equipped with a look-out open loop photosensor. It has been installed on the ceiling, following the installation handbook guidelines. This photosensor has been linked to a DALI electronic control ballast which send the signal to the luminaires. Figure 2 shows the pictures of the two photosensors.

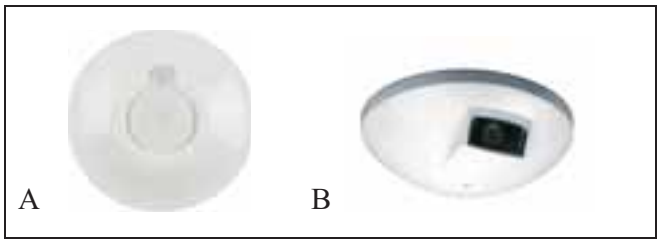

Fig. 2: Pictures of the closed loop sensor (A) and the open loop sensor (B).

In the first case, a target illuminance value can be set on the software menu after a "rapid" calibration of the photosensor, which is made with a remote-control device. After the measurement of the desired lighting level on the task area with a lux meter, the device sends a "calibration" command to the photosensor. This procedure has been made once with only artificial light and once with only daylight (without direct solar irradiance). It was the only option allowed by the software and naturally led to an approximate calibration of the system. Generally, it can be observed that with only artificial light or with diffuse daylight, a particular correlation between illuminance measured on the ceiling and on the work-plane is reliable only in case of low daylight levels (Bonomolo et al., 2017). The calibration of the second system has been shorter and more straightforward. It is based on the "memorizing" of "twilight points" (dimming the lamps to have task illuminance in the absence of daylight) and "daytime points" (dimming the lamps to have task illuminance in the presence of daylight). An accurate performance assessment of lighting and energy figures of a DLC system can be fulfilled by handling separate sets of natural and artificial illuminance data which together are present in the target area. This problem is easily solved in case of use of simulation software, which can separately calculate both the series. When data come from a real monitored space, a photosensor is no longer able to split the two contributions to the total illuminance. Moreover, provided that only an "ideal" system is able to ensure a constant illuminance setpoint over time, the actual contribution of artificial light becomes variable over the time. In assessing the artificial lighting contribution, it is possible to assume that the luminous flux is proportional to the power absorbed by the lighting system. The amount of artificial light has been calculated by applying a W/lx factor derived from measures made during the night-time. Natural lighting contribution has been estimated as the difference between the measured total illuminance and the calculated artificial illuminance.

4. Scenarios and configurations

During the measurement campaign, an office end-use has been tested. According to these case, as already said, several scheduled occupancy times, task level on the work-plane,

configurations and setup have been checked for each system. For the first part of the study, the installed luminaires have been controlled by the system A. In the last part, the System B has been tested. The electricity consumption has been calculated for two different control strategies: dimming and on-off. For the first case, consumption has been estimated merely using the measured power. In the second case, the energy consumption has been calculated assuming that the luminaires turn on when the illuminance value, due to the daylight contribution, is lower than the set-point value. Therefore, it has been taken into account the same time when the luminaires were turned on during the dimming case, but considering the absorbed power always at 100%. All the illuminance values have been calculated using the average of the measures taken by two pairs of photosensors (two in the ceiling and two on the work-plane). They have been placed in the task area where a good uniformity is observed. In total, 47 scenarios have been considered: 26 "office" scenarios with the system A and 21 with the system B. The illuminance target value has been set to around 500 lx on the work-plane at the height of 0.85 m.

5. The performance indices

The set of indices that are utilized to analyse and compare the DLC systems has been previously presented and commented in detail in another work (Bonomolo et al., 2017). Here, a brief description of them is provided. The first index is the Artificial Light Demand (ALD) (Eq. (1)) which is defined as the sum, during the operation time, of the differences between the illuminance target value on task area (E_{set}) and illuminance due to available natural light (E_{nat}), when this one is lower than the setpoint itself, times the hours:

$$ALD = \Sigma_{operation\ time} (E_{set} - E_{nat}) \times \Delta t \qquad \text{if} \quad E_{nat} < E_{set} \qquad \text{(eq. 1)}$$

This definition ensures that ALD changes according to the sky conditions for a given setpoint and a given period (for instance a day). Figure 3 shows this concept for two different days.

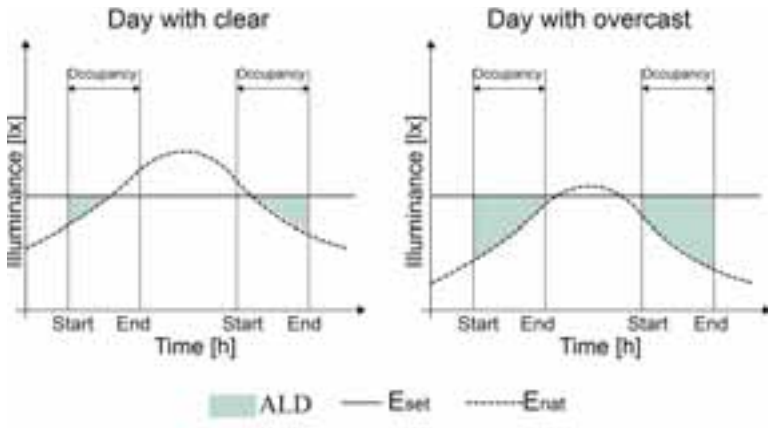

Fig. 3. Graphic scheme of ALD for two different days.

A normalization of energy consumption concerning the actual artificial light demand (ALD) is useful in comparing a DLCs operation with different hardware-software configurations (e.g. photosensors position) and calibration (Doulos et al., 2017). Moreover, it would be possible to make a comparison between different lighting systems. They would consume different amounts of energy according to their lighting efficiency and ability to

control the illuminance on the task area over time also according to the measured ALD. In this way, the second adopted index is the Energy Ratio of Illuminance (ERI) (Eq. (2)) as the ratio between the electricity consumption (ELEC measured in Wh) and ALD (lx·h) as follows:

$$ERI = \frac{ELEC}{ALD} \quad \left[\frac{Wh}{lx \cdot h}\right] \qquad \text{(eq. 2)}$$

If we look at an ideal system, the consumption due to lamps operation will be strictly proportional to the ALD by a factor k (Wh/lx·h) that can be intended to be a characteristic of the observed system and also a target value for the ERI of a real system. Indeed, in a real system, measured consumption could result in higher (or lower) than k·ALD and ERI will have a different result from k. In the tested systems the k value is 0.246 Wh/lx·h.
Anyway, it must be noted that when a system is not able to fulfil over the operation time the minimum E_{set} value (under-illuminated space), its electricity consumption is not related to the expected operating conditions and its low value is not reached thanks to its energy efficiency. At the same time, it is necessary to consider energy waste due to the quantity of "excess" of illuminance, which is highlighted by higher ERI values.
Two more indices can also account for values and times when the system provides an "excess" or a "deficiency" of illuminance for a given target value of illuminance on the task plane.

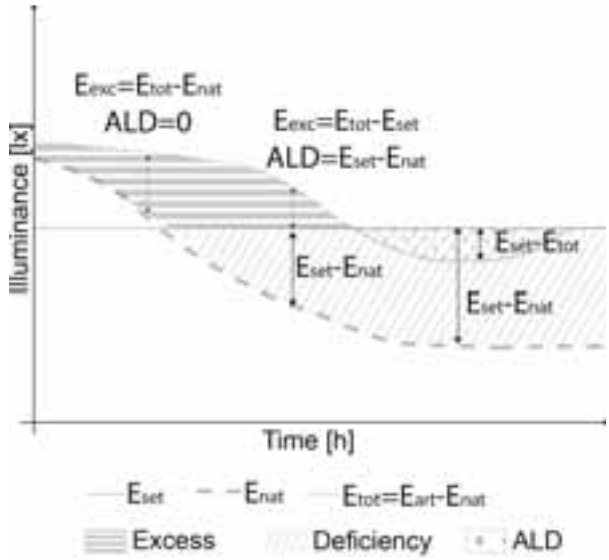

Fig. 4: Graphic scheme of the excess or the deficiency of illuminance compared to the illuminance target value on work-plane.

The index named OAR (Over illuminance Avoidance Ratio) is defined as the ratio, evaluated for an observed time period, between the minimum requirement of artificial light (ALD) and the sum of it plus the artificial light eventually provided in excess (E_{exc}).

$$OAR = \frac{ALD}{\sum_{t\,operation} E_{excess} \cdot \Delta t + ALD} = \frac{ALD}{\sum_{t\,operation} (E_{tot} - E_{nat})^{*} \cdot \Delta t} \qquad *\,\text{only if}\,(E_{tot} > E_{set}) \qquad \text{(eq. 3)}$$

where E_{tot} is the total illuminance due to the contributions of natural and artificial light.

Therefore, for a settled ALD, the higher the over-lighting (low values of OAR), the lower the capability of the system to fulfil the maintenance of the illuminance target value on

task area and thus the higher the related energy consumption.

If we want to account the "deficiency" of light, a UAR (Under-illuminance Avoidance Ratio) (Eq. (4)) index can be calculated. It can be defined as follows:

$$UAR = 1 - \frac{\sum_{t\ operation} (E_{set} - E_{tot}) \cdot \Delta t}{ALD} \qquad \text{(eq. 4)}$$

So, when a system does not cause much "under-lighting", E_{tot} is most of the time close to E_{set} and UAR will be close to 1. At the same time the closer E_{tot} to E_{nat} (when $E_{nat} < E_{set}$), the closer UAR to 0 which indicates the system has provided an insufficient contribution of artificial light..

As a result of previous considerations, to give a complete response to the performance of an observed system during the monitoring exercise, ERI, UAR and OAR indices must be considered together.–The scheme in Figure 5 shows how several combinations of the indices values can be interpreted as a system diagnosis checklist.

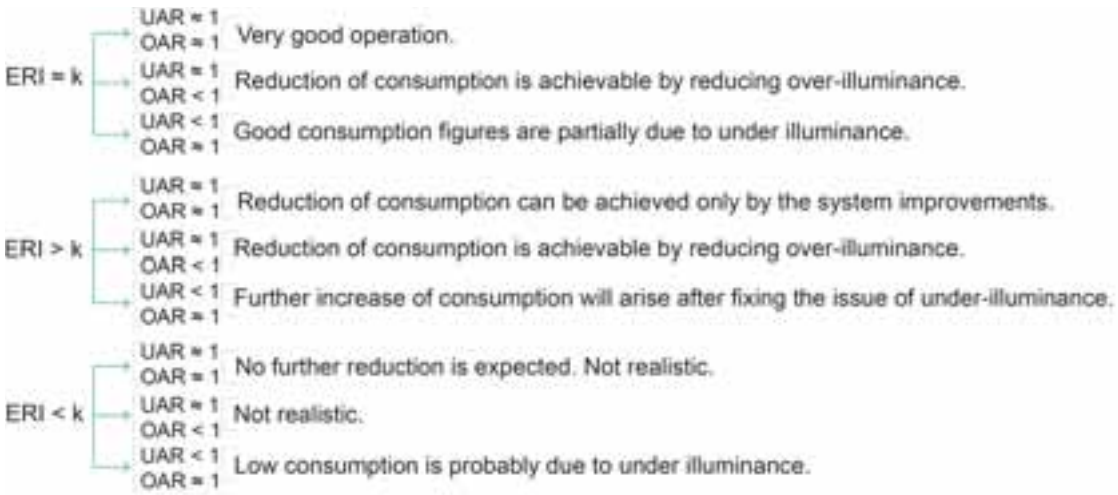

Fig. 5: Possible combinations of ERI, UAR, OAR and their meaning (Bonomolo et al. 2017).

For example, a system operating with an ERI close to the k value could have further improvement in its performance by avoiding a period of over illuminance (if the OAR resulted < 1). On the other side, if the measured UAR was <1 there is some "false" expectation of energy saving due to the occurrence of some under illuminance period.

6. Result and discussion/Data analysis

Two monitoring campaigns have been conducted from April 2016 to December 2016 and from May 2017 to July 2017. All the collected data have been analysed and the above indices have been calculated to test the actual performance of the systems for the different set-up, configurations and scenarios. In Table 1 some results of this calculation have been reported. It must be clarified that ALD values characterize the days when the systems worked. It ranges according to the season, the hours of the occupancy schedules and of the daily time. The scenarios reported in Table 1 are characterized by ALD values that range between 315 lx·h and 1797, for the System A, and from 322 and 1613 lx h, for the System B.

Tab. 1: Results for selected tested scenarios with dimming and on-off control.

Starting to compare how the two systems worked, it can be noted that in some cases, they ran in a different way during scenarios with ALD very similar. For instance, there are for the scenarios with ALD of about 322 lx·h. The first one is related to the system A and presented an OAR of 0.22 and a UAR of 1. In the second one, for the system B, the calculated value of OAR was 0.52, and the one of UAR was 0.88. Similarly, for scenarios

with ALD of about 703 lx·h an OAR of 0.19 and a UAR of 1 have been calculated for the System A while for the system B the associated value of OAR was 0.99 an of UAR was 0.23. The graphs in Figure 6 show the relation between OAR and ALD indices for the two systems operated by the two control strategies. In general, high values of OAR corresponded to high values of ALD. It means that the systems worked better when there was low a contribution of daylight. So, in general, the higher the ALD, the lower the possibility of having over-lighting problems. The same is for the ON-OFF control case.

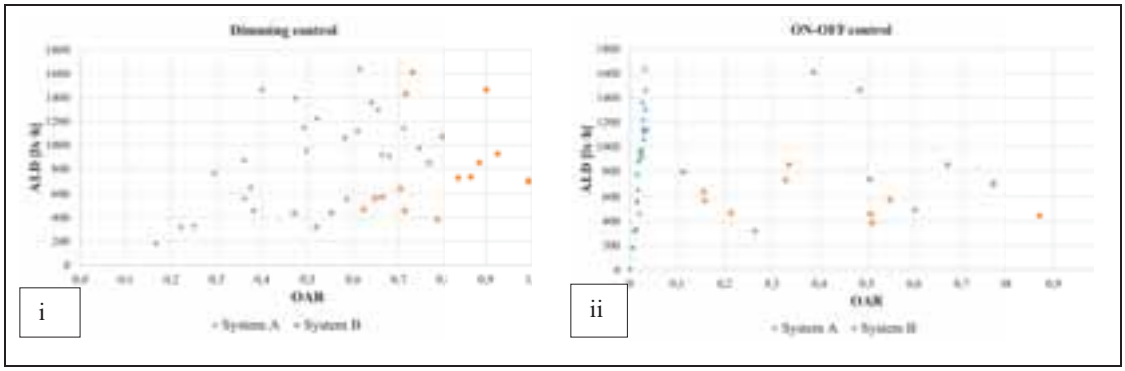

Fig. 6: Relationship between A.L.D and OAR indeces calculated in dimming and ON/OFF control for the two systems.

Generally, in dimming operation, system A had OAR lower than System B. For both systems a specific linear correlation with ALD can be observed. In ON-OFF operation (Figure 6ii) System A had a maximum of OAR equal to 0.07 (very poor result), while figures of System B are generally better, even if not well correlated with ALD. Also, observing figure 7i and 7ii, it can be noted that the higher ERI, the lower OAR values. It means that the system wastes energy over-lighting the room. On the other hand, small ERI values are coupled to low values of UAR (Figures 7iii and 7iv), because such energy "saving" is affected by an excessive under-lighting. The reason why correlations OAR vs ERI and UAR vs ERI are not very robust lays on the fact that the system can perform in under and over-lighting in the same day of operation. It can be noted that the System A in ON-OFF case did not have problems of under-lighting (Figure 7iv), but it had severe problems of over-lighting (Figure 7ii). As already noted looking at the calculated values, the System B had higher performances than the System A. Comparing the two control strategies, it can be observed that both systems had higher performances with dimmer control. Anyway, the gap between the performances of the two control strategies is more significant for System A. Indeed, the cloud of points calculated for the System B with dimmer control shifted slightly to higher values of OAR (Figure 7i). In the case of ON-OFF control, it is much more evident (Figure 7ii). The OAR values are very low for the System A (the highest value is 0.07). On the contrary, in the case of System B they are higher reaching value of 0.87), while, UAR are almost every time equal to1. In such a view it is useful to observe the ratio OAR/UAR vs ERI graphs. The higher the ratio, the higher is the influence of the under-lighting during the system operation. All the considerations related to the best performance of System B and the dimming control for both the systems are also confirmed in graph 7iii and 7iv. Also, the predominant behaviour of System A to provide exceeds of lighting (OAR/UAR very low) is confirmed.

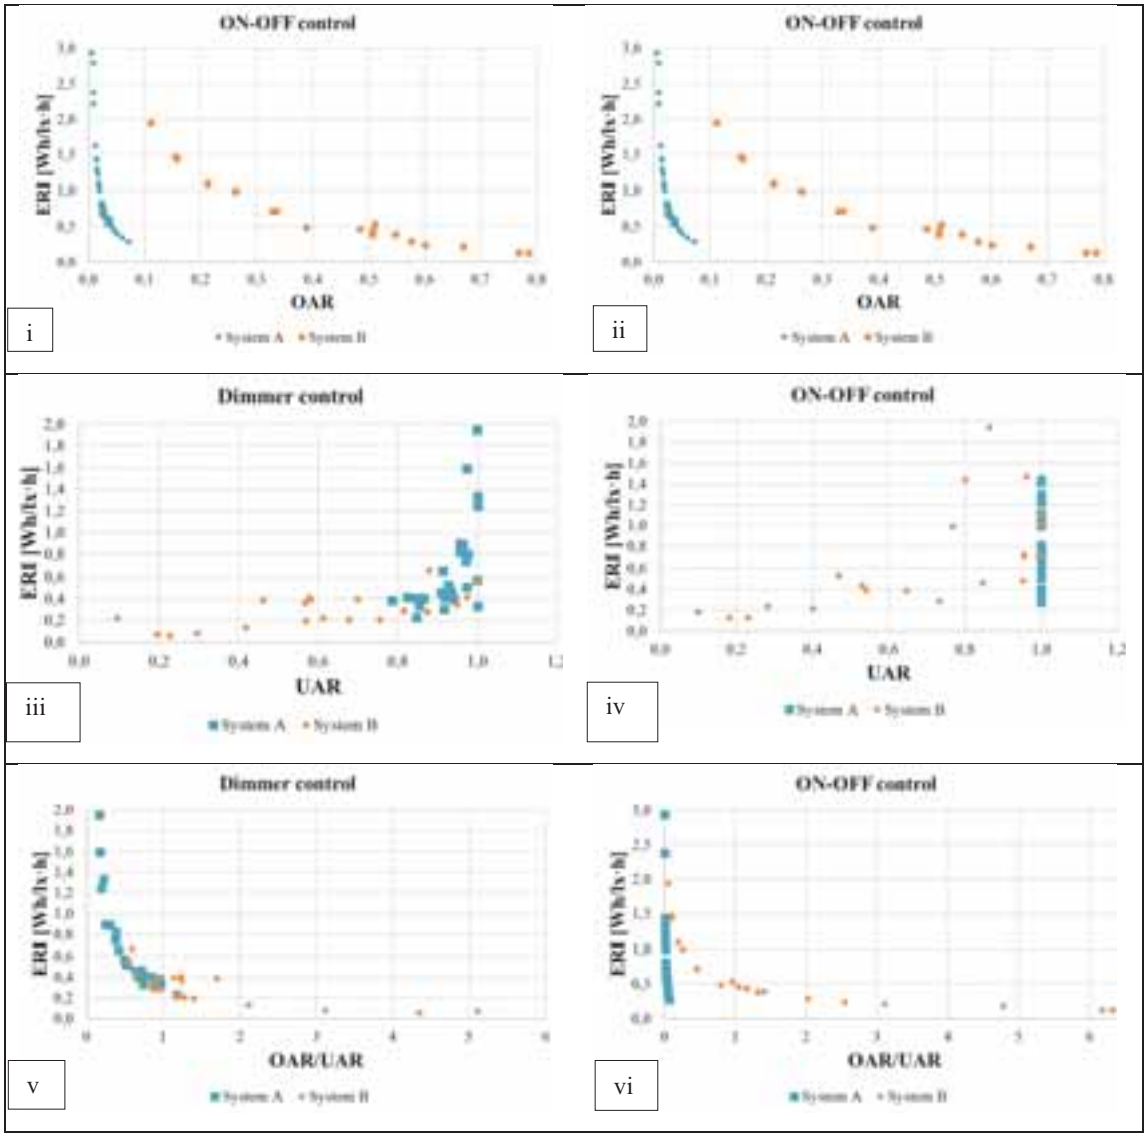

Fig. 7. Relation between ERI index and OAR index calculated in dimming control and ON/OFF control for the two systems.

The correlation between electricity consumption and ALD values (Figure 8) is helpful for analysing the ALD influence on the system performance. The ideal consumption has been calculated proportionally to the ALD. For this reason, the correlation is linear. On the contrary, looking at the actual consumption lines (both of System A and B), the correlation is not precisely linear as it is in the case of an ideal system (see the "ideal consumption" plot). It is because, as already said and observed, the control system did not work as expected and, some cases of incorrect operation associated to low values of UAR and the OAR have been found so, the consumption swung from the ideal figure. The more the points are closer to the ideal consumption line, the more a real generic system worked good. Moreover, the actual consumption regression lines shift from the ideal one by constant values because of the power absorbed by the control systems (around 18.3 W for the System A and about 10 W for the System B).

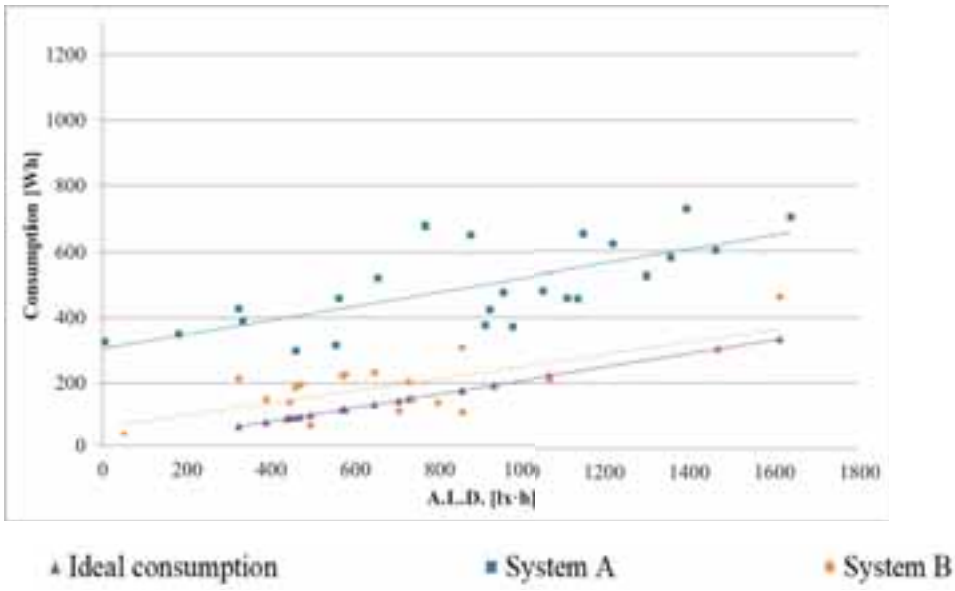

Fig. 8. Relationships between ALD index and the electricity consumption (systems A and B) and the ones for an ideal system..

7. Conclusions

This paper presents an experimental test of a new method developed by authors to evaluate the actual performance of two DLCs, based on the calculation of a set of indices. The index ERI has been used to account for the specific consumption *k* concerning the artificial light demand (ALD). Generally, it depends on the efficiency of the lamps, on the features of luminaries, electric systems and control systems. The indices OAR and UAR have been used to account their ability to maintain the target illuminance on the task area. The two systems have been tested under different operating conditions and control strategies (dimming and ON-OFF). In general, the closer the ERI index to the *k* factor the more the observed system works appropriately with very high values of UAR and OAR. The values of the indices have been calculated in different scenarios characterized by variable daylight availability and compared to have a picture of how each system performed. Furthermore, relationships between the indices have been carried out and analysed for large sets of data. In general, it has been proven the ability of the indices to highlight and analyse situations where consumptions far from the ideal ones are measured. For instance, it was possible to have evidence that a low specific consumption can be due to the inability of the system to fulfil the minimum target illuminance even though occasionally operated in over-lighting. Likewise, it can be noticed that the highest ERI values correspond to the lowest OAR values that means system is performing in over-lighting conditions. On the other hand, low ERI values are also coupled to very variable values of UAR. For this reason, it is useful to observe it as a function of OAR/UAR ratio. Accordingly, the higher the ratio, the more prevalent the under-lighting condition. In almost all the observed conditions System A performed worse than System B with a persistent behaviour characterized by frequent and relevant over-lighting. For both the systems the relationship between ALD and electricity consumption was only barely proportional. It was because the control system did not always work as expected in ideal cases (with UAR and OAR both equal to 1). Nevertheless, also through this approach, it has been possible to confirm the higher

efficiency of System B. Therefore, it can be affirmed that such method can be utilised to assess the system's performance on different days and, consequently, with different daylight conditions as well as different systems operating in similar daylight conditions. Further work will deal with the test of other commercial systems aiming also at a comparison of their performances in different seasons.

Abstract

This article presents a full-scale survey of the impact of colored/neutral glazing systems on occupants' visual and non-visual functions, as well as working performance in a daylit office in Beijing, China. Five glazing systems were investigated during a heating season from 17 November 2016 to 11 January 2017. Lighting measurements and subjective assessments were conducted to study the relationship between lighting conditions, glazing types, and visual and non-visual performances. Several key findings were achieved as follows: 1) According to visual performances, the blue glazing could be the best solution while the bronze glazing tends to be less acceptable; both grey and green glazing systems did not show significant differences from the clear glazing. 2) No clear divergences of non-visual performances can be found between various colored/neutral glazing systems. 3) The circadian light (CL) has an obvious link to occupants' non-visual performances. 4) Participants' working performance in a short-term GONOGO test will become worse when the blue glazing system is applied.

Keywords: Colored glazing; Visual and non-visual performances; Daylit office; Heating season; Beijing

1. Introduction

Daylighting has been recognized as a critical environmental factor in office buildings, due to its significant effects on workers' performances such as productivity, psychological and physiological aspects (Veitch et al., 2004; Aries et al., 2015). Studies of daylight's impact on occupants have recently become a focus in offices. Using a survey of ten office buildings in the Netherlands, Aries et al. (2010) found that workers' visual comfort and well-being can be substantially linked to configurations and installations of the external window, which can determine indoor daylighting conditions and view. Borisuit et al. (2014) pointed out that office occupants prefer to work with the occurrence of daylighting in terms of visual and non-visual functions. Another office survey in both winter and summer periods enhanced the importance of daylight availability and its positive influences on productivity, mood and sleep quality (Figueiro & Rea, 2016). As highlighted in a new report (Ticleanu & Littlefair, 2017) and a short commentary (Figueiro, 2013), nevertheless, more proofs would still be required to justify how daylight regulates sleep and mood, especially in the working spaces.

Due to the application of coated/tinted glass, currently, colored glazing systems can be broadly found in modern office buildings across the world (SLL, 2014; BSI, 2011). The primary function of these glazing systems is to adjust the external solar gains, and therefore help bring in a proper level of indoor thermal/visual comfort. In the meantime, the effect of those coated/tinted glazing systems on visual and color perception has been noticed (Bulow-Hube, 1995). A pilot study using scale models indicated that the neutral coated glazing with a high visual transmittance can receive more acceptances (Dubois et al., 2007). On the other hand, the colored coated glazing products in the current market can possibly distort the color appearances of daylight in modern buildings (Matusiak et al, 2012). Based on scale models and subjective assessments, a study showed that there is a preference for daylight filtered through colored window glazing and that the glazing color type may have a significant effect on arousal level of office workers (Arsenault et al., 2012). This study (Arsenault et al., 2012) also revealed that the bronze glazing receives more preferences than the blue and clear glazing. In the area of artificial lighting design, the light color temperature in working places does affect occupants' performance (Bellia et al., 2015). An interesting finding has been produced through a human experiment (Sahin & Figueiro, 2013): the narrow long-wavelength / red light (2568K) can obviously increase alertness and working performance during the daytime. However, few studies have been completed so far to fully explain how the broad-wavelength daylight combined with colored glazing works on human's psychological and biological functions.

Therefore, it is still necessary to carry on more investigations on the relationship between glazing types,

doi:10.18086/swc.2017.05.02 Available at http://proceedings.ises.org

daylighting and human performance in office buildings. Based on daylighting measurements and subjective assessment, this article presents a study in a full-scale office room with various glazing systems in Beijing, China. The aim is to investigate how the colored/neutral glazing affects the human visual comfort, non-visual functions including mood, alertness, well-being and relaxation and working performance.

2. Methods and materials

2.1. Office room, study design, and participants

During a heating season from 17 November 2016 to 11 January 2017, this study was conducted in an office room at the School of Architecture of Tsinghua University in Beijing (Lat: 39.9042° N, Long: 116.4074° E) in China (Figure 1). With a dimension of 6.2×3.2×3.8m, the office room has one side window facing south, and four sitting positions including A1 & A2 (working places for participants), B (for the person who did measurements and controlled the experiment) and T (for GONOGO test (section 2.4)). The reflectances of the room surface are 0.3 (floor), 0.88 (wall) and 0.88 (ceiling).

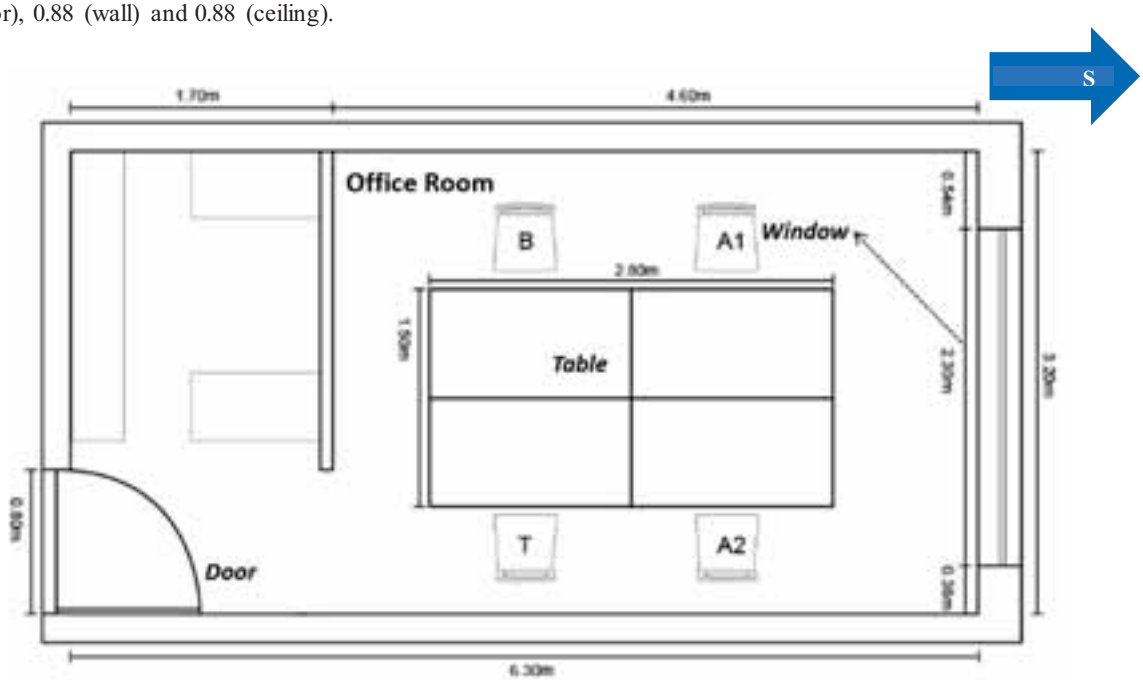

Fig. 1: Plan, dimensions, and sitting positions of the office room studied

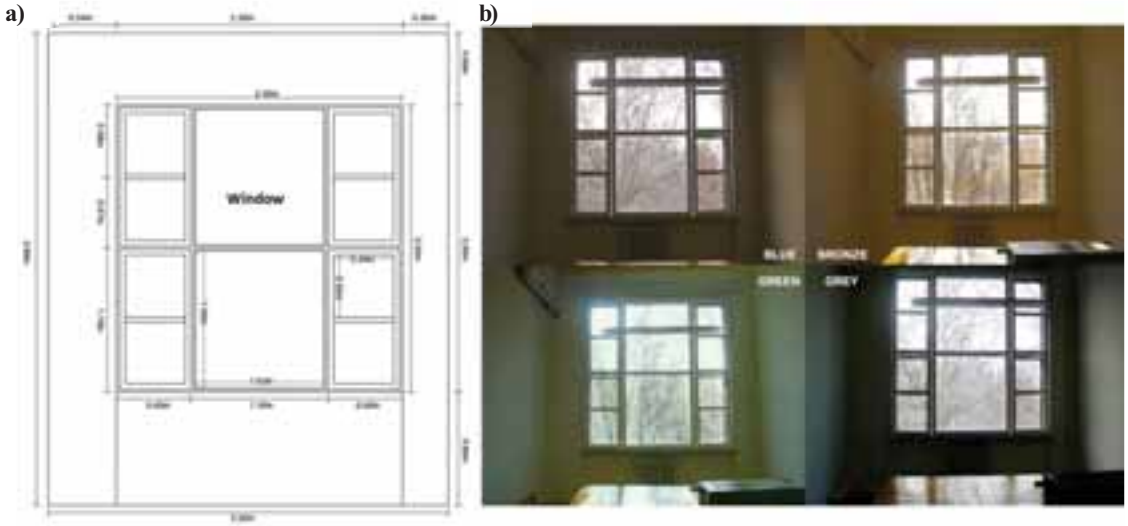

Fig. 2: Window configurations and dimensions (a); interior views of four glazing systems (blue, bronze, green and grey) (b).

Configures and dimensions of the side window can be found in Figure 2 (a). It has a dimension of 2.3×2.3m and a two-layer structure. The external layer is composed of single clear glazing and dividers, while the internal layer

adopts a removable structure with easily installed/dismantled glazing and dividers. Five types of glazing were studied including clear, blue, bronze, green and grey. They are typical products that can be found in current Chinese window market and have been widely used in modern non-domestic buildings. Except for the clear glazing, Figure 2 (b) displays pictures of the interior appearances with four glazing systems in the room. The transition spectrum of all glazing systems can be found in Figure 3. Then, overall visible transmittance (VT) values of them are 0.91 (clear), 0.55 (blue), 0.37 (bronze), 0.68 (green) and 0.22 (grey).

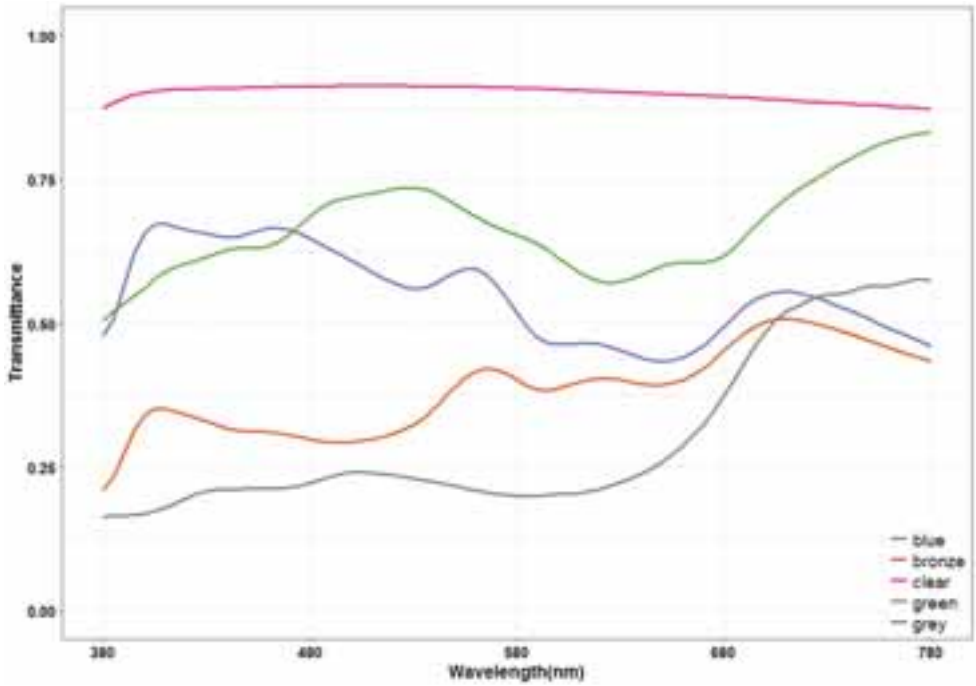

Fig. 3: Transmission spectrum of window glazing systems used in the office

A total of 17 participants were recruited from current students at Tsinghua University, with a mean age of 22.68 (±1.80) years. No participants should have medical and psychiatric diseases and sleep disorders. Each participant attended a five-day experiment, while only one type of glazing has been tested for each day. All participants were required to attend the experiment during a normal working time (8:30 – 16:00). The daily experiment was divided into two time-slots: 08:30-11:30 and 13:00-16:00, with a 1.5 hours lunch break in between. In order to control prior light exposure, each participant was asked to start his/her sleep earlier than 23:00 at the night before the testing day. During the experiment, the participants were just allowed to carry out regular office work in the office room, such as reading, writing, typing, etc. No food and drinks with caffeine or similar content can be taken on the testing day.

2.2. Light measurements and calculations

The experiment has been implemented under only daylighting conditions. No artificial lighting can be used in the experiment, even if the daylighting level was insufficient to meet the lighting standard at the working plane. The lighting condition was measured by a portable Illuminance Color Spectral meter (SPIC-200), in terms of three types of data: illuminance (lux), spectral distribution and correlated color temperature (CCT, K). The measured positions were the table and the vertical plane near the participant's eyes. Each meter reading was recorded every 10 minutes. Based on the collected light spectral distributions, Circadian Light (CL) and Circadian Stimulus (CS) were calculated according to a reference (Rea and Figueiro, 2016). The two values can be adopted as indicators of the nocturnal melatonin suppression due to the spectral response of the human circadian system. In addition, the indoor temperature and humidity were measured as a reference of thermal conditions.

2.3. Visual and non-visual assessment

Two VAS (visual analogue scale (Monk, 1989)) questionnaires were adopted to assess the visual and non-visual performances of participants. A paper-based VAS was used as a measuring tool for each question (scale range: 0-100mm).

The visual assessment questionnaire is composed of six questions: Q1, Lighting is comfortable? (0mm, extremely uncomfortable; 100mm, extremely comfortable); Q2, Room is bright? (0mm, very bright; 100mm, OK); Q3, Room is dark? (0mm, very dark; 100mm, OK); Q4, Glare? (0mm, intolerable; 100mm, no); Q5, Light color is comfortable? (0mm, extremely uncomfortable; 100mm, extremely comfortable); Q6, Color appearance is proper?

(0mm, absolutely not; 100mm, perfect). Four questions were given in the questionnaire for assessing non-visual performances as follows: Q1, Alertness (0mm, extremely sleepy; 100mm, extremely alert); Q2, Mood (0mm, very bad; 100mm, very good); Q3, Physical well-being (0mm, very uncomfortable; 100mm, very comfortable); Q4, Relaxation (0mm, very tense; 100mm, very relaxed). Each participant was asked to complete the two questionnaires every 45 minutes. Thus, a total of 16 questionnaires would be collected from each participant in each testing day. The feedbacks were statistically analyzed using IBM_SPSS(v23).

2.4. Working performance test

Participants' working performances in this experiment were tested using a computer GONOGO tool. This tool was produced by the authors according to fundamental GONOGO theories (Kreutzer et al., 2011). A GONOGO test is generally used to measure a participant's capacity for sustained attention and response control (Kreutzer et al., 2011).

In this study, the GONOGO test totally followed the method used in a human performance experiment (Sahin et al., 2014). Based on participants' responses via a computer mouse, this test lasted around 10 minutes. In each test, a smiling or frowning face was presented on a black background every 2-10 seconds. Participants were instructed to do the following actions: clicking the mouse when smiling face appears; stopping to respond when the frowning face occurred. The occurrence of smiling face will be around 70% of test time while only 30% of the time will be given to the frowning face. Once the participant clicks on the mouse, the face will disappear and the time from the face 'appear' to 'disappear' will be recorded. If the participant's response time is longer than 1 second, the face will vanish and therefore a 'miss' was recorded. In addition, a 'false alarm' will be recorded if the participant clicked the mouse before the face appears. In this study, each participant attended a GONOGO test every 90 minutes.

As mentioned in the experiment (Sahin et al., 2014), four GONOGO scores were adopted to measure the working performance: overall accuracy, mean response time, mean response time of the best 10% of response times, mean response time of the worst 10% of response times. A new value named as Tput was adopted in order to statistically analyze the collected data (Sahin et al., 2014), and it can be calculated through the algorithm: 100 × (# of valid responses) / (# of total responses) / median of the response times. A valid response used in the calculation did not include 'miss' and 'false alarm of an incorrect face shape'. Therefore, three Tput values can be achieved such as for a total test (Tput), the best 10% of response times (bTput) and the worst 10% of response times (wTput).

3. Results and discussions

This section includes results and discussions from lighting measurements, subjective assessments of visual and non-visual performances, as well as working performances using GONOGO in the office with various glazing systems.

3.1. Daylighting and color conditions

Figure 4 displays mean values of vertical illuminance and CCT near participants' eyes in terms of varying times and glazing types. Most of the time the grey and green glazing systems have higher illuminance levels than other types. The mean values of illuminance are 1454.3lux (±237.0) and 1407.7lux (±189.2) for grey and green glazing respectively. On the other hand, the lowest illuminance levels can be found with the blue and bronze glazing as follows: 701.1lux (±101.6) and 620.2lux (±86.3). The daylighting performance of clear glazing is in between (1025lux (±190.57)). It can be clearly noticed that a higher visual transmittance of glazing does not necessarily bring in a higher indoor illuminance. Certainly, external sky conditions are more critical. From around 10:00 to 15:00 all the glazing systems see a vertical illuminance above 500lux, whilst a higher illuminance (>1000lux) can be only found in a time slot of 12:00 -- 14:00. In the late afternoon (15:00—16:00) all the glazing types give rise to a lower illuminance level (<500lux). In general two peaks of illuminance variation occur at 10:45 and 13:45 for most of the glazing systems.

As for the mean values of CCT of light near participants' eyes, no big differences can be found in the daily testing time from 9:15 to 16:00. The blue glazing has the highest mean CCT of 5395.1K (±36.0), which could result in a relatively cold/blue lighting atmosphere. It is normal that the lowest mean CCT of 3986.2K (±54.8) occurs with the application of bronze glazing. This value will not be considered as 'warm', but 'neutral' or 'white'. However, the use of green, grey and clear glazing systems can lead to mean CCT values between 4000K and 5000K. A light color in this range tends to be called as 'cold white'. Interestingly the green and grey glazing systems achieve a similar CCT value: 4792K (±30.4) for green glazing; 4724.5K (±53.0) for grey glazing. The clear glazing,

nevertheless, has a slightly lower mean CCT of 4443.9K (±27.2). Accordingly, the three glazing systems might produce a similar light atmosphere in this office room during the testing time.

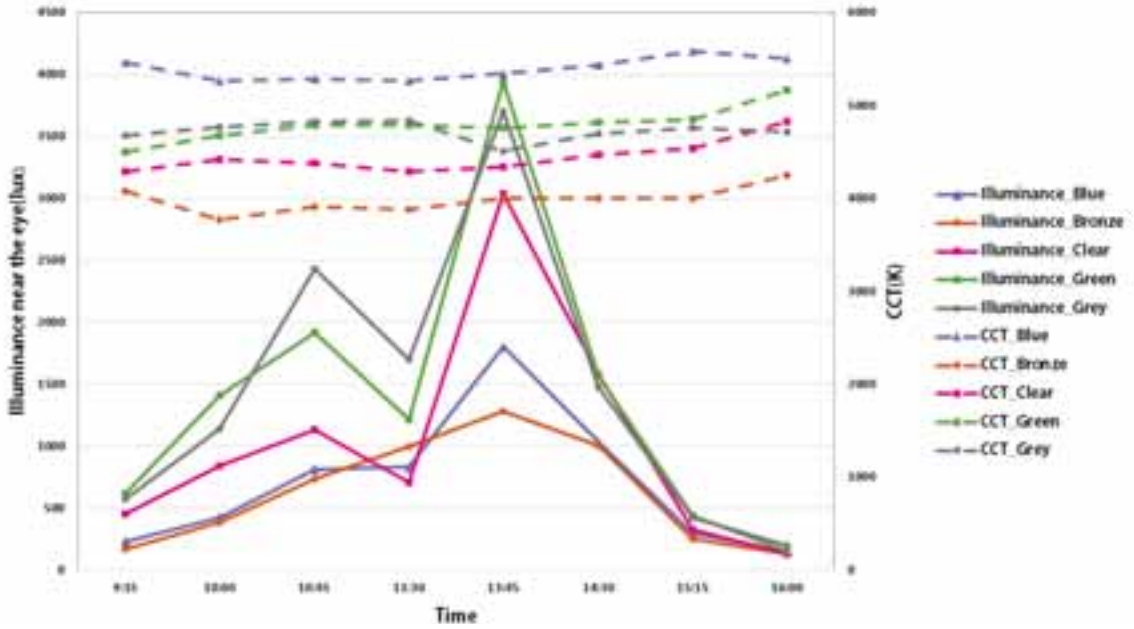

Fig. 4: Mean values of vertical illuminance and CCT (measured near the eyes of participants)

3.2. Visual performance

A 'five glazing types × eight times' repeated measures of variance (ANOVA) was performed using the feedback from the visual performance questionnaire including six questions (see section 2.3). A Post Hoc method (Least Significant Difference (LSD)) was used to further compare the main effects and interactions. The planned comparisons were performed to investigate whether the visual performances of five glazing types were significantly different from each other. All statistical analyses were completed using IBM SPSS (v23.0). The significance can be achieved based on $p < 0.05$.

Figure 5 & 6 display the impact of glazing type and times on the six questions of visual performance (ANOVA). For the visual performance, the assessment of seventeen subjects reveals a significant impact of glazing types on Q2 (Brightness) [$F(4, 678) = 4.468$, $p = 0.001$], Q3 (Darkness) [$F(4, 678) = 9.793$, $p < 0.001$], Q4 (Glare) [$F(4, 678) = 3.196$, $p = 0.013$], Q6 (Color appearance) [$F(4, 678) = 3.035$, $p = 0.017$]. The visual comfort (Q1) and color comfort (Q5) have no clear relationship with the glazing type ($p > 0.05$). Similarly, the time takes clear effects on the visual performances of Q2 (Brightness) [$F(7, 678) = 11.371$, $p < 0.001$], Q3 (Darkness) [$F(7, 678) = 9.465$, $p < 0.001$], and Q4 (Glare) [$F(7, 678) = 12.470$, $p < 0.001$]. No significant influence of time can be found for the Q1, Q5 and Q6 ($p > 0.05$). In addition, no significant interaction effects between glazing type and time were proved according to the feedback of six visual performance questions.

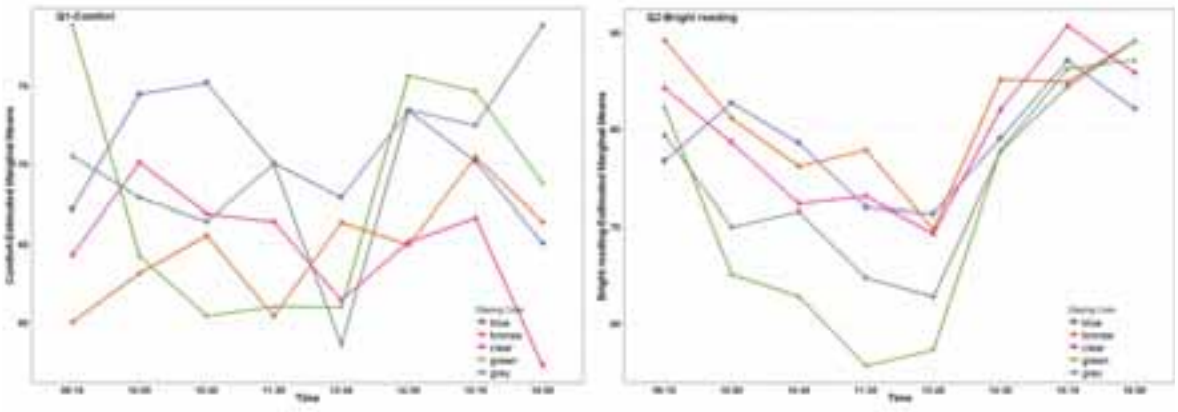

Fig. 5: Subjective assessments of visual performance (Q1--2): the impact of glazing types and time

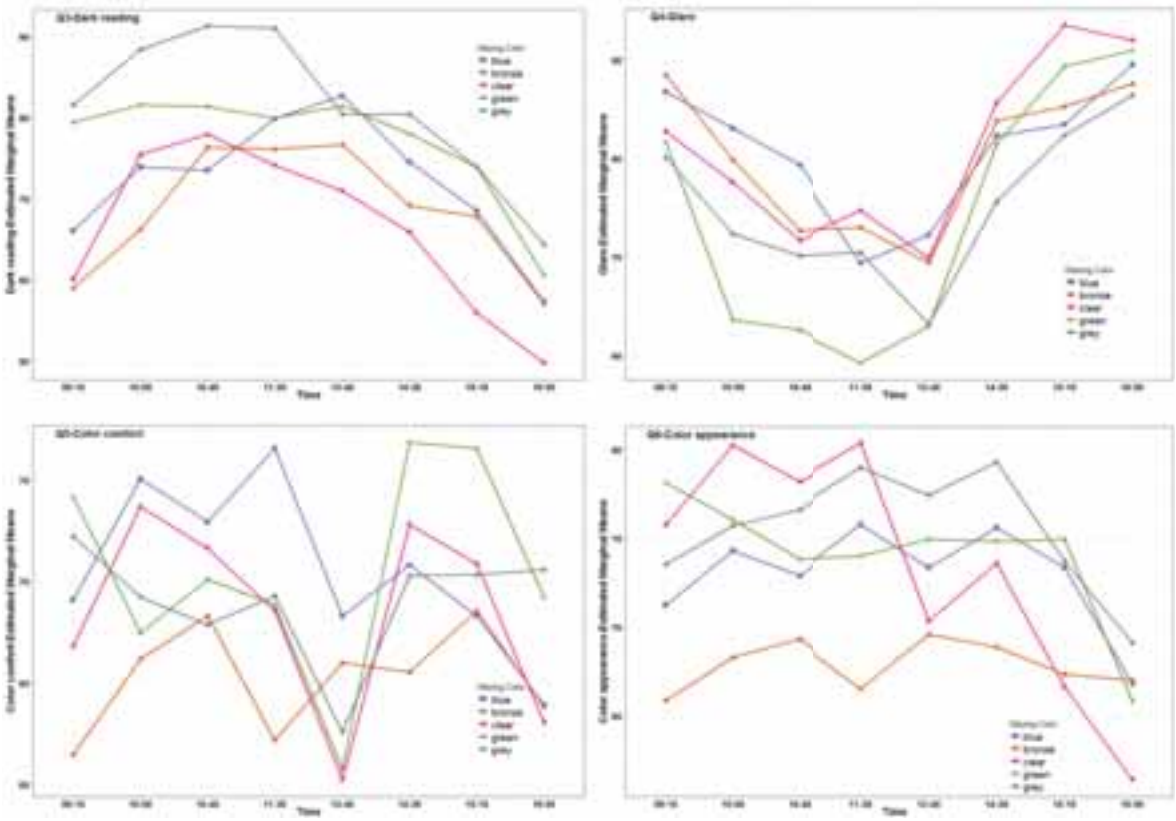

Fig. 6: Subjective assessments of visual performance (Q3--6): the impact of glazing types and time

Table 1 gives the multiple comparisons of visual performances between various glazing types (Post Hoc, LSD). Only the results with a significant difference have been presented ($p < 0.05$). For Q1 (comfort), the score of blue glazing is higher than both bronze and clear glazing ($p < 0.05$), whilst the score of bronze glazing is significantly lower than the grey glazing ($p < 0.05$). Even though the illuminance levels of blue and bronze glazing are similar, participants feel more comfortable with the occurrence of blue glazing. When compared with the clear type, the blue glazing can still receive a higher acceptance rate. The first feedback of comfort would support that participants in this office were more sensitive to the glazing's color than its visual transmittance and illuminance level. The questions Q2-4 focuses on the visual comfort and their feedback shows a similar statistical result. Compared with the green and grey glazing, generally, the blue, bronze and clear glazing would bring in a relatively darker lighting space and the lower risk to get glare problems in this office ($p < 0.05$). Taking Q2 (brightness) as an example, scores of blue, bronze and clear glazing are significantly higher than those of green and grey glazing. Interestingly, the clear glazing tends to deliver a darker lighting condition than the blue glazing ($p = 0.034$), although the former receives 40% higher illuminances than the latter. For the Q5 (color comfort), the only significant difference can be found between the blue, bronze and green glazing. Both blue and green glazing will give the participants a more comfortable color environment than the bronze type ($p = 0.026$ or 0.04). However, no clear differences of color comfort were achieved between the clear glazing and others ($p > 0.05$). On the contrary, the color appearance (Q6) shows an obvious difference between the bronze glazing and the blue, clear, green, grey glazing systems. The participants would agree that the bronze glazing can have a higher possibility to distort a normal color appearance even compared with the green glazing.

As regards Figure 5, 6 and Table 1, main effects of the time between various glazing systems also have some clear differences. It can be revealed that participants feel less comfortable (Q1) when the time is at 13:45 than 14:30 ($p = 0.023$) and 15:15 ($p = 0.013$). Also, participants would feel brighter when it is approaching the time 12:00, and therefore complaining of glare will start to increase at the same time. Also, the same feedback occurs for the color comfort (Q5): participants would feel less comfortable about the light color at 13:45 than other times, such as 10:00 ($p = 0.37$), 10:45 ($p = 0.42$), 14:30 ($p = 0.18$), 15:15 ($p = 0.15$). These findings indicated that under a higher illuminance level participants' comfort may not be linked with glazing color.

Tab. 1: Post-Hoc LSD: multiple comparisons of visual performances between glazing types (Sig. $p < 0.05$)

Dependent Variable	(I) Glazing type	(J) Glazing type	Mean Difference (I-J)	Std. Error	Significance
Q1-comfort	blue	bronze	6.00	2.603	.022
	blue	clear	5.88	2.603	.024
	bronze	grey	-5.13	2.599	.049
Q2-brightness	blue	green	6.77	2.638	.011
	bronze	green	9.88	2.634	.000
	bronze	grey	6.71	2.634	.011
	clear	green	7.74	2.634	.003
Q3-darkness	blue	clear	5.96	2.804	.034
	blue	grey	-9.23	2.804	.001
	bronze	green	-8.49	2.799	.003
	bronze	grey	-12.90	2.799	.000
	clear	green	-10.79	2.799	.000
	clear	grey	-15.19	2.799	.000
Q4-glare	blue	green	6.61	2.649	.013
	blue	grey	5.53	2.649	.037
	bronze	green	6.01	2.644	.023
	clear	green	6.98	2.644	.009
	clear	grey	5.90	2.644	.026
Q5-color comfort	blue	bronze	5.72	2.563	.026
	bronze	green	-5.26	2.558	.040
Q6-color appearance	blue	bronze	5.32	2.368	.025
	bronze	clear	-5.46	2.364	.021
	bronze	green	-6.21	2.364	.009
	bronze	grey	-7.68	2.364	.001

For the visual assessment, the application of blue glazing can generally benefit the occupants' performance and comfort, even compared with the normal glazing, i.e. clear product. In the contrast, the bronze glazing would receive the lowest acceptance rate when evaluating the visual performance. Other glazing types have no clear differences including green, grey and clear glazing. A higher illuminance level after 12:00 might increase occupants' discomfort.

3.3. Non-visual performance

Similarly, an analysis of the subjective feedback under 'five glazing types × eight times' were performed using ANOVA and LSD for the non-visual performance assessment including four questions (Q1-4). In addition, a correlation analysis (Pearson) was implemented between the circadian light and stimulus (Rea and Figueiro, 2016), and the four aspects of non-visual function. The significance can be achieved based on $p < 0.05$.

Figure 7 gives the subjective assessments of non-visual performance (Q1--4): the impact of glazing types and time. Different from the visual assessment discussed above, the ANOVA analyses exposed that there are no significant main effects of glazing type or time on the Q1 (alertness), Q2 (mood), Q3 (physical-wellbeing), and Q4 (relaxation). Also, it has not been found a clear interaction effect between glazing type and time exists. In Table 2, the LSD analyses show some differences of non-visual performance between various glazing systems. For the Q3 (physical well-being), scores of blue glazing are significantly higher than the clear one ($p = 0.035$). The blue glazing could make participants feel more comfortable than the clear type. Compared with the grey glazing, the clear glazing scores higher for the Q4 (relaxation) ($p = 0.046$). It could be reasonable that a relatively lower illuminance brought by the clear glazing would make occupants feel more relaxed. Based on both Figure 7 and Table 2, furthermore, it can be found that the alertness (Q1) can achieve a higher level at the time 11:30 than the

times 09:15 ($p = 0.030$), 13:45 ($p = 0.14$), 14:30 ($p = 0.005$) and 16:00 ($p = 0.003$). This indicates participants tend to be alerted with the time approaching the noon. At the time 13:45, a lower physical wellbeing (Q3) occurs compared with the time 15:15 ($p = 0.014$). This could be explained by one fact that these Chinese students would feel sleepy and tired at around 13:45 (a routine nap time for university students in China). The assessment of visual performances also shows a similar result as this finding.

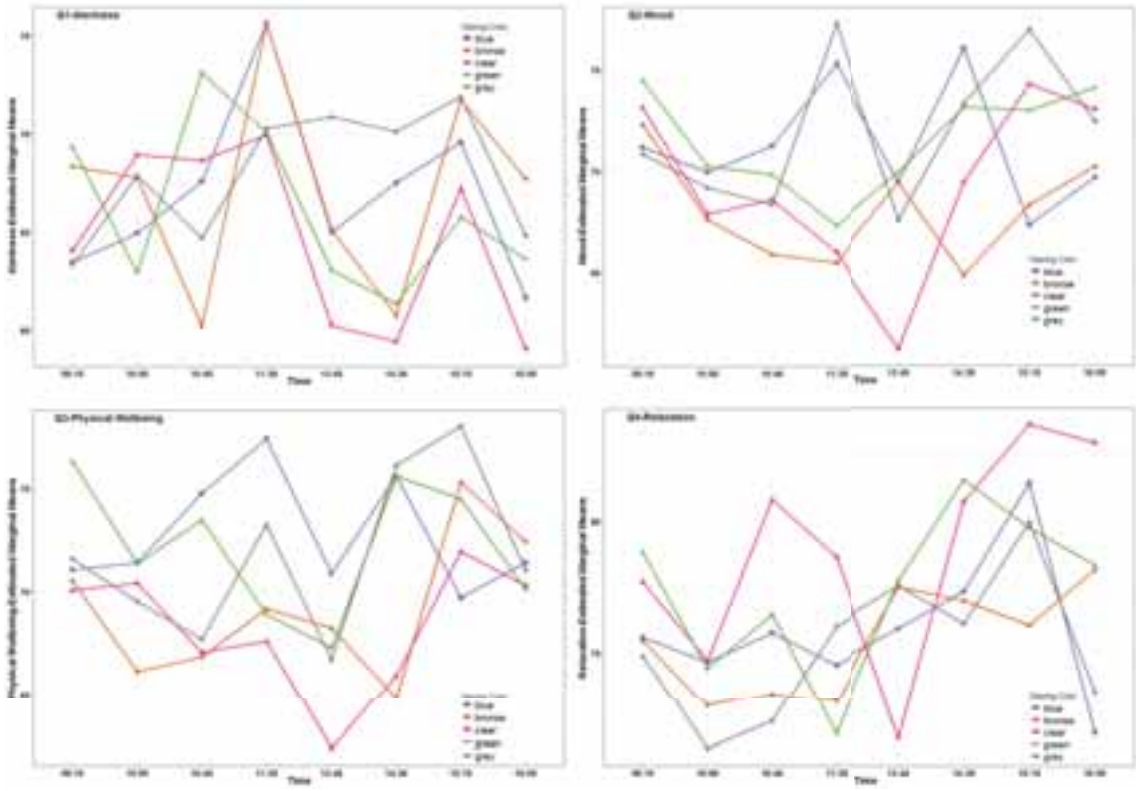

Fig. 7: Subjective assessments of non-visual performance (Q1--4): the impact of glazing types and time

Tab. 2: Post-Hoc LSD: multiple comparisons of non-visual performances between glazing types (Sig. $p < 0.05$)

Dependent Variable	(I) Glazing type	(J) Glazing type	Mean Difference (I-J)	Std. Error	Significance
Q3-physical wellbeing	blue	clear	4.48	2.114	.035
Q4-relaxation	clear	grey	3.68	1.843	.046

Tab. 3: Correlations between daylighting conditions and non-visual performances (Pearson Correlation)

		Alertness	Mood	Physical well-being	Relaxation
Circadian light (CL)	Correlation coefficient	-.041	-.136**	-.153**	-.147**
	Sig. (2-tailed)	.292	.000	.000	.000
	N	679	679	679	679
Circadian stimulus (CS)	Correlation coefficient	.002	.003	.013	-.066
	Sig. (2-tailed)	.962	.942	.739	.085
	N	679	679	679	679

Table 3 presents a correlation analysis (Pearson) between circadian light and stimulus (CL & CS) and non-visual

performances including four aspects. A clear link can be found between the circadian light, and mood (Q2, correlation coefficient = -0.136, $p < 0.001$), physical well-being (Q3, correlation coefficient = -0.153, $p < 0.001$) and relaxation (Q4, correlation coefficient = -0.147 $p = 0.001$). A higher level of circadian light may indicate a lower score of the three aspects. However, the circadian stimulus does not show any significant relevance to the three non-visual factors above ($p > 0.05$). In addition, the circadian light and stimulus have no clear relationship with the participants' alertness ($p > 0.05$). These analyses supported one fact that the Circadian Light should be used as an indicator of the non-visual effect of light instead of illuminance and CCT (Rea and Figueiro, 2016).

3.4. Working performances

An analysis of 'five glazing types × four times' ANOVA and LSD was performed for the GONOGO results (Figure 8 & Table 4). It has been found in Figure 8: there are significant main effects of glazing types on the 'mean response time' [$F(4, 339) = 2.246$, $p = 0.064$] and the 'Tput' [$F(4, 339) = 3.142$, $p = 0.015$]; however, no clear impacts from the glazing types can be found for the 'b-Tput', 'w-Tput', 'accuracy', 'average of best 10% response time', and 'average of worst 10% response time'. In addition, the main effect of time and the interaction effect between glazing types and time are not significant according to the working performance. The significance can be achieved based on $p < 0.05$.

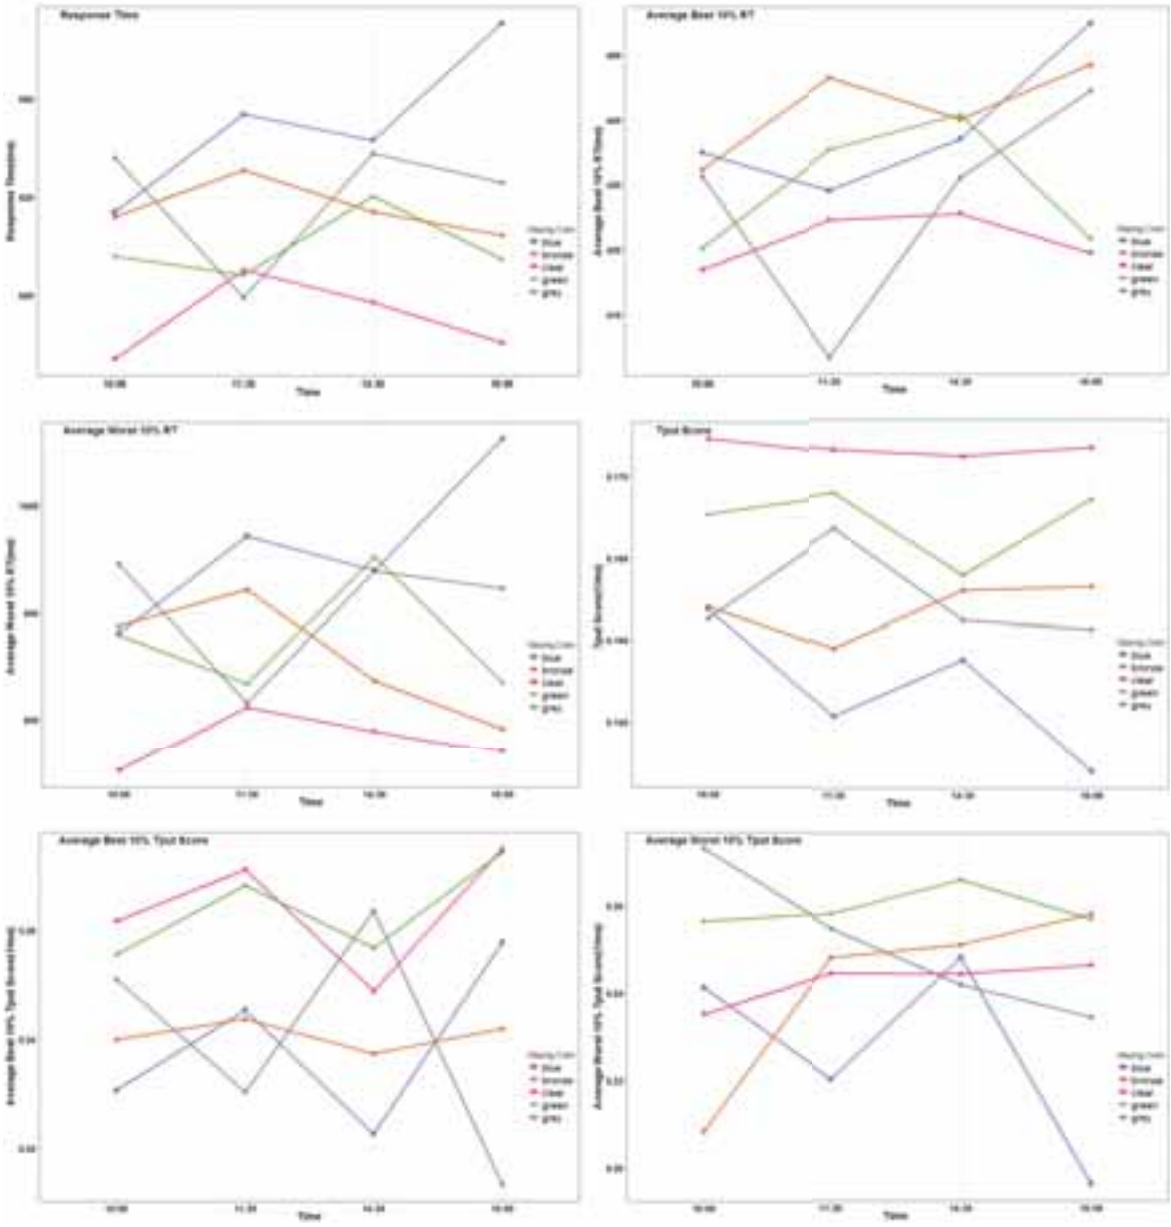

Fig. 8: Subjective assessments of GONOGO working performance: the impact of glazing types and time

Tab. 4: Post-Hoc LSD: multiple comparisons of working performances between glazing types (Sig. p<0.05)

Tput	blue	clear	-.014707	.0044735	.001
	blue	green	-.010298	.0044735	.022
	bronze	clear	-.009767	.0044735	.030
	clear	grey	.009216	.0044735	.040
w-Tput	blue	green	-.032999	.0135124	.015

As shown in Table 4, the performance differences with various glazing systems are given (only results with a significance < 0.05 are available). The accuracy of clear glazing is higher than blue glazing ($p = 0.044$), bronze glazing ($p = 0.030$), and grey glazing ($p = 0.046$). Compared with clear glazing, blue glazing has less mean response time ($p = 0.04$) and average 10% worst response time ($p = 0.011$). These indicate that the blue glazing helps participants deliver a quicker response, but a lower working accuracy. The clear glazing nevertheless gives rise to an opposite result. Compared to clear glazing, bronze glazing can help to reduce average 10% best response time. However, no clear difference of mean response time can be found in the two glazing systems. As for the Tput, the clear glazing shows significantly higher scores than blue glazing ($p = 0.001$), bronze glazing ($p = 0.030$), and grey glazing ($p = 0.040$); the blue glazing performances worse than the green type. For the green and clear glazing, it is still unclear of which one performs better in terms of Tput. Since a higher Tput value is associated with a better working performance, the application of clear glazing seems to improve the working performance.

4. Conclusions

A full-scale survey in an office room was given in this article, focusing on the impact of five various glazing systems on occupants' visual, non-visual and working performances across a winter period only under the daylighting condition. The key findings can be drawn from results and discussions above:

1) For the visual assessments, the blue glazing could achieve higher performances according to visual/color comfort, glare, and color appearance; while the bronze glazing has been recognized as the least acceptable choice. The grey and green glazing did not show a significant difference from the clear glazing.

2) Generally, the five glazing systems have no big differences in terms of alertness, mood, and relaxation in the office. However, the blue glazing seems to bring in more positive effects than the clear glazing according to the performance of physical well-being.

3) This experiment has found some aspects of non-visual performances of occupants have a significant link to the circadian light (Rea and Figueiro, 2016).

4) The clear glazing could be considered as the best choice according to the working performance in this office. Even though the blue glazing would improve occupants' visual performance, its effect on the working performance should be paid attention to.

5) It could be exposed that with the occurrence of daylighting the non-visual measurements are very hard to achieve; a non-linear statistical model would be required. Except for GONOGO, more practical methods to test the human working performance (e.g. reaction time task) could be considered.

6) Under daylighting conditions, human performances (visual and non-visual aspects) relating to the light color

could be very difficult to clarify, especially when considering the fact that the color preference is linked to the cultural and ethnic backgrounds.

Abstract

Lighting has been identified as a significant environmental attribute responsible for promoting physical and mental health of the elderly. However, present guide and standard focuses mostly on horizontal illumination requirements for specific tasks, but less on vertical lighting. This study attempts to evaluate lighting quality of the daytime activity space in Beijing's elderly facilities from the configuration of vertical daylighting on the eye by DAYSIM simulation based on dynamic climate, and to analyze the influence of position orientation on vertical daylight exposure on the eye so as to explore the possibility and design technology to optimize the non-visual based lighting quality.

Keywords: daylight; vertical daylight exposure; activity space; elderly facilities;

1. Introduction

With the discovery of ipRGCs (intrinsically photosensitive retinal ganglion cells, a type of neuron in the retina of the mammalian eye) (Berson, Dunn et al., 2002), the effect of light on human physiological and psychological health has become research hotpot in the lighting field. Light causes circadian, hormonal and other behavioral responses, from shifting sleep timing, jet-lag and melatonin suppression to pupil constriction, light adaptation and physiological activation (Price and Peirson, 2014), and then influences alertness, tension and sleep quality (Münch, Kobialka et al., 2006).

Lighting has been identified as a significant environmental attribute responsible for promoting physical and mental health of the elderly (Shikder, Mourshed et al., 2012).With the growth of age, the elderly suffer from evident overall optical changes that can cause one or more visual diseases and result in reduced visual performance (Weale, 1992). Besides, with the discovery of non-visual biological effects, light can help the elderly defeat depression, circadian sleep-wake disorder and behavioral disturbances among elderly (Sloane, Figueiro et al., 2008). Therefore, specialized lighting for the elderly was urgently considered to satisfy their physical needs and to enhance their psychophysical health and well-being (Shikder, Mourshed et al., 2012).

With non-visual biological effects, researches on elderly's lighting for physiological and psychological health (alertness, mood, performance and sleep quality) is taken more seriously. Several studies were made and the effects of light on alertness and mood has been found that the high-light regime always results in better alertness and mood than control group (Boyce, Beckstead et al., 1997). Meanwhile it was investigated that lighting during daytime hours can influence the sleep quality during the night (Riemersma-van der Lek, Swaab et al., 2008). A significant positive correlation between vertical illuminance at the eye level and sleep quality was shown (Aries, 2005). Many studies, besides mentioned above, indicate that lighting levels of at least 1000 lux on the eye are needed for biological stimulation (van Bommel, 2006). Besides, the influences of CCT (Correlated Color Temperature) of light on mental performances was also aimed that the blue-enriched white light experimented within an office has improved the subjective measure of alertness, mood, performance and other indicators of wellbeing (Viola, James et al., 2008). The efficiency of good natural light in the architectural context has also been investigated in several studies (Beauchemin and Hays, 1996).

It has been evident that non-visual biological effect of light is not directly governed by the illuminance on the

doi:10.18086/swc.2017.05.03 Available at http://proceedings.ises.org

working plane, but by light entering the eye (van Bommel, 2006), namely vertical light exposure at the eye level, which means that both vertical illuminance at the eye level and its time should be counted. The light entering the eye causes non-visual biological effect and provides the time information (the moment when the light exposure exists and its lasting time) at the same time (Bierman, Klein et al., 2005), which will influence the former. However, levels of illumination for various tasks and spaces are widely discussed in guides and specific values are suggested in lux (CIEUK, 1997, Light, 2002), while detailed recommendations for vertical illumination and vertical light exposure at the eye level are lacking in most guides (Shikder, Mourshed et al., 2012).

Therefore, in this study it was suggested that investigation into the effect of vertical light exposure at the eye level on the elderly's physiological and psychological health should be carried out on the base of acknowledgement of the difference of vertical daylight condition in elderly facilities, and then help optimize the non-visual based lighting quality.

Since China entered an aging society in 1999, aging trend has been presented the characteristics of the huge elderly population, fast speed of growth and the increasing proportion of the oldest old. People over the age of 60 account for 16.15% of the country's population of 1.37 billion in 2015, up from 10.3% in 2000, and will be 33.6% in 2050, according to the National Bureau of Statistics of China (2016). The ageing population has already been recognized as one of the greatest challenges of the 21st century for housing on both side of quantity and quality. A number of new elderly facilities for not only housing and health care but also social care services need to be built and the quality of those existing need to be updated to accommodate the increased service levels the ageing population will require.

As one of the biggest cities in China, Beijing has many typical conditions and was selected as the location of the model in this study. Daytime activity space was taken due to its various vertical daylight conditions. Therefore, this study attempts to evaluate lighting quality of the daytime activity space in Beijing's elderly facilities from the configuration of vertical daylighting on the eye and the illuminance on the working plane (UDI) by DAYSIM simulation (Reinhart, 2011) based on dynamic climate, and to analyze the influence of position orientation on vertical daylight exposure on the eye so as to explore the possibility and design technology to optimize the non-visual based lighting quality. It must be illustrate that as a simulation the spectrum of light could not be considered, and in the simulation the element of time has been simplified.

2. Methodology

2.1 Building model and simulation

The building model was a unit of the activity room in the elderly facilities located in the urban area of Beijing (39.80 N/ 116.47 W), where there were no obstructions all around. According to the survey of the content and characteristics of the elders' activity in elderly facilities in Beijing, the model was built on the widely used standard column grid of 8.4m×8.4m, with the floor height of 3.6m (Fig. 1). The basic unit was formed as Fig. 1 shows, with the available space of 16m×16m×2.8m excluding the space occupied by beam, column and other facilities. According to the survey, the unit consisted of two rooms separated by a hallway. Considering the elders' requirement of daylight, the depth of the south room (8m) was larger than the north (6m), between which was a 2m-wide hallway to ensure that two wheelchairs could pass through meantime. And French window was used for more daylight.

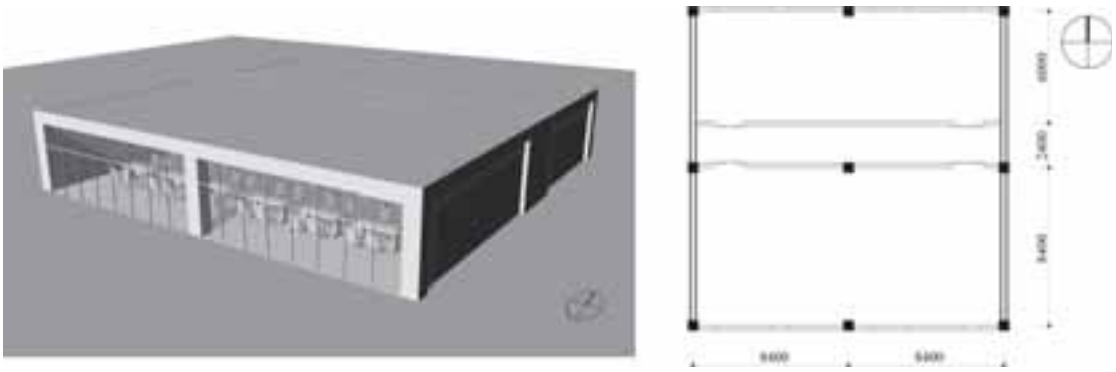

Fig. 1 perspective view and plan of the model

In the unit there were 3 typical furniture layout representing 3 common daytime activities in the elderly facilities (Tab. 1). The reflectances of the room surface are in Tab. 2.

2.2 Daylight simulation

The relative daylight metrics were obtained by annual dynamic daylighting simulation software DAYSIM based on dynamic climate, with three typical furniture layout and simulation period of 8:00-18:00, according to the survey of elderly facilities. Two daylight metrics were used: the annual vertical daylight exposure on the eye (simplified as H_v in this paper) and Useful daylight illuminance (UDI).

In this study, the vertical daylight exposure on the eye instead of vertical illuminance on the space's surface of the elderly facilities was selected to reflect the distribution of vertical lighting. This is because the latter of the seats in space changes between different moments, which cannot be used as an evaluation standard, while the former is more objective (it considered the effect of time although it supposes that person always sit here). And it was suggested that higher vertical daylight exposure on the eye is recommended under consideration of UDI

Considering the complexity of vertical daylight situation which changes by time, situation, and orientation, only the positions of the elderly's eyes when they sat in the seat instead of the whole room were considered in this paper. And it was supposed that the elderly would sit on the same seat and look at the front during the whole daytime activity in a year, so that the vertical daylight exposure the elderly received could be represented by vertical daylight metrics of the positions of the elderly's eyes when they sat on the seat.

There's some point must be illustrate that the position of the elderly, namely the seats and tables' usage periods in different position, is far more complex than supposed, which are related to the seasons, weather, the horizontal illumination, layout of activities, etc, and there will significantly influence vertical daylight exposure on the eye. Therefore, the annual daylight exposure can proximately reflect this phenomenon but not totally.

Useful daylight illuminance (UDI) was invoked to be comparatively analyzed with the annual vertical daylight exposure on the eye. UDI evaluates luminous environment with the effective horizontal illumination (from 100 lux to 2000 lux) in work plane, which is irrelevant to the face orientation. Therefore, the simulation of the study, which presents health concept, was treated as an addition to UDI to some extent.

In order to get H_v, a series of vertical working planes including the seats' position were chosen as calculation plane, on which the points of 1.15m above the floor (the eye position of a sitting elderly) were finally considered. As for UDI, the calculation position in the model was at a horizontal working plane height of 0.8m above the floor. A calculation grid with 1600 points was evenly distributed across the plane. Other detailed parameters for the simulation were shown in Tab. 2.

2.3 Data analysis

Data analysis paid attention to the effect of position, orientation on H_v, the difference between H_v and UDI, and the difference between the glass hallway and opaque hallway. Besides, the material of walls, which are the solid wall (opaque, and reflectance is 0.5) and the glass wall (visual transmittance is 0.65), on both sides of the hallway was also compared to find how much it would influence the daylight environment.

Statistical analyses were performed using SPSS version 23.0 for Windows (IBM SPSS Inc., Chicago, IL). A two-sided p value<0.05 was considered significant. One-Way ANOVA (one-way analysis of variance, a technique that can be used to compare means of two or more samples) (Howell, 2002) was adopted to determine whether H_v of different groups (columns or rows) have a significant difference. When comparing H_v with UDI, as for the seats at one table, visual task happened mainly on the tabletop, so the average UDI of tabletop was calculated to approximately reflect the level of visual task lighting of the seats at the table. In order to compare easily, the average H_v of the seats at one table was also calculated similarly.

In order to analysis conveniently, each table and seat in the 3 type of plans was numbered as Tab.3 showed.

Tab. 3 numbers of tables/seats

Type	Plan	Table numbers	Seat numbers
1			2			3			None

3. Results

3.1 Position and orientation

In this part, it was found that position orientation has a significant influence on annual vertical daylight exposure on the eye (H_v). For analyzing, position and orientation were discussed separately. Position was divided into the differences of the same row, the same column and whether in south or north, while orientation paid attention to whether facing or back to windows. And it is similar between the two different material of hallway, so in this part only the opaque hallway was discussed while the difference between the two hallway was shown in part 3.3.

According to H_v in all 3 types (Fig. 2.1 to 2.3), generally type-1 has the best evaluation (with MN of 4.2×10^6 lux·h) while type-2 has the worst (with Mean, simplified as MN, of 3.4×10^6 lux·h). And the distribution of H_v among the seats in type-2 is most uniform (with Standard Deviation, simplified as SD, of 2.5×10^6 lux·h) while the type-3 varies most (with SD of 4.4×10^6 lux·h).

Meanwhile, it was found that orientation of the room makes obvious effect on H_v. Generally the H_v of the seats in south room is higher than that in north room (with the MN of 5.5×10^6 lux·h in south vs 3.0×10^6 lux·h in north in type-1, 4.1×10^6 lux·h vs 2.4×10^6 lux·h in type-2, and 5.2×10^6 lux·h vs 2.4×10^6 lux·h in type-3), and varies more (with the SD of 5.8×10^6 lux·h in south vs 2.6×10^6 lux·h in north in type-1, 3.0×10^6 lux·h vs 9.8×10^5 lux·h in type-2, and 5.2×10^6 lux·h vs 1.9×10^6 lux·h in type-3).

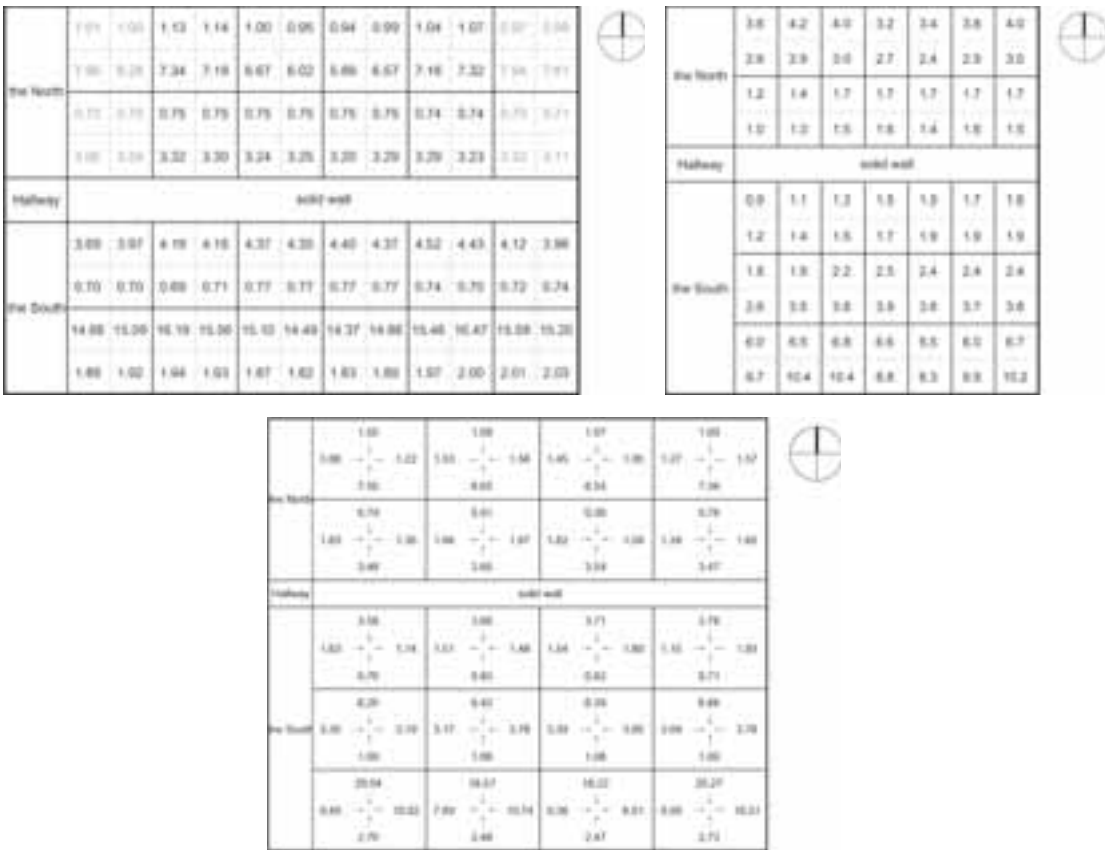

Fig. 2.1 to 2.3 the annual vertical daylight exposure on the eye (H_v, 10^6 lux • h) of each seat with solid walls on the side of the hallway, layout type-1 to type -3

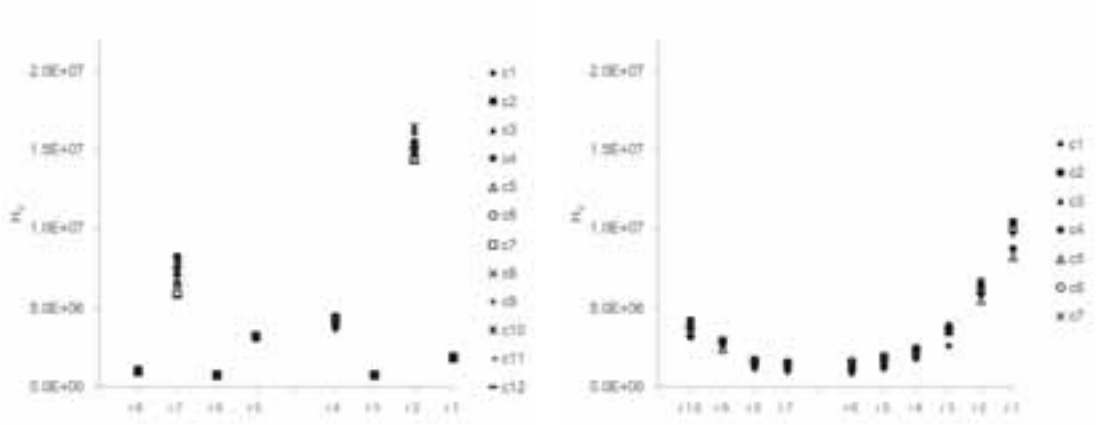
Besides, there is a big difference among the seats in the same column. From the result of One-way ANOVA (Tab. 4), it was shown that there is a significant difference of H_v among the column (F_7=2265.063, $p<0.05$ in type-1, F_9=312.153, $p<0.05$ in type-2, and F_4=571.305, $p<0.05$ in type-3). Among the seats of the same orientation in one column, H_v decreased with the raise of the distance to windows (Fig. 3.1 to 3.4).



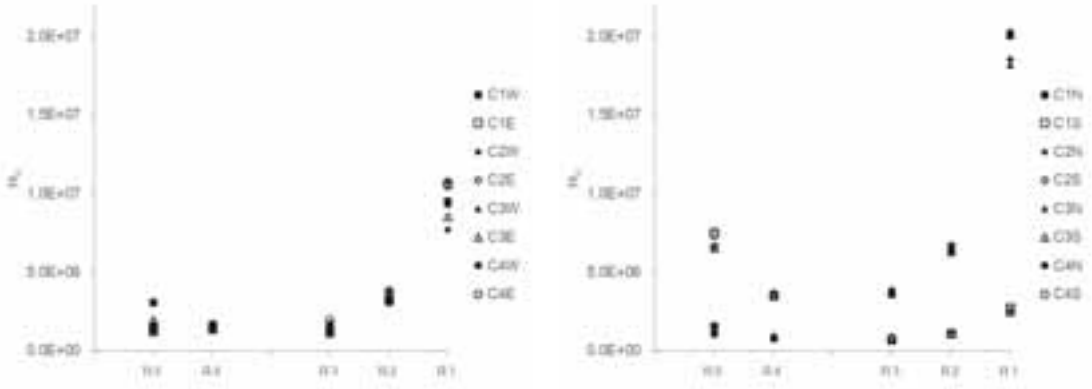


Fig. 3.1 to 3.4: the annual vertical daylight exposure on the eye of each seat (H_v, lux • h), layout type-1 to type -3

Note: 3.1 for type-1, 3.2 for type-2, and H_v in type-3 was divided into 2 parts: 3.3 includes seats westwards and eastwards, and 3.4 includes the north and south.

However, the H_v of the seats in the same row is similar according to One-way ANOVA result in Tab. 5 (F_{11}=0.007, p>0.05 in type-1, F_6=0.068, p>0.05 in type-2, and F_3=0.006, p>0.05 in type-3). In type-2, H_v among the seats in the row near the window varies more than those away from the window, and the conclusion is tenable in type-1 and type-3 when considering seat orientation (facing or back to windows). That is to say, within the 3 type plan, positions perpendicular to windows have more effect on H_v than positions parallel to windows.

	Total	198663554437390.000	19			

Considering orientation of seats, there is a significant difference in type-1 and type-3 (type-2 has only one orientation). In type-1 (Fig. 3.1) between the two orientation——facing (r8, r6, r3 and r1) or back to windows (r7,

r5, r4 and r2), H_v of the former seats is obviously larger than the latter in general, with a difference of 6.4×10^6 lux·h on average (7.5×10^6 lux·h vs 1.1×10^6 lux·h). As for the seats at the same table, H_v between facing and back to windows differs by 6.1×10^6 lux·h (r7 vs r8), 2.5×10^6 lux·h (r5 vs r6), 3.5×10^6 lux·h (r4 vs r3), and 1.3×10^7 lux·h (r2 vs r1), among which it showed that the difference between facing and back to windows enlarges with the distance to windows. Besides, the difference between the two orientations in south room is larger than that in south.

In type-3 (Fig. 3.3 and 3.4) among the 3 orientation——facing (R1N, R2N, R3N, R4S and R5S), side-facing (towards west or east) or back to windows (R1S, R2S, R3S, R4N and R5N), generally H_v of the seat facing windows (8.0×10^6 lux·h) is the highest compared with side-facing (3.5×10^6 lux·h) and back to windows (1.3×10^6 lux·h). Meanwhile, within the seats side-facing windows, there is no significant difference between towards west or east generally (differs by 2.5×10^5 lux·h, about 7.5%). Similar with type-1, in type-3 the difference between the different orientations increased with the distance to window, and the difference between the three orientations in south room is larger than that in south (R1 in type-3 is the largest of SD 6.0×10^6 lux·h).

From the discussion it could be said that as for the elderly at the same table, the one facing windows has the highest H_v, and the one back to windows has the lowest, and that generally H_v of the elderly in south room is higher than the one in north. Thus, the elderly sitting in the seats close to and facing windows in south room (r2 in type-1, r1 in type-2 and R1 in type-3) can receive the most daylight, while the elderly in the seats away from and back to windows (r3 and r6 in type-1, r6 and r7 in type-2, and R3 and R4 in type-1) have the least daylight. Meanwhile, sitting at the same table, the elderly near windows have more individual differences than those away from windows.

3.2 Health evaluation by the annual vertical daylight exposure on the eye (H_v) vs Visual task lighting evaluation by UDI

Based on the comparison, Health evaluation (H_v) differs significantly from Visual task lighting evaluation (UDI). According to UDI in all 3 types (Fig. 4.1 to 4.3), generally type-1 has the best evaluation (with MN of 82.17%) while type-3 has the worst (with MN of 79.01%), which is a little different from H_v (type-2 is the worst). And the distribution of daylight among the seats in type-1 is most uniform (with SD of 9.18%) while the type-3 varies most (with SD of 17.15%), which is in common with H_v.

Meanwhile, according to UDI in all 3 types the north room is better than the south both in general evaluation (with MN of 87.04% in north vs 77.30% in south in type-1, 89.90% vs 75.51% in type-2, and 88.40% vs 72.75% in type-3) and uniformity (with SD of 4.01% vs 10.26% in type-1, 1.78% vs 15.18% in type-2, and 3.33% vs 19.62% in type-3). However, according to H_v the north has advantages in uniformity but disadvantages in general evaluation compared with the south (mentioned in Part 3.1).

the North	81.67	81.50	86.13	86.75	82.25	81.83
	90.17	90.88	91.00	91.00	91.00	90.33
Hallway	solid wall

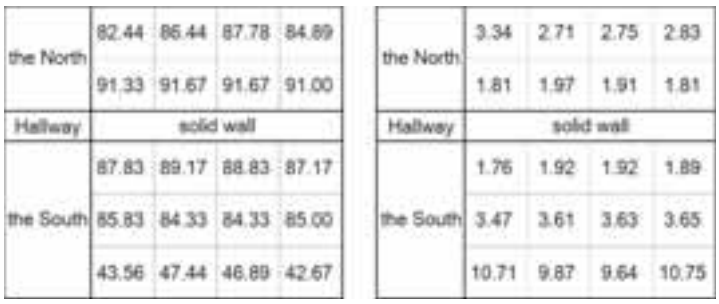

Fig. 4.1 to 4.3 Results of UDI (on left, %) and H_v (on right, 10^6 lux • h), Layout Type-1 to Type -3

Note: UDI refers to the average UDI on each desktop; and H_v is the average of the 4 seats at the table.

Besides, UDI showed that the tables near windows are more disadvantageous than others (with an average lack of 13.90% in type-1, 16.80% in type-2, and 22.88% in type-3), and those close to windows in the south-facing room (R1 in all 3 types) are the worst (with the MN of 67.08% in type-1, 54.17% in type-2, and 45.14% in type-3). On the contrary, as a result of H_v the seats close to window are more favorable than others, especially in the south-facing room (mentioned in Part 3.1). Moreover, even at the same table the elderly have a significant difference between each other because of the orientation of seats (mentioned in Part 3.1), which is not expressed by UDI, while discomfort and unwanted excessive levels of daylight such as glare is not considered in H_v.

3.3 Material of walls on both sides of the hallway

In general, solid walls on both sides of the hallway help increase the annual vertical daylight exposure (H_v), compared with glass walls. In type-1 and type-2, solid walls improve H_v on both sides of general level (by 5.8×10^4 lux·h in type-1 and 1.4×10^5 lux·h in type-2) and uniformity, while in type-3 the result is on the contrary (decrease 3.5×10^4 lux·h in type-3) (Tab. 6). Meanwhile, in the north room of type-1 and type-2 the improvement of using solid walls is better that in south (8.5×10^4 lux·h vs 4.1×10^4 lux·h in type-1 and 2.0×10^5 lux·h vs 9.4×10^4 lux·h in type-2). And in the north room of type-3 using solid walls decreases H_v, while in the south it increased. Besides, in general when using solid walls instead of glass walls, there is no significant difference between facing and back to windows but on the contrary a difference between near and away from windows (1.4×10^4 lux·h vs 1.0×10^5 lux·h in type-1, 1.0×10^5 lux·h vs 2.0×10^5 lux·h in type-2 and -1.4×10^5 lux·h vs 1.8×10^4 lux·h in type-3).

Tab. 6 descriptive statistics of H_v with the solid wall and the glass wall (10^6 lux·h), layout type-1 to type-3

			Solid wall	Glass wall	Difference				Solid wall	Glass wall	Difference
Type-1	MN	Whole	4.28	4.23	0.05	Type-2	MN	Whole	3.42	3.29	0.13
		North	3.04	2.96	0.08			North	2.38	2.18	0.20
		South	5.53	5.49	0.04			South	4.12	4.02	0.10
		Face	7.46	7.40	0.06			Face	/	/	/
		Back	1.10	1.05	0.05			Back	/	/	/
		Side-facing	/	/	/			Side-facing	3.42	3.29	0.13
	SD	Whole	4.65	4.66	-0.01		SD	Whole	2.53	2.59	-0.06
		North	2.57	2.61	-0.04			North	0.96	0.98	-0.02
		South	5.78	5.76	0.02			South	2.98	3.03	-0.05
		Face	4.75	4.76	-0.01			Face	/	/	/
		Back	0.49	0.55	-0.06			Back	/	/	/
		Side-facing	/	/				Side-facing	2.53	2.59	-0.06

			Solid wall	Glass wall	Difference

Type-3	MN	Whole	4.10	4.13	-0.03
		North	2.39	2.53	-0.14
		South	5.24	5.20	0.04
		Face	8.00	7.89	0.11
		Back	1.30	1.18	0.12
		Side-facing	3.55	3.73	-0.18
	SD	Whole	4.41	4.38	0.03
		North	1.93	1.90	0.03
		South	5.16	5.17	0.01
		Face	5.83	5.86	0.03
		Back	0.68	0.77	0.09
		Side-facing	3.13	3.06	0.07

Note: 'Whole' =all the seats in the type; 'North' and 'South' = the room orientations; the others= the seat orientations.

MN refers to Mean, and SD refers to Standard Deviation.

By comparison of H_v of each row in details, using solid walls instead of glass walls mainly changed seats in r6 (1.9×10^5 lux·h) and r8 (-3.5×10^4 lux·h) in type-1, seats side-facing windows in R4 in type-3 (1.3×10^6 lux·h), and seats back to windows in R3 in type-3 (1.7×10^5 lux·h). And remarkably the difference between type-3 and other types is caused by the large decreasing H_v of the seats side-facing windows in R4 (by 1.3×10^6 lux·h).

Therefore, in order to improve the daylighting quality of the elder away from windows especially in north-facing room, the solid walls on both sides of the hallway are recommended.

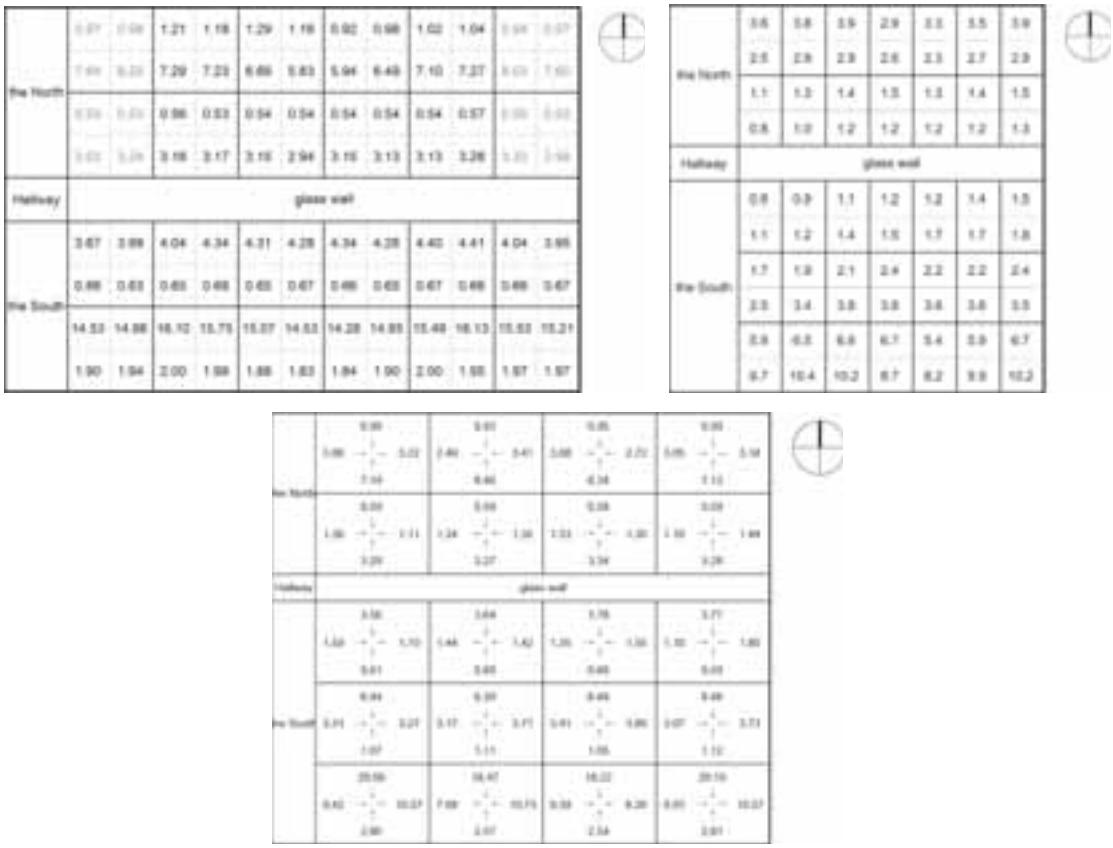

Fig. 5.1 to 5.3 the annual vertical daylight exposure on the eye (H_v, 10^6 lux • h) of each seat with glass walls on the side of the hallway, Layout Type-1 to Type-3

4. Conclusion

According to the discussion above, the main conclusions showed as follows:

- Position orientation has a significant influence on annual vertical daylight exposure on the eye (H_v);
- Health evaluation by the annual vertical daylight exposure on the eye (H_v) differs significantly from Visual task lighting evaluation by UDI, and both have shortage and need to be considered together;
- Compared with glass walls, solid walls on both sides of the hallway help improve the annual vertical daylight exposure (H_v) on both side of general level and uniformity.

All above can be applied to improve the daylight conditions for the elderly during activities. On one side, the layout of daytime activity space can be designed or redesigned to optimize the daylight quality based on non-visual effects. For example, a suitable room orientation and furniture layout of the space can be chosen according to the requirement of the activity. On the other side, the regulation of the elderly's activities can be optimized to realize the needs of the elderly and to avoid disadvantages.

Limitations and future work: in this paper, the regulation of the elderly's activities is simplified as a point, while actually it is more appropriate to describe it as a line. In other words, the movement of the elderly from one seat to another and from one room to another should be recorded so that the difference between different elderly will be more comparable. Some work has been made in this paper that if one always sit in the seat with the most/least vertical illuminance per hour, finally he will receive the H_v of 3.6×10^4 lux·h /2.0×10^3 lux·h in one day (for example in Sep. 23rd) and 1.8×10^7 lux·h /5.3×10^5 lux·h in a year (for example in type-1), which can somewhat reflect the influence of position on vertical daylight exposure on the eye in another view. With the real occupancy schedule of one's activities as well as his position record, specialized plan for improving his condition of vertical daylight exposure on the eye will be drawn up and the result of the improvement will be more efficient.

Abstract

This paper evaluates the daylighting performance of an integrated skylight and shading dome with natural ventilation (SDV) for residential buildings in the tropics using the RADIANCE lighting simulation program and the Energy Plus Weather (EPW) file for Bangkok, Thailand. Indoor illuminance levels at work plane height of a simulation model with the SDV was compared to that of from similar physical scale model located in natural environment. A typical unit base case model (1.35 m x 1.35 m x 2.80 m) with a circular translucent opening (60% transmittance, r = 0.175 m) was developed to relate with sizing of available conventional roofing materials and typical residence room's height. Daylighting performance of the base case based on Daylight Autonomy (DA 300 lux) was compared to the original SDV and the modified SDVs, which the skylight plate replaced with different translucent materials (40%, 50%, and 60% transmittance). The results show that the modified SDVs' DA are all above 50%. Four typical units of the modified SVD (60% transmittance) were developed to represent an application and compare to a conventional translucent sheet in an extended residence area. The results confirm that the modified SDV has better daylighting quality than the translucent sheet which has similar opening area and light transmittance value (60%). With proper design and material selection, the modified SDV (60% transmittance) could significantly reduce direct sunlight, which is the cause of glare and heat problems for buildings in tropical climates.

1. Introduction

In Thailand, most indoor spaces in low rise buildings (e.g. single house, row house, townhouse, etc.) have low daylight levels. Using electric lighting is costly and not a sustainable solution. Conventional translucent sheets have been widely used but it is difficult to control the quality of daylight and always be a cause of significance problems such as heat, glare, and ultra violet, which may be harmful to eyes, artworks, and furniture. Although many products were developed for the use of natural light such as typical transparent and translucent roof sheets with optional of external or internal shading devices. There are limitations of thermal resistance and quality of daylight. Advanced materials and advanced technology devices such as glass reinforced polyester, insulated glass, double panes, low-e coating, laminated glass with a polymer dispersed liquid crystal (PDLC), hyperboloid skylights, dome skylights, tubular daylighting devices, with and without sun tracker and reflective materials have been developed to improve the daylighting performance and thermal insulation. However, the cost of those materials and products are expensive and may not be cost effective.

Fig. 1: An integrated skylight and shading dome with natural ventilation (SDV)

doi:10.18086/swc.2017.05.04 Available at http://proceedings.ises.org

We are proposing an integrated skylight and shading dome with natural ventilation (SDV) (Fig.1), which was developed from the previous one (without natural ventilation system) (Visitsak et al., 2014) as a sustainable solution that could reduce significantly problems of heat, glare, and ultra violet. The opening and the shading form were developed to responds to sunpath (Stein and Reynolds, 2000) for Bangkok, Thailand (latitude 13.76° N, longitude 100.52° E) in order to protect direct light (100%) throughout the year. The design also allows building occupants to perceive external view through the opening and be connected with the environment.

The objective of this paper is to evaluate the daylighting performance of the SDVs (original and modified) and typical translucent skylight using the RADIANCE lighting simulation program (Ward, 1996), which was found to be the most generally useful software package for architectural lighting simulation program (Reinhart and Fitz, 2006) as well as a highly optimized daylighting and energy modeling plug-in, DIVA-for-Rhino (v.4).

2. Methodology

The SDV consists of two main parts: 1) a circular metal skylight plate (r = 0.175 m, area = 0.096 m^2,) on a metal tube (height = 0.185m) with an opening area to allow only indirect sunlight and the opaque area to obstruct direct sunlight and 2) a transparent acrylic dome (88% transmittance), which the shading area for protecting direct sunlight is silver painted. The reflectance values of ceiling, walls, and floor are 70%, 70% and 20%, respectively. The process of conducting and comparing daylight performance of the original and modified SDVs and typical translucent skylight using simulation and Bangkok weather comprised 3 steps:

2.1. Calibration of simulation model (original SDV)

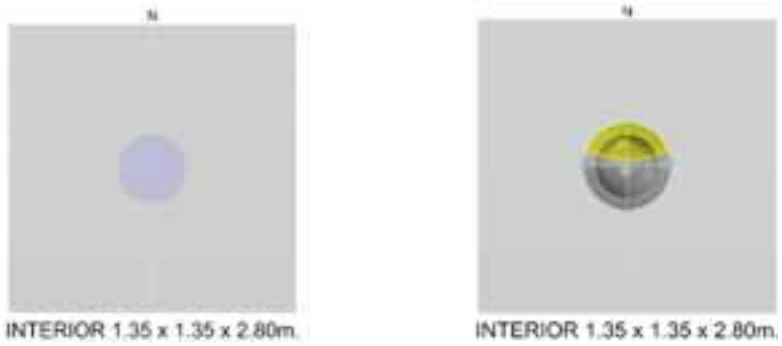
A physical scale model with the original skylight and shading dome (SDV) installed on the roof (Fig.2) was prepared and tested outdoor in Ayuthaya, Thailand (latitude 14.37° N, longitude 100.59° E). The model dimensions were 1.00 m wide x 1.00 m long x 2.30 m high. Indoor illuminance at work plane (0.80 m) on March 6th at noon, when the outdoor illuminance was similar to that of from Bangkok weather data (EPW), was used to calibrate with the results of simulation model using Bangkok weather data from Energy Plus Weather file (DOE, 2017).

(a) (b) (c)

Fig. 2: Simulation model of the skylight and shading dome (SDV): (a) Plan (b) Section and (c) Perspective

2.2. Daylighting performance: One unit (base case, original SDV, and modified SDVs)

A typical unit base case model with dimensions 1.35 m wide x 1.35 m long x 2.80 m high and a circular opening equivalent to the SDV's circular skylight plate (r = 0.175 m, area = 0.096 m^2) was developed to relate with sizing of available typical roofing materials and typical residence room's height. The daylighting performance at work plane (0.76 m) based on daylight autonomy (300 lux) during the occupied hours (8:00 a.m.-6:00 p.m.) throughout the year (Reinhart et al., 2006) of the base case with a circular translucent opening (60% transmittance) (Fig.3a) was compared to that of from the original SDV and modified SDVs, which the skylight plate (opaque part) was replaced with an alternative translucent material with different transmittance (40%, 50%, and 60%) (Fig.3b).



(a) (b)

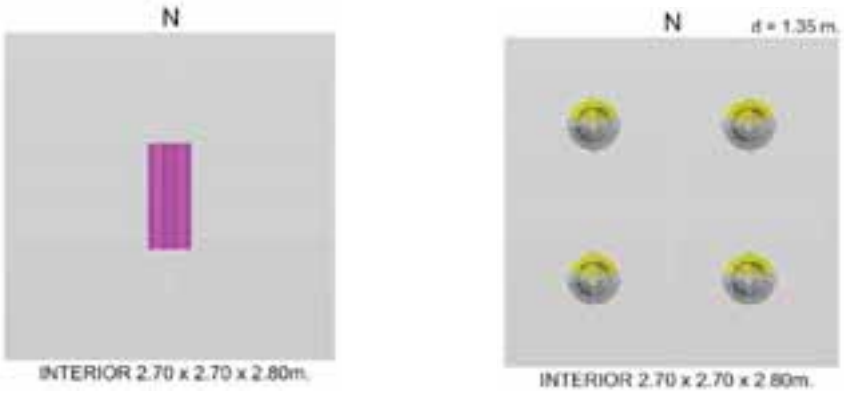
Fig. 3: Simulation model: One unit (a) Base case (Circular translucent material, τ = 60%) (b) Original SDV & Modified SDVs (τ = 40%, 50%, and 60%)

2.3. Daylighting performance: Four units (translucent sheet vs. modified SDVs)

Four typical units with dimensions 2.70 m wide x 2.70 m long x 2.80 m high represent an application of a conventional translucent sheet (opening area = 0.38 m^2, 60% transmittance) in an extended residence area with typical cement roof sheets. The daylighting performance at work plane (0.76 m) of the translucent sheet installed on the roof (Fig.4a) based on Daylight Autonomy (DA300 lux), which represents percentage of annual daytime hours during the occupied hours (8:00 a.m.-6:00 p.m.) that a given point in the area is above 300 lux, was simulated and compared with the results from four modified SDVs (Fig.4b) with 40%, 50%, and 60% transmittance, which have equal opening area and placed 1.35m apart from each other, installed on roof.

The best modified SDV option (60% transmittance) from the previous step was used to simulate and compare daylighting performance results to the translucent sheet. The daylighting performance results include mean indoor illuminance on the summer solstices (Jun 21st at noon) when the external daylight is critical and mean Useful Daylight Illuminance that indicates percentage of occupied hours per year when daylight illuminance falls within a range from 300-3000 lux (UDI 300-3000 lux) (Nabil and Mardaljevic, 2005; 2006), as well as the daylighting metrics in LEED v4, which are Spatial Daylight Autonomy (sDA300/50%) (IESNA, 2012) that indicate percentage of the area that meets or exceeds 300 lux at least 50% of the occupied hours per year, and Annual Sun Exposer (ASE1000/250) (IESNA, 2012) that identified potential of discomfort and should be no more than 10% of the area exposed to direct sunlight more than 1000 lux for 250 hours per year.

In addition, simulation glare images for sitting eye level from the corner of the room for the translucent sheet and the best modified SDV (60% transmittance) as well as glare indices results of Daylight Glare Probability Index (DGP) (Wienold and Christoffersen, 2006), Daylight Glare Index (DGI) (Hopkinson, 1972), Unified Glare Index (UGR) (CIE, 1992), Visual Comfort Probability Index (VCP) (IESNA, 1993) and CGI/CIE Glare Index (Einhorn, 1969) on the four representative dates (Mar 21st, Jun 21st, Sep 21st, and Dec 21st) at noon were also simulated and compared.



(a) (b)

Fig. 4: Simulation model: Four units (a) Translucent sheet (τ = 40%), (b) Modified SDVs (τ = 40%, 50%, and 60%)

3. Data analysis and results

3.1. Calibration of simulation model (original SDV) results

The indoor illuminance at work plane (0.80 m) of the physical scale model with the original skylight and shading dome (SDV) installed on the roof, which was located in Ayutthaya, (March 6, at noon) was used to calibrate with the results of simulation model using Bangkok weather file (March 6, at noon). Table 1 shows that the average indoor illuminance (125 lux) from simulation model, when the outdoor illuminance from Bangkok weather file (93,400 lux) is similar to the outdoor illuminance from field measurement (93,800 lux), corresponds to the indoor illuminance (129 lux) measured from the physical scale model. The results confirm that the simulation model is compatible with the physical scale model and could be used to modify and simulate daylighting performance of various conditions in the next step.

Tab. 1: Comparison of indoor and outdoor illuminance from simulations and field measurements (Mar 6, at noon)

Run	Simulation (BKK epw)		Measurement	
	Indoor Illuminance (lux)	Outdoor Illuminance (lux)	Indoor Illuminance (lux)	Outdoor Illuminance (lux)
1	126	93400	129	93800
2	128			
3	128			
4	122			
5	122			

3.2. Daylighting performance results: One unit (base case, original SDV & modified SDVs)

The simulation results of one unit (1.35 m wide x 1.35 m long x 2.80 m high) in Figs. 5 & 6 show Daylight Autonomy (300 lux) during the occupied hours (8:00 a.m.-6:00 p.m.) of the base case model with a circular translucent material (60% transmittance), the original SDV, and the modified SDVs, which the skylight plate (opaque part) was replaced with translucent material with different transmittance (40%, 50%, and 60%). As expected, the percentage of DA (300 lux) increases with the transmittance value. The percentages of DA (300 lux) of the original SDV and the modified SDVs (40%, 50% and 60% transmittance) are 0%, 2.44%, 6.72%, and 16.76%, respectively. Although they are all lower than that of the base case (60.4%), an alternative translucent material with different transmittance (40%, 50% and 60%) is effective and increases the percentage of Daylight Autonomy.

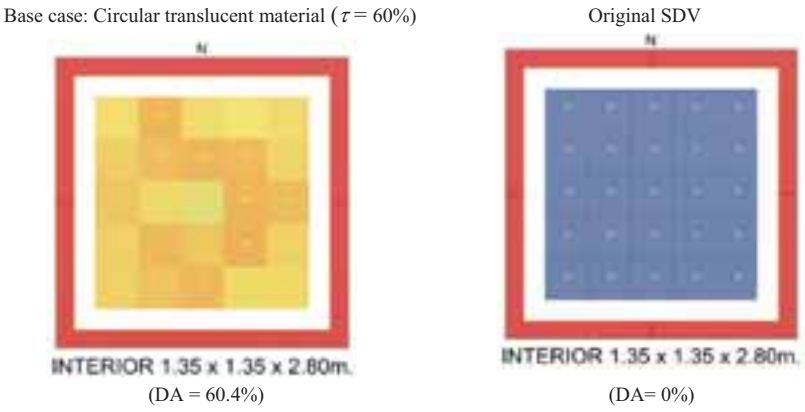


Fig. 5: Percentage of DA (300 lux) of one unit: Base case (Circular translucent material, τ= 60%) and Original SDV

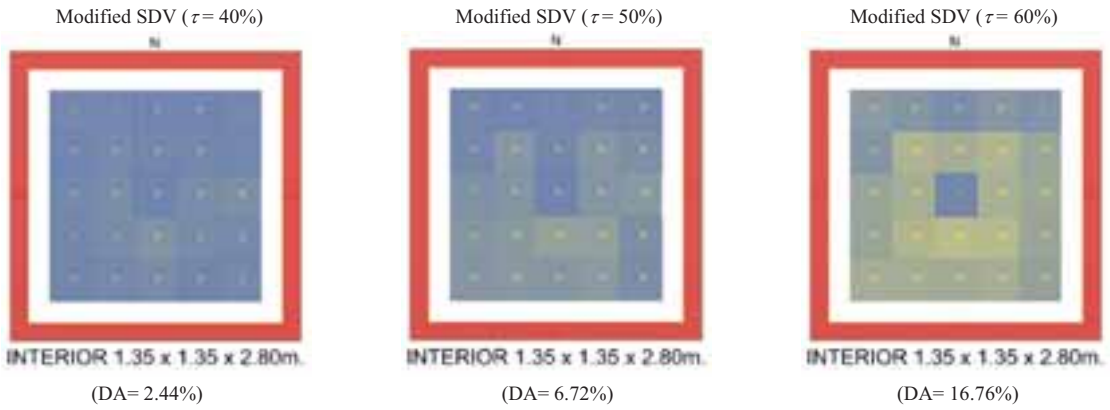

Fig. 6: Percentage of DA (300 lux) of one unit: Modified SDVs (τ= 40%, 50%, and 60%)

3.3. Daylighting performance results: Four units (translucent sheet vs. modified SDVs)

- *Daylight Autonomy (300 lux) results:*

In Fig.7, the results show that the percentages of Daylight Autonomy (300 lux) during the occupied hours (8:00 a.m.-6:00 p.m.) corresponds to the DA (300 lux) results in Figs. 5 & 6, which increase with the transmittance value. In addition they also increase with larger space for all cases. The percentages of DA (300 lux) of four units of the conventional translucent sheet (60% transmittance) and the modified SDVs (40%, 50% and 60% transmittance) increase to 86.57%, 52.64%, 66.3%, and 73.57%, respectively. Although the modified SDVs (40%, 50%, and 60% transmittance) have percentage of DA (300 lux) lower than that of the translucent sheet (60% transmittance), they are all above 50% DA (300 lux).

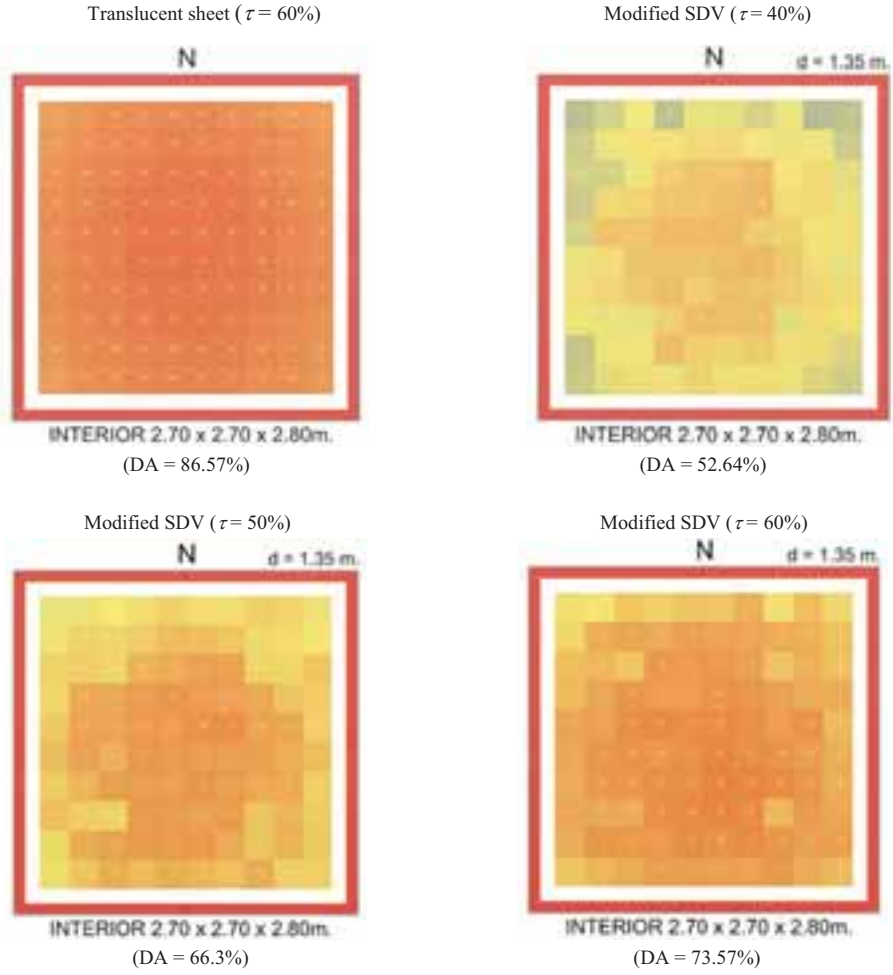

Fig. 7: Percentages of DA (300 lux) of four unit: Translucent sheet (τ= 60%) vs. Modified SDVs (τ= 40%, 50%, and 60%)

- *Mean illuminance results:*

Fig. 8 shows the results of mean illuminance on the June 21st (at noon) of the translucent sheet and the modified SDV with similar transmittance value (60%). Mean illuminance on the June 21st (at noon) of the translucent sheet is 1551 lux with illuminance level ranging between 1074-2148 lux for 98% of the area, which is much higher than the standard indoor illuminance requirements and that of the modified SDV with 60% transmittance. The mean illuminance of the modified SDV (60% transmittance) is 831 lux with illuminance level ranging between 537-1074 lux for 97% of the area. The results implies that the modified SDVs in larger space could provide sufficient daylighting and reduce incoming solar radiation significantly.

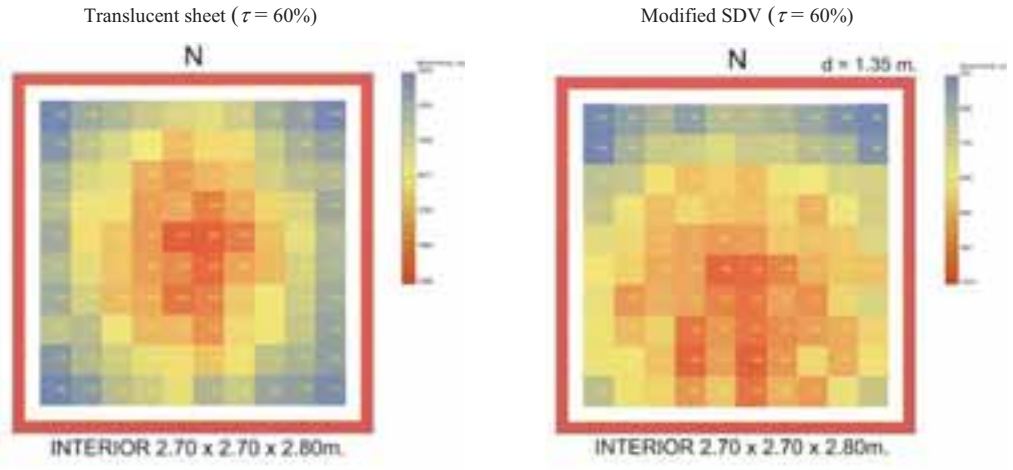

Fig. 8: Mean Illuminance of four units, Jun 21st at noon: Translucent sheet (τ= 60%) vs. Modified SDV (τ= 60%)

- *Mean Useful Daylight Illuminance (UDI 300-3000 lux) results:*

Simulation results in Fig.9 indicate percentages of occupied hours per year when daylight illuminance falls within a range from 300-3000 lux (UDI 300-3000 lux). For the translucent sheet (60% transmittance), there are 77% to 93% of the occupied hours per year that the partial areas have illuminance in the range from 300-3000 lux and the mean UDI (300-3000 lux) equals to 86.46%. The UDI (300-3000 lux) of the modified SDV (60% transmittance) vary from 50% to 85% and mean UDI (300-3000 lux) is 73.99%. UDI (300-3000 lux) of both cases are higher in the middle of the areas and spread out to lower value in the perimeters and in the corners of the areas.

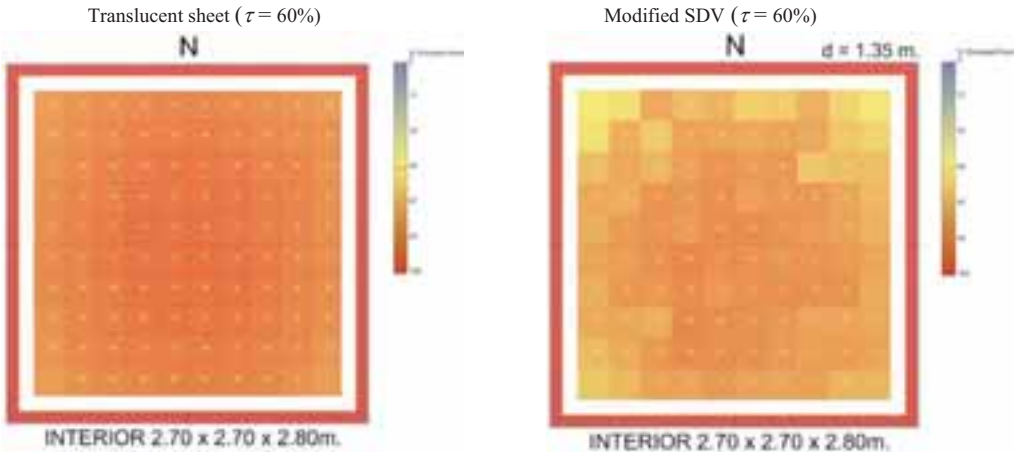

Fig. 9: Mean Useful Daylight Illuminance (UDI 300-3000 lux) of four units: Translucent sheet (τ= 60%) vs. Modified SDV (τ= 60%)

- *Spatial Daylight Autonomy (sDA300/50%) and ASE (1000/250) results :*

In Fig.10, the simulation results show that 100% the translucent sheet (60% transmittance) room area and 98% of the modified SDV (60% transmittance) room area have a *Spatial Daylight Autonomy* at 300 lux value for more than 50% of the occupied hours. For both cases, none of the areas are exposed to direct sunlight more than 1000 lux for 250 hours per year, which qualify for 3 LEED points in LEED v4.

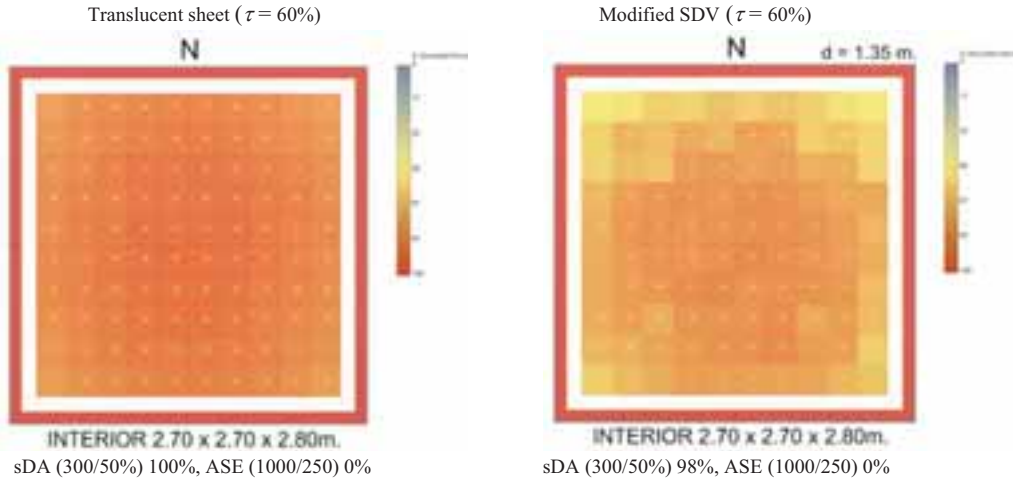

Fig. 10: Spatial Daylight (sDA 300/50%): Translucent sheet and Modified SDV (τ= 60%)

- *Glare Evaluations (DGP, DGI, UGR, VCP, CGI)*

In (Figs.11-12), the simulation glare images and glare indices *(DGP, DGI, UGR, VCP, CGI)* for sitting eye level from the corner of the room on Mar 21 st st, Jun 21 st st, Sep 21 st st, and Dec 21st (at noon) are presented. Green, Yellow, Orange, and Red colors that correspond to glare value ranges represent the levels of glare, which are imperceptible, perceptible, disturbing, and intolerable, respectively.

The results show that the glare value ranges of Daylight Glare Probability Index (DGP) and Daylight Glare Index (DGI) on all selected dates for the conventional translucent sheet (60% transmittance) and the modified SDV (60% transmittance) are imperceptible glare. Base case has higher DGP glare values and lower DGI glare values than the modified SDV, except on Dec 21st.

The results are different for Unified Glare Index (UGR), Visual Comfort Probability Index (VCP) and CGI/CIE Glare Index, which in general the modified SDV has better glare values than the translucent sheet (60% transmittance) for all selected dates. It implies that the modified SDV (60% transmittance) has less glare problems than the base case, especially on Dec 21st when the sun ray is lower. For base case, the results show significant problem of intolerable glare on Mar 21st , Jun 21st , and Sep 21st as well as disturbing glare on Dec 21st for the Visual Comfort Probability Index (VCP).

4. Conclusion

Daylighting performance of an integrated skylight and shading dome with natural ventilation (SDV) for the tropics and alternative materials were investigated using the RADIANCE lighting simulation program and the weather file (EPW) for Bangkok, Thailand. The daylighting simulation results show that, with proper design and material selections, the daylighting performance of the modified SDVs with part of the skylight plate replaced with an alternative translucent materials (40%, 50%, and 60% transmittance) are above 50% daylight autonomy (300 lux). The modified SVD with 60% transmittance provides appropriate indoor illuminance with mean UDI 73.99% of occupied hours in the range of 300-3000 lux as well as 98% of the area have a *Spatial Daylight Autonomy* at 300 lux value for more than 50% of the occupied hours without any of the areas are exposed to direct sunlight more than 1000 lux for 250 hours per year, which qualify for 3 LEED points. The modified SVD (60% transmittance) has better daylighting quality than a conventional translucent skylight with similar opening area and light transmittance value (60%). In addition, the modified SDVs could reduce glare problems and incoming solar radiation that exceeds indoor illuminance requirements, which is the cause of heat problem for buildings in tropical climates.

District Heating

Validation of a District Heating System Model and Simulation-Based Investigation of Bidirectional Heat Transport by Decentralized Solar Thermal Plants

Abstract

This work discusses a MATLAB/Simulink-based modelling approach for the simulation of bidirectional flow in district heating systems with decentralized solar thermal plants. Based on the results of a monitoring campaign of an operational district heating network with decentralized solar thermal plants, a simulation model of the system is validated. Modified components for pipes, thermal storages and network junctions are derived from the CARNOT toolbox and additionally validated by laboratory tests. These components are used to enhance the model for the simulation of a reversed flow in the district heating pipes. Based on this modification, a study is conducted to examine the performance of a return-supply feed-in compared to a return-return feed-in for different dimensions of solar thermal plants in the network. The comparison shows that for small plant sizes and low solar fractions, a pure return-return feed-in can be suitable, whereas for higher solar fractions, a return-supply feed-in increases the solar yield of the decentralized plants.

Keywords: district heating, modelling, bidirectional flow, decentralized solar thermal plants

1. Introduction

The integration of solar heat into district heating systems is a promising approach for the reduction of carbon dioxide emissions from domestic hot water and space heat consumption in urban areas. While large contiguous collector arrays are a cost effective way of supplying newly built areas and large ambitious renovation projects with solar heat, existing buildings and district heating networks in densely built-up quarters require adapted solutions to deal with the limited space. The decentralized integration of solar collectors and diurnal heat storages is one possible answer to this challenge. However, as this approach transforms the connected buildings from pure consumers to prosumers, a detailed planning of the design and operation of multiple plants interacting in one energy supply system is required. The simulation-based optimization of the hydraulic layout, the dimensioning and the control strategy is an essential step towards the realization of such projects.

Four major hydraulic schemes can be identified for the decentralized integration of solar heat. These are return-return (RR), supply-return (SR), supply-supply (SS) and return-supply (RS) feed-in (Schäfer et al. 2014). While the first three concepts do not lead to a change in the flow direction of the water circulating in the district heating pipes, the RS feed-in causes a reversed flow in the branches where decentralized heat generators are in operation. This operation mode is shown in Fig. 1, where the upper scheme represents the flow distribution when the central heating plant is the sole heat supply. The bottom scheme shows the same system while a decentralised heat generator is additionally active, which allows partly supplying other consumers in the system with the necessary nominal flow rate. While this feed-in strategy is very attractive due to the parallel operation of decentralised heat generators on the same supply and return temperature level as the central heating plant, it is on the other side more complex in terms of hydraulic layout and system operation. In some existing systems, additional solar pipes are used in parallel to the district heating supply and return pipe, allowing additional hydraulic design parameters (so called 2+1 or 2+2-systems). Examples can be seen in Mies and Rehrmann (2007) or Paulus and Papillon (2014). However, this leads to additional costs. Furthermore, for most existing district heating systems, it may be difficult to add another pipe in the ground. As this paper aims at renovation projects, this approach is not further discussed and the connection of the solar thermal plants to the existing district heating pipes is the focus of the work.

doi:10.18086/swc.2017.06.01 Available at http://proceedings.ises.org

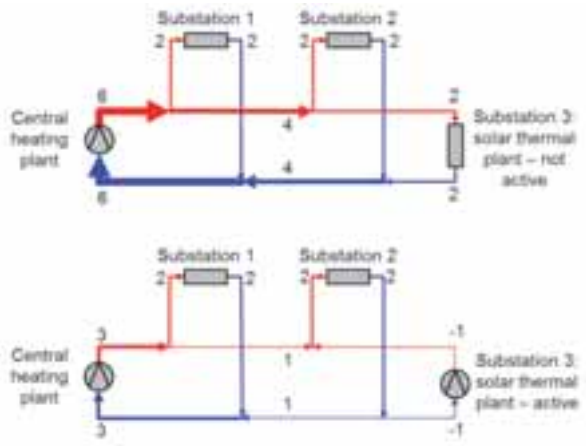

Fig. 1: Change in flow conditions during activation of a decentralized RS feed-in. Top scheme: solely supplied by central heating plant; bottom scheme: additional decentralized feed-in by solar thermal plant (numbers show nominal flow rates)

The CARNOT-toolbox in MATLAB/Simulink provides a block library with all necessary components to model heating systems – including district heating – for the conceptual design of these systems (Hafner et al. 1999). Due to the unidirectional information flow between Simulink blocks, it is, nevertheless, not straightforward to model the reversed flow in pipe connections between components like boilers, storages and heat exchangers. A modification and extension of the available CARNOT library is, therefore, necessary to enable the design of a district heating system with decentralized solar thermal plants utilizing an RS feed-in. One approach of such a modification is presented in this paper, validated by measurements and tested in a district heating network model.

2. Description of the existing district heating network

The basis of the system simulation is the metrological investigation of an existing, operational district heating network in Ingolstadt, Germany, which is shown in Fig. 2. The network was built in the 1970´s and was equipped with four decentralized solar thermal plants in 2016. It was decided to use single-cover flat-plate collectors in this case, to keep the investment costs on a low level. The standard CARNOT toolbox was used for designing this renovation project and all plants were equipped with comprehensive metrological equipment to measure the temperatures and volume flows in the systems as well as the heat flows in each branch continuously. While three plants have the same collector area of 71 m² and orientation, the hydraulic integration concepts differ. The similar sizing allows a comparison of the different utilization concepts:

- One solar thermal plant was installed on the roof of the main building (Hindenburg 57 – HB57), where the central heating plant is located. As the building has 85 residential units and, therefore, a high domestic hot water consumption, there is no need to feed in heat from the solar thermal plant into the network. Due to the high ratio of heat consumption to collector area and the resulting low operation temperatures, the plant can achieve a high annual yield of 42.5 MWh at the average local climate.
- Another system (Hindenburg 36 – HB36) is designed for pure feed-in and is very simple regarding the hydraulic layout and the control strategy. In addition, it has only small space requirements in the building, as it does not require a thermal storage, making it easy to integrate into the existing quarters. The feed-in strategy is a pure RR feed-in. The plant is directly connected via a plate heat exchanger to the main return pipe of the network passing by the building. Measurements show an average annual yield of 16.9 MWh at the current operation parameters of the network.
- Finally, there are two systems for a combined use, meaning that in a first step the solar heat is consumed directly in the building for domestic hot water preheating. Only if there is excess heat and the storage temperature reaches a certain level, the feed-in to the return of the network is activated. The plants achieve an annual yield of 26.6 MWh for the south oriented roof (Schubert 21 – SB21) and 31.8 MWh for the west oriented roof (Schubert 12 – SB12), where 21 m² vacuum tube collectors are additionally in operation. These collectors were already installed and integrated to the new plant. Local solar fractions for domestic hot water of the two plants are 73 % and 49 % respectively. During summer, this fraction increases up to monthly values of 140 %. The installed excess heat feed-in reliably transfers the heat into the district heating return.

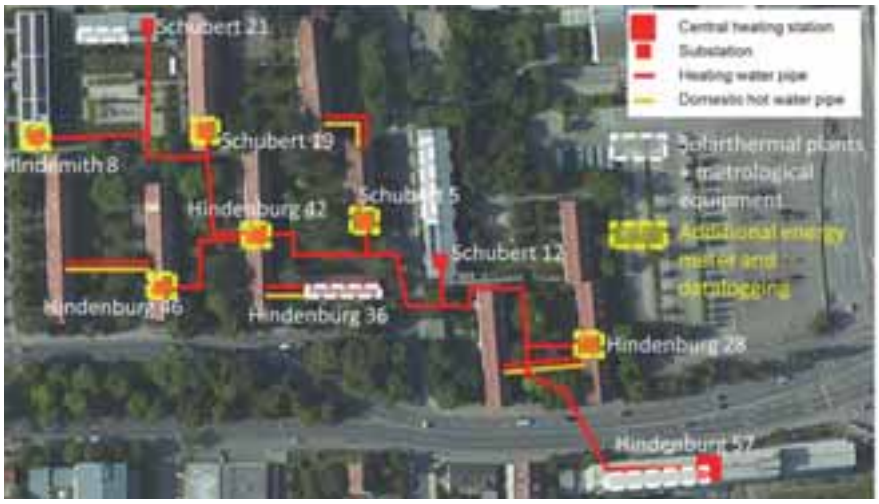

Fig. 2: Scheme of the existing district heating network with decentralized solar thermal plants

3. Description of the simulation model

Fig. 3 shows the layout of the complete district heating network model. The single components used in this model are introduced in the following section.

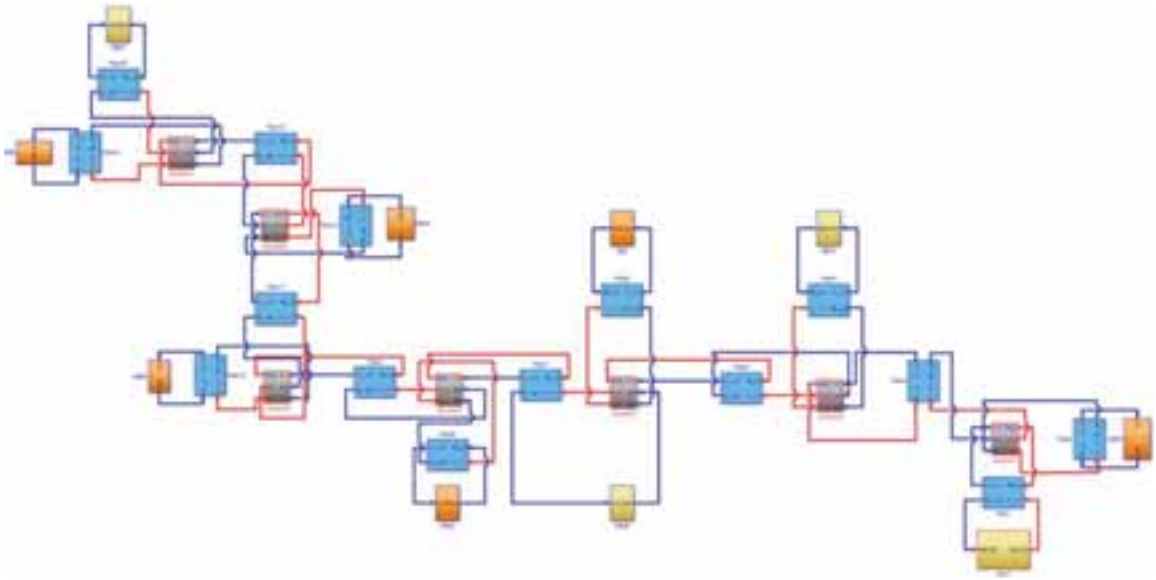

Fig. 3: Depiction of the district heating network simulation model with consumers (orange), producers/prosumers (yellow), pipes (blue) and network junctions (grey)

3.1 Pipe model

For the simulation of a district heating network with decentralized feed-in, four properties of the pipe model are particularly of interest:

- Calculation of the heat losses
- Calculation of the stored energy due to the thermal capacity of pipe and fluid
- Calculation of the time delays of the fluid flow in the network
- Ability to simulate a reversed flow in the pipe

To cope with these demands, a new setup of pipe model was developed based on Simulink. As the buildings and other system components are modelled in CARNOT, the thermo-hydraulic vector (THV) was the basis for the new calculation procedure. Besides the temperature and the mass flow, the THV contains several data, which are not relevant to the energy balance of the district heating network and can be simplified without losing accuracy in

this application. As the fluid is always pure water and pressure loss calculations are only of interest for the detailed system design but not for the conceptual layout and control strategy, only the temperature and the mass flow were selected and structured in a 2-component vector for all calculations in the network. To realize the reversed flow in Simulink, the pipe model consists of a *Supply*- and a *Return*-pipe, merged in one block. Fig. 4 shows the structure of this block. It is connected via the *Supply_in*, *Supply_out*, *Return_in* and *Return_out* ports to the superior model. Depending on the sign of the mass flow (positive = heat generation, negative = heat consumption), the *Switch* blocks conduct the information from the *Supply_in* port to the *Supply* pipe and the *Supply_out* port for standard operation. During a decentralized feed-in, the *Return* pipe is connected to the *Supply_in* and *Supply_out* ports to establish the reversed flow. The *Memory* blocks are used to break algebraic loops by adding a one integration step time delay. As the time step is always below 10 s (approximately 3 s in average), this does not lead to a significant error in the simulation.

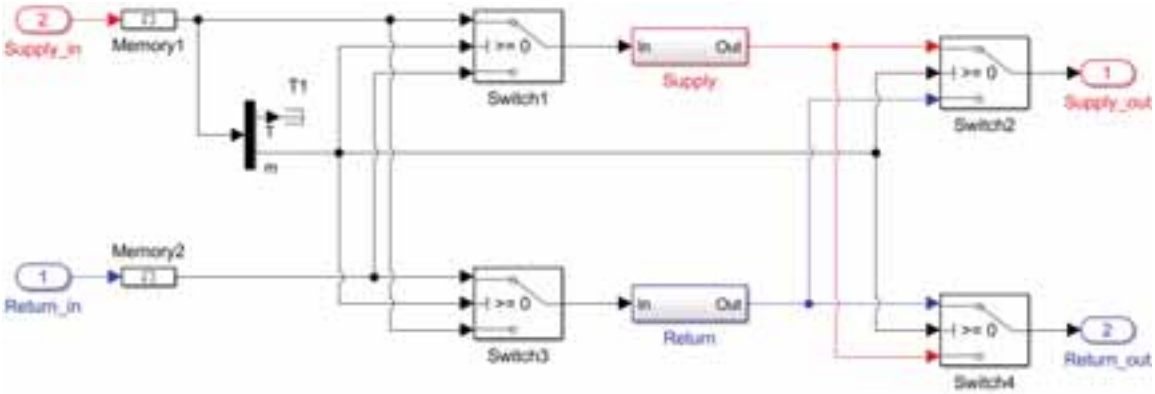

Fig. 4: Pipe block with *Supply* and *Return* pipe and *Switches* for change of the flow direction

Inside the *Supply* and *Return* blocks, several calculations are performed to emulate the pipe behavior (Fig. 5). The *Delay* sub-model takes the current mass flow of the fluid in the pipe, calculates the fluid velocity and, based on the pipe length, the transport delay from the inlet to the outlet. The temperature information at the inlet is then kept for the calculated delay duration until the fluid is conducted to the *Q_loss* and the *E_pipe* block. These blocks represent the energy balance at the pipe (losses through insulation, stored internal energy due to fluid, pipe wall and insulation capacity). Integrating the sum of these two terms after multiplication with the total pipe capacity leads to the time-dependent outlet temperature. The same calculation is performed in the *Return* pipe of the block.

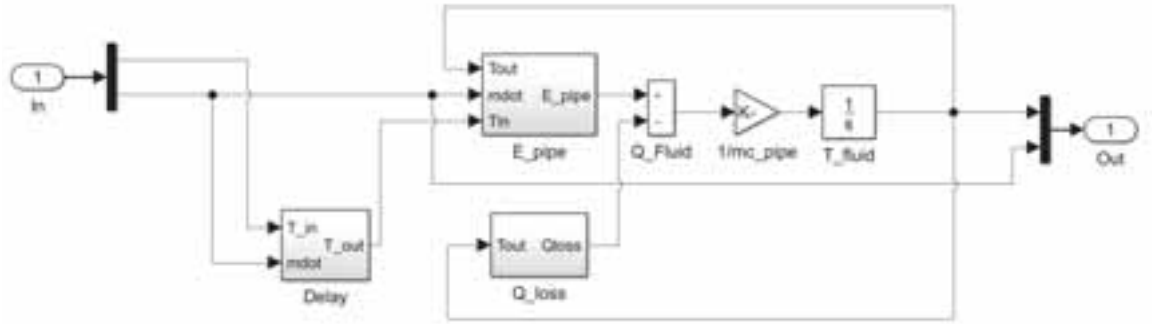

Fig. 5: Layout of a single pipe component with time delay, energy loss, energy balance of inlet and outlet and thermal node of the pipe

Some simplifications are introduced in this pipe model. Firstly, the heat capacity of the water is assumed to be constant at 4,188 J/(kgK). This is justified as the maximum deviation of the real value within the temperature range between 0 °C and 100 °C is less than 0.5 %. Secondly, the temperature of the pipe wall is assumed to be the same as the fluid temperature, which is acceptable if the thermal resistance of the pipe insulation is much higher than the thermal resistance of the pipe wall and the convective heat transfer between fluid and pipe wall. For thermal conductivities of the insulation material around 0.04 W/(mK) and thicknesses in the range of the pipe diameter, this assumption is sufficient. For the calculation of the insulation capacity, an average insulation temperature has to be defined. This results from the fact that when assuming a linear temperature gradient along

the insulation thickness, more than half of the insulation material mass is closer to ambient than to fluid temperature due to the increasing lateral surface at larger distances from the pipe wall. For a pipe with an insulation thickness equal to the inner diameter, this results in a weighted temperature of 37 % of the inner temperature compared to ambient, meaning that e.g. at 80 °C fluid and 20 °C ambient temperature, the average insulation temperature is only at 42 °C. To cope with this fact, 37 % of the total capacity of the insulation are added to the fluid capacity and set to fluid temperature whereas the other 63 % are neglected. Fig. 6 illustrates this correlation.

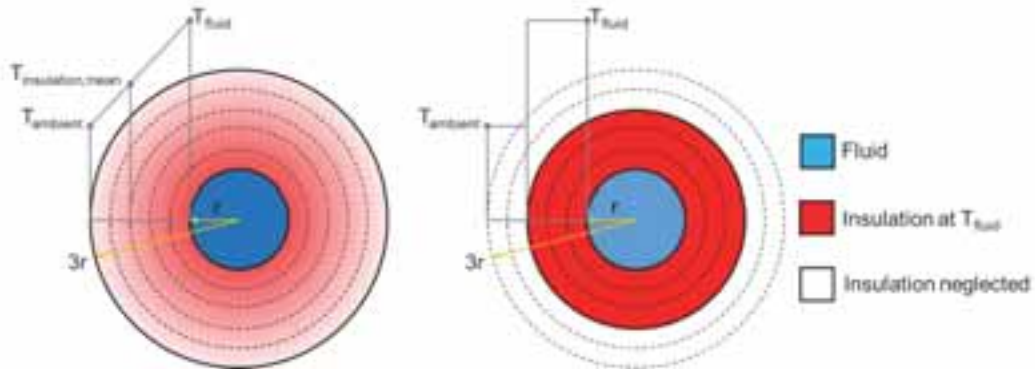

Fig. 6: Real (left) and discretized (right) temperature distribution across the pipe cross-section with equal stored energy

As the thermal conductivity of insulation materials can be highly dependent on the temperature, a temperature-conductivity function is introduced using a set of temperature-conductivity pairs and a linear interpolation between the known values. Equation 1 gives the heat loss of the pipe:

$$loss = \frac{2 \cdot \pi \cdot l}{ln\left(\frac{D+\frac{2 \cdot P_i}{100}}{D}\right)} \quad \text{(eq. 1)}$$

The thermal capacity of the fluid, the pipe wall and the insulation can be calculated by:

$$mc_f = l \cdot \frac{D}{2} \cdot \pi \cdot \rho_f \cdot c_f \quad \text{(eq. 2)}$$

$$mc_w = l \cdot D \cdot \pi \cdot t_w \cdot \rho_w \cdot c_w \quad \text{(eq. 3)}$$

$$mc_i = l \cdot \left[(0.5 \cdot D + \frac{D \cdot P_i}{100})^2 - (0.5 \cdot D)^2\right] \cdot \pi \cdot \rho_i \cdot c_i \quad \text{(eq. 4)}$$

The delay time of the fluid particle and temperature information between inlet and outlet of the pipe is given by:

$$delay = \frac{l}{\frac{\dot{m}}{\left(\frac{D}{2}\right)^2 \cdot \pi \cdot \rho_f}} \quad \text{(eq. 5)}$$

The change of the internal energy of the fluid in the pipe is:

$$\dot{E}_{fluid} = (T_{in} - T_{out}) \cdot c_w \cdot \dot{m} \quad \text{(eq. 6)}$$

With the change in internal energy and the loss, the new outlet temperature of the pipe can be calculated by:

$$T_{fluid} = \int \frac{1}{mc_{fluid} + mc_{wall} + 0.37 \cdot mc_{insulation}} \cdot (\dot{E}_{fluid} - \dot{Q}_{loss}) \delta t \quad \text{(eq. 7)}$$

With:

$\dot{m}$	*mass flow in the pipe*	*kg/s*
$mc_{w,\,f,\,i}$	*mass times thermal capacity of the pipe wall, fluid or insulation*	*J/K*
l	*length of the pipe*	*m*
D	*inner diameter of the pipe*	*m*
t_w	*wall thickness of the pipe*	*m*
P_i	*relative insulation thickness based on pipe diameter*	*m*
$\rho_{w,\,f,\,i}$	*density of the pipe wall material, fluid or insulation*	*kg/m³*
$c_{w,\,f,\,i}$	*specific thermal capacity of the pipe wall material, fluid or insulation*	*J/(kgK)*

Another simplification is to define the pipe as a one-node capacity along the pipe length. This results in the fact that a temperature gradient along the pipe length cannot be simulated in detail. In addition, the heating and cooling process of the pipe wall and insulation are neglected, as the temperature of these parts is assumed to be immediately at fluid temperature.

3.2 Network junctions

A dedicated *Junction* component is used for the pipe couplings of the network. As at every point in the network, there is a supply and a return temperature, this component has an "upper" and a "lower" node, representing these temperatures. The upper temperature is calculated as the mass-flow-weighted mean value of all incoming supply flows, whereas the lower temperature represents the mass-flow-weighted mean value of all incoming return flows. The decision of whether an incoming flow is directed to the upper or lower node depends on the sign of the mass flow. Similar to the pipe supply and return component, this is performed by *Switch* blocks in the *Junction*. As on the network level, the mass flows are calculated in a bottom-up approach from the single buildings back to the flow at the central heating station, the flow in branch one, connected to the junction is the sum of branch two and branch three. Fig. 7 shows the junction sub-model.

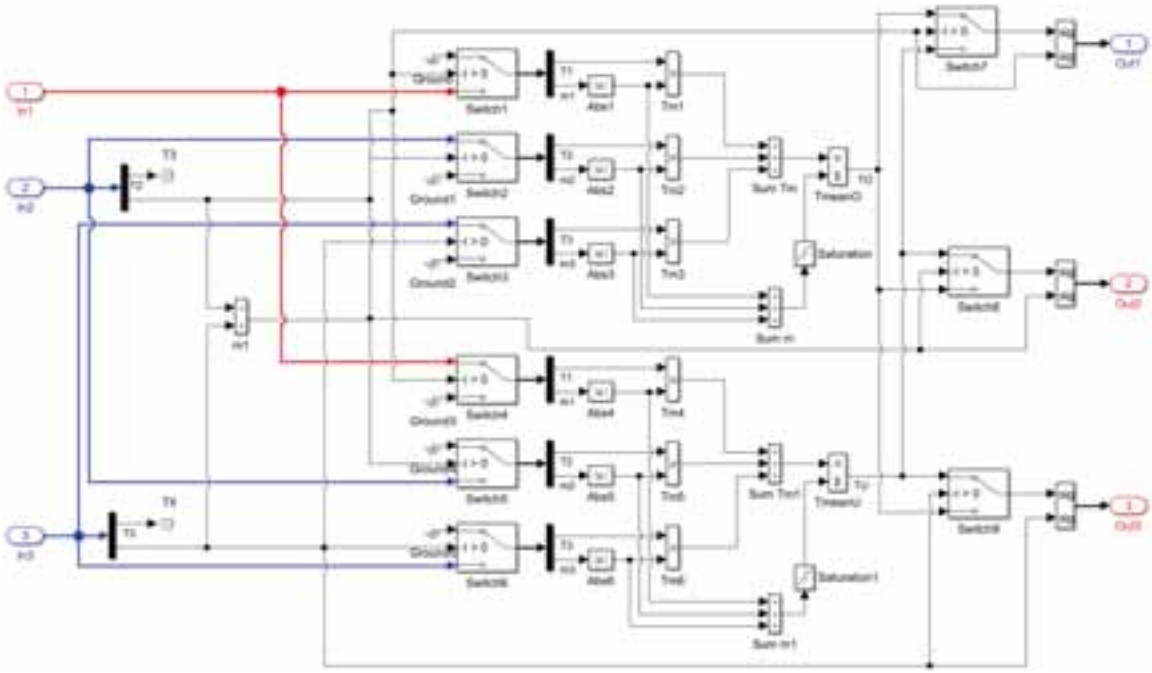

Fig. 7: Sub-model of a network junction

3.3 Substations

The connection of the modified network model to the CARNOT-based building models is realized by a hydraulic compensator that is based on the CARNOT storage model. Fig. 8 shows the sub-model with the relevant connections for space heating, domestic hot water storage, solar thermal plant and the bidirectional connection to the district heating network. Inside this block, the same *Switch*-based decision is performed like described for the pipe and the junction components, if there is currently a consumption from or a feed into the network. By selecting the storage connection heights either to a flow from top to bottom or vice-versa, the bidirectional flow is implemented.

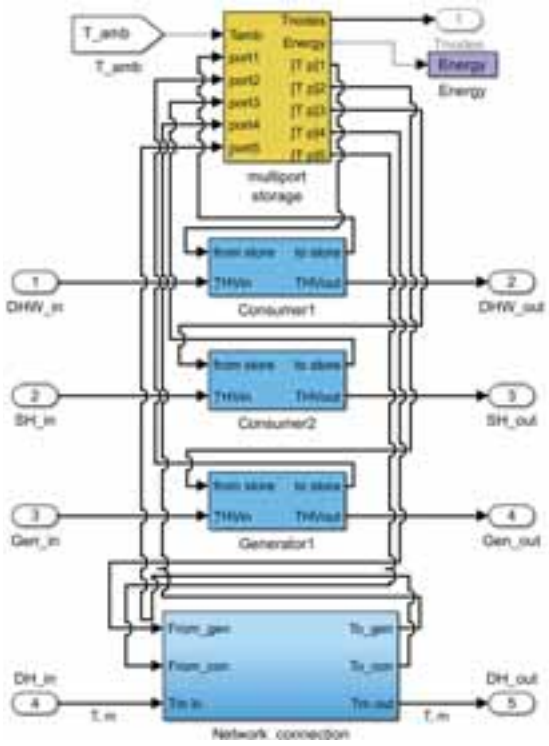

Fig. 8: Substation between modified district heating network model and CARNOT-based building model

4. Validation of the model

4.1 Description of the laboratory test

While the network junctions and the connections between district heating network and buildings can be solved by a purely logical approach, the pipe model includes physical properties, which need to be examined in detail. Due to the choice of a one-node model for the pipe, the question arises of how the pipe performs under a sudden temperature change e.g. caused by a reversion of the flow direction. To answer this question, a laboratory test was set up to validate the pipe model. The layout of the test rig is shown in Fig. 9. Main component of this test was a 2.12 m long copper pipe with an inner diameter of 20 mm and a wall thickness of 1 mm. The pipe was equipped with five thermocouples along the length and insulated with a 19 mm EPDM foam insulation. The parameters of the components are listed in Tab. 1. A computer-controlled thermostat maintained a constant inlet temperature at the pipe. A pump and a motor valve were used to set the volume flow in the circuit. To get an immediate temperature load on the pipe, the heated water was conducted through a bypass tube in the first step (green arrow), while cold water was flowing through the pipe (blue arrow). After starting the data logging, valve 2 and valve 1 were closed while valve 3 was opened and the 3-way-valve 4 set to connect the inlet with the pipe sample and to start the temperature load (red arrow). The temperatures of the inlet and outlet sensors as well as the five temperatures along the pipe and the ambient temperature were logged in a one-second interval. In addition, the volume flow was monitored with a magnetic flow meter (MID).

Tab. 1: Parameters of the laboratory test for validating the pipe model

Length of pipe in mm	2,120
Inner diameter of pipe in mm	20
Wall thickness of pipe in mm	1
Thickness of insulation in mm	19
Thermal conductivity of insulation in W/(mK)	0.04
Temperature sensor inlet / outlet	PT100 4-wire 1/10 DIN
Pipe temperature sensors	Thermocouple type T

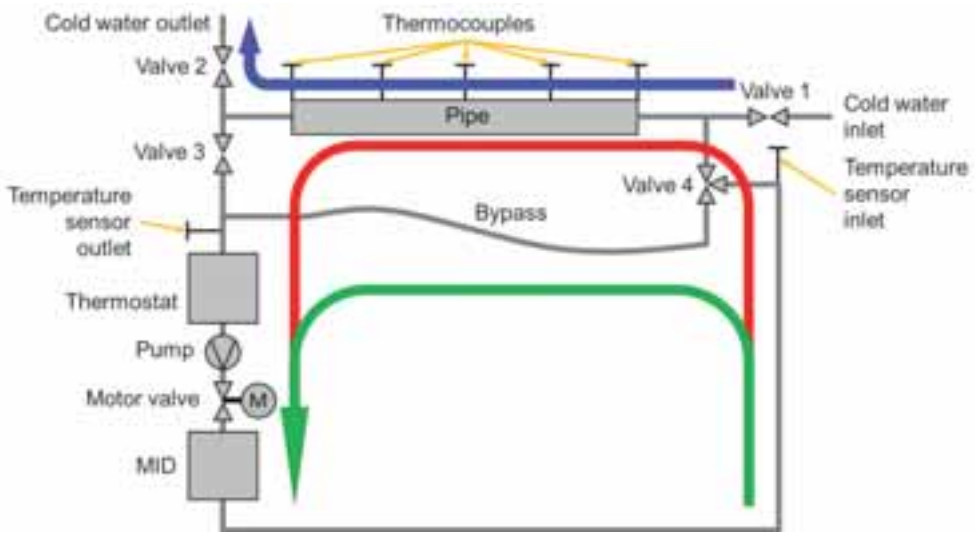

Fig. 9: Layout of the test rig for validating the pipe model

Several measurements were conducted to validate the model at different conditions. The conditions of the presented tests are listed in Tab. 2. In the test *Step Response*, the step response of the pipe was tested at a volume flow of 150 l/h and a sudden inlet temperature change from 22 °C to 47 °C. In the test *Heat Loss*, the pipe was heated up to 70 °C and then the volume flow set to zero to observe the cooling behavior.

Tab. 2: Conditions of the laboratory test for validating the pipe model

Test name	Initial temperature in °C	Inlet temperature in °C	Volume flow in l/h
Step Response	22	47	150
Heat Loss	71	-	0

4.2 Validation of the pipe model

The most interesting results of the first test are the time delay of the temperature change along the pipe length and the shape of the temperature curve after the heating process starts. Fig. 10 shows the comparison of the temperature sensors of the measurement compared with the outlet temperature of the simulation model for the scenario of a sudden inlet temperature increase from 22 to 47 °C. “Tin_measured” describes the measured temperature step at the inlet. “Tout_measured” is the measured value of the temperature at the outlet of the pipe. For the CARNOT pipe, two models were simulated. The first one has only one node (Tout_CARNOT_1). This leads to an instant but slow temperature increase at the outlet. The second model with 100 nodes (Tout_CARNOT_100) describes the time delay very well but shows a too steep temperature increase, when the hot fluid reaches the outlet-node. No node number could be found, where the time delay and the slope of the curve fitted the measured data. For the newly set up model, two variants were simulated, where the first one (Tout_w_I) includes the fractional capacity of the insulation and the second one (Tout_wo_I) only includes the fluid and pipe wall capacity. Due to the fast heating process, the model without insulation capacity fits the measured curve better than the other one. But still, the pipe including the insulation capacity is very close to the measured value and has a more realistic behavior than the CARNOT pipe model in this comparison. The fractional capacity of the insulation was also added to the capacity of the pipe wall in the CARNOT models for better comparison.

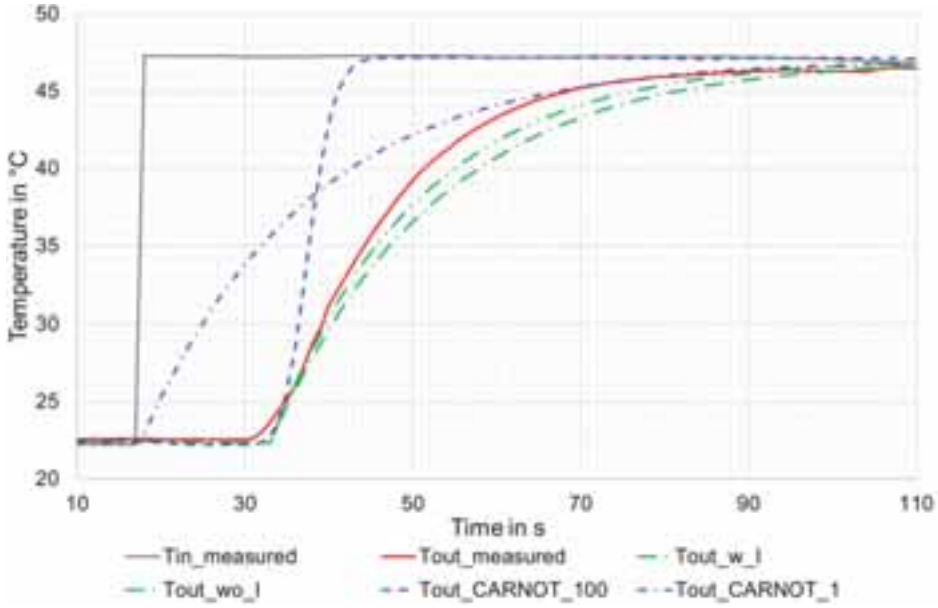

Fig. 10: Temperature curves over time for the step response from 22 to 47 °C

Another important information when discussing the control strategy of the district heating network is the stored energy in the pipes. Fig. 11 shows this energy for the measured pipe, the CARNOT pipe (1 node and 100 nodes) and the new model with insulation capacity. As expected from the faster temperature increase at the outlet, the CARNOT pipe model stores less energy than the measured pipe. The new model calculates slightly higher energies within the period of observation due to the overestimated contribution of the insulation but differs by only 6.3 % in this case.

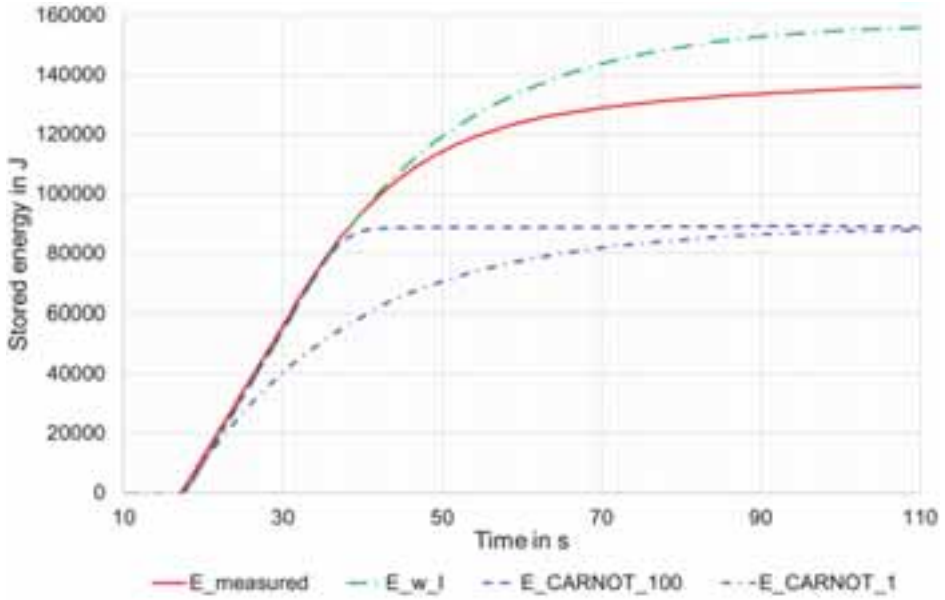

Fig. 11: Stored energy over time for the step response from 22 to 47 °C

The third important point is the calculation of the heat losses in the district heating network. The pipe in the laboratory test was heated up to a constant temperature of 71 °C and then cooled down by the losses through the insulation for approximately 50 minutes. As convection losses in the fluid at the ends of the pipe cannot be completely excluded, only the temperature sensor in the center of the pipe is evaluated. It could be seen that both models are within acceptable tolerance and the temperature loss is 0.8 % too low and 1.7 % too high for the new model and the CARNOT model respectively.

4.3 Validation of the system model

The validation of the complete network model is presented by two exemplary weeks (week 16 and week 20) in 2017. These two weeks represent both, higher and lower ambient temperatures as well as high and average irradiation in the collector plane (Tab. 3). This ensures that sufficient accuracy of the models is achieved under different conditions. The individual components, the overall system and the real control devices were validated in the model. The same collectors and solar stations are installed in all buildings. A distinction is only made in the length of the collector array piping, the array connection and the orientation of the collectors. In addition, the downstream components, e.g. buffer storage, and the connections to the existing local heating or hot water system in the basements are of different designs.

Tab. 3: Average ambient temperature and irradiation on the collector plane for two weeks in 2017

Week	Average ambient temperature in °C	Irradiation on collector plane in kWh/m²
16	4.6	23.9
20	16.1	46.1

In order to be able to make a reliable statement about all different concepts of solar thermal systems, the three different types of installations "local hot water use", "network supply" and "combined solution" are presented using the buildings HB57, HB36 and SB21. Of particular importance are the deviations of solar yields between measurement and simulation over a week, which are defined as follows:

$$Deviation\ in\ \% = \frac{E_{solar,simulated} - E_{solar,measured}}{E_{solar,measured}} \quad \text{(eq. 8)}$$

The measured network temperatures, cold water temperatures and domestic hot water consumption as well as the irradiation in the collector plane and the ambient temperature were set as boundary conditions for the simulations. Tab. 4 shows the results of the metrological investigation and the simulation. It can be seen that the deviations are below 4 % for all considered configurations. Therefore, it can be stated that the accuracy of the model is sufficient for further simulation studies and optimization of the existing network.

Tab. 4: Measured and simulated solar yields for the three plant concepts

	Measurement in kWh	Simulation in kWh	Deviation in %
Solar yield week 16 HB36	253	251	-0.8
Solar yield week 20 HB36	1,033	1,041	0.8
Solar yield week 16 HB57	671	693	3.3
Solar yield week 20 HB57	1,492	1,499	0.5
Solar yield week 16 SB21	386	381	-1.3

5. Simulation study on decentralized feed-in

As the goal of this work is to define a Simulink-based model for the investigation of RS feed-in concepts, a simulation-based comparison based on the operational network is discussed. While in this network, only a RR feed-in could be implemented and the collector area is limited, the simulation model allows additional investigations of the influence of a RS feed-in and larger solar thermal plants. The following designs are compared based on a one-year simulation of the complete network:

- Type 1: Model of the real network and RR feed-in based on CARNOT toolbox
- Type 2: Model of the real network and RR feed-in based on new components
- Type 3: Model of the real network and RS feed-in based on new components
- Type 4: Model with optimized network operation and RR feed-in based on new components
- Type 5: Model with optimized network operation and RS feed-in based on new components
- Type 6: Model with larger collector arrays, optimized network operation and RR feed-in based on new components

- Type 7: Model with larger collector arrays, optimized network operation and RS feed-in based on new components

Type 1 represents the existing, operational network, using only CARNOT components. The operation strategy and the solar thermal plants are designed like in reality. Type 2 is the same but using the modified components for the network. Type 3 is based on type 2 but includes the change from a RR feed-in to a RS feed-in for the plants with combined utilization, while the pure feed-in plant (HB36) keeps the RR concept. Nevertheless, the network operation and plant dimensions are still the same. In type 4, the operation of the district heating system is improved in a way that reduced flow rates are set at the substations to keep the return temperature at an average value of 60 °C during the year, while using a 5 K lower supply temperature during summer. In the existing network, this is not yet implemented but would be possible. Type 4 uses the same RR strategy like type 1 and type 2 but includes a lower feed-in temperature threshold to adapt to the lowered return temperature. Type 5 is again the same as type 4 but with RS feed-in from type 3. Types 6 and 7 contain larger collector arrays as compared to types 4 and 5. The flat-plate-collector areas on the buildings HB57 and SB21 are tripled, as this would still be a feasible design in the existing network. Due to limited roof space, HB36 is kept at 71 m². SB12 has a large available roof area. For these types, the removal of the vacuum tube collectors and a flat plate collector area of 142 m² on the east and 142 m² on the west roof is discussed. This results in a total collector area of the network of 781 m² compared to 305 m² for the other types.

For the simulation study, average climate data for Ingolstadt were used. The thermal loads in the district heating network were derived from measurements of the load profile at the substations in combination with yearly energy consumption data. For the space heat demand, simulations of the buildings were included in the CARNOT model. Tab. 5 shows the solar yields for the plants of all types and their contribution to the heat production of the complete network.

Tab. 5: Annual solar yields and solar fraction of decentralized plants of the simulated system types

Type	Annual solar yield HB57 in MWh	Annual solar yield HB36 in MWh	Annual solar yield SB12 in MWh	Annual solar yield SB21 in MWh	Fossil heat production in MWh	Solar fraction in %
1	42.5	16.9	31.8	26.6	4,289	2.67
2	42.5	16.6	31.1	25.9	4,299	2.63
3	42.5	16.6	31.6	26.2	4,294	2.65
4	42.5	21.2	31.6	26.4	4,261	2.78
5	42.5	21.2	32.4	27.8	4,254	2.83
6	81.2	19.1	57.8	60.1	4,189	4.95
7	79.9	18.8	62.4	70.2	4,165	5.26

Several conclusions can be drawn from the simulation results. Firstly, due to the modified pipe components and resulting variations in the temperatures of the network, there is a difference of the solar yield between the pure CARNOT model and the modified model of 1.6 %. This is considered as acceptable within the scope of this work. Secondly, a RS feed-in has no benefit over the less complex RR feed-in in case of small solar fractions. For the existing network, it increases the solar fraction from 2.63 % to 2.65 %, which cannot compensate for the higher investment costs. The same applies for the existing network with reduced supply temperatures and optimized flow rates. For larger plants, the benefit increases. Type 7 produces 231.3 MWh of solar heat compared to type 6 with 218.2 MWh, meaning an increase of 6.3 %. Thirdly, it can be seen that the pure feed-in concept in HB36 produces less solar heat, when larger plants are connected via RS instead of RR feed-in. This is due to the reduced volume flow passing by the building, when the decentralized plant in SB21 is in operation and supplies the north-west part of the district. Therefore, a combination of the different feed-in concepts is to be avoided. Fourthly, the optimized system operation slightly increases the yield of the plants with partial feed-in but distinctly increases the yield of the pure feed-in plant, which only depends on the return temperature of the network.

6. Conclusions and outlook

For the simulation of district heating networks with decentralized solar thermal plants, a new MATLAB/Simulink-based model was set up. While for the solar thermal plants and the buildings, the standard CARNOT library was used, the network pipes, junctions and substations were modified to allow reversed flow in the network, as is necessary for the simulation of RS feed-in. The pipe model was validated in a laboratory test and shows satisfying performance, which is, in terms of the dynamic behavior of the pipe, closer to reality than the CARNOT pipe. Solar thermal plant models with different hydraulic concepts where validated based on a real district heating network in Germany and also show adequate accuracy. Based on the validated plant and pipe models, a simulation-based comparison was done, showing the difference between RR and RS feed-in for different plant sizes and network operation modes. It can be seen that small plants work well with RR feed-in, which is a simple and reliable configuration for the retrofit of a district. If higher solar fractions are desired, it is beneficial to use RS feed-in to increase the plant performance. Based on the introduced model, further simulation studies will be done to derive recommendations for decentralized solar thermal plants in different districts and to show the possible improvement in performance by an intelligent control strategy for the interaction of the plants.

FLEXYNETS – A new district heating network concept for higher renewable and waste heat share

Ilyes Ben Hassine, Xavier Jobard[1], Linn Laurberg Jensen [2]

[1] University of Applied Sciences Stuttgart (Germany)

[2] PlanEnergi, Aarhus (Denmark)

Abstract

The FLEXYNETS project on low-exergy district heating and cooling systems has been started in summer 2015 in the framework of the European H2020 program. The project aims to develop a new generation of intelligent district heating and cooling networks that reduce energy transportation losses by working at temperature levels lower than 40 °C. Reversible heat pumps and chillers are used at laboratory scale to exchange heat with the DHC network on the demand side. In this way, the same network can provide contemporary heating and cooling. FLEXYNETS solutions integrates effectively multiple generation sources (including high- and low-temperature solar thermal, biomass, cogeneration and waste heat) where they are available along the DHC network. Two network types are considered in simulation: the classic supply-return type and the single-pipe system. This paper describes possible operation strategies and some control aspects related to the second network type.

Keywords: district heating/cooling, low temperature, low exergy, solar thermal feed-in, waste heat

1. Introduction

Traditional District Heating and Cooling (DHC) networks distribute energy from a centralized generation plant to a number of remote customers. As such, actual DHC systems suffer from significant heat losses, highly unexplored integration potential of different available energy sources into the same DHC network and high installation costs. Lowering the network temperature and including multiple distributed sources could reduce these issues. However, a distributed energy generation approach would also introduce issues for heat marketability and management. Hence, a true change of paradigm is needed to move from the "monopolistic" structure (for generation, distribution and trading) implemented in today's DHC networks, to a structure where multiple actors can play the role of energy providers and where even the final consumers can economically profit from their waste heat rejected to the network.

Centralized/High-level control solutions integrating multiple energy generation sources and sinks within a DH network are today under evaluation in a number of research and demonstration projects (ehub 2016, EnEff:Stadt 2016). However further innovations as the use of very low temperatures within the network loop, exploitation of pipelines storage capacity and bi-directional communication among multiple energy sources and sinks require further research at simulation level.

FLEXYNETS aims to develop a new generation of district heating and cooling networks, which will combine (i) multiple energy sources at different temperature levels, (ii) systems capable of using that heat efficiently (such as Organic Rankine Cycle (ORC) based polygenerative systems, absorption cooling systems) (iii) a low-temperature (<40°C) DH, and (iv) devices able to exploit such low temperature energy in residential buildings, like reversible heat pumps (see fig.1).

Fig. 1 The FLEXYNETS concept with several prosumers connected to the main loop

Depending on the substation needs, heat is supplied to or removed from the network

The Flexynets concepts considers the low temperature network as infrastructure for storage and heat exchange between geographically dispersed (renewable) prosumers with different sizes. The decentralization of heat and cooling sources as well as the linking of several small networks to independent large systems are topics of high interest. While supplying energy to consumer substations is common in today´s systems, the reverse flow from prosumers into the network remains one of the challenging tasks.

In this paper we briefly go through state-of-the-art concepts for feed-in substations. We comment some weaknesses related to the return-supply feed-in strategy. The Assumption is that in order to facilitate the energy exchange within the system and to increase the share of renewable and waste heat sources, one needs to adapt/optimize the network side. Targets of the adaptation should be high distribution efficiency, high effectiveness of feed-in, less auxiliary energy for better primary energy factors.

In this context we propose the FLEXYNETS concept as an option for new 'liberalized' DHC networks where prosumers can easily feed (excess-) heat and enhance the primary energy balance of the whole system. The discussion of the results at the end of the paper is related to district heating and will be extended to cooling networks in the future.

2. Heat feed-in into DH systems

The substation

In accordance to SDH (2012) 0 "distributed" or "decentralized" means that the feed-in plant is not closely located to another major heat generator like a biomass or fossil fuel fired plant. These substations generally make use of the network fluid content instead of providing own storage capacities. Their size is mostly small with regard to the whole district heat demand. Among the feed-in principles described in 0 (2012) and Bucar et al. (2005), two concepts have been realized in the past twenty years: the return-return (RR) and the return-supply (RS) concept as shown in fig. 2.

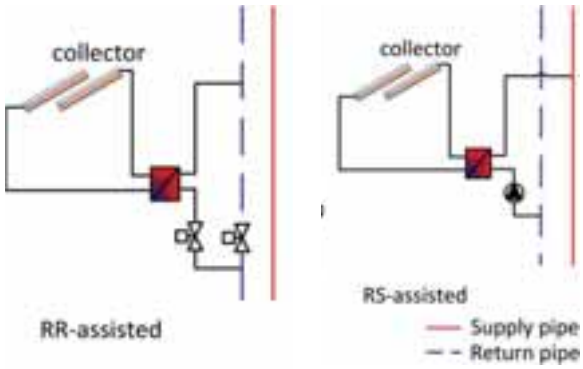

Fig. 2 The most common feed-in layouts

The solar collectors shown in fig. 2 are generally representative for every decentral heat source (waste heat incinerator, heat recovery etc.). The feed-in principles remain the same. In the RS case, the return temperature of the network remains low which is more advantageous/efficient for operating central CHP units. Among the nine European plants assessed in Schlegel (2014), seven are of RS type. In Hamburg Berne (Germany) a combined feed-in substation has been realized (Großmann, 2015) to work in winter and summer mode. In addition to the shortcomings of the RS concept that were discussed in Schlegel (2014), we want to highlight another aspect related to the control.

Due to the dynamic behavior of the network (consumers´ regulating valves, variable speed pumps), the control of RS substation becomes challenging. The pressure difference in two pipe networks changes by more than 30% within short fractions of time. The feed-in substation itself adds through head rise new dynamics to the whole system. The difficulty of regulating the flow under a fluctuating 'resistance' is demonstrated in fig. 3 (Gunnar 2014). The measurements show how the flow changes from no flow to maximum flow in the range of few percent of the pump speed.

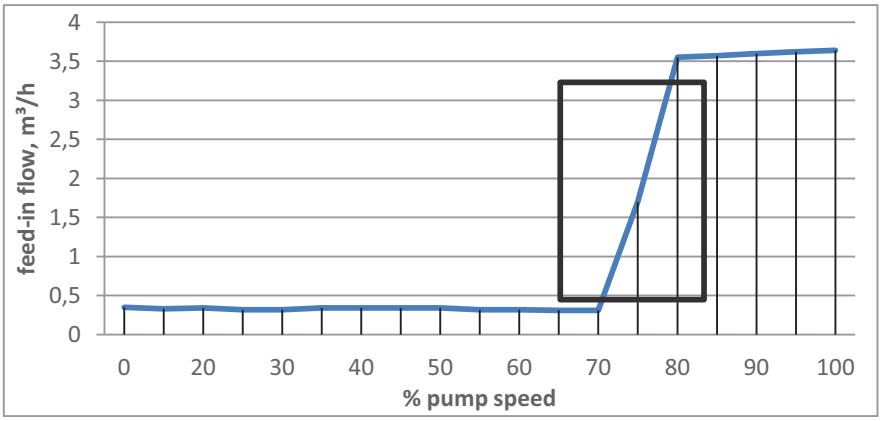

Fig. 3 Example of feed-in flow dependency on pump speed from a Swedish network

The problem is more relevant for small feed-in substations because they are generally equipped with (relatively) small feed-in pumps that are not able to cope with the network dynamics, at least not as able as high pressure/high flow pump stations which are common for large supply units. In substations without storages, supply interruptions due to too low or too high temperatures are common (Gunnar (2014), Eicker et al (2012)). Bucar (2005) reported about longer feed-in outages in Austrian networks due to too high pressure differences in the network.

This –among other reasons- may explain the decline of the reported solar gains in small size installations which is plotted in fig. 4.

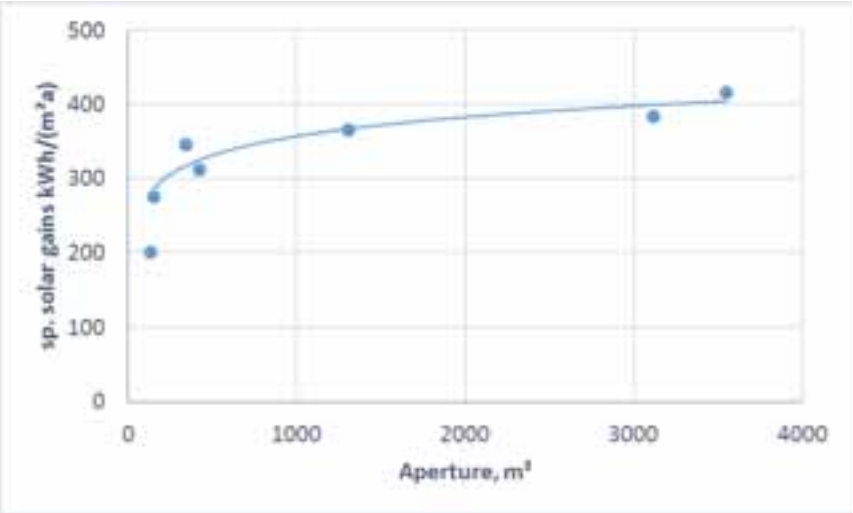

Fig. 4 Specific solar gains of seven European installations from Schlegel (2014)

The network

In conventional 2-pipe networks, the pump illustrated in fig. 2 needs to overcome the pressure difference between return and supply lines. This makes the feed pump power and rate depend on two factors: the governing network head and the substation location. Fig. 5 shows how much power is needed to supply approx. 200 kW of heat into a 6.3 km long DH network under different governing pressure differences. Fig 6 presents the pressure difference in a 13.5 km long network in the south of Germany. Halmdienst et al (2014) expect that substations which are closer to the main supplier need more power to provide the same heat amount to the network than those outside. However, we recognized in recent investigations within the FLEXYNETS project that the dimensions of the existing pipes as well as the flow direction (opposite or inline with main flow) are affecting.

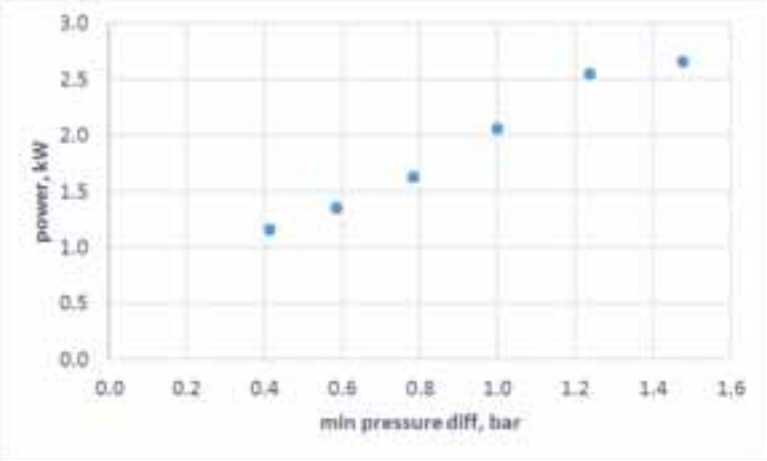

Fig. 5 Power requirements as function of lowest pressure difference

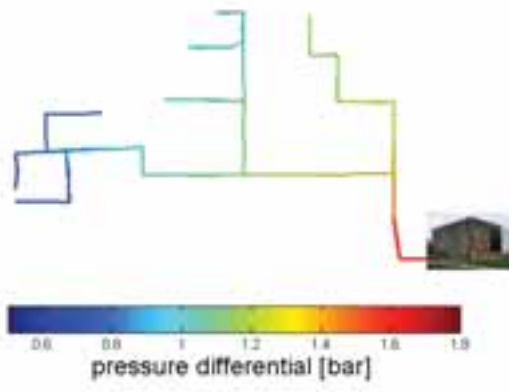

Fig. 6 Pressure profile in a tree-type network

3. The case study

With regard to the difficulties encountered in regulating feed-in substations, the following question arises: can the network be adapted/designed to facilitate (excess-) heat supply from decentralized prosumers with limited capacities? Keeping the auxiliary energy consumption low while assuring stability of supply is of course of high interest.

In the context of the FLEXYNETS project, two new network topologies were proposed as alternative to an existing 2-pipe system in the city of Aarhus in Denmark. The network contains -as part of the city DH system- more than 500 consumer substations and was aggregated to 23 nodes for the current study. The systems are simulated afterwards in TRNSYS and compared using some performance indicators.

The system aggregation

The map of the Aarhus south west area is shown in the left hand side of fig. 7. In order to aggregate the demands to 23 nodes, an affiliation function in the software program Termis is used. Termis is a hydraulic modeling tool that simulates the behavior of flow directions, pressure, and thermal conditions in a DH or Cooling network. The network from the geographic information system (GIS) tool and the demand points from the Heat Atlas is loaded in Termis as shape files. To affiliate the demand, the nodes are placed on different locations in the network chosen strategically for the affiliation of demand to be dependent on typology type. The nodes are placed manually by the best individual ability and evaluation in each case. The purpose of this process is to estimate the sum of the capacity of the collected demands in each of the chosen nodes for further analysis in TRNSYS.

In this way, the demands from the reference towns can be used in the analysis. The demands from Heat Atlas is an expression of actual demands for each building from these reference towns, in this case Aarhus. The Heat Atlas is developed by Aalborg University. It is designed to explore the possibility of development and application of a detailed mapping of the buildings' heating needs in Denmark. The Heat Atlas is developed for use in GIS software with the purpose to extract building data from the Building and Housing Register (BBR) and a number of heat consumption specifications that are developed by the Danish Building Research Institute (SBi). The Heat Atlas includes data such as construction year, building area and heat demand for each building.

The Danish reference towns are divided in areas according to the FLEXYNETS typologies, as seen in the figure. A GIS software is used as tool to establish the town or city boundary and the boundaries for the different typologies. For this purpose, municipality planning and the Heat Atlas is used. In Denmark, the data from the Heat Atlas, local planning and municipality planning is available for all towns and cities. Each reference town is divided into the different typologies based on the specific use category in the municipality planning.

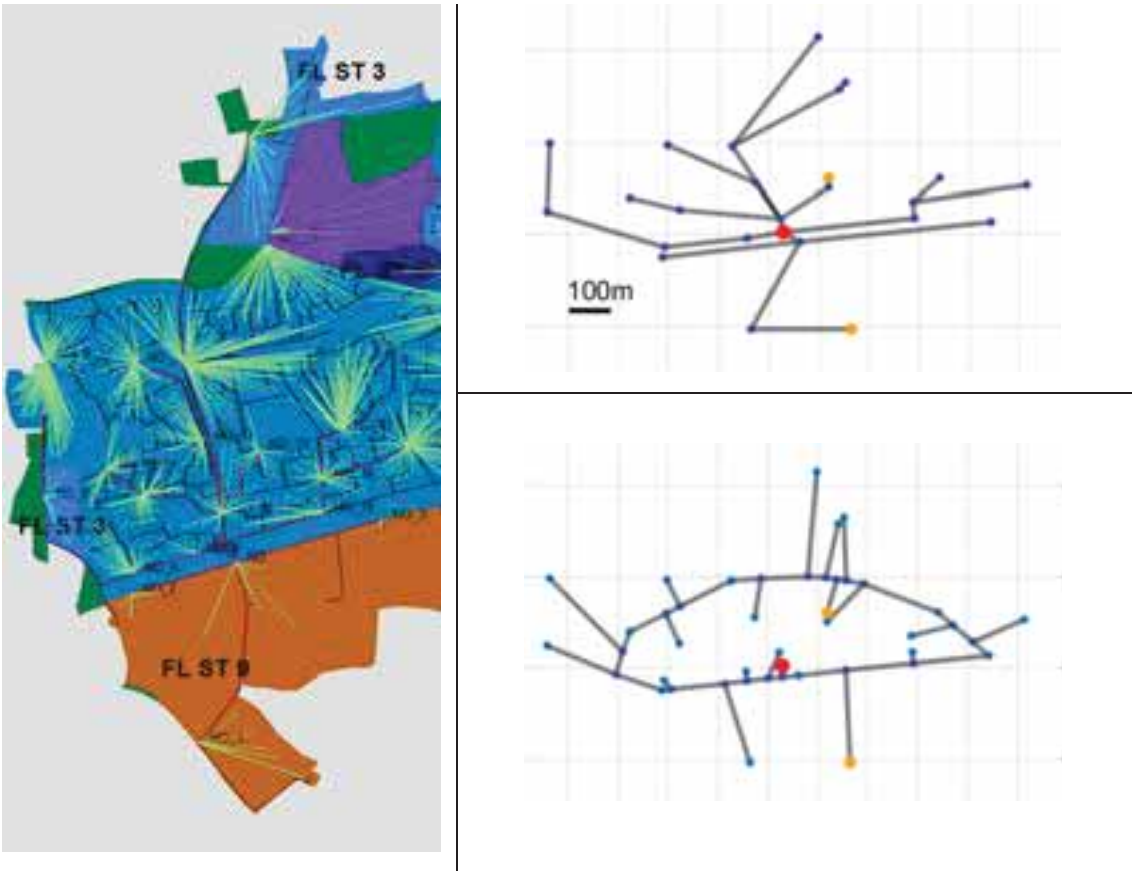

Fig. 7 Map of Aarhus SW (left), tree-type and loop-type network (right)

The network types

Additionally to the tree-type network of the south west of Aarhus (fig. 7), two additional models have been designed out of the loop-type system presented in the same figure. As can be seen in fig 8, the first model incorporates two loops (each for low and higher temperature) that are connected through a stratified storage tank. The system is called low-pressure type due to the low head difference between supply and return line. Storage inlets and outlets generally cause minor head losses in the range of <10 mbar. Feed-in substations inject hot water into the supply loop. In case of low demand, the injected heat can be stored in the central tank. The energy balance of the whole system is performed in the storage level, where heat can be removed or added via heat exchangers.

The operation of the feed-in pump is favorized by the fact, that other consumer substations circulate water in the same direction of flow. However, in real installations two aspects should be taken into account: a) the formation of small loops between two neighboring substations (one consumer and one producer) which may result in too low supply temperatures. b) the overflow of the feed-in pump due to high pressure rise in the consumer substations.

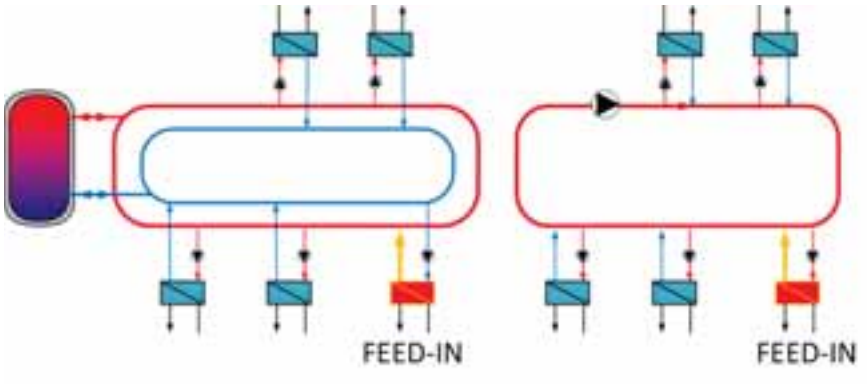

Fig. 8 Simple layouts of the loop-type networks

The second loop-type network contains a single circuit for both removal and feed of heat. At least one substation is needed to balance the network. The main loop pump recirculates water at high flow rates to e.g. compensate for the water cooling after each substation (in case of heat consumers). The feed-in concept is similar to the RR layout of fig. 2 where a part of the circulating volume is heated up and reinjected in the loop. Large differences between the inlet temperatures of the different substations are expected. If the consumers are equipped with heat pumps, their coefficients of performance (COP) will vary. The pump power requirements of the individual substations are assumed to be very low: the major head losses are due to the heat exchanger and service pipe friction.

General design and operational aspects

The modification from a conventional 2-pipe network to the proposed systems has some advantages for the operation of feed-in substations. Not only the power consumption of the decentral pump decreases, but also the flow control is expected to be more stable. This can be deduced from the open-loop behavior of the system. In fig. 9 the heat demand of the considered network is varied from full to partial by keeping both main and feed-in pumps at constant speed. If only 1/3 of the consumers are supplied, the decentral feed-in flow drops by 24% in the tree network compared to 11% in the low-pressure one. The same tendency is seen in the case of small variations. The single loop system exhibits the most robust behavior towards these variations. The substations are almost ‘decoupled’ from each other.

Fig. 9 Feed flow variation depending on demand decline

We also calculated the power needed to feed 32kW of heat into the three network types at different nodes. Head losses associated with mountings like heat meters and gate valves or pipe connections are not considered in this paper. The power requirements in the 2-pipe network are higher by a factor of five to ten than in the other two loop-based systems (see fig. 10). Also in the 2-pipe case, no clear dependency between the pumping power and the distance to the main supply node can be recognized. The power requirements logically depend on the distance to the consumers to be served, which can be variable depending on the current flow/demand situation. In the loop-based systems, the power consumption depends on the distance to the main loop. In other words, pipe friction in the service pipes presents the major head loss independent on the flow situation.

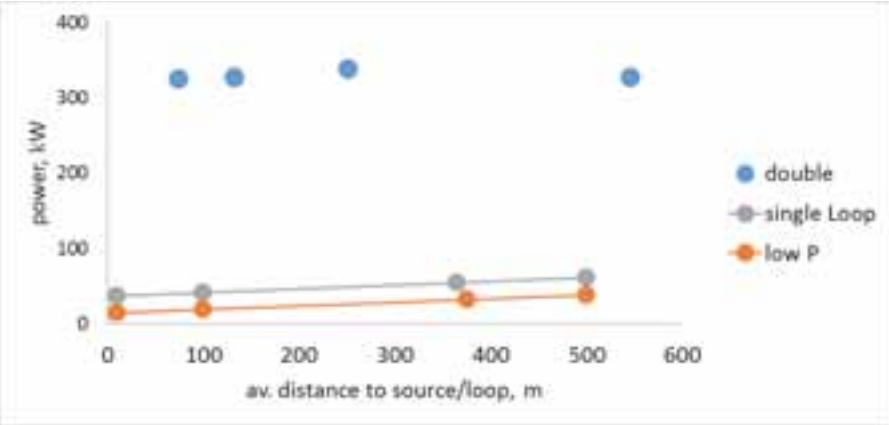

Fig. 10 Power requirements of feed-in pump at different nodes

The fluctuating (wavy) temperature profile in the case of single loop system made the control of the substations unstable. The heat pump model used was valid for a certain temperature range on the evaporator side. Many heat pumps would not be able to run adequately in case of too low temperatures. The study was therefore limited to the 2-pipe and low-pressure systems. The pipes were designed to a maximum velocity of 0.65m/s. The following table summarizes the obtained network sizes:

Table 1 Network dimensions

	2-pipe system	**Low-pressure system**
Length of pipes, m	6365.5	7313.5
Av. size of pipes	DN 150	DN 200
Total volume, m³	129.7	289.8

4. The simulation results

The system setup

The systems simulated in TRNSYS are the district heating networks of fig. 7. They distribute heat at low temperature (in a range between 20 °C and 30 °C) to decentralized heat pumps, which have to fulfil the heat demand of the buildings in the given area. The yearly heat demand is approximately 20.7 GWh with a peak load of approximately 6.0 MW. The network manager NM of the considered system is responsible for balancing the energy flows and owns the central supply station of the district heating grid that consists of a 2.2 MW gas-fired reciprocating engine that produces combined heat and power (CHP) and a 2.3 MW auxiliary gas boiler (GB) assumed here to have a constant efficiency of 80%. The NM is placed at the red dot of fig. 7. A 330 m³ central storage tank is used to buffer the heat supply by the CHP unit- Figure 11 shows the layout of the central heat supply station. In the low-pressure case, the central storage CS is directly connected to the network without any pump. The flow direction on the network side can be from top to bottom or reversed depending on the amount of feed-in. The CHP unit covers the base load whereas the gas boiler GB is operated during peak phases.

Two decentral substations supply heat to the network, that is gained out of two solar collector fields of different sizes (200 and 2000m² aperture). The solar pump is run in high flow mode (30l/hm²) and the feed-in temperature is regulated to 5K above the network temperature. The corresponding integration nodes are colored in orange in fig. 7.

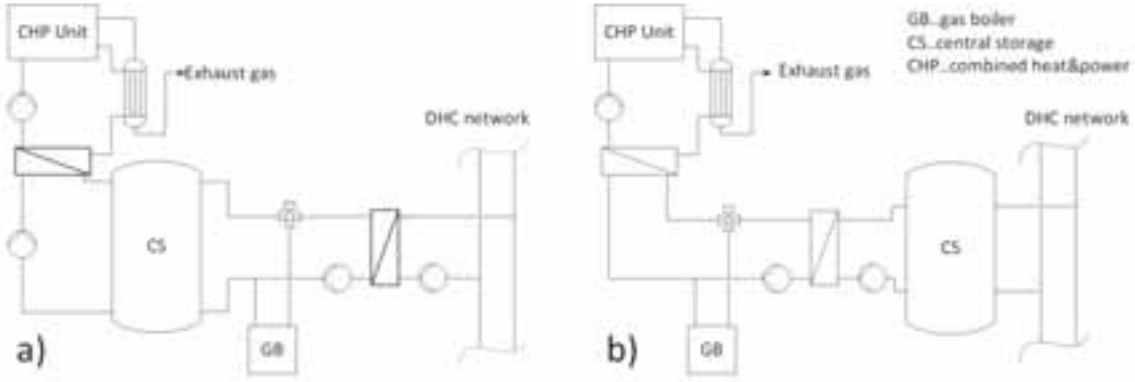

Fig. 11 Layout of main heat supply station in a) 2-pipe and b) low-pressure system

The water-to-water heat pumps use R407c as refrigerant and provide water to the buildings at 55-65°C. The performance of the heat pumps is affected by the temperature of the water supplied by the DH network. A higher network temperature increases the COP of the heat pumps, which turns into a lower power consumption of the compressors for a given heat demand of the buildings. As long as the power consumption is reduced, a higher amount of heat is extracted from the DH network.

Results

The two systems composed of the network, the main supply station, the consumer heat pumps and the solar feed-in substations were simulated over one year with a time step of 15 minutes. Due to the fact that the time constant of the hydraulic system is much lower than the simulation time step, continuous control of the feed-in pumps would be time intensive. We decided to run the pumps with an offset value that allow them to overcome the pressure difference at any time. The simulation study lead to the results of table 2.

The network pipe losses of the low-pressure system were higher than those obtained in the 2-pipe one. This can be explained by the larger size of pipes used as indicated in table 1. The main loop pipe with DN300 causes the major part of the losses. The average network temperature is slightly lower, which is reflected in the average COP of the heat pumps. The CHP unit produces more electric energy and enhances the primary energy balance of the system (lower PER). The solar gains of both small (200 m²) and large (2000m²) collector fields are comparable in the low pressure network. In the pressurized case, the larger installation feeds less heat than the smaller one. Further investigations are needed to find out if the feed-in flow is at nominal level in the 2000 m² installation.

Table 2 Simulation result summary

	2-pipe system	**Low-pressure system**
Users´ end energy, GWh	20.77	20.77
Net delivered energy, GWh	16.52	16.33
CHP thermal energy, GWh	13.74	13.42
CHP electric yield, GWh	13.48	13.22
Network heat losses, MWh	17.02	458.8
Average COP	4.88	4.67
Solar irrad., kWh/m²	1204	1204
Solar gains small, kWh/m²	446.16	462.56
Solar gains large, kWh/m²	427.61	460.28
Network pump consumption, MWh_{el}	71.98	24.45
Feed-in pump consumption, kWh_{el}	2519.8	288.1
Primary energy factor PER	0.638	0.648

When coming to the electric pump consumption, the low-pressure system is more advantageous and requires around one third of the energy needed in the other case. At feed-in substation level, the power requirements are much lower ($1/9^{th}$) which confirms the results presented in fig. 10. Here we need to repeat that only the heat exchanger and the pipe friction are considered to calculate the pressure drop. In reality, other substation mountings and pipe connection will lead to higher electric consumption.

5. Conclusion and outlook

The paper focuses on feed-in substations as measure to enhance the share of renewable and waste heat in DH networks. The weaknesses related to the flow stability in conventional 2-pipe systems are shortly discussed. In the context of the FLEXYNETS project, two alternative (loop type) topologies were suggested out of which the low-pressure one was considered in simulation.

The simulation results of the low-pressure system show some advantages related to the pump power demand. Considering the open loop response, the low-pressure system is expected to operate with higher stability and to reach higher feed-in rates over the whole year. This can be assessed by testing the dynamic flow behavior under real conditions and with discrete controllers. The Energy Exchange lab established by the project partner EURAC in Italy will allow to perform this kind of investigations. The lab recreates on a small scale the various stages involved during the operation of district heating and cooling systems, from heat generation and distribution to consumption by end customers. This enables it to investigate the best network management solutions as well as the supply of heat from several sources. The flexible lab infrastructure allows various configurations as well as hardware and control software to be tested.

Higher heat losses were calculated in the low-pressure system and were explained by the larger pipe size. It is planned to redesign the main loop taking the head losses (and not the flow velocity) into account and to check if the system can be optimized in both investment and operational costs.

Solar district heating in Europe: supplying renewable zero-emission heat

Magdalena Berberich, Dirk Mangold

Solites, Steinbeis Research Institute for Solar and Sustainable Thermal Energy Systems, Stuttgart (Germany)

Abstract

District heating is one major approach to increase the overall energy efficiency in urban areas and an important platform to increase the share of renewable energies in the heat supply. Solar thermal energy is emission-free, available everywhere and offers stable operating costs for decades. Together, they can play an important role in the energy transition of the heating sector in Europe and beyond.

The integration of solar thermal systems into district heating offers different technical solutions, whereof some are applied since decades, some others, like decentral direct feed-in, are in evaluation. Generally, solar thermal systems are sensitive to the levels of the supply and return temperature and the detailed system integration, here especially regarding the hydraulics and the control strategy.

In the case that the solar thermal system is applied to combined heat and power productions, the overall system can be designed to the best economics if the electricity market, the dynamics in the heat consumption and the solar thermal production etc. are considered. The integration of a large heat storage volume might be helpful to separate production and supply powers and therefore can lead to a system with lowest heat cost, although the investment cost can be quite high. At least such complex systems ask for dynamic system simulation during the design phase to ensure best economics and to enable a risk analysis for varying prerequisites.

Keywords: Solar district heating, large-scale solar thermal system, smart cities

1. Introduction

Solar district heating (SDH) plants are a large-scale solar thermal technology supplying renewable, zero-emission heat from large collector fields via district heating networks to residential and industrial areas. Combined with large seasonal heat storages, the solar thermal plant can contribute to more than 50 % of the yearly heat demand even in high latitudes. The main market for SDH consists of plants with a solar fraction of up to 20 % of the yearly heat demand, including the application of a short-term heat storage or even without any heat storage.

New solar district heating projects show an interesting variety of technical concepts and operator models. This underlines also the high potential of district heating and cooling with renewable energy sources as flexible technical and organizational solution for the energy transition at local level.

2. Basic systems for solar thermal integration

A solar thermal plant can be connected to the district heating system by means of central feed-in or decentralized as shown in Figure 1. Central feed-in means the solar heat is integrated in the main heating central where the heat storage is located. The schematic in Figure 1 shows a seasonal heat storage; it depends on the size of the collector area and the performance of the additional heat productions in relation to the fluctuating heat demand if a smaller short-term heat storage can be sufficient or even neglected.

In the case of decentral feed-in of solar thermal heat, the solar collectors are placed at suitable locations and are connected directly to the district heating circuit. In several large solar thermal plants in Sweden, Austria and in a few first plants in Germany, a decentral feed-in of solar heat into district heating systems has been realized.

doi:10.18086/swc.2017.06.03 Available at http://proceedings.ises.org

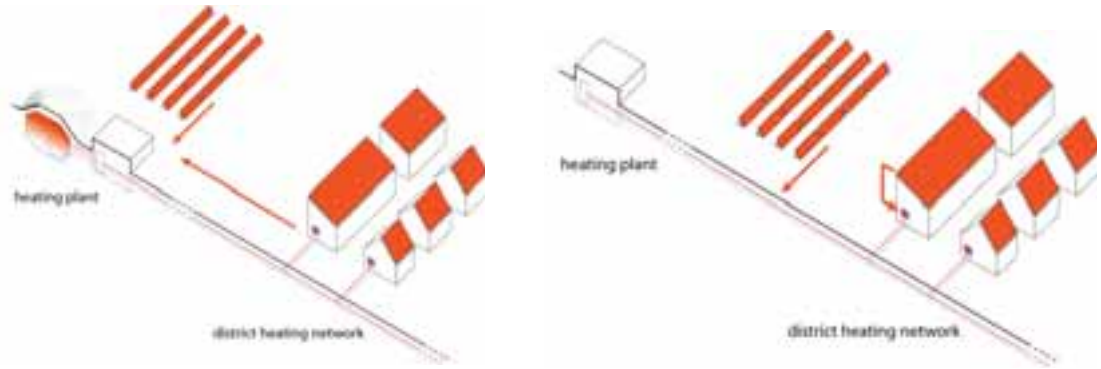

Figure 1: Schematic of central (left) and decentral (right) feed-in of solar thermal heat

For both, central and decentral feed-in of solar thermal heat in a district heating net, the solar thermal plant can be operated to produce the supply temperature or to preheat the fluid in the return flow. Figure 2 shows a basic schematic of a solar thermal plant for district heating. Usually it is applied for a solar thermal integration in the central heating plant. The broken grey line shows the system boundary for the solar system. To separate the solar circuit and the net circuit hydraulically a heat exchanger is applied. Often a heat storage is integrated into the system to store the heat from the solar collectors before it is transported to the additional heater and then delivered with the supply temperature to the district heating net.

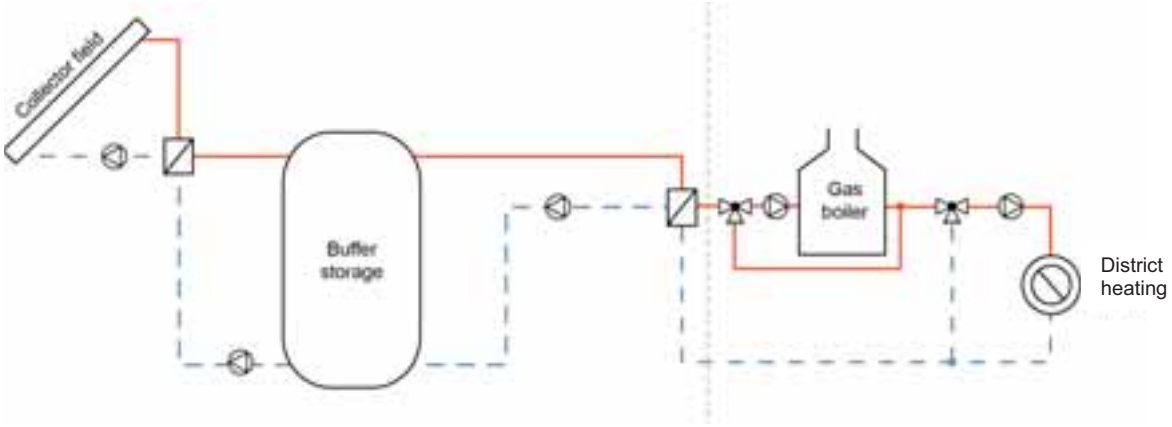

Figure 2: Schematic of a solar thermal plant for solar district heating

In case of delivering the supply temperature for the district heating net, the solar collectors only can produce heat if the solar irradiation is high enough.

In the case of preheating the return flow, the solar collectors heat up the return flow with a predefined temperature difference. For supplying the heat to the district heating net the fluid is heated up to the supply temperature by an additional heater (e.g. a gas boiler as shown in Figure 2). The variation of the solar irradiation can be balanced by a volume-flow control of the pumps in the solar circuit to keep the temperature of the preheated flow from the collector field to the buffer storage within the predesigned range.

The sizing of the buffer storage depends on several parameters like the intended solar fraction, the operation characteristics of the collector field and the dynamics of the heat demand in the district heating net and in the unload circuit of the buffer storage etc. The larger the intended solar fraction and the higher the complexity of the hydraulic system concept are, the more a dynamic simulation of the overall system is recommended.

3. Solar collector area

Within the last 30 years the technology for realizing large collector areas was developed, first by pilot plants that were supported by R+D funding. Within the last 10 years the technology is on its way to a state-of-the-art heating technology for utilities, energy companies, cooperatives etc. The developments differed due to different boundary conditions in different European countries. All developments comprise specialized collectors for district heating application. They cover up to about 12 m² of collector area per collector. Their internal hydraulic scheme is optimized to facilitate the realization of long collector rows by a simple connection of the collectors and to run these rows with low flow. This saves installation costs as well as electricity consumption of the solar circuit pumps. The following figures show different mounting systems of solar collector areas for district heating systems:

1. Ground mounted (Figures 3 and 4)
2. Roof integrated (Figure 5)
3. On roof (Figure 6)

Figure 3: Vacuum tube collectors in Büsingen, Germany

Figure 4: High-temperature flat plate collectors in Dronninglund, Denmark

Figure 5: Roof integrated solar thermal collectors on "solar@home"-building in Crailsheim, Germany

Figure 6: Solar collectors elevated on flat roof in Neckarsulm, Germany

Without regarding the cost for the ground, to mount the collectors on simple subconstructions directly on the ground offers the possibility to achieve the lowest cost for the realization of a solar collector area. The availability of ground is restricted especially in urban areas. Thus it might be also applicable to integrate the collectors in a roof. Figure 5 shows a so called "solar roof" that was realized within an energetic retrofitting of an old army building. The "solar roof" replaces the roof tiles and integrates roof windows, drip moulding, snow guard etc. Another possibility is to mount a collector field on a flat roof as shown in Figure 6. In this case, to achieve low cost for the subconstruction can be a challenge due to the statical requirements to carry especially the wind loads.

The market offers two main constructions of collectors, flat plate collectors and vacuum tube collectors (see Figure

3 and Figure 4). The specific products of the collector producing companies vary in performance and construction. To find the best suitable collector for a specific project it is recommended to invite offers from the solar companies and to decide according to the specific heat price. The solar heat price is calculated from the overall costs of the solar thermal plant in relation to the usable solar heat. To compare different offers, this usable solar heat should be calculated for all offers with the same simulation program, using the characteristic figures for every offered collector type according to test certificates like “Solar Keymark”, that is valid all over Europe (ESTIF, 2017).

4. System design

For a favorable performance of the solar thermal system, the overall system design is important. First of all the location of the solar thermal plant decides about the amount of solar irradiation that the collectors receive. The solar thermal plant is able to heat its inlet temperature only if the irradiation is high enough for that. The following Figure 7 shows the differences between the global irradiation of two cities in Germany over ten years, whereas Würzburg is a location with very good solar irradiation conditions and Hamburg is a location with quite low solar irradiation. The solar irradiation in the years 2007 to 2016 fluctuates with +4 to -6 % of the average in the ten years for Würzburg (broken line). For Hamburg, the variation comprises the range of +7 to -5 % of the average level. There is a significant difference in the global solar irradiation of the two locations, which is very variable over the ten years.

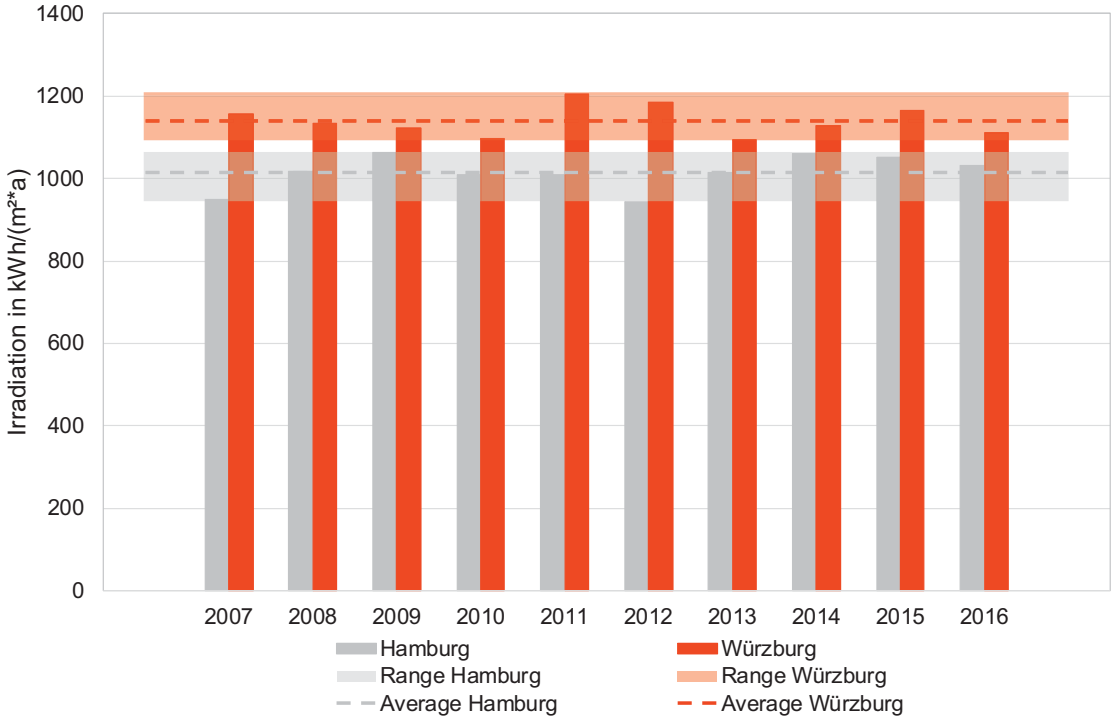

Figure 7: Yearly global solar irradiation in the years 2007 to 2016 for Würzburg and Hamburg (Deutscher Wetterdienst, 2017) on horizontal plane

Therefore, it is recommended to dimension a solar thermal plant using climate data of the location of the plant over a longer period, e.g. 10 years. By varying the solar irradiation in a sensitivity analysis within a system simulation program, its effect on the energy gain of the solar system can be analysed and valuated. If necessary, the solar thermal plant can be dimensioned with a safety factor to reach the needed solar heat gain even in years with poor irradiation.

In addition to that, the solar heat gain depends on the operation temperatures. The higher the average operation temperature of the collectors is, the lower the efficiency of the collectors gets because of higher heat losses of every collector. Therefore, the return temperature to the collector field and the needed supply temperature, which shall be produced by the collectors, are decisive for the achievable solar energy gain.

This correlation is shown in Figure 8 for high-temperature flat plate and vacuum tube collectors in the German market. The sample collector is a high-temperature flat plate collector with average specific values. The results are calculated with average climate data over 10 years (Meteotest, 2017) of the German city Frankfurt. The average net temperatures in the diagram are the yearly average for the arithmetic value of the supply and return temperatures of the regarded collector in every hour of the year.

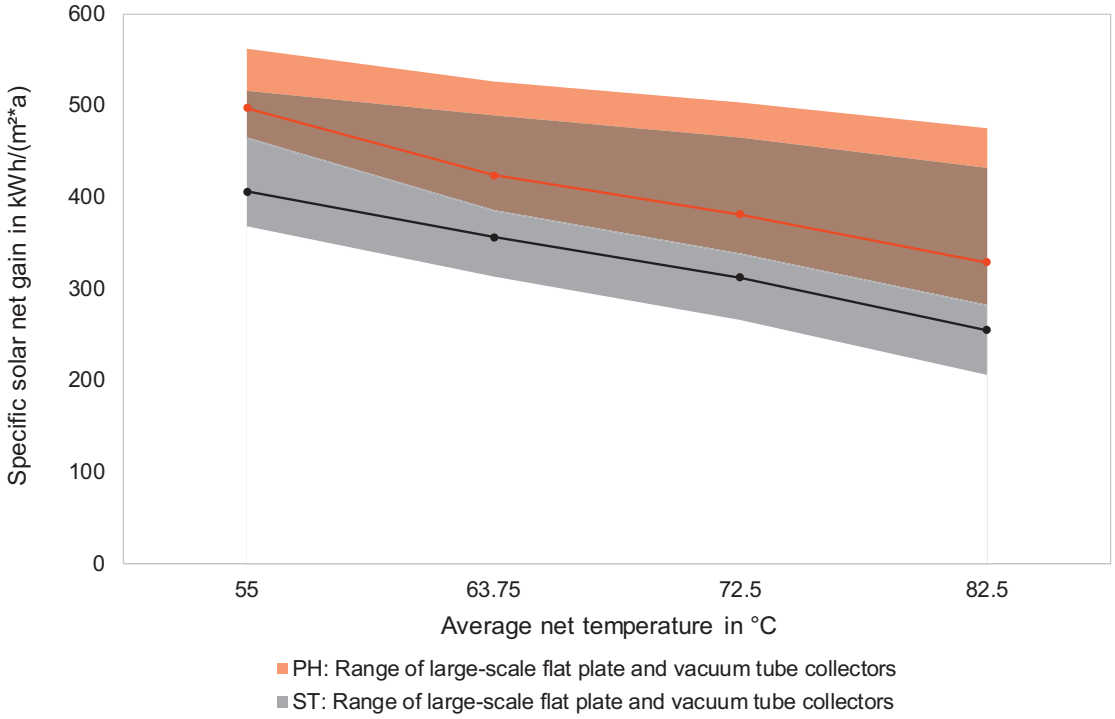

Figure 8: Usable solar heat of large-scale collectors in the German market with two different control strategies for the delivered temperature of the solar thermal plant: ST = heating up to the supply temperature, PH = preheating. The lines represent a sample collector (m²: brutto collector area)

In the preheating mode (PH, Figure 8), the solar thermal plant delivers heat at a lower temperature level than the supply temperature of the district heating net. Therefore, the solar thermal plant can produce heat even if the solar irradiation is low. The solar heat production in this mode mainly depends on the return temperature of the district heating net that should be heated by the solar thermal plant. This is visible by the strong reduction of the solar heat gain between the cases with 55 °C and 63.75 °C average temperature. The return temperature increases between these two cases from 40 to 50 °C in a yearly average.

A first idea of the performance of one single collector gives the Solar Keymark certificate (ESTIF, 2017). Each collector is tested and certified under standardized conditions with a constant average temperature in the collector. Neither the influence of the system integration nor the realistic supply and return temperatures are considered in the tests. In the certificate the performance indicators and yearly heat productions are declared for the climate data of four different locations in Europe.

As mentioned above, the solar irradiation influences the solar heat production of the collector field to a strong extend. This is shown in Figure 9 for the sample collector and with the application of the formerly mentioned climate data from Würzburg and Hamburg (see Figure 7).

The calculations of the solar heat production, whose results are shown in Figure 9, are based on a solar thermal system with a decentral feed-in and without a heat storage. This system is operated to deliver always the supply temperature of the district heating net. The average net temperature is 63.75 °C, in summer the supply temperature amounts to 75 °C and the return temperature to 55 °C. The results show the direct dependency of the solar heat gain on the solar irradiation and the strong variation from the average in single years. The variation around the 10-years-average lies in a range of +10 to -15 % for Würzburg and +20 to -14 % for Hamburg.

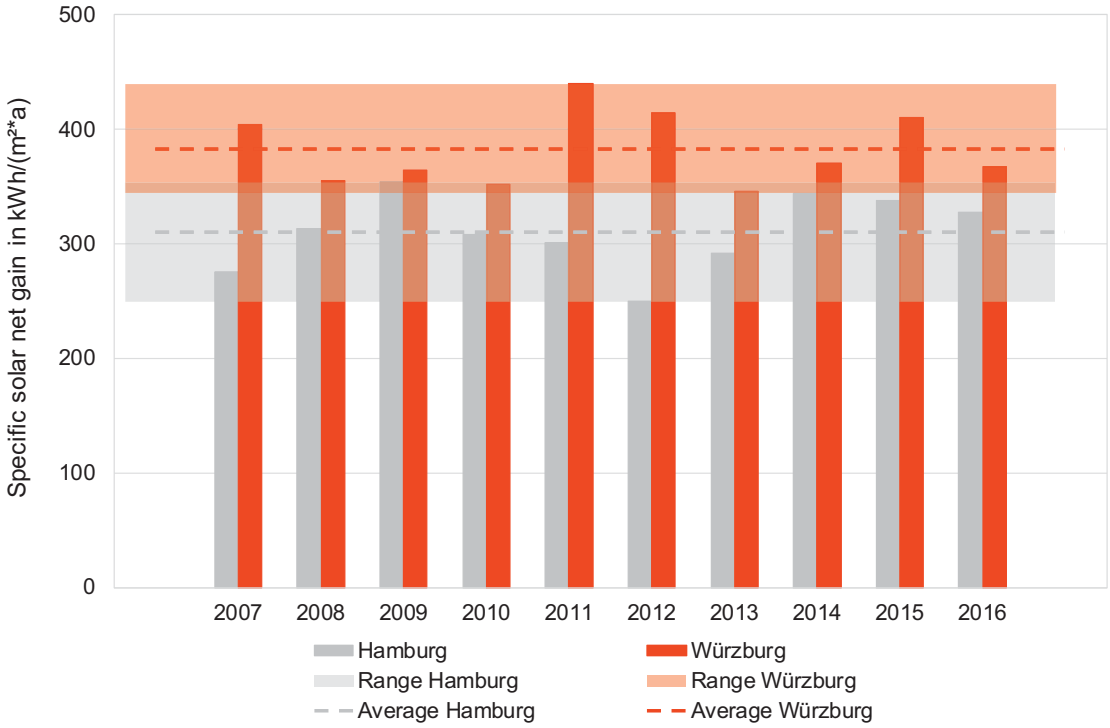

Figure 9: Calculated specific solar heat gain per m² brutto collector area of a sample collector with climatic data for the years 2007 to 2016 for the cities of Würzburg and Hamburg. The solar thermal plant is operated to always reach the supply temperature in a district heating network with 63.75 °C average temperature.

Such variations in the solar heat gain need to be considered when dimensioning a solar thermal plant. That is why the careful calculation of the solar heat gain with all available data and, in addition, based on realistic assumptions is essential for the feasibility of solar district heating systems. Compared to conventional heat producers, dynamic system behavior and the variations of the solar irradiation, the mass flow and the temperatures of the district heating net need to be considered in detail.

If a solar thermal plant is dimensioned to deliver the entire heat demand of the district heating net during the summer time, in most cases a short-term heat storage is necessary to store the heat from day to night and for the case of some cloudy days. In Europe the heat demand during summer usually is defined by tap water heating and the heat demand of industrial processes. The solar fraction of these solar thermal systems depends on the seasonal distribution of the yearly heat demand and is usually between 10 to 15 %. The higher the solar fraction, the more solar heat needs to be stored, not only for some days but for weeks. In case of high solar fractions of solar heat in the region of more than 40 % of the yearly heat demand, a seasonal heat storage is necessary, because the heat from summer has to be used in winter. Due to the longer storage time of the solar heat, the heat losses increase and the specific net solar heat gain of the collectors decreases. Figure 10 gives an example for the interrelations of the main parameters for such systems.

Therefore, it is assumed that the collector field comprises high temperature flat plate collectors of the sample type (see Figure 8), located in the city of Frankfurt in Germany. The collector field feeds in decentrally into a district heating net with a supply temperature of 78 °C in a yearly average and a yearly heat demand of 4 GWh/a. To increase the solar fraction of the yearly heat demand of the district heating net (see red line in Figure 10), the collector area has to be increased (see x-axis in Figure 10). The higher the solar fraction gets, the larger the heat storage volume has to be. The dashed grey line shows the specific storage volume in m³ water, related to the brutto collector area, that is necessary to reach the intended solar fraction. By mathematical variation, the specific storage volume was fitted to the respective collector area in a way that the storage volume is used completely and stagnation in the collector field is just avoided. For a solar collector area of 10,000 m² a solar fraction of 70 % of the yearly heat demand of the district heating net can be reached with a specific storage volume of 2.3 m³/(m² brutto collector area). In Figure 10, this specific storage volume is set to 100 % (see y-axis). The black broken

line in Figure 10 gives the specific solar net gain of the entire solar thermal system (see Figure 2). The solar net gain is the usable solar thermal energy that is fed into the district heating net. Heat losses by the storage etc. are subtracted already. The maximum value of 313 kWh/(m² a), equals 100 %, is quite low and caused by the overall system layout that asks for a feed-in of the solar net heat gain always on the supply temperature of the district heating net of 78 °C in a yearly average. This specific solar net heat gain declines with rising solar fraction due to rising heat losses of the necessary storage and rising average operation temperatures in the collector field.

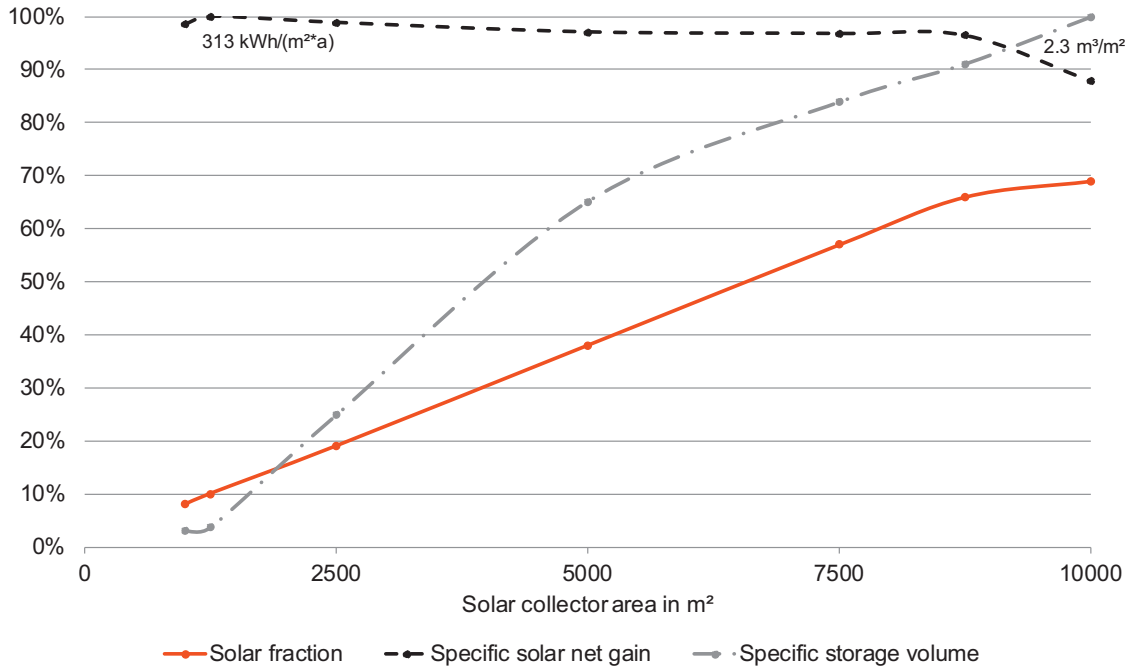

Figure 10: Correlation of solar collector area, specific heat storage volume, solar fraction of the yearly heat demand and solar heat gain for a solar thermal plant that feed in decentrally in a district heating net and always delivers the supply temperature of 78 °C in a yearly average (sample collector and weather data of the German city Frankfurt (see Figure 8))

For a real plant, possible next steps in the overall system design would be to change the system integration of the solar thermal system to a preheating mode (see Figure 8) or to integrate a heat pump into the solar system to unload the heat storage to lower temperatures. Both possibilities allow to reduce the operation temperatures of the solar collector field to reach higher specific solar net gains per year.

The results in the diagrams of chapter 4 are calculated with the Excel-calculation program SCFW ("ScenoCalc Fernwärme", in German: "ScenoCalc for solar district heating systems") which is free of charge and can be used for first assessments of SDH systems (Solites, 2017).

5. Market development in Europe

The first solar thermal plants that delivered heat to district heating nets were realized in Europe in the beginning 1980s driven by national research and demonstration programs as a reaction on the worldwide oil crises in the 1970s. Since then, the technical developments in different fields like the technologies for solar thermal collectors that are specialized for their application to district heating, the system integration of a solar collector field into district heating, the available heat stores, the possible operation modes of the solar thermal system etc. were immense. First large pilot plants were built in Sweden and Denmark, followed by a continuous development in Germany and other European countries like Austria etc.

In the last years, Denmark showed an impressive success story regarding solar district heating driven by national laws that increase the price for fossil gas if it is used only for heating. Since 2010 a capacity of more than 500 MW_{th} of solar thermal collectors has been newly installed. These solar thermal plants are connected to the heating central of a district heating net according or similar to the schematic system in Figure 2. The largest plant in operation

has a total collector area of 15 hectares and a thermal capacity of 100 MW_{th}. In other European countries, the market conditions of the heating and cooling sectors significantly differ from the particular situation in Denmark. But also in Germany, Austria and in other countries with starting markets large scale solar thermal plants become an economically competitive heat generation option for district heating. Figure 11 gives an overview of the market status of solar district heating in Europe.

Fig 11: Solar district heating market status in Europe (May 2016) (red dot: solar thermal system for district heating, blue dot: solar thermal system for district cooling, number: amount of solar thermal systems in respective European country) (Solites, 2016)

At the end of 2015, 252 plants with more than 350 kW_{th} nominal power were in operation in Europe. The total installed capacity amounts to 750 MW_{th}. Moreover, an increasing number of countries are following this trend and new markets have started to develop, for example in Italy, France and even in South Korea.

New solar district heating projects show an interesting variety of technical concepts and operator models: So called 'energy villages' are a solution for rural areas, where whole villages switch from individual, often oil-based heating systems to district heating systems for larger parts of the village. Local biomass plants combined with a solar thermal system are seen as one of the applicable renewable heat sources for such systems and operators are often cooperatives, municipalities themselves or their utilities. Solar district heating is, however, also an advantageous solution for new built or retrofit districts in innovative urban development projects. In several large solar thermal plants in Sweden and Austria a decentral feed-in of solar heat into the district heating has been realized. A decentral feed-in is in particular interesting for larger city district heating systems, where sufficiently large roof or infrastructure areas are available along the district heating lines.

The energy transition with its growing part of renewable power supply in the electricity nets in some European countries leads to an additional market push for solar thermal systems in district heating nets. More and more fossil-driven CHP-plants (CHP: combined heat and power) reach a shut down during the summer months due to uneconomic operation conditions that are caused by high amounts of renewable power in the electricity grids. The missing heat can be replaced by renewable solar thermal energy.

Economical competitiveness and heat generation costs between 30 and 50 Euro/MWh are reached whenever the solar thermal plants are sufficiently large (> 1 MW_{th}), the overall concept is kept simple (e.g. ground-mounted collector fields, see Figures 3 and 4) and the district heating system is operated at suitable temperatures (< 100 °C). In addition subsidies for the introduction of renewable energy sources into district heating are available in many

European countries. The low share of operation costs leads to a long term stability and calculability of heat generation costs for the whole operation period of typically 25 years.

6. The European SDHp2m project

SDHp2m stands for “Solar District Heating and actions from Policy to Market”. The project addresses market uptake challenges for a wider use of district heating and cooling systems (DHC) with high shares of renewable energy sources (RES). The action specifically focuses on the use of large-scale solar thermal plants combined with other RES in DHC systems (Solites, 2016).

The key approach of the project is to develop, improve and implement advanced policies and support measures for SDH in nine participating EU regions. In three focus regions Thuringia (DE), Styria (AT) and Rhône-Alpes (FR) the regulating regional authorities are participating as project partners to ensure a strong implementation capacity within the project. In six follower regions from BG, DE, IT, PL, SE the regulating authorities are integrated through letters of commitment. The project activities aim at a direct mobilization of investments in SDH and hence in a significant market rollout.

In each region, a stakeholder advisory group has been created, gathering market and policy actors to identify the actions that have to be taken to enable a market roll-out of SDH. A detailed action plan has been set up that the regional teams are implementing. The planning of activities by local actors at a regional level ensures the development and implementation of ideas adapted to the local framework. On the other hand, thanks to the international level of the project, know-how and experience from frontrunner regions are available and partners can exchange ideas and methods on how to tackle their challenges. Several factsheets are under development regarding the policy, financing and market development actions in each region.

Addressed market uptake challenges are: Improved RES DHC policy, business models and better access to plant financing, sustained public acceptance and bridging the gap between policy and market through market support and capacity building. Denmark and Sweden reach already today a high share of RES in DHC and are used as a role model for this project.

Some European countries supplement the market development for SDH by national market development projects. As an example, the German Federal Ministry for Economic Affairs and Energy started the project “Solnet 4.0”. Within this project, eight suppliers of solar thermal plants for district heating works together with SDH specialists, the German district heating industry federation AGFW e.V. and media suppliers to increase and strengthen the growing development of the German SDH market.

7. Perspectives

The technologies for large collector fields that can be integrated into district heating systems in Europe are already offered by at minimum eight companies. Further technical developments are necessary to further adopt the solar thermal technologies to district heating for centralized and decentralized feed-in. One of the main focuses of research lies in the system integration of large collector fields into complex district heating networks with several heating centrals, several combined heat and power plants etc. The energy transition leads to fundamental changes in the district heating technologies with good opportunities to integrate solar thermal as a heating technology into these systems. The technical questions how this integration should be realized are not yet answered. Within first pilot plants this new, broad field of research and development is investigated like in the new project “renewable district heating 2020 – the multifunctional district heating network as a heat hub” in the city of Hennigsdorf in Germany. The utilities of Hennigsdorf are going to raise the amount of renewable energies up to 100 % for their district heating net of about 50 km length that delivers about 120 GWh/a heat on a temperature level of up to 105 °C supply temperature. Therefore the utilities cooperate with technical consultancies and Solites as scientific experts to develop the technical-economical optimum for the overall district heating system and its operation strategy.

Safeguarding the SDH market development to a stable and durable market still is a comprehensive task that asks for huge efforts within the coming years - with Denmark as the only worldwide exception. These efforts mainly comprises non-technical developments. Some first European countries show that if the political will to further develop the SDH market is expressed clearly and in addition finds its way into market incentive programs and

long term stable market conditions, the district heating companies increasingly welcome solar thermal plants as a sustainable, future-proof heating technology and start their own way into a solar future. The possible variants are extensive: from a first small solar thermal plant to the 100 % renewable solution for whole (smart) cities.

Central versus Semi-decentralized Solar District Heating for Low Heat Demand Density Housing Developments in Germany

Isabelle Best, Janybek Orozaliev and Klaus Vajen

University of Kassel, Solar and Systems Engineering, Kassel, Germany

Abstract

District heating risks to lose competitiveness the lower the linear heat density of a district is. The distribution network needs to be highly efficient in order to ensure economic feasibility. The heat distribution temperatures are crucial to keep distribution heat losses as low as possible. For a new housing area in Germany consisting mainly of single family houses, solar district heating concepts at two different supply temperature levels of 70°C supply and 40°C supply are examined in terms of economic and efficiency aspects. Depending on the required temperature level of the heat supply concept the component's design differs. A system with 70°C supply temperature is based on a central heat supply with a heat pump and ground-mounted solar collectors, whereas the system with 40°C supply temperature is a semi-decentralized concept with central heat pump for space heating and decentralized solar thermal systems and electric back-up heaters for domestic hot water preparation.

1 Introduction

Future smart thermal energy systems are based on a combination of renewable technologies using wind, geothermal, and solar thermal power along with residual resources to meet the heat demand (Lund et al., 2014). District heating infrastructures and large thermal storages play an important role in future energy systems as demonstrated by various projects in Denmark in recent years (SDH solar district heating, 2017). The heat supply system should distribute heat with low heat losses. However, district heating risks to lose competitiveness the lower the linear heat demand density of a district is. The planned new housing area "Zum Feldlager" (Kassel, Germany) comprises of 131 buildings on a land area of 115,000 m². The housing area will consist mainly of single family houses, resulting in a low building density with a plot ratio of 0.25 according to (Persson and Werner; Persson and Werner, 2011). It represents a heat demand sparse area with a very low linear heat demand density of around $580\ \mathrm{kWh/(m_{trench} \cdot yr.)}$. In this case the distribution network needs to be highly efficient in order to ensure economic feasibility. The heat distribution temperatures are crucial to keep distribution heat losses as low as possible. Likewise, the heat supply system should include renewable energies, as much as possible.

Therefore, two solar district heating concepts for the new housing area "Zum Feldlager" at different supply temperature levels are examined in terms of economic and efficiency aspects in this study. In Denmark, the implementation of solar heat is characterized by large central ground-mounted solar thermal collector fields connected to thermal networks and seasonal storages. The opposite case occurs in Germany. A broad implementation of ground-mounted large-scale solar thermal collector fields in district heating systems is limited because of high land prices. Individual solar thermal systems are currently dominating the German market. Key issue is, under which boundary conditions a central solar district heating system is more beneficial than a semi-decentralized district heating system for very low linear heat density areas in Germany, like the housing development "Zum Feldlager". Accordingly, the heat generation costs have been calculated considering components' investment, system operating costs as well as maintenance and service costs for two exemplary heat supply systems.

2 Boundary Conditions

2.1 Description of the New Housing Development

The planned new housing development "Zum Feldlager" (Kassel, Germany) comprises of 131 buildings on a land area of 115,000 m². The housing development will consist mainly of single family houses, resulting in a low building density with a plot ratio of 0.25 according to (Persson and Werner, 2011). The buildings were calculated to meet the requirements of the German KfW-70 low-energy building standard according to the Energy Saving Ordinance 2016 (Gesellschaft für Rationelle Energieverwendung e. V., 2016). This means that the buildings were designed to have a specific heating demand below $50\ \mathrm{kWh/(m^2 \cdot yr)}$. The space heating demand of each building was calculated according to the German standard DIN V 4108-6 (Deutsches Institut für Normung e. V., 2003). Additionally, the peak heating load for every building was computed according to DIN EN 12831 (Deutsches Institut für Normung e. V., 2012). Regarding the domestic hot water demand, demand profiles were generated by using a stochastic modelling tool developed by Jordan et al. for IEA SHC-Task 26, which takes into consideration the Gaussian-Distribution and different time scales to generate various load profiles (Jordan and Vajen, 2001). The total heat demand was calculated to amount $\approx 1{,}656\ \mathrm{MWh}/yr$, that comprises of one quarter DHW ($\approx 380\ \mathrm{MWh/yr}$) and of three quarter for space heating (SH) ($\approx 1{,}285\ \mathrm{MWh/yr}$). It represents a heat demand sparse area with a low linear heat demand density of around $580\ \mathrm{kWh/(m_{trench} \cdot yr)}$ assuming a total district heating (DH) pipe length of 2.89 km.

2.2 Generation of Heat Load Profile

Within the framework of the joint research project "Geosolare Nahwärmeversorgung für die Siedlung Zum Feldlager" the new building development and the corresponding semi-decentralized solar DH system was modelled with the software TRNSYS. Dynamic simulations were conducted in cooperation with the Fraunhofer Institute of Building Physics from Kassel. The model consists of all heat supply units, a simplified distribution infrastructure, and clustered consumers. The distribution infrastructure was simplified calculating the average pipe diameter of the district heating network branches and the corresponding pipe length. The characteristics of standard plastic jacket compound pipes with standard insulation were assumed. The 131 buildings were clustered in 22 building typologies and then displayed as single thermal zone models. According to design characteristics of each building type, there were various possibilities for the number of consumers of domestic hot water. These possibilities were sub-grouped into three main cases: typical single family houses, double single family houses and multi-family houses. All other possibilities were realized by taking into account multiplication factors for each case. Precise and realistic domestic hot water systems consisting of all system engineering components were designed in accordance to VDI 6002 (Verein Deutscher Ingenieure e. V., 2014) and VDI 2067 Blatt 12 (Verein Deutscher Ingenieure e. V., 2000). The resulting annual heat load profile is shown in Fig. 1. The space heating (SH) demand is depicted in blue, while the domestic hot water (DHW) demand is displayed in red. The heat load profile is taken as a base for system design and calculation of the central solar DH system (see section 2.3).

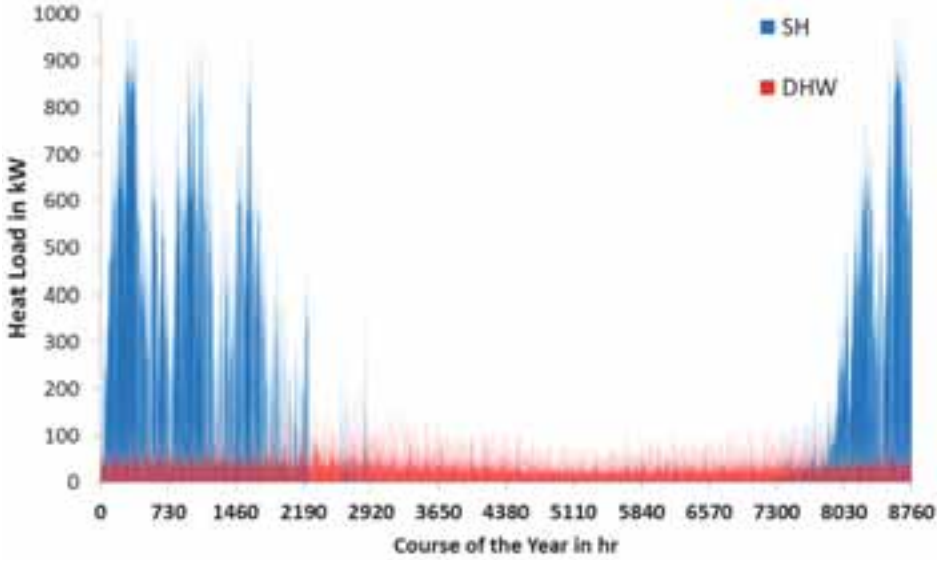

Fig. 1: Calculated hourly heat load profile of the housing development "Zum Feldlager", in blue the space heating demand, in red the domestic hot water demand

2.3 Design Requirements and Basis of Comparison

Both solar DH systems presented were designed to achieve a renewable heat supply of ≈ 80 % of the total heat demand of the new building development. Considering that the renewable energy already covered roughly 29% of gross electricity generation (total volume of electricity generated in Germany) in 2016, the electricity consumption of each solar DH system had to be below 427 MWh/yr. The number of buildings and inhabitants, as well as the DH geometry and pipe length were kept constant. Depending on the required temperature level of the heat supply concept the components´ design differs. Also, the heat distribution network design (pipe diameters, pumps) was adapted according to the distribution temperatures. The central solar DH system is compared to the semi-decentralized DH system for low heat density housing developments in Germany taking following criteria into account:

- Investment for heat supply components
  (decentralized versus central solar thermal system, heat pump, electric peak load heater,
  borehole thermal energy storage, pit thermal energy storage, tank thermal energy storage)
- Investment for the distribution infrastructure (material and burring costs for pipes)
- Prices for land area
- Maintenance and service costs
- Operating costs.

The discounted present value of capital costs, service and maintenance costs, and operating costs was calculated on a base period of 30 years including proportional reinvestments after 15 operating years (central heat pump, decentralized hot water storages, electric back-up heater, components of the uncovered collector field) with an interest rate of 5.6 %. All heat supply components, the DH infrastructure, pumps, the energy centre (centre building with utilities), site development costs, connection, and commissioning costs were considered. Furthermore, the characteristic operating costs were computed at the base of the results from dynamic simulations and static calculations. The maintenance and service costs were evaluated according to VDI 2067 Blatt 1, which recommends fixed rates of investment to calculate the maintenance and service costs depending on the technology used (Verein Deutscher Ingenieure e. V., 2012).

3 System Design

3.1 Central Solar District Heating System

The first concept introduced in this paper is similar to Danish systems like the DH system in Braedstrup and the German DH system in Crailsheim (Nußbicker-Lux, 2010; SDH solar district heating, 2017). The supply temperature of 70°C ensures DHW preparation and SH supply via a low-temperature district heating network. The heat supply system consists of (see Fig. 2):

- A central large-scale, ground-mounted collector field,
- A central heat pump supplemented by an electric peak load heater,
- A Pit Thermal Energy Storage (PTES),
- And a low-temperature district heating network of 70 °C supply and 40 °C return temperature.

The shown functional diagram of the heat supply concept shows only the main components and does not include heat exchangers, pumps, valves etc. for reason of simplicity (see Fig. 2). The district heating network is simplified and represented by a supply line and a return line. The DH network is operated throughout the year with a fixed supply temperature. A linear heat demand density of $576\ \mathrm{kWh/(m_{trench} \cdot yr)}$ was determined.

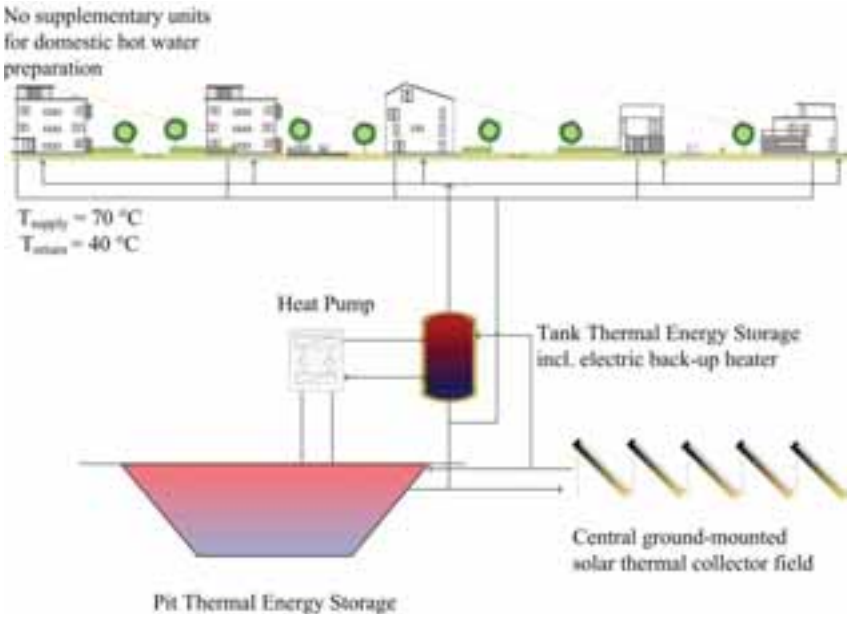

Fig. 2: Central solar district heating based on low-temperature district heating network

The solar thermal system was designed with the free software ScenoCalc Fernwärme 2.0 (Solites, 2017). The heat demand profile shown above served as a basis for the system design. The seasonal PTES is dimensioned in order to achieve a high solar fraction and at the same time low solar heat surplus. A specific storage volume of 3.3 m³/ m² collector area was found to be reasonable (via parameter variations) resulting in the lowest solar heat surplus. The collector field is connected through a heat exchanger to the PTES (heat exchanger temperature difference 5 K). An additional heat exchanger is assumed between the PTES and the DH network (heat exchanger temperature difference 5 K). In order to meet the requirements of renewable heat share of 80 %, the system was designed as follows:

Tab. 1: System design of the central solar district heating system

Component	Size
Flat plate collectors (ground mounted)	2,400 m²
PTES	8,000 m³
Heat Pump	593 kW_{th} (at W0/W35) / SPF 3.8
Tank Thermal Energy Storage (TTES)	100 m³
Electric peak load heater	740 kW nominal power
DH operating Temperatures	Summer: 70 °C / 40 °C Winter: 70 °C / 30 °C
Software for design and calculation	TRNSYS and ScenoCalc Fernwärme 2.0

3.2 Semi-decentralized solar district heating system

The second concept is a semi-decentralized concept based on an ultra-low-temperature district heating network. The supply temperature of 40°C ensures space heating. However, supplementary components for Domestic Hot Water (DHW) preparation are needed. A linear heat demand density of $432\ \mathrm{kWh/(m_{trench} \cdot yr)}$ has been determined, as only space heating is provided by the district heating.

The heat supply consists of (see Fig. 3):

- Distributed solar thermal systems (mounted on the building roofs) for DHW preparation,
- Uncovered solar thermal collector fields for thermal ground regeneration,
- A central Ground Source Heat Pump (GSHP) supplemented by an electric peak load heater,
- A Borehole Thermal Energy Storage (BTES),
- And an ultra-low-temperature district heating network with 40 °C supply and 25 °C return temperature.

Furthermore, a seasonal operating strategy is applied in order to keep distribution losses low. The heat network is operated during the space heating period from October to April only and distributed solar thermal systems on the building roofs combined with electrical back-up heaters ensure DHW preparation throughout the year. The GSHP and the DH is offline in the period of May to September. Only the thermal ground generation is operated through one DH branch. The uncovered solar collector field supplies the BTES with low temperature heat. Thus, the ground temperature is kept constant over the calculated 30 operating years. Also here, the shown functional

diagram of the heat supply concept shows only the main components and does not include heat exchangers, pumps, valves etc. for reason of simplicity (see Fig. 3). The district heating network is simplified and represented by a supply line and a return line.

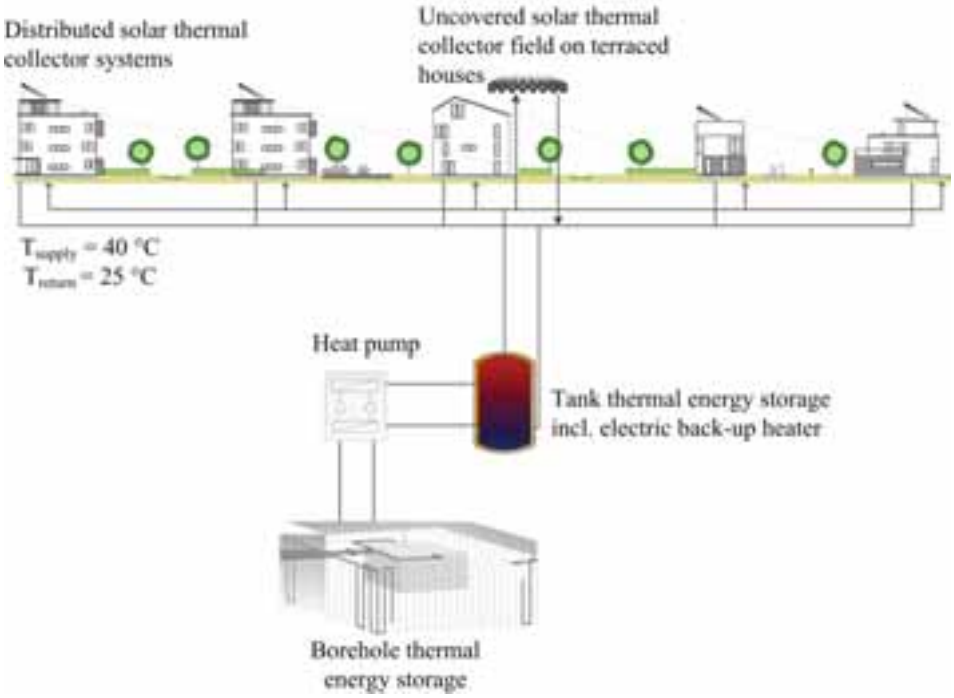

Fig. 3: Semi-decentralized solar district heating based on an ultra-low-temperature district heating network

The semi-decentralized solar DH system was modeled with the software TRNSYS (see section 2.2). The GSHP was designed to meet 60 % of the maximum heat load. The distributed solar collector systems are determined to ensure a solar fraction $f_{sol\ in}$ of ≈ 70 % (average solar fraction of the energy input into the hot water storage).

Tab. 2: System design of the semi-decentralized solar district heating system

Component	Size
Distributed solar DHW systems	820 m² (on the buildings roofs)
Distributed hot water storage tanks in buildings with electrical back-up heaters	300 l (for single family houses) to 1,700 l (for large multifamily houses)
BTES	92 boreholes, 120 m depth
Heat pump	593 kW_{th} (at W0/W35) / SPF 4.6
Tank Thermal Energy Storage (TTES)	20 m³
Electrical peak load heater	740 kW nominal power
Uncovered solar collectors for thermal ground regeneration	1,800 m² on several large building roofs
DH operating temperatures	Summer: - C / - °C Winter: 40° C / 25 °C
Software for design and calculation	TRNSYS

3.3 Network Design

The housing development has been sub-divided in three parts that are supplied by three DH branches. The DH network geometry was kept constant. For each building a connection capacity was determined. The piping network was designed for the maximum heat load. Depending on the heat supply system, it has been differentiated between two design temperature levels: for 70 °C supply and 40 °C return (temperature difference ΔT = 30 K) as well as for 40 °C supply and 25 °C return (ΔT = 15 K). Additionally, the piping manufacturer's recommendation (ISOPLUS) for maximum flow velocities were applied (Nussbaumer and Thalmann; Nussbaumer and Thalmann, 2014). According to the connected capacity a volume flow and the corresponding pipe diameter were computed for each branch. The resulting pipes sums up to 2.89 km pipe length. The connecting pipes were defined to have 1.71 km, while the transportation pipes were calculated to have 1.18 km. The following bar chart depicts the sum of supply and return pipe length (including the connecting pipes) broke down into nominal pipe diameter (see Fig. 4).

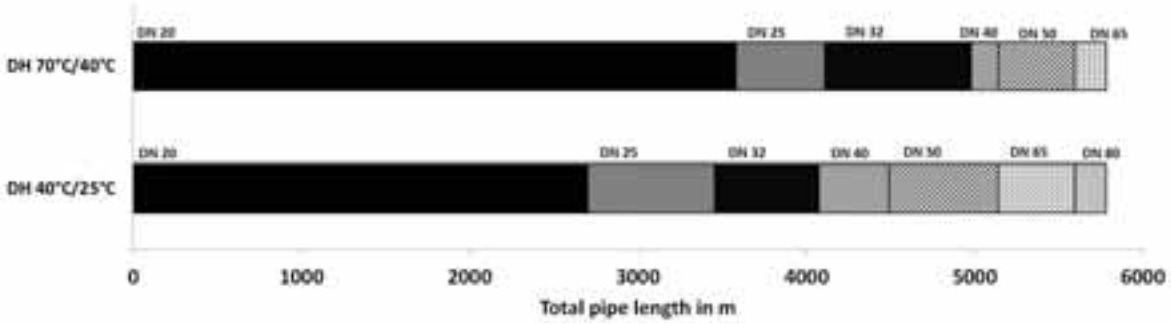

Fig. 4: Nominal pipe diameter distribution showing the sum of supply and return pipes

Based on the nominal pipe diameter (DN) distribution, the network costs were determined with a medium cost approach for new building developments for unmade terrain and rigid pipes after (Nast et al., 2009) (see Fig. 5, red dashed line). The medium cost approach was also approved by (Klöpsch et al., 2009) and can still be considered valid in 2017. Nevertheless, there is an optimization potential according to Manderfeld, who showed that specifically in rural areas the specific network construction costs can be reduced using for example flexible pipes (see grey dashed line) (Manderfeld et al., 2008). This data applies only for Germany, they may differ in other countries.

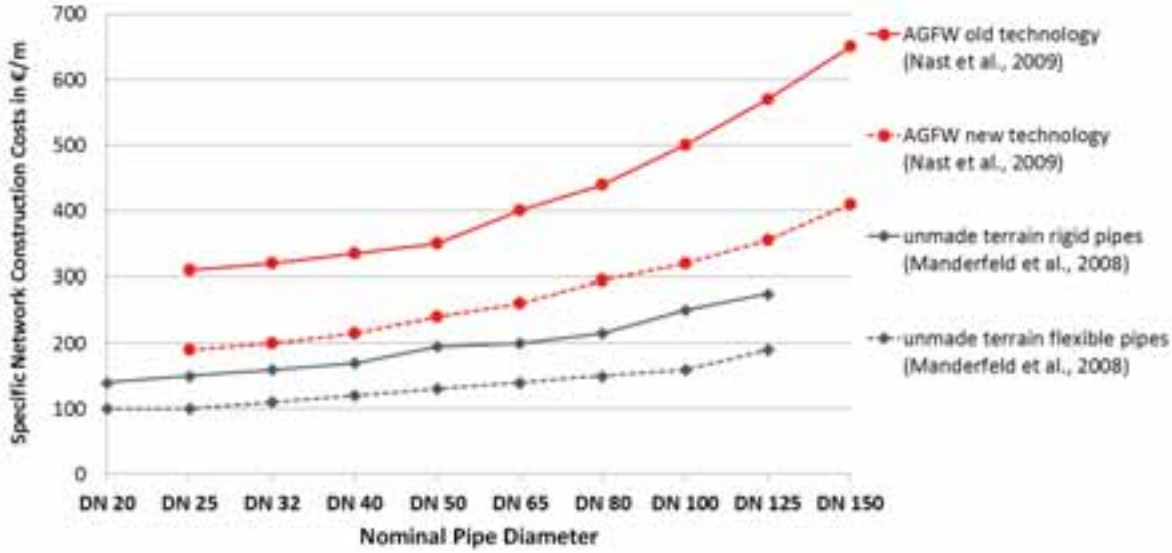

Fig. 5: Specific network construction costs including construction costs and pipe material costs

In operation a DH network shows a characteristic heat loss rate that depends mainly on the pipe type, pipe diameter, insulation, and the temperature gradient between the pipe and the surrounding ground. The relative heat distribution losses increase, the lower the linear heat demand density is. Consequently, the operating costs are affected. For this reason, the heat losses have been calculated and modeled for the two different heat supply systems taking single rigid pipes as a basis (Arbeitsgemeinschaft QM Fernwärme: Nussbaumer, Thomas et al., 2017).

4 System Efficiency

The central solar DH network was designed to meet the requirement of ≈ 80 % renewable heat supply of the total heat demand of the new building development. Thus the electricity consumption has to be below 427 MWh/yr. On the basis of the designed DH network ≈ 18 % distribution heat losses occur within one operating year (see section 3.3). The HP was assumed discharging the PTES from 40°C to 10°C, which results in a seasonal performance factor *SPF* of 3.8. The corresponding maximum electricity consumption of the HP was calculated to be ≈ 310 MWh/yr. taking distribution heat losses and auxiliary energy demand of the system into account. According to these assumptions, the solar collector field needs to ensure ≈ 40 % solar fraction of the total heat demand (fraction of solar energy that meets the heat demand including distribution heat losses). Thus, a large collector field of 2,400 m² of flat plat collector gross area was determined. This corresponds to a solar heat supply of ≈ 800 MWh/yr. to the DH network. The remaining ≈ 60 % of the heat demand are met by the HP. The seasonal storage,

which consists of 8,000 m³, causes ≈ 14 % heat losses, which are already subtracted from the yearly solar heat supply. The electrical peak load heater was assumed to supply only 4 % of the heat demand which shall be covered by the HP.

In contrast to the central DH system, the distributed solar collector systems were designed only for the DHW preparation. They were calculated to meet fully the DHW demand during the non-SH period, which allows keeping the DH network and the HP offline during this period. The simulation's results demonstrated a solar fraction of DHW demand $f_{sol\ out}$ of ≈ 58 % (average solar fraction of the DHW net energy). Besides this, the DHW is preheated via DH network during space heating period up to ≈ 29 % (fraction of the DHW net energy). The remaining ≈ 13 % are covered by electrical back-up heaters. Regarding the HP design, the approach was to keep supply temperatures of the DH network as low as possible in order to achieve a high seasonal performance of the HP and at the same time to avoid heat losses through the network. The calculations showed that a *SPF* of 4.6 (without peak load heater) is achieved following this approach (supply 40 °C return 25 °C). Add to this, only 5.5 % heat distribution losses occur through the DH network, due to the low operating temperatures and the seasonal operating strategy. The uncovered solar collectors (roof top installation) fully ensure thermal regeneration of the BTES during the non SH period. This means, the BTES is charged or rather regenerated with the amount of energy which was subtracted during space heating period. The total electricity consumption amounts to 413 MWh/yr., thus it meets the requirement of 80 % renewable heat supply. The resulting total electricity consumption of the different solar DH system is listed in the following table:

Tab. 3: Comparison of Electricity Consumption

Component	Central Solar DH system Electricity Consumption in MWh/yr.	Semi-decentralized Solar DH system Electricity Consumption in MWh/yr.
Heat Pump, DH heat losses	55	16
Heat Pump operating	251	294
DHW electrical back-up heaters	-	50
Central electrical peak load heater	47	16
Sum without auxiliary energy demand	***353***	***376***
Auxiliary Energy demand (pumps)	54	37
Total Sum	**407**	**413**

5 Economic Evaluation

Hereafter, the results of the economic evaluation are presented. This section examines the net annual costs without and with subsidies of the two different solar DH systems. Thereby, specific costs of the components are discussed. Also, the maintenance and service costs as well as the operating costs are considered. Additionally, the impact of land area prices and the type of seasonal storage are highlighted.

5.1 Net Annual Costs of the Central Solar DH System

The specific investment for each component was evaluated. First, the DH network costs for transportation pipes were calculated on the basis of the computed DN distribution of the network. The network was characterized by a majority of small diameters of DN 20 and DN 32. This results in an average 226 €/m pipe length (Nast et al., 2009) (see section 3.3) Together with costs for substations, house-lead-in costs, and network pumps, they build total investment for the central distribution infrastructure. Secondly, the central flat plate collector field was calculated based on a gross collector area of 2,400 m². Taking the economy of scale into account, specific collector costs of 380 €/m² were assumed. Furthermore, the pit storage (PTES) was examined. It was designed according to the Danish principle. The Danish pit storages are typically without surface sealing and only covered by insulation material and a canvas cover. Thus, costs of only 45 €/m³ water equivalent incur. However, as a result the seasonal storage cover is not usable as leisure space for example. Consequently, costs for land area use for the PTES installation and the collector field incurred (blue parts in the pie chart, see Fig. 6). Land area prices for green areas and for solar system installations were assumed according to standards in Kassel. The specific investment for each component is listed in the following table:

Tab. 4: Specific investment of the central solar DH system's components

Network construction costs	226 €/m_{tr}	(Nast et al., 2009)
Costs for substations	4,000 €/unit	(Stuible et al., 2016)
House-lead-in costs	3,600 €/unit	(Stuible et al., 2016)
Network Pumps	3,350 €/unit	(wilo, 2017)
Solar System Collector Costs	380 €/m²	(Verein Deutscher Ingenieure e. V., 2017)
PTES	45 €/m³ water equivalent	(Solites, 2016; Freistaat Thüringen Ministerium für Umwelt, Energie und Naturschutz, 2016)
Land area	8 €/m² for green areas, 15 €/m² for land areas for solar system installations	(BORIS Hessen, 2016)
HP	195 €/kW_{th}	(Lambauer et al., 2008; Wolf et al., 2014)
Peak load heater	100 €/kW	Assumption, expert knowledge

According to the specific investment the total annual investment was determined based on the system components design. The following figure shows the results of the detailed economic evaluation of the central solar DH system (see Fig. 6). The net annual heat costs comprise of operating costs, maintenance and service costs, as well as the investment. The bar chart shows the net annual costs without taken subsidies into account. In absolute values the total annual system costs are ≈ 415 k€/yr. Thereof 61 % are investment (252 k€/yr.), 22 % result from maintenance and service and only 18 % are caused by system operating. Thus, the fixed cost rate is 83 %.

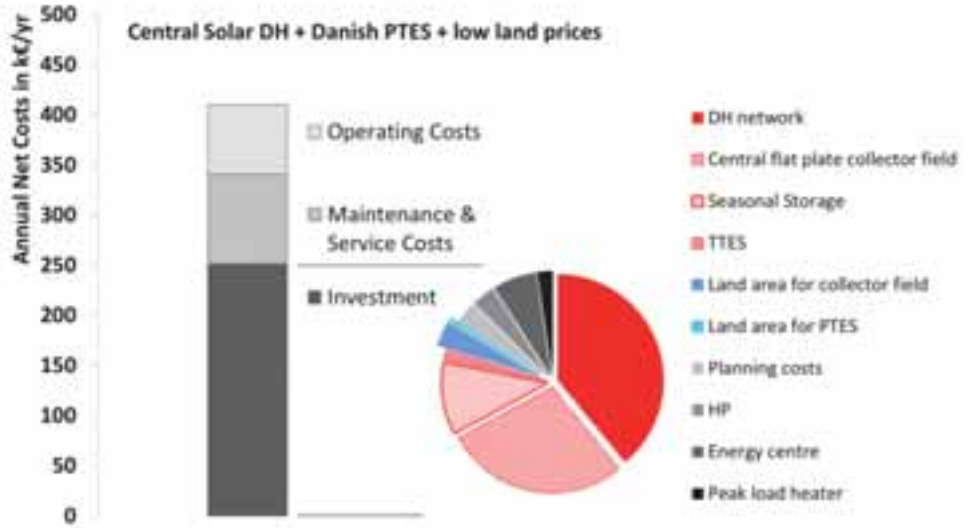

Fig. 6: Net annual costs for a central solar district heating system (left) and the breakdown of the investment (right) at a base period of 30 years

The break-down of investment demonstrates the three most cost-intensive system components: the DH network (39 %), the central collector field (28 %), and the pit storage PTES (11 %). The pie chart shows also several other points of expenses marked in grey. They are considered to be nearly constant through the different heat supply systems. They comprise of planning costs, the heat pump, the peak load heater, and the energy centre. Together they amount to 16 % of the investment. The land area costs represent an ideal situation and can be seen as a low cost approach. Nevertheless, they amount to 4 % of the total investment (marked in blue).

On top of the investment, maintenance & service costs and operating costs are added. The maintenance and service costs were evaluated according to fixed rates recommended by VDI 2067, whereas the operating costs represent the system operating characteristic. Here, the operating costs result only from the yearly electricity consumption, which mainly reflects the HP performance and secondly the auxiliary energy demand of pumps (see section 4). The HP achieves a SPF of 3.8 and supplies 60 % of the total heat demand. To sum up, the net annual costs amount to 415 k€/yr. This results in specific net heat generation costs of 249 €/MWh for a total heat demand of 1,665 MWh/yr. without subsidies.

5.2 Net Annual Costs of the Semi-decentralized Solar DH system

Similar to the economic evaluation of the central solar DH system, the calculations were conducted for the semi-decentralized solar DH. First the specific costs for system components were investigated. The DH network costs resulted to be almost the same as the costs of the central solar DH network, despite the lower temperature level and the smaller temperature difference of 15 K between supply and return. The DH network transportation pipes amount of average 233 €/m_{tr} (Nast et al., 2009), which is an increase of 3 % compared to the central solar DH system. The costs for substations as well as house-lead-in costs were assumed to be the same as previously shown. In contrast to the central solar DH system, distributed flat plate collector systems were planned of 820 m² in order to supply the DHW demand during non-space heating period. Thus, higher specific solar thermal system costs incur of 742 €/m² (Stuible et al., 2016). The BTES was designed in cooperation with the Institute of Geotechnics of the University Kassel, which computed the BTES to have 92 boreholes of 120 m depth. Specific costs of 63 €/m borehole depth were determined. The land area above the BTES was assumed to be still usable as green space, because the boreholes are installed 1 m under the surface. Consequently, no additional costs for land area occur.
The specific investment for each component is listed in the following table:

Tab. 5: Specific investment of the semi-decentralized solar DH system's components

Network construction costs	233 €/m_{tr}	(Nast et al., 2009)
Costs for substations	4,000 €/unit	(Stuible et al., 2016)
House-lead-in costs	3,600 €/unit	(Stuible et al., 2016)
Network Pumps	3,490 €/unit	(wilo, 2017)
Solar System Collector Costs	742 €/m²	(Stuible et al., 2016)
BTES	63 €/m borehole depth	(Institute of Geotechnics of the University Kassel)
Land area	-	
HP	195 €/kW_{th}	(Lambauer et al., 2008; Wolf et al., 2014, & requests for proposals of manufacturers)
Peak load heater	100 €/kW	assumption

The central solar DH system shall be compared with a semi-decentralized solar DH system, which was designed especially for the new building development "Zum Feldlager". Therefore, the net annual costs were examined similarly to the central solar DH system. The results are shown in the following diagram. Fig. 7 displays the net annual costs of the semi-decentralized solar DH system. The net annual costs consist of 64 % investment (284 k€/yr.). Furthermore, maintenance and service costs amount to 22 % of the total heat generation costs, which can be summed up to a fixed cost rate of 86 %. The investment is dominated also by three main system components: the DH network (37 %), followed by the BTES (31 %), and the distributed solar collector systems (17 %). In case of the semi-decentralized solar DH system the operating costs were determined via dynamic simulations (see section 2.2). Similar to the central solar DH system analyses, the specific electricity costs were assumed to be 0.17 €/kWh, which applies to large consumers. Regarding DHW preparation, the electricity consumption of the electrical back-up heaters was rated with 0.21 €/kWh, which applies to small consumers in Germany. The HP performance, thus the *SPF* has the largest impact on the operating costs. The electricity consumption of the HP is 310 MWh/yr. (*SPF* = 4.6) that generates costs of 68 % of total operating costs. This implies the distribution heat losses through the network already. To sum up, the net annual costs amount to 443 k€/yr.. This results in specific net heat generation costs of 266 €/MWh for a total heat demand of 1,665 MWh/yr. without subsidies.
In conclusion the semi-decentralized DH system shows 7 % higher net heat generation costs than the central solar DH system. However, this applies only for the given boundary conditions. Specifically, this applies for sites with very low land area costs and for the assumed seasonal storage type. In order to investigate the impact of these parameters on the total net heat generation costs, a sensitivity analysis was conducted.

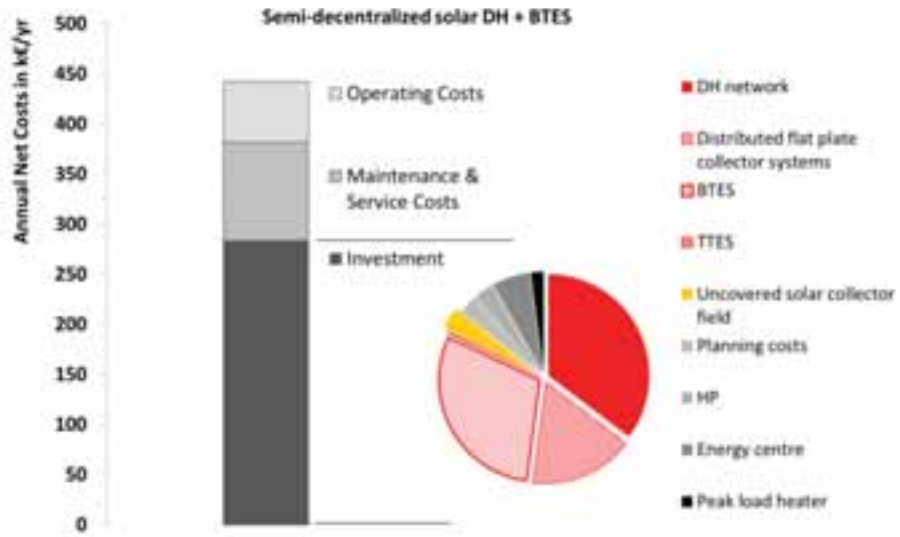

Fig. 7: Net annual costs of the semi-decentralized solar DH system for the new housing development „Zum Feldlager“ at a base period of 30 years

5.3 Sensitivity analysis of land area prices and PTES type

In Germany the availability of open space is restricted, which results in high land prices. In order to demonstrate the upper limit of heat generation costs, the land use for solar system installations (3.5 times the collector area) was calculated with land prices of 175 €/m² land area. This represents the land value of the district, where the new housing development “Zum Fedlager” will be build. Additionally, seasonal storages with surface sealing were realized in Germany in the recent years in order to be able to still use the area as leisure space. In case of PTES with a surface sealing, the specific costs increase significantly as demonstrated from various German projects (Solites, 2016). The specific costs can increase up to 200 €/m³ water equivalent (Freistaat Thüringen Ministerium für Umwelt, Energie und Naturschutz, 2016). For sensitivity evaluation reasons, the central solar DH system was calculated with a PTES with surface sealing applying 142 €/m³ water equivalent, which represents the average of several projects realized in Germany. The results of the sensitivity analysis are presented in the following bar chart (see Fig. 8). The light grey bars show the total net annual costs without subsidies (left axis) and the net heat generation costs (right axis). Besides this, the net heat generation costs considering subsidies are displayed by the striped bars. Compared to the initial event of the central solar DH (bar pair on the left side) the net heat generation costs increase about 38 % in case of high land area prices (second bar pair from the left). The semi-decentralized solar DH system was optimised to use as little land as possible. The distributed solar collector systems as well as the uncovered solar collector field for ground regeneration were planned as roof installations. No supplementary land is needed, which makes this heat supply concept competitive. In case of PTES with surface sealing, land costs are saved, because it is assumed that the storage cover can be used as leisure space (third bar pair). Despite this, the net heat generation costs do not increase significantly (5 % increase) compared to the second version of the central solar DH due to the high investment of the PTES with surface sealing. Considering subsidies, a new funding program (Wärmenetze 4.0, in English district heating 4.0) aiming at the implementation of sustainable and renewable DH systems entered into force end of September 2017. On this basis, subsidies of 30 % - 40% of the total investment can be received. This leads to the lowest specific heat generation costs of 198 €/MWh in case of the initial central solar DH system, and 207 €/MWh in case of the semi-decentralized solar DH system. Compared to the previous funding programme for renewable energies in Germany (KfW, 2016), this means a cost reduction of 10 % in case of the central solar DH system and 19 % in case of the semi-decentralized solar DH system.

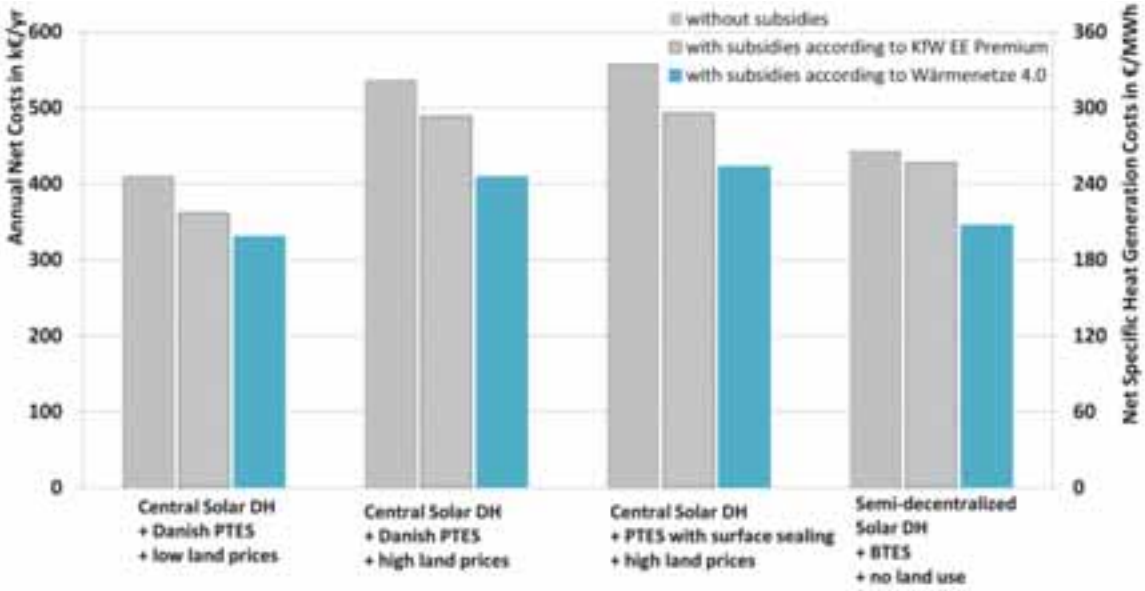

Fig. 8: Net annual costs and net heat generation costs of the central solar DH system under different PTES types and land prices compared to the semi-decentralized solar DH system with and without subsidies

In conclusion, in case of low land prices and a cost-efficient PTES without surface sealing a central solar DH system is 4 % less expensive than the semi-decentralized solar DH system taking subsidies according Wärmenetze 4.0 into consideration. Thus, the semi-decentralized is an economically competitive heat supply system under the given boundary conditions and assumptions. Without subsidies the central solar DH system is 6 % less expensive than the semi-decentralized solar DH system. Thus, in case of low land prices below 15 €/m², a central solar DH following the Danish example is slightly more beneficial than the semi-decentralized solar DH system from an economic point of view. In case of high land prices the heat generation costs of the central solar DH system increase about 30 % without subsidies and 24 % with the subsidies of the funding programme Wärmenetze 4.0. Thus, land prices have a high impact on the system feasibility and have to be considered within economic analyses.

6 Discussion

Two different solar district systems have been designed for the new building development “Zum Feldlager”, which represents a low heat density area. Both developed heat supply systems were designed under the precondition to achieve a renewable heat supply of ≈ 80 %. Key issue was to identify the preferable system from the economic point of view. Detailed economic analyses were conducted in order to determine the net heat generation costs of each system comprising of investment, maintenance and service as well as operating costs. At this point, it has to be said, that a medium cost approach was chosen. The specific costs for solar thermal collectors were considered conservatively. The maintenance costs are determined applying fixed percentages of investment according the German VDI 2067, which might be overestimating the costs in case of large systems. In conclusion, the economic analyses showed that the central solar district heating system is only favorable under specific boundary conditions: low land prices and low costs for the seasonal pit thermal energy storage. If the land prices are greater than 15 €/m², the semi-decentralized solar district heating system is to be preferred. In conclusion the semi-decentralized DH system shows 6 % higher net heat generation costs than the initial central solar DH system at low land prices (without subsidies). However, this applies only for the given boundary conditions. Specifically, this applies for sites with very low land prices and for the assumed specific solar thermal system costs. Due to the fact, that the central solar collector field makes 28 % of the investment of the central solar DH system (based on a PTES following the Danish examples), the specific solar thermal system costs represent a sensitive parameter. Furthermore, both heat supply systems were designed to achieve 80 % renewable heat supply. If this is not the requirement, the solar fraction can be reduced by lowering the collector area and likewise increasing the HP operating hours. This would lead to lower net heat generation costs. On the other hand, in case of lack of open space, the semi-decentralized solar DH system represents an energy efficient, sustainable and economic alternative to the central solar DH system.

Abstract

Detailed measurements were carried out on a large scale solar heating plant located in southern Denmark in order to evaluate thermal performances of the plant. Based on the measurements, energy flows of the plant were evaluated. A modified Trnsys model of the Marstal solar heating plant was developed to calculate thermal performances of the plant. In the Trnsys model, three solar collector fields with a total solar collector area of 33,300 m^2, a seasonal water pit heat storage of 75,000 m^3, a simplified CO_2 HP, a simplified ORC unit and a simplified wood chip boiler were included. The energy consumption of the district heating net was modeled by volume flow rate and given forward and return temperatures of the district heating net. Weather data from a climate station on the site of the plant were used in the calculations. The Trnsys calculated yearly thermal performance of the solar heating plant was compared to the measurement result. Validity of the Trnsys model was analyzed. Recommendations are given with an aim to develop a Trnsys model that can be used to optimize design of a solar heating plant under different scenarios.

Keywords: Solar heating plant, Thermal performance, Monitoring, Trnsys simulations, Design optimization

1. Introduction

Modern district energy systems provide heating and cooling services using technologies and approaches such as combined heating and power (CHP), thermal storage, large scale heat pumps and solar heating. District energy creates synergies between supply and demand of process heating and cooling, space heating, cooling, domestic hot water and electricity. Tackling the energy transition of district heating to a sustainable future will require the intelligent use of synergies, flexibility, and short and long term energy storage solutions (Lund etc. 2014).

Denmark is one of the leading countries in district heating. Around 60% of Danish buildings are connected to district heating and district heating covers more than 50% of the total heating demand of Denmark (Nussbaumer & Thalmann 2014). The development of Danish district heating targets the transition from current 3rd generation district heating to the future 4th generation low temperature district heating with a large share of renewable energies. In 2009, a total 54,500 m^2 solar collectors were installed in Denmark, of which 35,000 m^2, i.e. 64%, were used in large solar district heating systems. In 2015, the solar collector areas installed in solar district heating plants reached 241,000 m^2, increased by 342% in six years. Supplemented by cogeneration technologies for biomass and large scale heat pumps fueled by electricity from wind power, it is possible to achieve a district heating and cooling system with 100% renewable energy. In these large scale solar heating plants, seasonal water pit thermal energy storages (PTES) are implemented. PTES is a viable solution of thermal energy storage both economically and environmentally since it is simple in construction and relatively cheap. Larger storage volumes lead to increased efficiency in practice, since the heat losses do not increase with the volume proportionally. With a large water pit heat storage, solar fraction of a district heating system could be significantly increased to for example 50% of the heat demand. Examples of large scale solar heating plants are the Marstal plant (33,300 m^2 solar collectors and 75,000 m^3 PTES), the Dronninglund plant (37,573 m^2 solar collectors and 60,000 m^3 PTES), the Vojens plant (70,000 m^2 solar collectors and 200,000 m^3 PTES) and the Gram plant (44,801 m^2 solar collector and 120,000 m^3 PTES) (PlanEnergi 2016).

Thermal behaviors of water pits have been investigated both experimentally and theoretically. Kielsgaard Hansen et al. (1983) investigated for the first time a small 500 m^3 pilot water pit heat storage at the campus of the Technical University of Denmark. Later, Kübler etc. (1997) presented investigations on a pilot heat storage of about 600 m^3 volume built in Rottweil. The pilot heat storage was applied as short term storage in connection with a combined heat and power (CHP) plant. The storage container was made of concrete with a stainless steel liner and mineral wool as insulation. The aim of the paper was to demonstrate the feasibility of the technology and to gain practical experience for the construction of larger stores. A gravel /water storage pit was built in Steinfurt, Germany (Pfeil M.

doi:10.18086/swc.2017.06.05 Available at http://proceedings.ises.org

2000). The ecological compatibility of the used materials in the storage was proved. Another focus of the paper was analysis of the cost-reduction potential of the PTES (Pfeil M. 2000). Thermal behavior of a model PTES was experimentally investigated in a test rig and numerically investigated by means of CFD simulations (Chang and Wu, 2017). The investigated PTES was a scaled down model that facilitates measurements on a test rig. However experimental investigations on thermal behaviors of large solar district heating plants in real operation were not found.

Theoretical investigations were carried out to gain knowledge and to optimize thermal performances of solar heating plants. Trnsys (Trnsys 2016) is used to calculate performance of a combined solar thermal and ground source heat pump (HP) system and to investigate different operation strategies of the system (Li H., 2018). Tian et al. investigated thermal performance of a solar heating plant with combined parabolic trough collectors and flat plate solar collectors. The focus of the investigation was on thermos-economic analysis of the plants with different types of collectors connected in series (Tian Z., et al. 2018). Cioccolanti et al. investigated performance of a solar trigeneration system for residential applications by means of a modelling study. The potential of a small scale concentrated solar Organic Rankine Cycle (ORC) plant coupled with an absorber was investigated using a Trnsys simulation analysis of a small scale 50 m^2 CPC solar field, a 3.5 kWe ORC and a 17.6 kWc absorption chiller to satisfy respectively heating, electricity and cooling needs of a residential user (Cioccolanti L., et al. 2018). However there is a lack of theoretical investigations on large scale solar heating systems with PTES.

The aim of the paper is to investigate thermal behaviors of the Marstal solar heating plant. The operation of the solar heating plant was monitored in detail in the period 2014-2016. Temperatures and fluid volume flow rates of the solar collector fields, the PTES storage, the heat pump and the district network were measured constantly. Energy flows in the plant were analyzed. A Trnsys (Trnsys 2016) simulation model of the solar heating plant is developed to investigate thermal performances of the plant. The calculated energy flows will be compared to the monitored energy flows with an aim to validate the simulation model. The Trnsys model could be used to optimize design of a solar heating plant under different scenarios in terms of levelized cost of heat (LCOH).

2. Monitoring of the plant operation

As shown in Table 1, the Marstal solar heating plant (Fig. 1) has been under continuous developments throughout the years. During the Sunstore 1 project in 1996, a 9045 m^2 solar collector field was installed with 12.53 m^2 large flat plate solar collectors produced by ARCON A/S. Additionally a 2100 m^3 accumulation tank was built as short term storage. Due to an increase of consumers of the solar heating plant, the Sunstore 2 project was introduced in 2001-2004 in which flat plate solar collectors of 8019 m^2were added in the plant. Heat produced by the collectors installed in Sunstore 1 and 2 is fed in the 2100 m^3 accumulation tank.

In 2012 the SUNSTORE 4 project was built. 15,064 m^2 solar collectors were installed and a 75,000 m^3 PTES was constructed, see Fig. 1. The aim of the Sunstore 4 project was to increase the solar fraction of the plant up to 55% of the thermal energy production, focusing on sustainability, increased efficiency and low costs. Marstal's 75,000 m^3 PTES was commissioned in 2012 and it has a capacity of 6.96 GWh according to PlanEnrgi (Jensen 2014). Heat produced by the collectors installed in the Sunstore 4 is fed in the 75,000 m^3 PTES. The operating temperatures vary depending on the season and the depth of the water layer, however the pond is designed to operate in a range of 10-90 °C. An electricity generator based on ORC and a CO_2 heat pump were added in the plant. The Organic Rankine Cycle (ORC) uses heat at around 300ºC produced by a wood chip boiler to generate electricity. The CO_2 heat pump utilizes heat from the water pit heat store as heat source to provide heating for the district heating network.

Detailed measurements were carried out in the period 2014-2016 to evaluate thermal performances of the plant. Temperatures and fluid volume flow rates of the solar collector fields, the PTES storage, the heat pump and the district network were measured constantly. The sensors in the inlet/outlet pipes of the PTES are located at the end of the transmission pipes 300 m away from the pit storage. Thirty-three temperature sensors were installed in the middle of the water pit storage to measure water temperatures at different levels. The volume flow rate is measured with flow meters in m^3/h with an accuracy of 2% (Schmidt 2013). The temperature sensors are PT resistance thermometers with an accuracy of +/- 0.1 K (Schmidt 2013).

Tab. 1: Components of the Marstal solar heating plant

Sunstore 1	- 9,045 m^2 field consisting of arrays of 12.53 m^2 Arcon HT collectors (Collector field 1)
Sunstore 2	- 8,019 m^2 field consisting of arrays of 12.53 m^2 Arcon HT collectors (Collector field 2) -
Sunstore 4	- 15,064 m^2 field consisting of arrays of 13.88 m^2 Sunmark solar collectors (Collector field 3)
Other utilities	- 2,100 m^3 accumulation tank (Sunstore 1 & 2) - 75,000 m^3 water pit thermal storage (Sunstore 4) - 1,500 kW (produced heat) CO_2 heat pump - 4.15 MW wood chip boiler that runs a electricity producing Organic Rankine Cycle with a power of 750 kW

3. Dynamic simulations of plant thermal performances

A Trnsys model of the Marstal solar heating plant was developed in the Sunstore 4 project (Kate 2013). The Trysns model was modified in this paper to accommodate changes in the system, see Fig.2. The Trnsys model includes three solar collector fields with a total solar collector area of 32,138 m^2, an accumulation tank of 2100 m^3, a seasonal water pit heat storage of 75,000 m^3, a simplified CO_2 HP, a simplified ORC unit and a wood chip boiler. The energy consumption of the district heating net was modeled by volume flow rates and given forward & return temperatures of the district heating net. Forward temperatures of the district heating net are 72-74ºC in summer and 75-77ºC in winter. Temperatures of the fluid back to the plant vary in the range 33-41ºC from summer to winter. Weather data including total solar irradiance, diffuse solar irradiance and ambient air temperature from a climate station on the site of the plant were used in the calculations. In order to eliminate influence of initial conditions of the water pit heat storage, calculations were repeated for 2 years with a time step of 1 hour. Result from the 2nd year was used in the analysis.

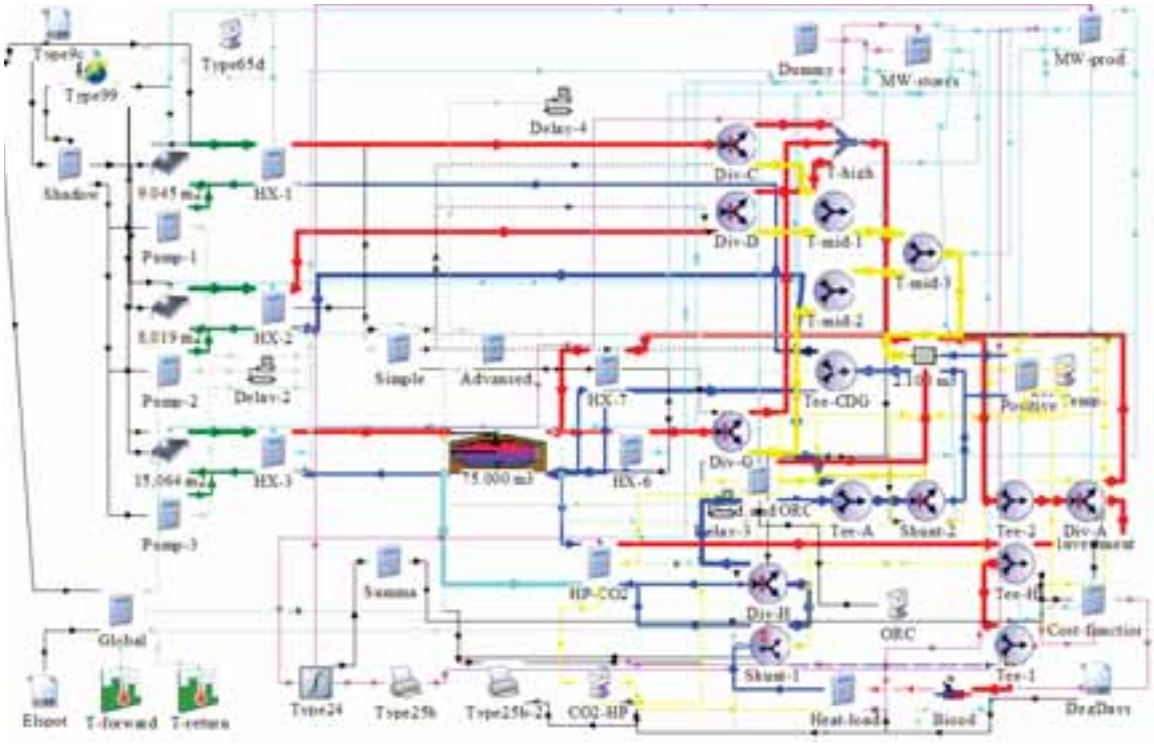

Fig. 2: The Trnsys model of the Marstal Solar heating plant

In the solar collector field model developed in Trnsys, parameters such as coefficients of the collector efficiency expressions, collector area, collector orientation, collector inclination and number of collectors per row are used as inputs. The following collector efficiency expression is used in the model.

$$\eta = \eta_0 K_\theta - \frac{a_1(T_m - T_a)}{G} - \frac{a_2(T_m - T_a)^2}{G} \qquad \text{(eq. 1)}$$

η_0: the start or the maximum efficiency, [-].
a_1: the first order heat loss coefficient, [W/(m^{2}K)].
a_2: the second order heat loss coefficient, [W/(m^{2}K^2)].
K_θ: incidence angle modifier, [-].
G: the total solar radiation, [W/m^2]
T_m: the mean temperature of the solar collector [ºC]
T_a: the ambient air temperature [ºC]

Table 2 show the coefficients of efficiency expressions for the collectors used in the solar collector fields. Collector efficiency for the collector field 1 is taken from a test report issued in 1991 (Fan etc., 2009). Collector efficiency expression of the collectors in the collector field 2 was reported by Vejen (2004). In the collector field 3, 13.88 m^2 flat plate solar collectors produced by Sunmark were installed. Efficiency of the collector was tested by SP Technical Research Institute of Sweden (2010).

Tab. 2: Collector efficiency expressions used in the Trnsys simulations

Collector field no.	Area, m2	η_0, -	a_1, W/(m^{2}K	a_2, W/(m^{2}K^2)
1	9045	0.76	3.5	0.002
2	8019	0.82	2.44	0.005
3	15064	0.80	3.43	0.015

The water pit thermal storage was modeled in Trnsys with a 2D multi-node storage model that includes both the water volumes at different layers and the ground soil around the storage. The Trnsys calculations starts with an uniform temperature of 35ºC for the store as the initial condition. Initial temperature of the ground was 8ºC.

Yearly thermal performances of the solar heating plant calculated by the Trnsys model were compared to the measurement results. Preliminary results calculated by the Trnsys model were analyzed.

4. Thermal performances of the solar collector fields

4.1 Analysis of the collector fields by the input/output method

Thermal performance of the solar collector fields were calculated by the Trnsys model with a time step of 1 hour. Fig. 3 shows the collector energy output of the solar collector field 1 in kWh/m^2/day as a function of the total solar radiation in kWh/m^2/day. It can be seen in Fig. 3 that there is a 2nd order polynomial function between the modeled collector field output and the total solar radiation on the collector panels. This is in good agreement with the collector efficiency expressions used in the calculations. The modeled outputs are however a bit scattered, which means that for the same total solar radiation on the collector panel the collector energy outputs are different. A possible explanation could be the varying collector fluid temperatures during operation. Even though there is the same total solar radiation on the panel the collector fluid temperature might vary depending on temperatures of the storage. A higher temperature of the storage means a higher temperature at the inlet of the collector field and thus a lower energy output of the field, vice versa. The measured collector outputs have a much larger deviations, most likely due to differences in collector operating temperatures and/or failures in operations of the systems. For instances there were some days with a daily total solar radiation in the range 3.5-5.5 kWh/m^2/day, however the collector outputs of the field were almost zero, indicating there was a failure or interruption in the collector field operation. There are also points with a significantly lower collector energy output than the modeled values, which could be caused by differences in collector inlet temperatures, uneven flow distribution among collector rows or malfunction of the controller etc. For the days when the collector field was in a good operation condition, the collector energy output follows nicely the trend with the simulations.

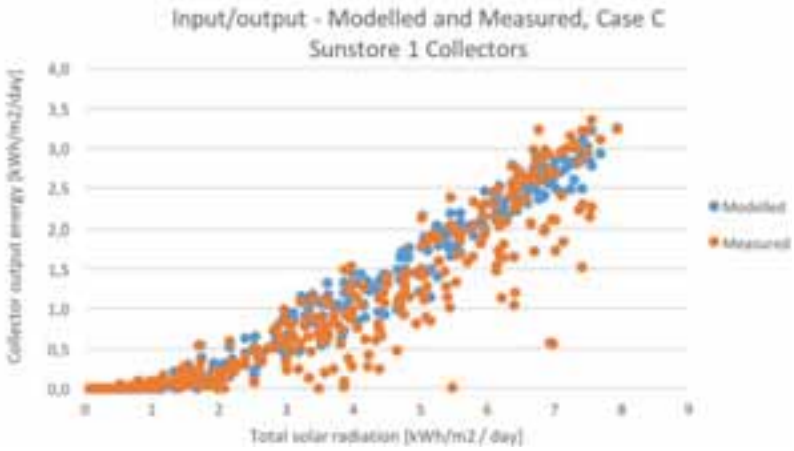

Fig. 3: Input/output diagram for the Sunstore 1 collector field with collector output [kWh/m^2/day] in 2015 as a function of total solar radiation [kWh/m^2/day]

The modeled and the measured collector energy output for the collector field 2 are shown in Fig. 4. There is a similar trend between the modeled collector energy output and the total solar radiation on the collector surface as it is for the collector field 1. With a change of the total solar radiation, the measured collector field output follows nicely a similar trend line as the modeled output does. The measured output has deviations of similar magnitude as the calculations. It is indicated that the solar collector field 2 has a much steadier operation than the solar collector field 1. It is shown that the solar collector model used in Trnsys is able to predict thermal performances of the solar collector fields with an acceptable accuracy.

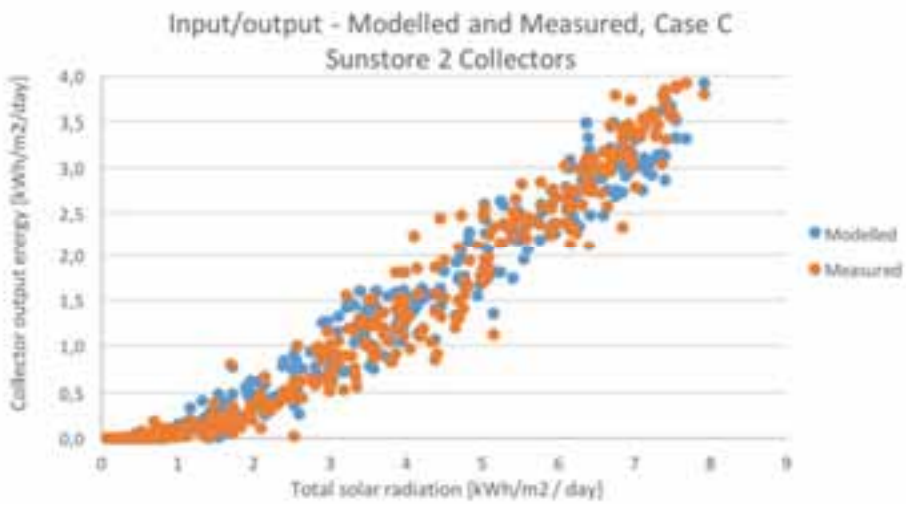

Fig. 4: Input/output diagram for the Sunstore 2 collector field with collector output [kWh/m^2/day] in 2015 as a function of Total solar radiation [kWh/m^2/day]

Fig. 5 shows the modeled and the measured collector energy output for the collector field 3 installed in the Sunstore 4 project. There is a similar trend between the modeled collector energy output and the total solar radiation on the collector surface as for the collector field 1 and 2, but the deviations of the data points are much larger. That indicates larger variations of collector field output for the same total solar radiation, which could be caused by large temperature variations at the bottom of the water pit thermal storage. Since the collector field 4 is connected to the water pit thermal storage, water is taken from the bottom of the water pit and is circulated through the solar collector field 4. Water temperature at the bottom of the water pit has a larger variation throughout the year. In summer or autumn when the water pit is almost fully charged, there is a higher temperature at the bottom of the water pit, for instance, 40-50ºC, while in spring or winter when the water pit thermal storage has been discharged, there is a lower temperature at the bottom of the water pit, for instance, 20-30ºC. A temperature difference of 20 K or more will result in different collector energy outputs even though the total solar radiation on the collector panels is the same. Deviations of similar magnitudes are also seen in the measured collector output that proves conclusion of the simulations. A detailed investigation on individual days is therefore necessary in the future in order to understand thermal behaviors of the solar collector field.

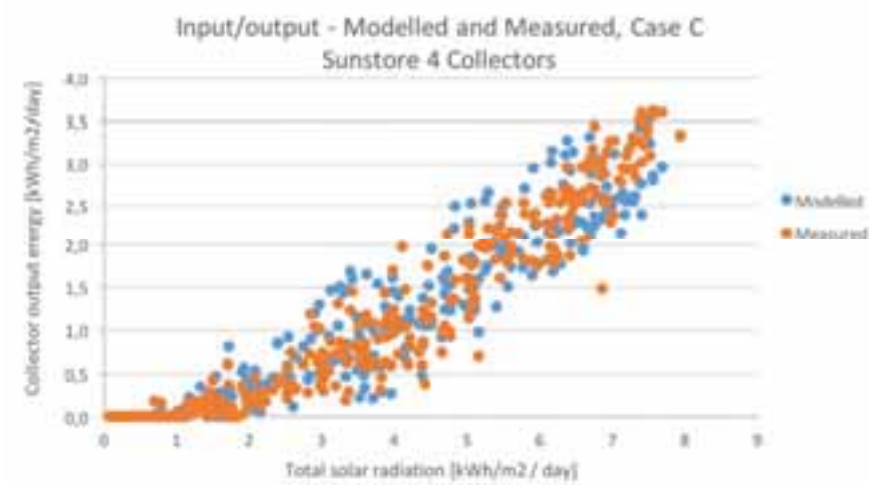

Fig. 5: Input/output diagram for the Sunstore 4 collector field with collector output [kWh/m^2/day] in 2015 as a function of Total solar radiation [kWh/m^2/day]

4.2 Daily collector energy outputs throughout the yearly

It is important to examine thermal behaviors of the collector fields throughout the year. Fig. 6 shows the measured and the calculated collector outputs [kWh/m^2/day] throughout the year for the Sunstore 1 Collectors. Not surprisingly there is a large variation of collector energy output throughout the year. At the start of the year, there was almost no solar heat produced by the field. After the middle of March, a significant increase of collector output is seen due to increasing solar irradiance in late spring. Throughout the summer and even late autumn there are notably solar heat

gains. The daily energy output of the collectors lies in the range 0.5-3.0 kWh per m^2. The calculated energy output agrees quite well with the measured ones, except an overestimation of the model occasionally in the summer and in the autumn (October).

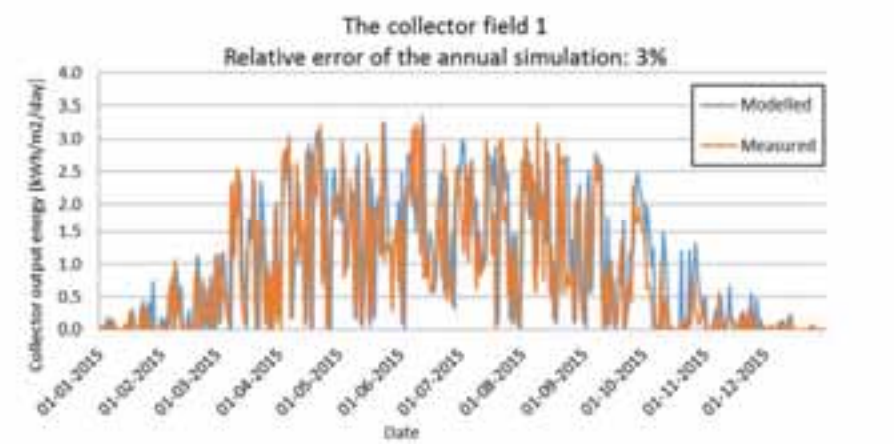

Fig. 6: The measured and the calculated collector outputs [kWh/m2/day] throughout the year 2015 for the Sunstore 1 Collectors

The measured and the calculated collector outputs for the collector field 2 and 3 are shown in Fig. 7 and 8 respectively. The Trnsys collector model predicts satisfactorily the energy outputs from the solar collector fields.

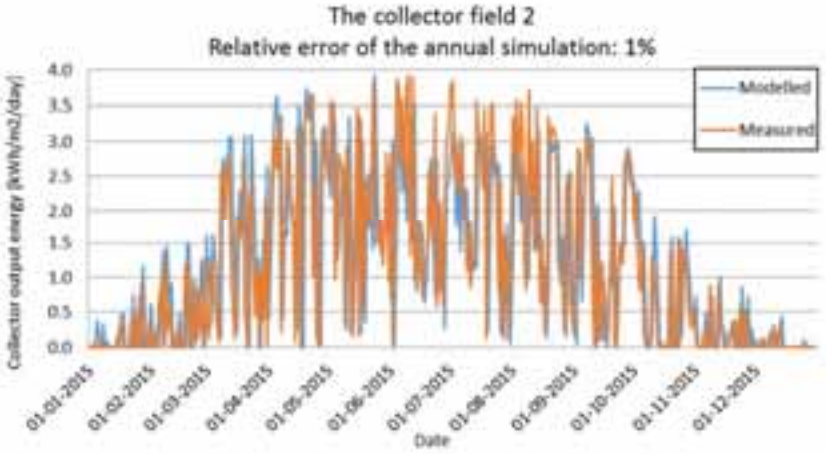

Fig. 7: The measured and the calculated collector outputs [kWh/m2/day] throughout the year 2015 for the collector field 2

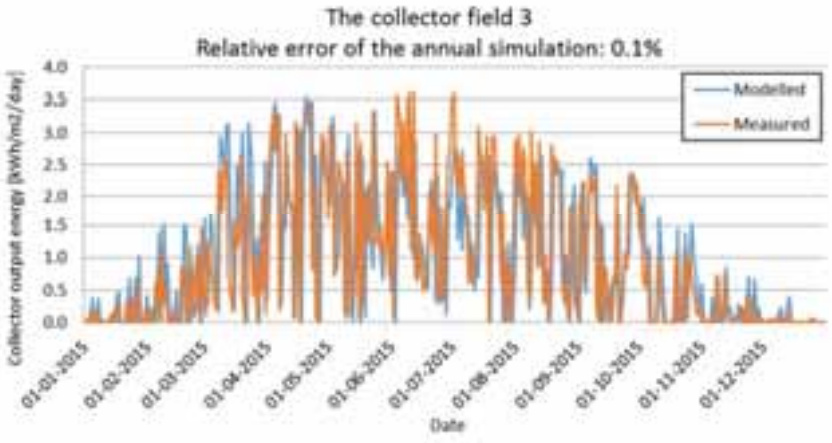

Fig. 8: The measured and the calculated collector outputs [kWh/m2/day] throughout the year 2015 for the collector field 3

4.3 Yearly collector energy outputs

The energy outputs of the collector fields are summarized and presented in Fig. 9. It is shown that the yearly energy outputs of the solar collector fields predicted by the Trnsys model agree well with the measured values. For the solar collector field 1, the Trnsys model predicts a yearly energy output of 3320 MWh in comparison to a measured value

of 3430 MWh. The deviation is 110 MWh, corresponding to a relative error of 3%. For the solar collector field 2, the accumulated energy output is measured to be 3617 MWh per year, while the Trnsys model calculates an energy output of 3600 MWh per year with a deviation of less than 1%. For the solar collector field in Sunstore 4, the measured and modeled energy outputs are respectively 5620 and 5624 MWh. Heat losses through the connection pipes account for 5-10% of the energy gain of the field and are therefore subtracted in the energy calculations. It can be concluded that the Trnsys model can predict satisfactorily the yearly energy outputs of the solar collector fields.

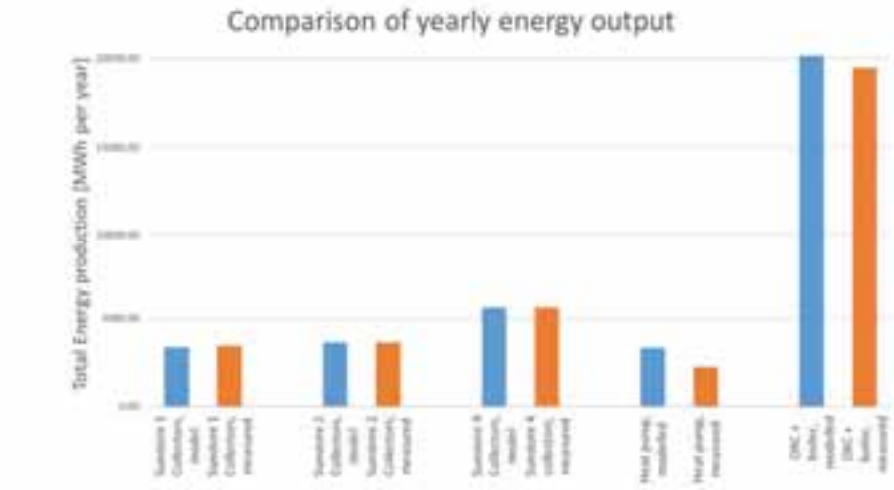

Fig. 9: The measured and the calculated yearly collector outputs in 2015 [kWh/m^2/day]

5. Thermal performances of the water pit thermal storage

Thermal behaviors of the water pit thermal storage were investigated experimentally by the monitored data and numerically by the Trnsys model. Fig. 10 shows a comparison of the measured and the calculated charge power of the PTES. A charge power of up to 55 MW was observed in the measurement in the middle of June because in June 2015 there was a lower consumption in the district heating net while on the other hand the solar irradiance was quite high. The Trnsys model underestimates the charge power of the PTES with a difference up to 12 MW. The significant error of the model is most likely caused by wrong prediction of water temperatures in the PTES, which could be a consequence of oversimplified models used in the calculations. Detailed investigation is therefore suggested for the future to identify the cause of errors. During the winter when there is a low solar irradiance, the model seems to overestimate the charge power.

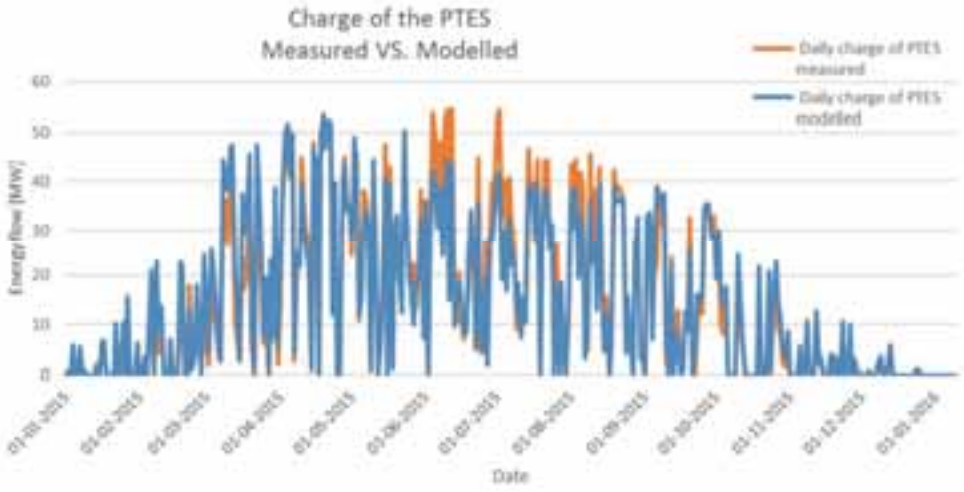

Fig. 10: The measured and the calculated charge power of the PTES in 2015

Fig. 11 show the measured and the modeled temperatures in the water pit thermal storage throughout the year. The measured temperature were shown as square or triangle dots. At the start of the year, there was a measured temperature of 62ºC at the top of the PTES, while the temperature was measured to be around 30ºC at the bottom of the PTES. Since there was a quite high temperature at the top of the PTES, heat was directly taken from the top of

the PTES and was mixed with hot water produced by the wood chip boiler or the backup oil burner so a mixed temperature of around 75-77ºC can be achieved for the district heating net. The direct discharge of the PTES continues except when temperatures at the top of the PTES drops below 50-55ºC or when price of electricity is sufficiently low. In that case, the heat pump will operate in order to utilize heat in the PTES with medium or low temperatures. The operation of the heat pump created a sudden decrease of temperatures at the bottom of the PTES. For instance, in the period from March 14 to March 21 there was a significant decrease of water temperatures at the bottom of the PTES. Due to discharge by heat pump, water temperatures at the top of the PTES was significantly decreased as well. In the middle of April the PTES reached a uniform temperature of 31-33ºC. After the middle of April thermal stratification was built up again by the use of heat pump since temperature of the water flowing from the heat pump back to PTES was much lower than 30ºC. The strategy for the discharge procedure was to extract heat from the PTES as much as possible. The benefit of the use of heat pump in April was not only a higher utilization ratio of the stored heat but also an empty PTES to store more solar heat for the coming summer. After the middle of May, temperatures in the store gradually increased. At the start of October, the PTES reaches the highest heat content. In the period October-December water temperatures in the store were kept quite constant.

The Trnsys modeled store temperatures were shown in curves in Fig. 11. It can be seen that the modeled temperatures follows the trend of developments as shown by the measurements. However there is quite a large difference between the modeled and the measured store temperatures, especially after the middle of April when heat pump cooled down the whole store to much lower temperatures. The likely cause of the difference could be oversimplification of the heat pump model or the control algorithm used in the Trnsys calculations. For an example, the operation of ORC unit has a significant influence on temperatures of the store since the ORC unit will be cooled by the store if there is not sufficient consumption of the district heating net. Whether the ORC unit will operate or not depends on an economical analysis of electricity generation by the manager of the plant. A detailed decision making algorithm for operation of ORC was difficult to obtain so the Trnsys model was not able to accurately determine the operation time of the ORC unit.

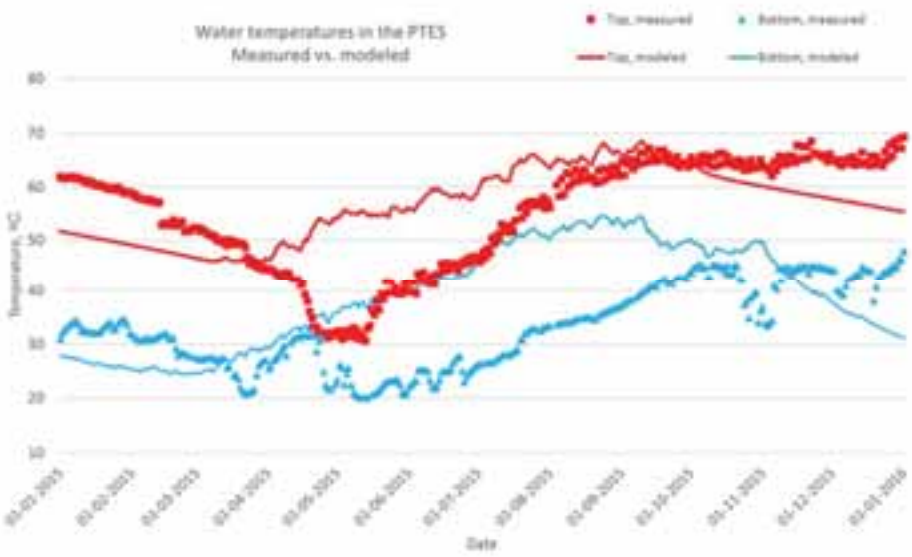

Fig. 11: The measured (orange) and the modeled (blue) temperatures through the top inlet/outlet on an hourly basis during year 2015

6. Conclusions

Detailed measurements were carried out on the Marstal solar heating plant. Based on the measurements, energy flows in the plant were calculated and thermal performance of the plant was analyzed. The monitored energy flows were compared to the energy flows calculated by a simplified Trnsys model of the plant. Preliminary results show that the Trnsys model predicts satisfactorily energy output of the solar collector fields. A max. deviation of 3% between the measured and the modeled energy output of the field was observed. A comparison between the measured and the modeled water temperatures in the PTES shows that the Trnsys model is able to predict the trend of temperature development in the store but fails to reproduce temperatures of the store especially in the period May-August. A likely cause of the error could be oversimplified heat pump model, inaccurate plant control algorithm etc. Detailed

investigation is therefore suggested for the future to improve the Trnsys model with focuses on the interaction between the heat pump, the ORC unit, the collector field and the store and on accurate inputs of boundary conditions of the model. The ultimate goal is to develop a Trnsys model that can be used to optimize design of a solar heating plant in terms of levelized cost of heat (LCOH).

Extension of Germany's Largest Solar District Heating System with Seasonal Thermal Energy Storage

Natalie Gohl, Dominik Bestenlehner and Harald Drück

Research and Testing Centre for Thermal Solar Systems (TZS)
Institute for Thermodynamics and Thermal Engineering (ITW)
University of Stuttgart, Stuttgart (Germany)

Abstract

This publication introduces several measures to extend and optimize Germany's largest solar district heating system with seasonal thermal energy storage, located in southern Germany in the city Crailsheim. The aim of the extension is to achieve a solar fraction above 50 % in order to reduce CO_2 emissions and to demonstrate the functional and economic attractiveness of solar district heating systems with seasonal thermal energy storage. The investigated measures comprise different concepts for the extension of the solar thermal collector area with high-efficiency flat-plate collectors and the extension of the borehole thermal energy store, which serves as seasonal thermal energy store in the system. As an alternative, the installation of an overground hot water thermal energy store is considered to increase the heat storage capacity. Other measures are the installation of a second heat pump as well as the reduction of the return flow temperature of the district heating grid. Further, combinations of the above mentioned measures are investigated. The effects of the specific measures are quantified by means of annual system simulations with the transient simulation software TRNSYS 17.

Keywords: solar district heating, seasonal thermal energy storage, high solar fractions, system simulation, TRNSYS

1. Introduction

The currently largest central solar district heating plant with seasonal thermal energy storage (CSHPSS) in Germany is located in Crailsheim, which is a small city with a population of about 33 000 in the south of Germany. The CSHPSS was built between 2004 and 2011 in two main construction phases. With an initially planned solar fraction of 50 %, the system is a flagship project for solar thermal district heating grids.

The CSHPSS in Crailsheim supplies heat to the district heating grid Hirtenwiesen II. Fig. 1 shows the development of the annual heat demand of the district heating grid as well as the solar fraction. Through the years, the heat demand of the district heating grid increased continually due to the construction and connection of new buildings. With over 7 000 MWh at the beginning of the year 2017, the heat demand is more than 1.7 times higher than the 4 100 MWh which were assumed in the original plans for the current stage of the heat generation system. The solar fraction reached a maximum of about 42 % in the year 2014, but due to the increasing heat demand, the solar fraction of the entire system is decreasing and was at a level of about 27.5 % in 2016. In order to enlarge the share of solar energy in the system, an extension and optimization of the solar district heating system is planned. Various measures to reach this aim were investigated with the help of transient system simulations, carried out with the simulation software TRNSYS 17. The aim of these measures is to achieve a solar fraction of more than 50 %. Finally, the most promising concept will be further investigated for implementation, considering ecological, technical, energetic as well as economical aspects. However, the focus of this publication lies only on the technical and energetic aspects.

More detailed descriptions of the CSHPSS in Crailsheim as well as the results of the system monitoring over the last years can be found in various publications, e.g. Bauer et al. (2009, 2013 and 2015), Bodmann et al. (2005) or Kurz and Schopf (2012).

doi:10.18086/swc.2017.06.06 Available at http://proceedings.ises.org

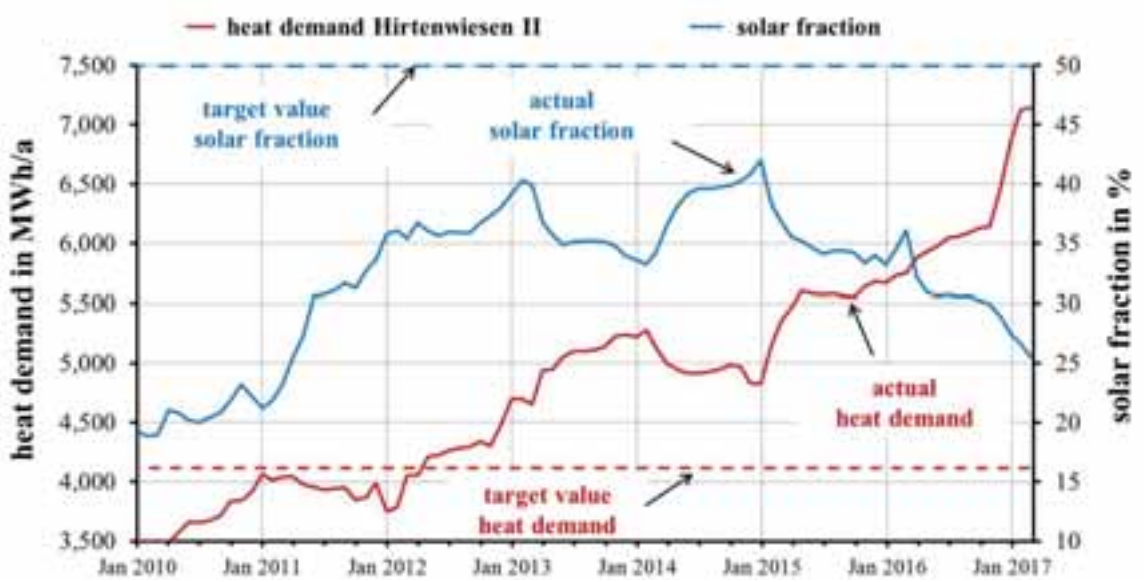

Fig. 1: Development of the heat demand and solar fraction of the district heating grid Hirtenwiesen II.

2. Reference system and methods

The simulation software TRNSYS 17 was used to develop and assess different measures and concepts for the extension and optimization of the CSHPSS in Crailsheim.

The performance of the existing system, see Fig. 2, which serves both as reference for the investigated concepts and as source of validation for the simulation model with monitoring data, is described in the sections 2.2 and 2.3. The definitions of the performance figures are defined in section 2.1. Finally, section 2.4 introduces the different investigated concepts.

2.1 Performance figures

Four performance figures are used in this publication in order to assess the performance of the system and specific components namely

- the solar fraction f_{sol},
- the efficiency of the borehole thermal energy store η_{BTES},
- the efficiency of the hot water thermal energy store η_{HWTES} and
- the seasonal performance factor of the heat pump SPF_{HP}.

The fraction of heat in the district heating grid Hirtenwiesen II covered with solar thermal energy is expressed using the solar fraction f_{sol}, which is defined as

$$f_{sol} = \frac{Q_{SHE} - Q_{HWI} - W_{HP,el}}{Q_{HWII}}, \qquad \text{(eq. 1)}$$

with

Q_{HWI} heat transferred to the district heating grid Hirtenwiesen I in order to prevent stagnation [MWh],

Q_{HWII} total annual heat consumption of the district heating grid Hirtenwiesen II [MWh],

Q_{SHE} solar heat transferred at the preheating solar heat exchanger [MWh] and

$W_{HP,el}$ electrical energy consumption of the heat pump [MWh].

The efficiency of the borehole thermal energy store η_{BTES} is described as

$$\eta_{BTES} = \frac{Q_{BTES,dischar}}{Q_{BTES,char}} \qquad \text{(eq. 2)}$$

with

$Q_{BTES,char}$ heat charged to the BTES over the period of one year [MWh] and

$Q_{BTES,dischar}$ heat discharged from the BTES over the period of one year [MWh].

The efficiency of the hot water thermal energy store η_{HWTES} is defined in an analogous manner.

In order to quantify the efficiency of the heat pump, the seasonal performance factor of the heat pump SPF_{HP} is used

$$SPF_{HP} = \frac{Q_{HP,cond}}{W_{HP,el}} \qquad \text{(eq. 3)}$$

with

$Q_{HP,cond}$ annual useful heat provided by the heat pump [MWh] and

$W_{HP,el}$ annual electrical energy consumption of the heat pump [MWh].

2.2 Description of the existing system

The CSHPSS in Crailsheim was built for the heat supply of a new part of the city erected on the area of a former military base. The current system setup is shown in a schematic design in Fig. 2 and is described in brief in the following.

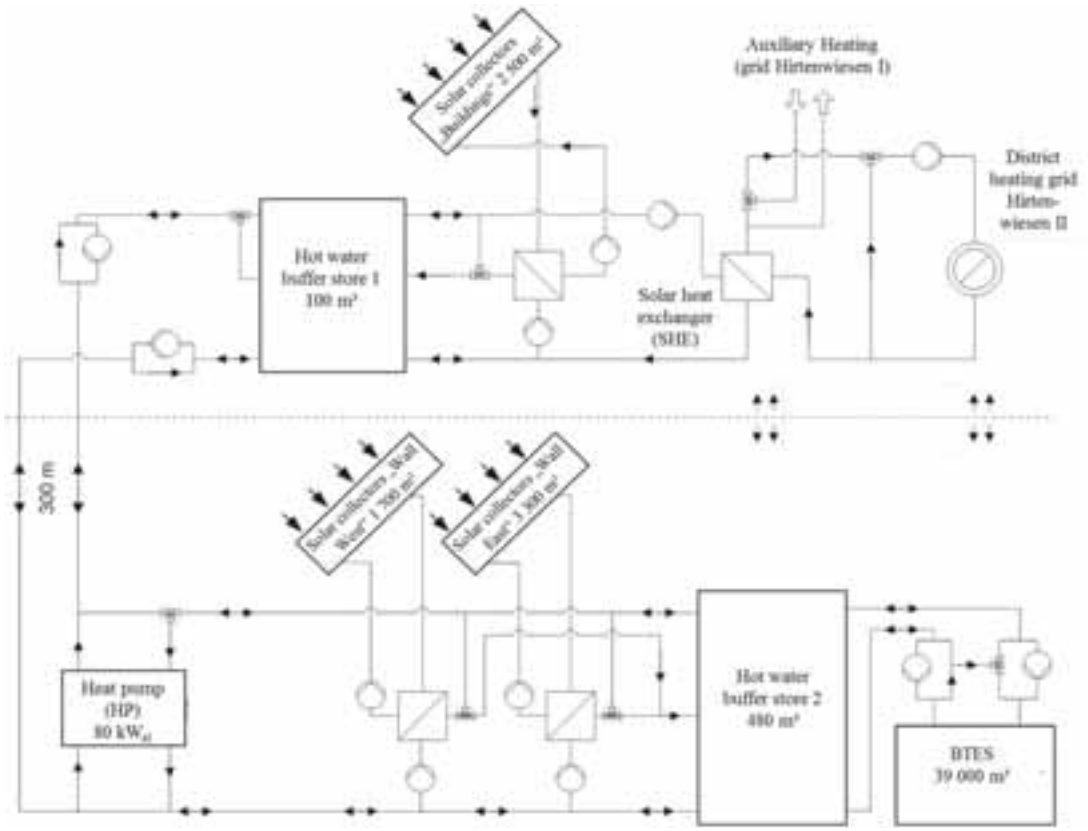

Fig. 2: Schematic design of the existing solar district heating system in Crailsheim.

The solar thermal system consists of three collector fields. Two collector fields are installed on noise barrier walls ("Wall West" and "Wall East") with a collector aperture area of 1 700 m² and 3 300 m², respectively. Additionally, there are flat-plate collectors mounted on the roofs of the former and retrofitted barracks buildings as well as on the local school building and gymnasium with a total collector aperture area of 2 500 m². The total thermal power output of the solar thermal systems is at present about 5.2 MW. A borehole thermal energy store with a volume of 39 000 m³ serves as seasonal thermal energy store. The BTES can be charged by the collector fields "Wall West" and "Wall East" via a hot water buffer store with a volume of 480 m³. In order to discharge the BTES to lower temperatures, a compression heat pump with an electrical power of 80 kW is installed. The second part of the system consists of a hot water buffer store with a volume of 100 m³, which is charged by the collector field installed on the buildings. If necessary, thermal energy can be transferred between the two buffer stores. The annual heat consumption of the solar district heating grid was 6 862 MWh in 2016.

2.3 Validation of the simulation model

Transient system simulations were carried out with the simulation software TRNSYS 17 based on a simulation model that was validated beforehand with extensive monitoring data from the years 2013 to 2016. Because the conditions in 2016 were nearest to the mean values of the considered years, the measured weather data of the year 2016 were used as input data for the simulation of the reference system. Tab. 1 shows the comparison between the measured and simulation data for the reference year 2016.

Tab. 1: Absolute and relative deviations between measurement and simulation data of the CSHPPS in the reference year 2016.

Quantity	Unit	Measurement	Simulation	Δx_{abs}	Δx_{rel} [%]
f_{sol}	[%]	27.5	28.3	- 0.8	- 2.9
η_{BTES}	[%]	57.3	63.6	- 6.3	- 11.0
SPF_{HP}	[-]	4.8	4.7	0.1	2.1
Q_{HWII}	[MWh]	6 862	6 861	1	0.0
Q_{SHE}	[MWh]	2 283	2 336	- 53	- 2.3
Q_{HWI}	[MWh]	175	158	17	9.7
$Q_{HP,cond}$	[MWh]	1 061	1 114	- 53	- 5.0
$W_{HP,el}$	[MWh]	221	235	- 14	- 6.3
$Q_{BTES,char}$	[MWh]	731	647	84	11.5
$Q_{BTES,dischar}$	[MWh]	419	411	7	1.7

Generally, there is a good consistence between measured and simulation data. The explanation for the relatively high deviations in the values concerning the BTES is the different conditions in the simulation and in reality. In the simulation, the time period is three years, where every year has the same boundary conditions. Only the third year of the simulation is used for the evaluation. Consequently, the final and initial temperature profiles of the BTES and the buffer stores at the beginning and the end of the year are exactly the same which is not the case in reality. The deviations in the heat transferred to the district heating grid Hirtenwiesen I can be explained by the fact, that the heat transfer is often controlled manually in reality, for example if the weather forecast predicts a hot and sunny day and the stores are already full. This behavior cannot be reproduced in the simulation.

2.4 Concepts for system extensions and optimization

Several single measures as well as their combinations were considered and assessed in order to increase the solar fraction of the CSHPSS in Crailsheim to a value above 50 %. Tab. 2 shows an overview of the single measures presented in this publication.

Tab. 2: Overview and description of possible measures for the extension and optimization of the solar district heating system.

Measure	Description
HFC	Installation of high-efficiency flat-plate collectors (HFC)
BTES	Enlarging of the borehole thermal energy store (BTES) from 80 to 160 borehole heat exchangers
HWTES	Integration of a seasonal hot water thermal energy store (HWTES) with a volume of 8 000 m³
HP	Installation of a second heat pump with a rated electrical power of 80 kW
RFT45	Reduction of the mean return flow temperature of the district heating grid from 48.1 °C to 45 °C
RFT40	Reduction of the mean return flow temperature of the district heating grid from 48.1 °C to 40 °C

One measure is the extension of the collector field energy output by the installation high-efficiency flat-plate collectors (HFC). Different collectors and combinations of collectors were simulated. Tab. 3 shows the resulting collector field power output of the four collector configurations HFC1 to HFC4.

Tab. 3: Total collector field power output[1] of the CSHPSS for the four different HFC configurations.

Collector configuration	Power output [MW]
HFC1	7.24
HFC2	7.17
HFC3	7.38
HFC4	7.34

As the solar gain is increased, the capacity of the seasonal thermal energy store should be increased as well. For that purpose two different measures were investigated: The first measure (BTES) extends the BTES by doubling the current number of borehole heat exchangers, the second measure integrates an overground seasonal hot water thermal energy store (HWTES) with a volume of 8 000 m³ into the system. In order to increase the thermal energy extracted from the BTES and therefore its efficiency, the integration of a second heat pump (HP) with the same rated electrical power of 80 kW as the existing heat pump was investigated.

The volume weighted mean return flow temperature of the solar district heating grid was 48.1 °C in the year 2016, according to monitoring data. A reduction of the mean return flow temperature would increase the efficiency of the collectors as well as reduce the heat losses of the grid and the thermal energy stores and therefore increase the solar fraction of the system. Simulations with mean return flow temperatures of 45 °C (RFT45) and 40 °C (RFT40) were carried out.

3. Simulation results

The actual configuration of the CSHPSS with the measured weather data of the year 2016 serves as the reference system for all simulations. Due to the assumption that more buildings will be connected to the district heating grid in the following years, an annual heat consumption of the district heating grid Hirtenwiesen II of 7 000 MWh is assumed for the simulations. Due to the slightly higher heat consumption, the solar fraction of the reference system is reduced to 27 %.

Fig. 3 shows the solar fraction, the seasonal performance factor of the heat pump as well as the efficiency of the BTES for simulations with all four HFC configurations and all of their possible combination with one additional measure. Generally, the differences between the HFC configurations are relatively small at about 2-3 %-points

[1] Basis: Solar Keymark certificates: Power output of the collector module at a temperature difference between collector and ambience of 50 K.

between the configurations HFC2, which shows the lowest solar fractions, and HFC3, which shows the highest solar fractions. Regarding the single measure HFC, the solar fraction can be increased by 11 %-points compared to the reference system to a total value of 38 %. The extension of the BTES has no positive influence on the solar fraction. The reason for this is that the energy output of the heat pump is not increased as well. Consequently, more heat is charged to the BTES, but the amount of heat that is discharged from the BTES does not increase in the same magnitude. This also leads to a decrease in the efficiency of the BTES but also to the best seasonal performance factor of the heat pump in both measures BTES and HWTES. The reason for the higher performance of the heat pump are the higher temperatures in the BTES and therefore a smaller temperature lift for the heat pump. The installation of a second heat pump has the opposite effect than the extension of the storage capacity. The seasonal performance factor decreases significantly due to lower BTES temperatures while the efficiency of the BTES increases significantly due to the higher heat pump power output.

The most promising measure in terms of increasing the solar fraction is the reduction of the mean return flow temperature of the district heating grid to a value of 40 °C. This leads to an increase of the solar fraction by at least 5 %-points compared to the measure HFC, depending on the collector configuration. However, none of the concepts shown in Fig. 3 turned out to be sufficient to obtain a solar fraction of 50 %. Accordingly, other concepts combining several measures have been investigated.

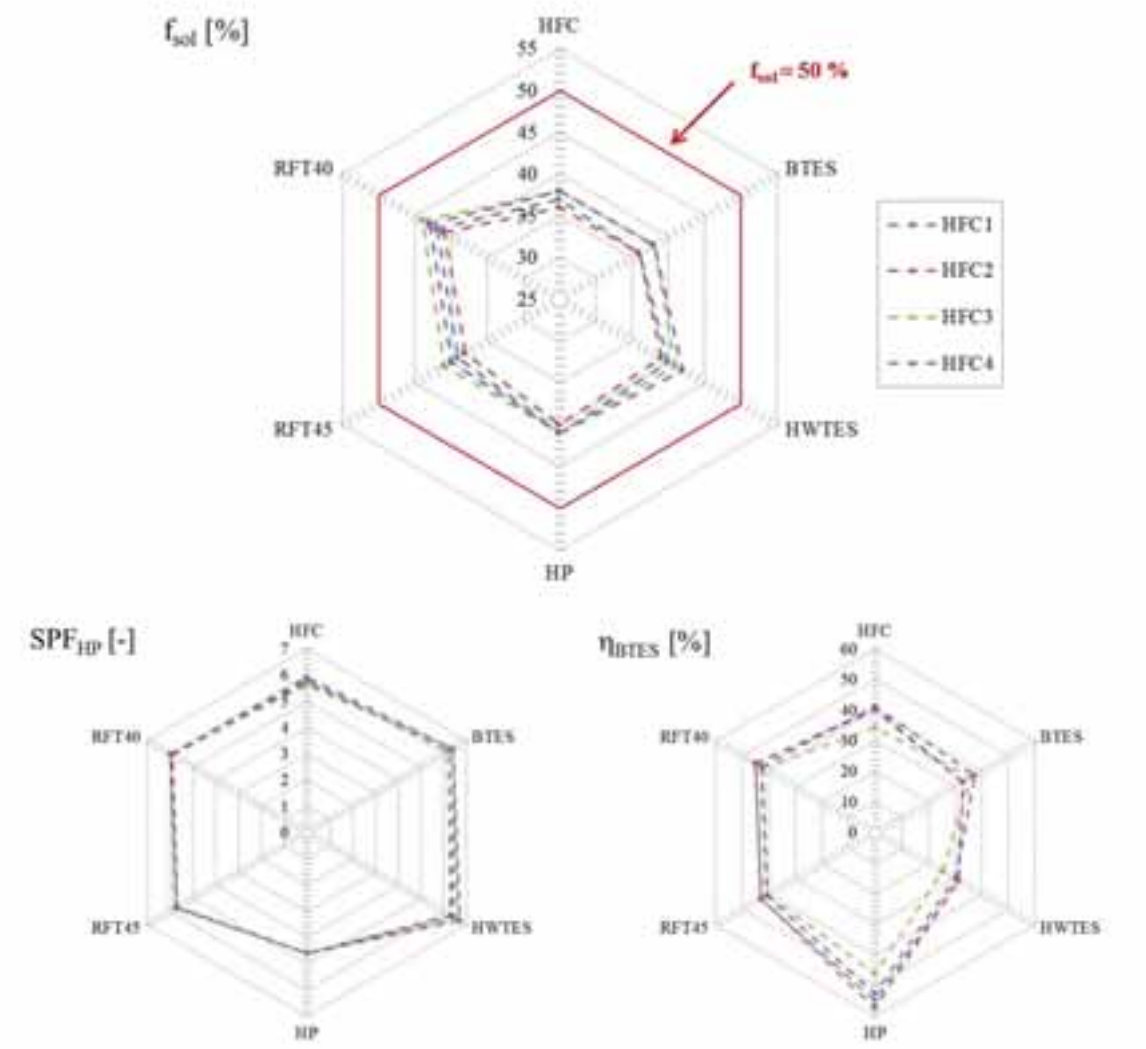

Fig. 3: Simulation results for selected investigated system concepts.

The installation of a HWTES was preferred compared to the extension of the BTES, consequently only concepts including a HWTES are shown in Fig. 4. Additional to the performance figures shown in the previous figure, the efficiency of the HWTES is presented in Fig. 4.

Like before, the concepts including a second heat pump have a positive effect on the efficiency of the BTES. Since the BTES and the HWTES are installed in parallel and the heat pump can discharge both, the efficiency of the HWTES is increased as well. The seasonal performance factor of the heat pump on the other hand is reduced due to lower temperatures in the stores.

With the concept using a HTES, a second heat pump as well as the reduction of the mean return flow temperature of the district heating grid to 45 °C a solar fraction of 50 % can only be reached using the collector configuration HFC3. A further reduction of the mean return flow temperature to 40 °C leads to a further increase of the solar fraction to or above 50 %, except for HFC2 with a solar fraction of 49 %. High solar fractions of almost 50 % can also be reached with the collector configurations HFC3 and HFC4 by a combination with the measure RFT40, without the installation of a second heat pump. However, the installation of a second heat pump is recommended because it leads to an extension of the effectively usable storage capacity of the CSHPSS.

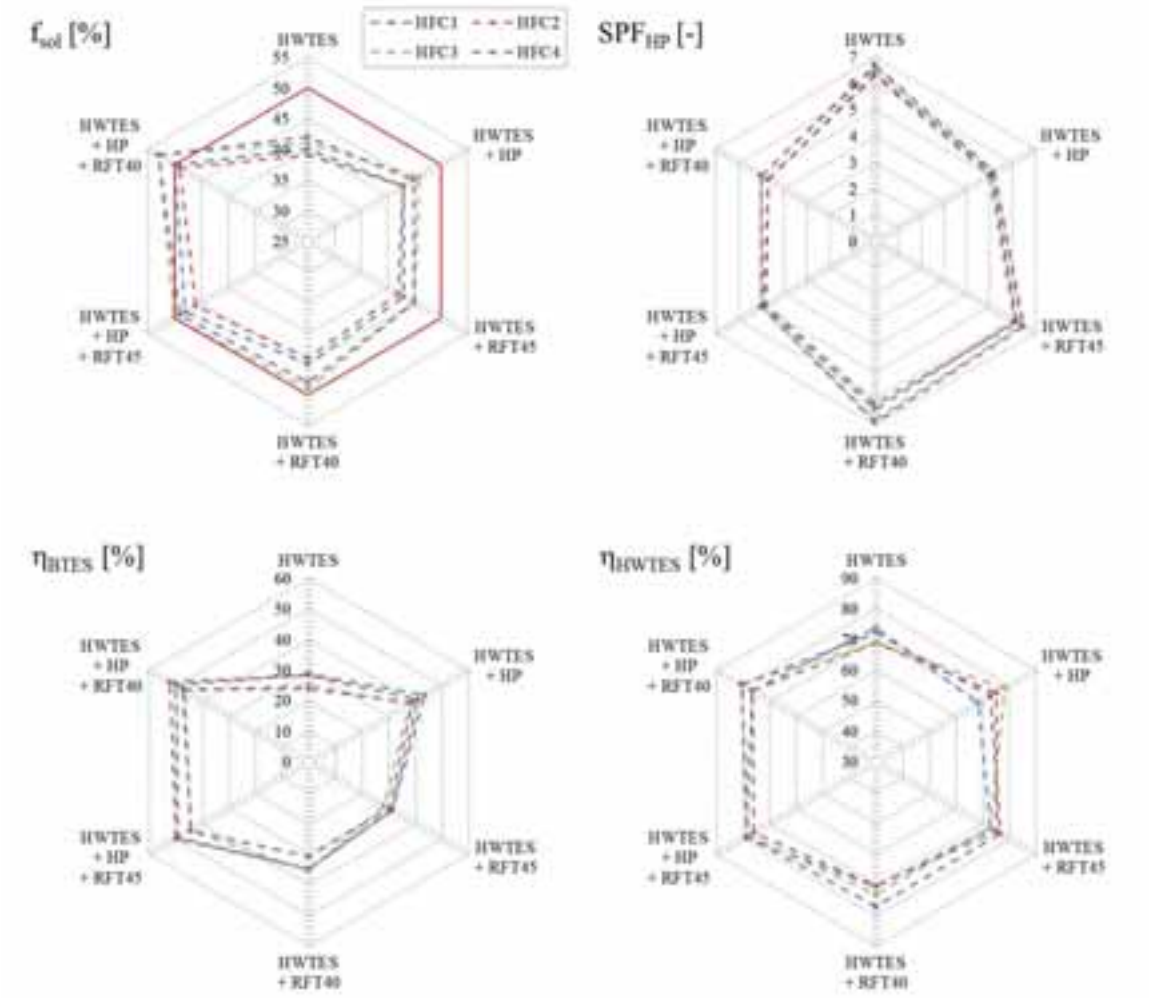

Fig. 4: Simulation results for selected investigated system concepts.

Conclusions

The concepts assessed regarding the extension and optimization of the solar district heating system in Crailsheim were presented and discussed in this publication. The concepts which lead to a solar fraction of around 50 % comprise the option of enlarging the solar thermal system with high efficient flat plate collectors (HFC) with a collector area of about 2 500 m² as well as the integration of a second heat pump (HP) with an electrical power of 80 kW and a hot water thermal energy store (HWTES) with a volume of 8 000 m³. A further increase of the solar fraction above 50 % can be achieved by the additional reduction of the return flow temperature of the district heating grid to 40 °C.

Considering the simulation results, the owner of the CSHPSS intends to extend the system with an enlargement of the collector area, a HWTES and a second heat pump. Additionally it is planned to introduce measures which offer the consumers incentives to reduce the return flow temperature of their heat transfer stations. The detailed planning of the enlargement of the CSHPSS is currently in progress, considering amongst other issues different locations and hydraulic integrations of the HWTES, as well as an adaption and optimization of the control strategy.

Potential Analysis On Solar District Heating in China

Junpeng Huang[1], Jianhua Fan[2] and Simon Furbo[2]

1 Department of Civil Engineering, Technical University of Denmark, Copenhagen (Denmark)

2 Department of Civil Engineering, Technical University of Denmark, Copenhagen (Denmark)

Abstract

Abstract: This paper analyzes the potential of solar district heating (SDH) in China from the perspective of incentive policy making, selection of technology solutions, regional adaptability and economic feasibility for clean heating. Based on the analyzation, this paper proposes a road map for the development of SDH, and predicts its market potential in China.

Key words: solar district heating, potential analysis, road map, 13th-Five-Year Plan

1. The urgency moving from coal to clean energy

China's urbanization rate is currently only 54.8%, leaving a huge potential for future growth. Over the past decade, increasing heating requirements have led to the fast deployment of district heating systems in big cities, as shown in Fig.1, the heating area increased from 2.5 billion m^2 to 6.7 billion m^2 in the past 10 years from 2005-2015. Meanwhile although rural population has been decreasing, rural energy demand most notably for heating has also been increasing steadily. This rise has been on par with economic development and improvements in lifestyle. District heating is therefore increasingly being deployed to meet heating loads in rural regions.

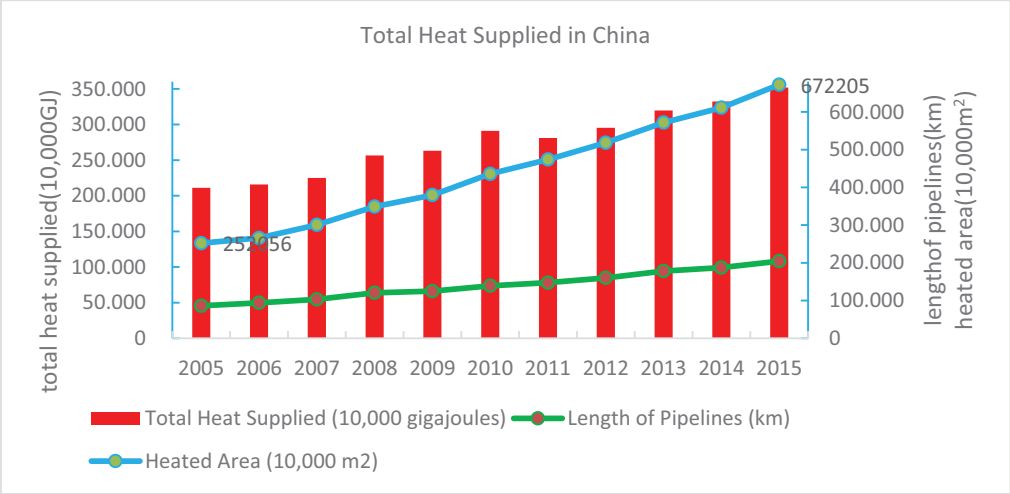

Fig. 1: Growth of the heating capacity in China[1]

To cope with the rapidly increasing demand for heating, authorities have deployed district heating systems throughout north of the country. However, as shown in Fig.2, district heating systems in China are coal intensive, accounting for 81%[2] of the total heating energy, which caused serious air pollution. It's reported that over 366,000 people died earlier from diseases in China in 2013 caused by air pollution due to burning of coal[3].

doi:10.18086/swc.2017.06.07 Available at http://proceedings.ises.org

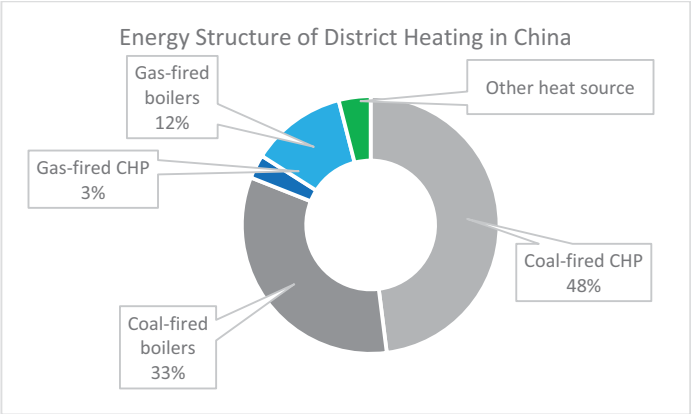

Fig. 2: Energy structure of district heating in China

According to the Sino-US Joint Statement on Climate Change[4], China will reach its CO_2 emission peak in 2030, and will increase the share of non-fossil energy to 15% by 2020, 20% by 2030. But there is a big gap from the objectives until now. Only taking Beijing as an example, by the end of 2015, the proportion of renewable energy in total heating energy consumption is only 0.8%. To increase the proportion of non-fossil fuels accounted for primary energy consumption, large-scale using solar heating is imperative.

2. Why solar district heating

50% of total air pollution source comes from coal consumption in China, especially in rural area, raw coal (~80% bituminous and ~20% anthracite) is often consumed in stoves with low efficiency. In 2013, Chinese government published Air Pollution Control Action Plan, which set a target for coal reduction, by 2017, consumption of coal will fall to below 65% in terms of total energy consumption. Beijing-Tianjin-Hebei Province, the Yangtze River Delta and the Pearl River Delta will try to achieve negative growth of total coal consumption.

To fulfill this target quickly and effectively, the government takes two main strategies which are called Coal to Gas and Coal to Electricity, with a subsidy policy on clean heating transformation. Now, these two strategies are widely used under the emission reduction pressure and being stimulated by subsidy policy. From the actual implementation effect of view, these two strategies may reduce the raw coal combustion temporarily, but there're still problems on the real effect of reducing air pollution and the sustainability of policy.

2.1. Coal to Gas is difficult to be applied widely

Coal to Gas in power plants was first implemented in Beijing and quickly adopted by other cities. However, currently most of them have suspended or canceled the initiative, mainly because natural gas is still scarce and costly in China.

High natural gas prices, increased burden of heating companies, it is difficult for long-term stable operation. In addition to the initial expenditure for transformation of equipment, the using cost is also great. The price of natural gas per kWh is about 3-5 times the price of coal with the same thermal value. Due to fuel costs rose sharply, and government subsidies declined year by year, many small heat companies which have completed the coal to gas transformation tend to change back to coal-fired boilers.

Evidence show that Coal to Gas also indirectly results in wind power curtailment and PV power curtailment. At present, the wind power and PV installed mainly concentrated in the "Three North" area (northeast, northwest, North China), accounting for 77% and 68% of the country with large-scale centralized development. During heating season due to the output power of CHP is determined by heat demand, which makes the CHP units less flexible, power supply surplus, which leads to huge wind and PV power

curtailment. According to "China Building Energy Annual Development Research Report 2017"[5], in "three North" area, the amount of abandoned wind power in 2015 was 9.48 TWh, 8.34 TWh and 16.55TWh, accounting for 99.9% of the total abandoned wind power. From the time distribution point of view, 67% of the country, more than 90% of the northeastern region, wind power curtailment occurred in the heating season.

In 2016, the natural gas gap between supply and demand reached 60 billion m^3 in China, and it's estimated that the gap will reach 130 billion m^3 by 2020, which means there would be not enough gas supply for a lot of households installed gas boilers when the heating demand reaches to peak. Natural gas is currently easy to be accessed in urban areas, but the infrastructure for gas supply in rural area is still under plan or under construction. Coupled with the difficulty of laying the gas pipe network, high costs, not sufficient gas production and other factors, the Coal to Gas strategy is difficult to be applied widely.

2.2. Coal to Electricity is difficult to be sustained

Coal to Electricity means replacing coal-fired boilers with low-temperature air-source and ground-source heat pumps, in some cities, including regenerative electric boilers, but direct heating types of electric heater are prohibited by this program. The government will provide about $3,600 subsidies per household for heating equipment, and additional 0.6 US cent per kWh electricity price subsidies in heating season, almost reducing 2/3 cost for using electric heating equipment.

But the Coal to Electricity is also in dispute on cleanness and the sustainability of subsidy policy.

Most of the electricity used in Beijing, Tianjin and Hebei comes from the off-peak electricity in Inner Mongolia, and the main source is coal. The implementation of Coal to Electricity is a method with rob Peter to pay Paul, and finally pollution will eventually be grafted to the western region.

Another disputation is the heavy financial burden. Taking Beijing as an example, it is expected that there will be 1.1 million households finishing the Coal to Electricity transformation at the end of 13th -5-Years Plan. If calculating in accordance with maximum subsidy of 10 thousand kWh per household, the government needs 334 million US dollars in the following years. In addition, to reduce the burden on the residents, the government must invest substantial money to improve thermal insulation performance for the residents' houses.

So, the Coal to Electricity is not a problem for cities with higher economic level, but it is unsustainable in economically backward areas. Therefore, coal reduction cannot engage in "one size fits all", and solar-aided energy systems that integrating multi-energy types and multi-heat sources, such as geothermal energy, biological energy and other clean energy should also be valued to replace the scattered coal combustion.

2.3. Advantages of solar district heating

Compared with Coal to Gas and Coal to Electricity technologies and policies, SDH is the only strategy to substitute fossil energy completely, which will also improve energy security by reducing energy imports, especially natural gas importation for China.

The most advantage of SDH for end users is the great operating cost savings. In a combination system of solar and gas boiler, solar will contribute 66.6% energy cost savings by saving gas consumption[22] in Hebei area, for a solar combined with air-source heat pump heating system, solar will contribute 45.6% energy cost savings in Xi'an City[23].

SDH can also create local jobs related to the manufacturing, commercialization, installation and maintenance of solar thermal systems.

3. Feasibility of SDH in China

3.1. Stringent environmental protection pressure national wide

To deal with the serious air pollution problem, the Chinese government has made systematic favorable

policies for clean energy space heating.

Fig. 3: Favorable policy structure for clean heating in China[6]

The detailed indexes and targets which address clean heating issued by different government departments:

Table.1 Regulations and Plans on Clean Heating and Renewable Development in China

Regulations and Plans	Indexes and Targets
Solar Energy Development 13th-5-Years Plan	In 2020 and 2030, non-fossil energy accounted for 15% and 20% of the primary energy consumption. In 2020, the number of large SDH stations in suitable areas reached more than 200, the total area of collector is more than 4 million square meters. Combined with the construction of New Countryside, more than 3 million demonstration projects of solar hot water and solar heating in rural areas will be promoted nationwide.
Renewable Energy Development13th-5-Years Plan	In 2020 and 2030, the proportion of non-fossil energy in primary energy consumption reached 15% and 20% respectively. In 2020, all types of renewable energy substitute about 1.5 tce in heating and civilian fuels, in which, solar thermal utilization (heating and hot water) reached 800 million square meters, equivalent to 96 million tce.
Energy Development 13th-5-Years Plan	In 2020, the supply capacity of non-fossil energy reached 750 million tce, the proportion of non-fossil energy consumption increased to more than 15%.
Building Energy Efficiency and Green Building Development 13th-5-Years Plan	In 2020, renewable energy substitutes conventional energy consumption accounted for more than 6% in civil buildings. The new solar thermal application area will reach to more than 2 billion square meters in buildings.
Suggestions on Promoting Renewable Energy Heating	In 2020, renewable energy heating area reached 3.5 billion square meters, Beijing, Tianjin and surrounding areas up to 1 billion square meters, Solar heating reached 400 million square meters nationwide.
Air Pollution Prevention and Control Action Plan (2013-2017)	In 2017, the proportion of non-fossil energy consumption increased to 13%.

3.2. Choose suitable region

China has abundant solar resources, equivalent to 1.7 trillion tons of standard coal equivalent (tce) per year[7], but most Chinese cities are densely populated with high land price and limited places for installation of solar collectors. So, at the beginning phase for solar district heating(SDH) in China, the most suitable area for developing large-scale solar heating is the area with rich solar resources, longer heating period, many free lands available, and no power grids and gas pipe network coverage, such as Tibet, Gansu, Tsinghai provinces.

In the outskirts of the central city, as well as rural areas without municipal heating infrastructure, it is also appropriate to develop small SDH pants to reduce the use of coal, while creating the conditions for using of rural biomass and municipal solid waste incineration.

3.2.1 North urban area

Heating in urban areas of northern China is mostly district heating, including many city level heat supply network and community level heat supply network. According to the heat source and size, heating systems can be divided into cogeneration, regional coal fired boiler, gas boiler, residential area coal-fired boiler, gas boiler, heat pump residential district heating etc.; And household gas stove, household coal stove, air conditioning heating, direct electric heating etc.

The heating area of Chinese cities reached 12.6 billion m^2, and the energy consumption of heating in northern cities was 184 million tce, accounting for 21% of total building energy consumption in 2014. In 2001~2014, the heating area of northern urban buildings increased from 5 billion m^2 to 12.6 billion m^2, increased by 1.5 times, the total energy consumption increased less than 1 times, the total energy consumption growth was significantly lower than the growth of construction area. The heating energy consumption per square meter decreased from 22.8kg tce/m^2 in 2001 to 14.6kg/m^2 in 2014, and the energy consumption per square meter decreased by 34%[25-26].

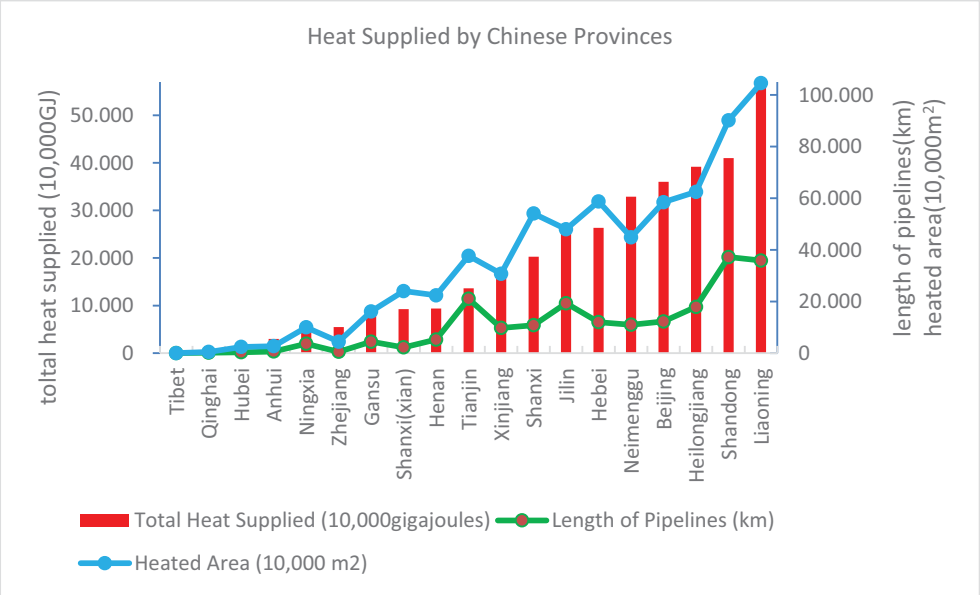

Fig. 4: Heat supplied by Chinese Provinces[1]

The vast existing heating area means great potential for clean heating transformation, and a good opportunity for solar heating, but there're great challenges from the economic point of view.

Affected by the welfare heating system under the planned economy, most residential heating systems are single pipe vertical series system, in which vertical imbalance is serious, uneven heat and cold between high

and low stories of buildings, difficult to achieve heat charging by metering. At the same time, heating equipment obsolete, poor reliability, lack of advanced heat metering means[12].

"Heat" as a commodity is not accepted by users and part of enterprise, it is difficult for users to change from the welfare heating system to buy heat, auxiliary heat metering equipment is expensive, the reform from the tandem network to metering per household is difficult.

The urban area has large population density, high land price, and limited installation space for solar collectors. In the short term, it is not the best choice for developing SDH. But the heating demand of urban area is large and the users are concentrated. The economic and environmental benefits from SDH are more significant, which will be the focus of future development.

3.2.2 North Rural areas

The northern rural heating mainly relies on heated brick bed, hot wall, household coal stove, gas stove, electric heating and solar assisted biomass boiler heating in some developed rural area around Beijing and Tianjin, some rural areas also develop small district heating systems.

Zhang Wei of Tianjin University summarizes the current heating technologies, heating fuel in north rural area, household evaluation of indoor thermal comfort, and the distribution of heating technologies based on a survey to rural residential buildings in the cold area between 2007 and 2010[27]. As shown in Fig.5, small coal fired boilers and heated brick beds are the main heating solution for rural area, accounting for 84% in total.

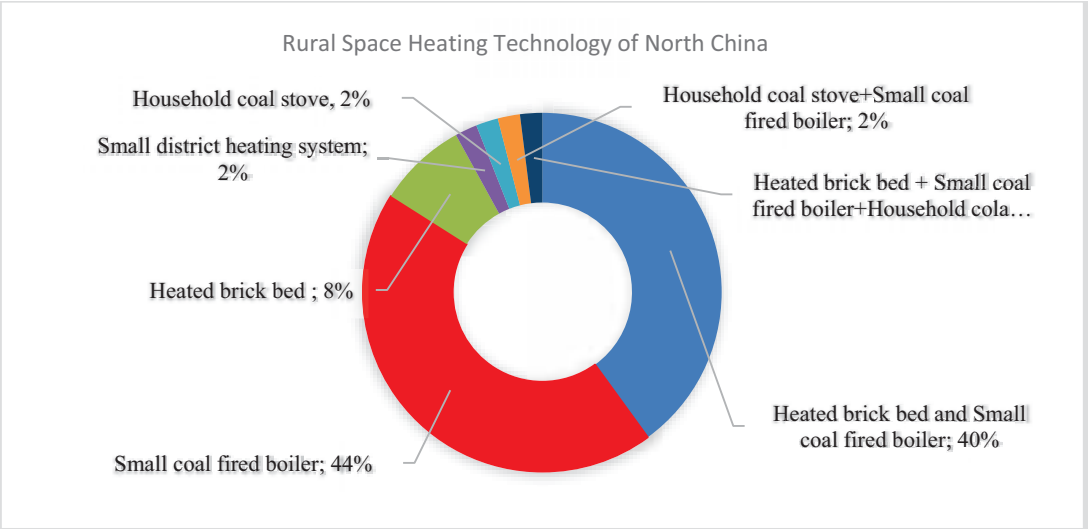

Fig. 5: Rural Space Heating Technologies in North China

There are many deficiencies for current heating solutions in rural heating in North China, such as low indoor temperature, large heating energy consumption, serious pollution and so on. Energy utilization rate of heated brick bed and hot wall is about 60%, stove is only 40%, while no insulation measures for heating pipes, the heat loss of pipelines is large. Heating safety is not guaranteed, the improper operation or design easily lead to gas leakage, and even explosion accident, stove heating easily leads to carbon monoxide poisoning[28].

In terms of district heating in rural area, Shandong province is far more developed than other provinces. Beijing, Shanxi, Liaoning, Heilongjiang and Hebei have developed rapidly.

Rural and small towns in northern China are good places for developing large-scale SDH projects due to cheap lands, backward heating pipe network infrastructures, serious air pollutions caused by raw coal burning, and the great pressure to improve quality of life.

3.2.3 South Area

Air conditioning is still the largest portion of household heating in South China, reaching 30%[1]. Due to the short heating time in South China, even if the heating effect is not good, many families still use air conditioning as the only heating source, to save a large amount of installation of other heating equipment. Household gas-fired boilers and electric floor heating accounted for 1% and 0.1% in southern households, respectively. The heat pump as a relatively new product, accounting for only 0.03%. With characteristics of energy saving and environmental protection, more suitable for the southern climate, heat pumps are currently the fastest growing household heating products in the South. Affected by the rainy, not enough sunshine time and other factors in the south, solar heating applications are relatively limited, accounting for only 0.005%.

Short heating time in southern China, usually about 1-3 months, household heating dominates, not conducive to develop SDH. In order to reduce operating costs, residential property management companies are also considering adding a solar collector field on the existing heating system.

3.3. Choose suitable technologies

Although China shares 71% of the total installation of solar collectors in the world, but no more than 0.3% of solar collectors have been used for solar heating[8], as shown in Fig.6, there're only 154,971m^2 solar collectors used for heating, accounting for 0.3% of the annual production in 2014 in China. Most of solar collectors were used in rural area as a home appliance, solar water heaters.

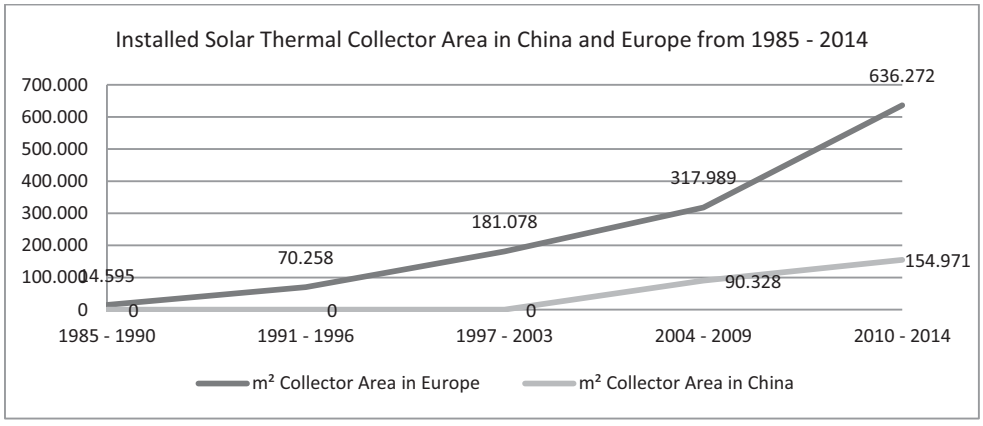

Fig. 6: China-EU collector installation area for solar heating[9]

3.3.1 Centralized solar heating system is better than household solar heating

Solar heating has been used for more than 10 years in China, and is widely used in rural areas as household heating in the early stage. In recent years, solar heating has gradually developed into schools, public buildings and residential communities etc. Without municipal heating.

Year 2016, we conducted a post-survey on some solar household heating projects in Beijing rural villages(Fig.7). The on-site survey reveals that solar heating system can save more than 50% of the coal burning annually, but it doesn't run steadily. Caused by the easily damaged all-glass vacuum tube solar collectors and bad installation, there're lots of deficiencies found after 2 years' installation, e.g. leaking in the pipelines and water tanks. The operation and maintenance of household heating system mainly conducted by the user personal, due to lack of professional knowledge, many users face the helplessness when the system fails. But it is easier to build a regional operation and maintenance service points in a centralized heating station than decentralized household heating.

A farmhouse heated by solar energy

A village with solar heating

Fig. 7: Typical household solar heating project in rural areas of Beijing

After more than 10 years of rural solar heating pilot and experience accumulation, from the economy, safety and operation and maintenance work convenience point of view, the author thinks that district heating with solar and biomass as the main heat source is more suitable than household heating in rural areas.

3.3.2 Flat plate solar collector is better than all-glass vacuum tube solar collector

The authors investigated many solar heating projects in northern China. All-glass vacuum tube solar collectors are mostly used in those household solar heating systems. Due to poor maintenance and improper operation, the real life span for all-glass vacuum tube solar collectors is only 2-3 years. Many all-glass vacuum tube solar collectors are broken for overheat or freezing in the first year since installation. The Investigation Report on Solar Heating Demonstration Projects in Mentougou of Beijing (ICA, 2010) gives the same suggestions, for solar heating projects, flat plate solar collector with simple structure, long service life and low maintenance rate should be preferentially selected.

3.3.3 Solar heating can prolong the life of existing ground source heat pump system

In the past more than 10 years, part of local Chinese government in cold northern area promoted ground source heat pump (GSHP) heating, only in Shenyang City, GSHP heating area reached 59.41 million square meters in 2012, accounting for nearly 1/3 of the city's total heating area. But now, there are many residential communities with GSHP heating system cannot get normal heating because of long term imbalance between heating and cooling.

Because heating load in winter is greater than cooling load in summer in cold areas, the heat extracted from the underground soil by GSHP systems is much greater than the heat injected to the soil, which makes the soil temperature decreasing yearly. The lower soil temperature will decrease the system's evaporation temperature in winter, reduce the heating capacity, and increase the energy consumption. According the Study on Heat Balance of Ground Source Heat Pump in Severe Cold Area[11], when soil temperature decreases by 1℃, the energy consumption of the GSHP will increase by 3-4%.

Solar collectors can be added to those dysfunctional GSHP systems to form a hybrid energy heating system. With proper control strategies, this hybrid energy system can achieve direct solar heating, direct heat pump heating, heat injection from solar collectors in summer and heat extraction by GSHP in winter, and prolong the life span of GSHP systems, at the same time improve the system energy efficiency.

3.4. Economic feasibility

There are mainly two district heating models in China – district boiler heating and district CHP heating, the fuel is coal or gas. This paper selects a Chinese standard building (heating index: 50W/m^2) in Xi'an as a sample, with 10^6 m^2 heating area, 50MW heating load. Suppose the efficiency of coal fired boiler is 0.68,

gas fired boiler is 0.9; pipe network transmission efficiency is 0.9. The heating mode is setting as single heat source, double pipe heating system. Based on a 25 years' payback time, we can calculate the heat price and analysis the economy for different district heating technologies[13].

Based on land cost, energy price, O&M cost etc. in China, we analyze the economy of SDH in China with successful models from Denmark. The annual global solar irradiance is 1247.4KWh/m^2.a in Xian, total district heating load is 144 GWh/a, heating time is 2900 hours, designed solar fraction is 20%, the price for different energy in Xi'an is shown in Table.2.

Table.2 Basic assumptions and price structure in Xi'an

Biomass	29.5$/MWh
Electricity	149.6$/MWh
Power grid price	225.0$/MWh
Bank loan interest rate	5%
Years of investment	25 Year

According to the above design parameters and prices of fuels, we analyzed the economy for four SDH systems in China by means of the SUNSTORE4-Feasibility-Evaluation-Tool[12]. And the heating prices is shown in Fig.8 based on 25 years' payback time. Solar collector area is 144,300 m^2 for all district heating systems, the volume of PTES is 288,600 m^3, BTES is 1,154,400 m^3, and TTES is 31,746 m^3.

Table.3 Four types of SDH technologies combination

Types	Technologies combination
SDH1	Solar + Biomass + HP + Pit Thermal Storage
SDH2	Solar + Biomass + Pit Thermal Storage
SDH3	Solar + Biomass + HP + Borehole Storage
SDH4	Solar + Biomass + Tank Thermal Storage

Coal is the mainly energy source in China, but the heating price of coal fired CHP is very high, so government allocates large amount of subsidy to coal fired CHP to maintain price competitive advantage. we calculate the heating price for traditional district heating technologies, heating price is very high, but the price of SDH systems are relatively low. SDH not only will save a lot of fossil fuels, but also reduce the heating price.

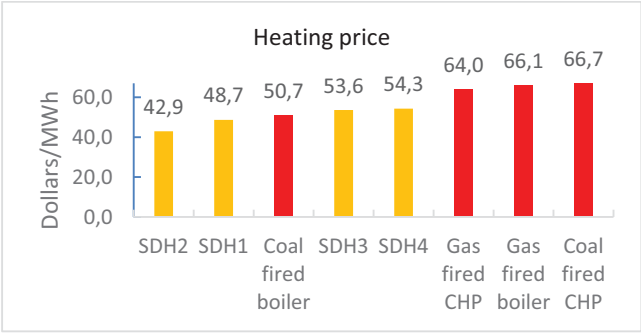

Fig. 8: Heating price of different district heating systems

From Fig.8, we can conclude that the heating prices of gas fired CHP, Gas fired boiler and coal fired CHP are very high; comparing heating price of the eight district heating systems, in the 50MW heating load condition, the heating price of SDH2 is the lowest, with a price 42.9$/MWh, then SDH1, with a price 48.7$/MWh; and the price of coal fired CHP is the highest, the heating price is 66.7$/MWh. Generally, the heating price of SDH systems is lower than traditional CHP and gas fired boiler district heating. So SDH has

price competitive advantage in China.

4. Major barriers

Although SDH has many benefits, it is still very difficult to implement this environmentally friendly clean heating technology in China. The major barriers include no demo project, and lack of mature supply chain support such as design, construction and operation of SDH plants. Besides the above-mentioned barriers, there're two facts for development of SDH in China.

4.1. Backward idea

When promoting SDH, the most common voice is that "land price is high" in China, this centralized solar heat station needs to take up a lot of land, completely inconsistent with China's national conditions. The reality is that, from an economic point of view, compared with conventional agriculture, the economic benefits of solar heat stations are much higher than those of agriculture, and due to the arrangement of collectors, a large interval distance is required, which makes the land can still develop livestock and facilities agriculture. In addition, in the sparsely populated, resource-poor Tibet, Gansu and other regions, as well as some areas with strict ecological protection requirements, SDH is the best choice.

4.2. Difficult to be connected into existing heating pipe networks

District heating technology in China is still the second generation, supply and return water temperature is higher in main pipe network, it's difficult for solar heating to be connected into existing heating pipe networks without a heat pump or reheat device[17~18]. In addition, space heating is mandatory in heating season as a livelihood project in China, but there's no heating demand in the rest of the year, which means a waste of solar energy in summer, or will increase the payback time of a SDH system. Therefore, to make full use of solar energy, improve annual solar fraction, building a seasonal heat storage facility is necessary[19~20].

5. Huge market potential

China's district heating capacity shows an increasing trend year by year, which is in line with the level of China's economic development, the demand for improving indoor thermal comfort in winter is becoming higher. Not only compulsory heating in North, the voice for heating in South in winter is also stronger in recent years. It can be predicted that district heating load will further increase in near future. Based on the analysis to the data of district heating capacity in recent ten years, we can get the annual growth rate of district heating capacity, about 9%, we can predict the district heating capacity development trend in future 5 years by this growth rate. By 2020, China's district heating capacity will reach 727,100 MW, an increase of 254,544 MW compared with 2015, see Figure 10.

Assuming the annual solar irradiance is 800 W/㎡, the efficiency of high performance flat plate heat collector is 0.6, transmission efficiency of pipe network is 0.9, the average daily sunshine hours was 7 h, the share of SDH used in clean energy heating is 5%, 10%, 15%, 20%, we can calculate the market potential and environmental benefit from the clean transformation of existing district heating network and newly installed district clean heating network.

By calculation shown in Table 4, when clean heating accounts for 5% of total district heating capacity and SDH accounts for 5% of clean heating, SDH installation capacity is 1,200 MW, and the maximum installation area of solar collector is 1.5 million m^2. When clean heating accounts for 20% of total district heating capacity and SDH accounts for 20% of clean heating, SDH installation capacity would reach to 19,000 MW, and the maximum installation area of solar collector would be 23.8 million m^2.

Table.4 Potential SDH capacity and solar collector area in the clean transformation of existing district heating system

SDH loads and Solar collector area in existing district heating system（10^3MW）				
	DH-5%	DH-10%	DH-15%	DH-20%
SDH-5%	1.20	2.35	3.55	4.75
SDH-10%	2.40	4.70	7.10	9.50
SDH-15%	3.60	7.05	10.65	14.25
SDH-20%	4.80	9.40	14.20	19.00
Solar collector area（10^6m^2）				
	DH-5%	DH-10%	DH-15%	DH-20%
SDH-5%	1.50	2.94	4.44	5.94
SDH-10%	3.00	5.88	8.88	11.88
SDH-15%	4.50	8.81	13.31	17.81
SDH-20%	6.00	11.75	17.75	23.75

Note: DH-5% represents clean heating account for 5% in clean heating transformation of existing district heating capacity, SDH-5% represents SDH account for 5% in clean heating capacity. The rest are similar.

6. Conclusions

By above technical and economic analysis, we can summarize a SDH development road map as shown in Table.5.

Table. 5 SDH Development Road Map in China

Steps	Pilot demonstration	Technology accumulation	Technology innovation
Years	2017-2020	2021-2025	2026-2030
Target market	Rural area, small villages, towns	Industrial parks, large residential communities	Small cities, integration with existing heating network
Technology application	Solar + GSHP, Solar + Tank Thermal Storage, high performance flat plate solar collector	Low temperature heating, remote monitoring, seasonal heat storage	System integration, large scale solar district heating

Northern China owns the basic conditions for the implementation of SDH with a developed district heating network. With the national energy saving renovation of existing buildings and clean energy transformation of existing district heating system, development of low temperature heating technology, and more stringent restrictions to coal-fired boilers, heating enterprises must actively look for clean energy alternative to fossil energy, and SDH will be the best choice. There are already some enterprises begin to build pilot and demonstration projects in Tibet, Beijing suburbs and other regions. It is expected there would be many SDH projects finished by the end of 2017.

Even though there are many challenges for SDH in China, we still believe that the implementation of SDH is an inevitable requirement for economic development and environmental protection. The next five years would be the best time to promote SDH with the mature technologies, favorable policies, and huge market potential.

Abstract

The interest on solar thermal systems in district heating networks has been growing all over the world for several years. The integration of solar heat into the district heating network along with the conventional combined heat and power plant requires special concepts. This contribution describes the recent implementation of a large-scale solar heating system into a low-temperature network in the city center of Chemnitz. The technical specification of different subsystems such as the solar collector fields, the two-zone thermal energy storage and the heat transfer substation for auxiliary heating is presented. Special features of this plant are e.g. the use of water in the complete system and the extraction of heat from the return line of the main district heating network. First monitoring results are presented for the period from May to September 2017. In general, the system works as expected and a solar fraction of 21 % could be reached in the observed period. A potential for optimization is identified e.g. related to the network return temperature.

Keywords: large-scale solar heating system, district heating, low-temperature, network, two-zone storage, heat transfer substation, auxiliary heating system

1. Introduction

In order to achieve the national and international energy and climate goals, the potential of solar energy should be exploited. A large-scale solar district heating is a sustainable and environmentally friendly solution for the supply of thermal energy in urban quarters. The AGFW, the German industry association for district heating and cooling, predicts that there will be an expansion of solar thermal systems with 800,000 m^2 of collector field area in the district heating systems until 2020 in Germany (IKZ, 2017). The integration of solar thermal energy in a district heating system along with the existing cogeneration plant enables many advantages such as the reduction of non-renewable primary energy consumptions, of the CO_2 emissions and of the operating costs of the system.

This paper is intended to describe the implemented solution in Chemnitz, Germany. Chemnitz is a typical East German industrial city with a large-scale district heating system. This hot water system was planned as a municipal heating system in 1928 and had grown steadily until 1990. The heat generation in this system is based on a very high share on combined heat and power (CHP), which is produced by large lignite blocks. For ecological and energy policy reasons, it is very important to find solutions for the cities which are currently supplied by such conventional district heating systems. A favorable situation was present in Chemnitz from 2009 to 2011. It was recognized that the Brühl quarter (part of the northern city centre of Chemnitz) had to be renovated completely including the infrastructure due to the condition of the buildings (Municipality of Chemnitz, 2017). A brief description of the urban design situation is available online (Staedtebaufoerderung, 2017). The main problem was the very high vacancy rate of residential and commercial units which exceeded 50 %. Hence, several major steps were taken to preserve the quarter and to fundamentally improve the social conditions. The authors (Urbaneck et al., 2015) got involved for a complete restructuring of the heat supply, in particular to increase the share of renewable energies. First, the building structure and the heat consumers

doi:10.18086/swc.2017.06.08 Available at http://proceedings.ises.org

as well as possible renewable energy sources were analyzed. A preliminary study (2011-2012) lead to the design of the heat supply concept with measures to increase energy efficiency and the use of solar thermal energy showing the best results (Urbaneck et al., 2015). The concept has been implemented as proposed except a few technical modification. In summer 2016, the plant was put into operation. The pilot plant consists of a heat transfer substation with two solar collector fields, a two-zone storage, a district heating connection as well as a low temperature network for the quarter with the house connection stations (Fig. 1). The monitoring and analysis are carried out as part of the project "Solar district heating for the Brühl district in Chemnitz – accompanying research (SolFW)" which is located in the 6th energy research program of the German federal government. Further objectives and tasks can be found online (Urbaneck, 2017).

Fig. 1: Scheme of the supply station at the Georgstrasse, Chemnitz, Source: inetz 2016.

2. Solar heating system concept

The quarter (Hertelt et al., 2012) covers an area of more than 10,000 m^2 and includes mainly apartment buildings with around 1300 residential units. About 25 % of the buildings are subjected to preservation order. A low-temperature network with a supply and return temperature of 70 and 40 °C, respectively (design-supply temperature of 70 °C at an ambient temperature above 0 °C, linear rise to 80 °C at -14 °C ambient temperature) was built. Moreover, heat exchangers (pre-heating and post-heating stage, Fig. 2) decouple the quarter hydraulically from the existing main district heating network. The temperature reduction in the network enables the efficient use of solar thermal energy. That means, a "low-temperature island" is created in the city and in the district heating area. Additionally, in order to achieve low return temperatures, special heat transfer stations for the apartment residential units were chosen which are based on a solution by Mahler (Mahler, 2004). The construction of a supply station (transfer station between the existing district heating system (primary line) and the low-temperature network) with relatively large collector fields and a relatively large storage brings several advantages in the present urban situation:

- using existing brownfield areas close to the quarter,
- effective realization of construction measures outside the residential area,
- the reduction of specific investment costs due to large units,
- a central operation and
- no problems related to buildings being subject of a preservation order.

The structure of the transfer station is shown in Fig. 2. The main components of this supply station are described in the following sections.

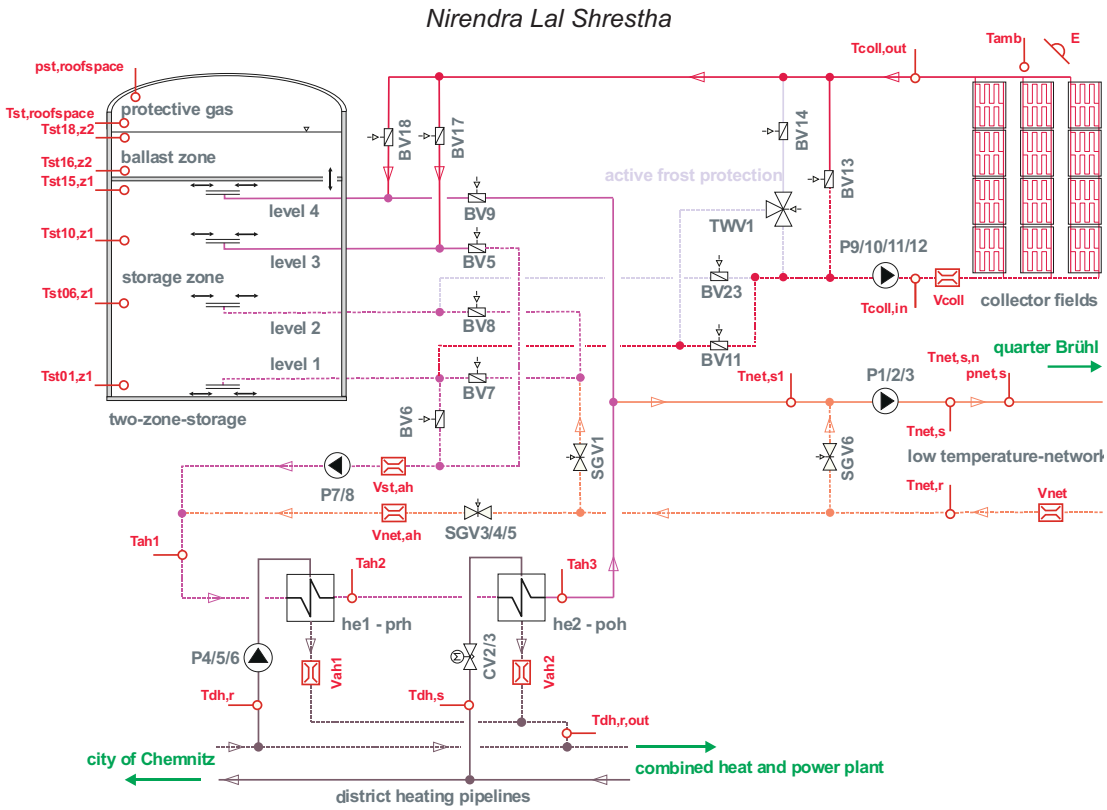

Fig. 2: Structure of the transfer station (supply center).

2.1 Solar thermal field

The large flat plate solar collectors were installed in two fields (north and south) based on the model of systems in Denmark (Holm, 2000) and cover a collector aperture area of 2093 m^2 (Fig. 3). The collectors were mounted on the ground with a tilt angle of 35° and field azimuths of 0° and -30° (south and north field, respectively). Two sizes of solar collectors provided by Wagner Solar GmbH, were installed for charging the storage and for supplying hot water directly to the network (Tab. 1).

Tab. 1: Parameters of the collector fields.

	Collector field south	Collector field north
Aperture area	1007 m^2	1086 m^2
Collector type	Wagner WGK133AR, Wagner WGK80AR	Wagner WGK133AR, Wagner WGK80AR
Number of rows	10	17
No. of WGK133AR	79	86
No. of WGK80AR	4	3

The special feature of the Chemnitz solar system is that water is used as heat transfer medium in the two solar fields. Additionally, there is no hydraulic separation between the solar fields, the storage and the customer's heating surface (e.g. radiator, floor heating). This reduces the heat and temperature losses along the supply path and increases the collector efficiency. Furthermore, a faster availability and the reduction of auxiliary energy requirements are achieved. In the collector, the heat transfer is improved due to the thermo-physical properties of water. From a practical point of view, deaeration is facilitated leading to simple and efficient operation. Cost reduction can be achieved by eliminating large heat exchangers, avoiding water-glycol mixtures, omission of pumps and valves on the secondary side, etc. However, in minus temperatures during winter the collectors must be heated with low heat amounts from the network in order to keep them frost-free. In the SolFW project, this active frost protection (Fig. 2) which was previously practiced only with compound parabolic concentrators (CPC) by Paradigma (Paradigma, 2016) is to be investigated in detail.

The solar fields are operated with matched flow. The specific volume flow rate is 15 l/(m^2·h) at maximum and controlled between 30 % and 100 %. The aim is for each string to reach the desired supply temperature of ca. 70 °C. This is performed by the setting of regulating valves being located at the outlet of each collector row. These valves are adjusted in such a way that the desired flow distribution is reached in nominal operating conditions. The control strategy (on the system side) ensures supply temperatures of 70 °C – 80 °C (possibly higher). In case of stagnation, the solar fields are separated from the system.

Fig. 3: South solar collector field and two-zone storage (left) and north collector field (right) in the Brühl system, Chemnitz.

2.2 Storage

For buffering short-term solar surpluses and as short-term storage for the CHP plants, a welded flat bottom tank was installed above the ground close to the south field (Fig. 3). It is constructed as two-zone storage according to a patent application by Thümmler (Thümmler, 2014) with a thermal useful volume of 1000 m^3 (storage zone) and a volume in the ballast zone of approx. 500 m^3. It is possible to store hot water with a charging temperature of up to 108 °C in the tank with stratification. The high temperature is possible due to the hydrostatic load of the upper zone (ballast zone) which increases the pressure in the lower storage zone and thus influences the boiling temperature of the water to be stored. The increased temperature leads to a higher storage capacity. The two zones (Fig. 2) are separated by a rigid and tightly sealed intermediate ceiling with insulation. For pressure balance, both zones are interlinked by a pipe system. Thus, the static pressure in the storage zone is always above the boiling pressure and evaporation or cavitation are prevented reliably. Additionally, this design helps in absorbing the volume difference due to expansion of water in the storage tank or the entire distribution system.

The total height of the storage is 20 m and the two zones are separated at the height of 13.4 m. The inner diameter of the storage is approx. 10 m. and it is insulated with mineral wool being 0.50 m thick. The outer surface of the insulation was covered by aluminum trapezoidal profiles. Furthermore, in order to charge and discharge the storage at different temperatures, four radial diffusors with diameters of 1.4 m are arranged in different levels.

This new construction of the storage is one of the first of its type being built in a solar district heating system. To avoid a contact of the water surface in the storage with air, nitrogen is injected in the roof space inside the tank.

2.3 Heat transfer substation

Since the solar energy yield can only cover the demand on favorable summer days, auxiliary heat for charging the storage and direct supply of the low-temperature network is provided by the existing district heating system. For this purpose, a two-stage system was installed in the heat transfer substation. The first group of heat exchangers (pre-heating stage, Tab. 2) contains two parallel plate heat exchangers for transferring heat from the main district heating return line. Depending on the return temperature from the low-temperature network or the storage (Tah1 in Fig. 3) and the current temperature of the main return line (Tdh,r), pre-heating can be conducted. Then the water with the temperature Tah2 flows to the post-heating stage where two parallel shell and tube heat exchangers supply heat from the main supply line in order to reach the desired supply temperature.

Tab. 2 Technical parameters of the heat transfer substation (Source: Requirements specification for Brühl district heating, AIC Ingenieurgesellschaft für Bauplanung Chemnitz GmbH, 2015).

plate heat exchangers (pre-heating)		**shell and tube heat exchangers (post-heating)**	
capacity	2.7 MW	capacity	3.3 MW
primary side:		*primary side:*	
allowable operating over pressure	25 bar	design pressure	25 bar
max. allowable operating temperature	140 °C	design temperature	160 °C
inlet- / outlet temperature	60/50 °C	inlet- / outlet temperature	120..130/63..65 °C
max. pressure loss	0.20 bar	max. pressure loss	0.25 bar
secondary side:		*secondary side:*	
allowable operating over pressure	16 bar	design pressure	16 bar
max. allowable operating temperature	140 °C	design temperature	160 °C
inlet- / outlet temperature	45/57 °C	inlet- / outlet temperature	60/80..108 °C
max. pressure loss	0.25 bar	max. pressure loss	0.25 bar

2.4 Network

A buried two-pipe network connects the buiding's heat transfer substations to the supply center and distributes heat with constant/annually varying supply temperature. Most of the pre-insulated pipes with sizes from DN25 to DN250 have been newly laid since 2014. So far, the owners of 198 out of 259 buildings (76 %) have taken up the connection offer by the utility inetz. The current load of the connected buildings amounts to 12.6 MW. This is about 200 % of the load expected for the first stage of network construction which was assumed for designing the solar plant (Urbaneck et al., 2015).

3. Monitoring results

Although the operation of the solar plant started from August 2016, the recording of all the required parameters has been only available since May 2017 onwards. Therefore, at first the thermal behavior of the system from May to September 2017 is shown and evaluated:

- The continuous supply of the low-temperature network is depicted in Fig. 4. The supply temperature is slightly above 70 °C, which is due to the safety reasons. The return temperature is in the range of 52…63 °C. Several factors are responsible of this higher return temperature, e.g. the supply being used only for domestic hot water systems during the summer period, maintaining the network temperature in the low-temperature circuit and fluctuations in the charging cycles of the transfer station.
- The daily sums for the output of collector field (sum of north and south field), auxiliary heating demand and demand of the low-temperature network are shown in Fig. 5. The solar thermal system has been designed for the first stage of network construction (Urbaneck et al., 2015). As the interest of building owners exceeded the expectations, the number of connections and thus the load values (Fig. 5) already correspond to the second stage of construction. Therefore, the output of the collector fields can be seen below the network demand. Even during summer, auxiliary heating is necessary. No off-peak periods (e.g. vacation) can be detected in the analyzed period. The base daily demand is 10…15 MWh/day.
- The relatively high return temperatures in the low-temperature network (Fig. 4) have an effect on the auxiliary heating system (Fig. 6). A fluctuating temperature profile can be seen (mainly because of the control behavior of the pre-heating stage). The increase of the temperature to the desired value is mainly performed in the post-heating stage because the return temperature of the low-temperature network is close to the temperature of the main return line being used as heat source in the pre-heating stage.
- The daily sums of thermal energy transferred by the auxiliary heating system (stages 1 and 2) are depicted in Fig. 7. The pre-heating stage covers ca. 15 % of the total auxiliary heat demand. It is expected that during the heating season from autumn to spring, the return temperature in the network

will be lower which leads to an increasing contribution of the pre-heating stage to the total auxiliary heat supply.

- The desired supply temperature is hold ready in the upper level of the storage zone (Fig. 8). However, fluctuations between 65 and 82 °C can be observed due to the operation of the collector fields and the auxiliary heating system.
- The high return temperature of the network has an effect on the operation of the collector fields. During the day, the outlet temperature of the solar collector in the south field is between 70 °C and 80 °C (Fig. 9) and sometimes it exceeds 80 °C for a few hours. The inlet temperature is in the range of 50…60 °C (Fig. 10). The design temperature difference between the inlet and outlet of the collector field with nominal operation is 30 K. However, the observed temperature differences are often lower (ca. 20 K, Fig. 11) due to high return temperatures in the network.
- Fig. 12 and Fig. 13 show a regular behavior with respect to the solar collector yield. There are a few outliers which indicate temporary malfunction. Generally, the fluctuation range is relatively narrow and confirms continuous operation of the solar plant.

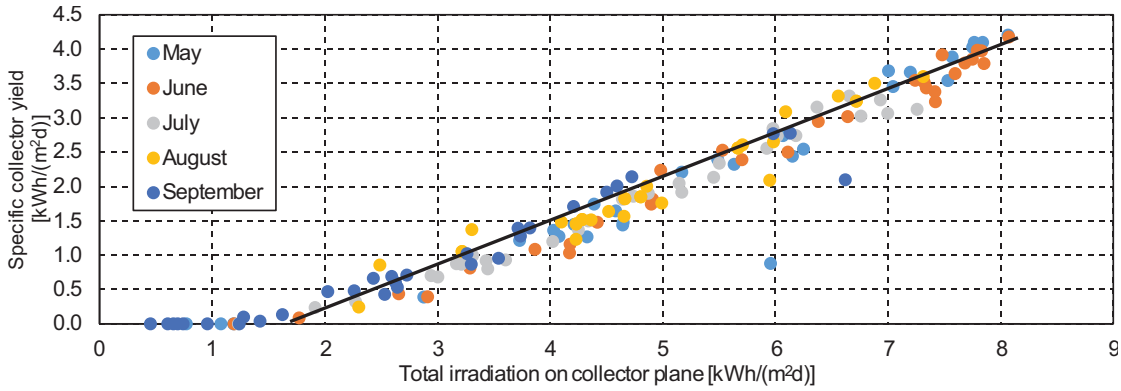

Fig. 13: Solar collector yield depending on the total irradiance on the collector surface in north field, 2017.

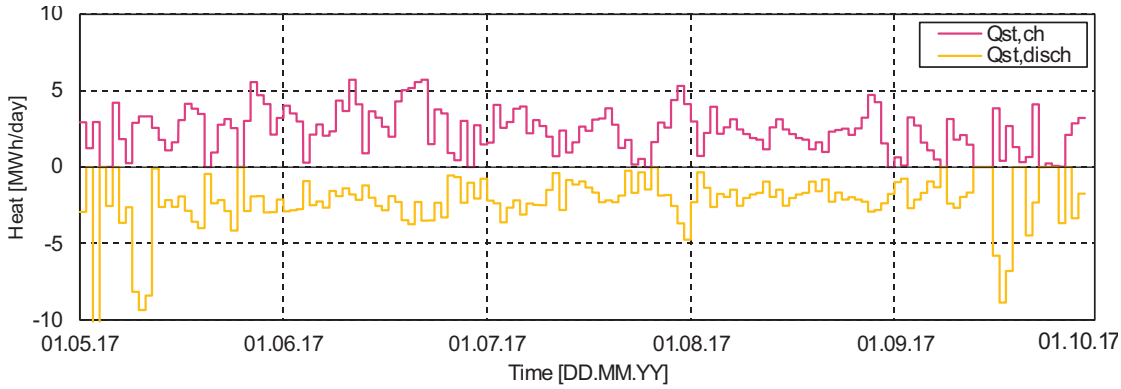

Fig. 14: Daily heat sum, charging and discharging of the storage.

On the basis of the monitoring data from May to September 2017, the heat quantities were calculated and are listed in Tab. 3. Furthermore, the key figures were listed which facilitate the evaluation:

- The summed yield of the solar collector fields is 599 MWh from May to September. In the design phase, a specific collector yield of about 402 kWh/(m²·a) was simulated for a net collector area of 1800 m² (Urbaneck et al., 2015). Thus, 71 % of the predicted yield was achieved so far. The solar fraction for the analyzed summer period amounts to 21 %, which is quite small because the solar collector field has been designed for the first stage of network construction. However, the second stage of construction has been reached faster than expected.

- The difference in yield between the south field with ideal south orientation and the north field with an azimuth of -30° (east) is quite small with about 4 %. The azimuth of -30° was chosen for avoiding shading by the main district heating pipes (Fig. 1).
- The high return temperature of the network during the analyzed period lead to a relatively low share of the pre-heating stage in the total auxiliary heat supply.

Tab. 3: Heat quantities and key figures.

Heat		**Key figures**	
Generation:		specific collector yield (north field) [kWh/m^2]	281
yield from collector field (north field) [MWh]	305	specific collector yield (south field) [kWh/m^2]	292
yield from collector field (south field) [MWh]	294	solar fraction [%]	21
auxiliary heating (stage 1) [MWh]	356	share of stage 1 in auxiliary heating [%]	15
auxiliary heating (stage 2) [MWh]	2037	share of stage 2 in auxiliary heating [%]	85
Consumption:		collector field efficiency (south) [%]	39.9
supply to low-temperature network [MWh]	2808	collector field efficiency (north) [%]	39.6
losses [MWh]	184		

4. Conclusions

In this paper, the implementation of large flat plate solar collectors into a low-temperature district heating network is presented. First monitoring results for the period from May to September 2017 show that the system in general operates as expected. The return temperature of the network has a very high influence which has been known since the 1990s. Optimization measures are planned here. Further work will be conducted for improving e.g. control of the auxiliary heating system. It is possible to transfer this concept to other urban quarters. Moreover, with the scale-up of collector area and storage capacity, higher solar fraction can be achieved. Therefore, this concept is one useful technical solution for large-scale heating systems.

Abstract

Drake Landing Solar Community is a Canadian solar district heating system with seasonal thermal storage. The demonstration project, designed to achieve over 90% solar fraction, was commissioned in the summer of 2007, reaching its 10th year of operation in 2017. The present work describes the system and its operation, presenting simulated and measured performance indicators for 10 years of operation, together with relevant operational data. Monitoring has proven the design simulations to be generally very accurate. During the last 5 years, the measured average solar fraction was 96%, including 100% achieved during the 2015-2016 heating season. The ability to easily access and view detailed system operating data combined with the ability to compare actual operation against predicted has proven to be extremely valuable for the successful commissioning and the efficient operation of energy systems at DLSC. Overall, the system has successfully demonstrated the reliable operation of a high solar fraction solar district heating system with seasonal thermal storage in a very cold climate. Although that Drake Landing system is too small to be economically competitive with the current very low price of natural gas in North America, subsequent feasibility studies show that larger systems of similar design can deliver solar energy at about half the cost compared to Drake Landing.

Keywords: Solar district heating, seasonal heat storage, borehole thermal energy storage, BTES, Drake Landing, high solar fraction, monitored performance.

1. Introduction

In Canada, space and domestic water heating account for more than 80% of greenhouse gas emissions in the residential sector. Despite that and the good levels of annual solar irradiation available in the most populated areas of the country, adoption of solar thermal technologies has been slow. This is partly due to the seasonal mismatch between the solar resource and the heating load, in particular for space heating applications. The Drake Landing Solar Community (DLSC) project was created to demonstrate the technical feasibility of achieving conventional fuel energy savings of more than 90% by using solar energy collected and stored during the summer to provide residential space heating during the following winter (seasonal storage). The system was commissioned in late June 2007, achieving 10 years of space heating operation during the 2016-2017 winter.

2. System Description

DLSC consists of 52 detached homes in Okotoks, Alberta (latitude 50.73N, longitude 113.95W). Each home has a detached garage behind the house, facing onto a lane (Figure 1). Each garage has been joined to the next garage by a roofed-in breezeway, creating 4 continuous roof structures, as seen on Figure 2. On those roof structures, 2293 m^2 (gross) of flat-plate solar collectors were installed.

The houses are located along two streets running east-west. Six different house models were available to buyers, with an average above-grade floor area of 145 m^2. The houses were built to meet Canada's R-2000 performance standard, with upgraded building envelopes, including higher insulation, low-e argon filled double panel windows and improved air tightness and construction details. The higher standard was estimated to reduce space heating load by 30% when compared to baseline houses at the time of construction. Space heating is supplied to the 52 houses through 4 parallel branches of a 2-pipe district heating system. An integrated air handler and heat recovery ventilator, incorporating fans with electronically commutated motors and a large water-to-air heat exchanger, supplies forced-

doi:10.18086/swc.2017.06.09 Available at http://proceedings.ises.org

air heating and fresh air. An independent, 2-collector, solar domestic hot water system, backed-up with a high-efficiency gas-fired water heater, supplies service hot water.

Fig. 1: View of houses with adjoined garages and houses street view

Fig. 2: Aerial view of Drake Landing Solar Community

A seasonal borehole thermal energy storage (BTES) field was installed under a corner of a neighborhood park and covered with a layer of insulation beneath the topsoil. The BTES is composed of 144 boreholes, each 35 m deep and radially plumbed in 24 parallel circuits, each with a string of 6 boreholes in series. Each series string is connected in such a way that the water flows from the centre to the outer edge of the BTES when storing heat, and from the edge towards the centre when recovering heat, so that the highest temperatures will always be at the centre. Figure 3 shows the borehole field under construction and currently, as a landscaped park.

Most of the solar district energy system mechanical equipment (pumps, controls, auxiliary gas boilers, etc.) is in a dedicated building (Energy Centre, at top right corner of Figure 2), which also houses two short-term thermal storage (STTS) tanks with a combined water volume of 240 m^3. The STTS acts as a buffer between the collector loop, the district loop, and the BTES field, accepting and dispensing thermal energy as required. A 22 kW photovoltaic array is installed on the roof of the energy centre (not visible in Figure 2, as the picture was taken before its installation)

The specially designed air-handlers and separate water heating systems allow the district system to operate at low temperatures, leading to increased effective storage capacity and higher collector performance. Typically, the supply temperature for the district heating system is below 40°C, and return below 30°C.

Fig. 3: Borehole field under construction and currently, as a landscaped park

A schematic diagram of the system is shown on Figure 4, and more details on its design and early results of operation can be found elsewhere: McClenahan et al. (2006), Wong et al. (2006) and Sibbitt et al. (2012, 2015).

3. System Performance Results

3.1. Simulated system performance

During the design phase, a detailed TRNSYS model was developed to simulate the system operation. The model includes solar collectors, heat exchangers, short-term and bore-hole storage, piping, controls and district heating system. The house heating loads were calculated using ESP-r, and the results used as input into TRNSYS. Simulations were done both with 50 years of historical weather data and by repeating the typical meteorological year, CWEC – Canadian Weather for Energy Calculation, for the site. Both analysis predicted average solar fractions above 90% over 50 years of operation. The TRNSYS simulations were used to optimize some of the main design parameters, such as solar collector area, short-term storage size and number and depth of boreholes. Table 1 presents the results of the simulated 10 years of operation with repeated CWEC data.

The results of 50 years simulations using the same load and weather data show very little change beyond the 10th year of operation. Therefore one can see the results for the 10th year on Table 1 as the final steady state condition for the simulations. The system reaches a maximum solar fraction of 91%, with an all pumps electrical COP of 46. COP calculations are based on home heating load as a way to compare its values to distributed heat pump systems. Two different COPs are defined: COP_{ss}, based on the solar and storage pumps electricity consumption and the solar

contribution to the houses heat load, and COP_{ap}, based on all pumped electricity consumption and the houses heat load.

$$COP_{ss} = {(Q_h f)}/{E_{ss}} \quad \text{(eq. 1)}$$

$$COP_{ap} = {Q_h}/{E_{ap}} \quad \text{(eq. 2)}$$

Although the results on Table 1 were obtained with the TRNSYS model developed at the time of system design, many efforts have been made to improve and calibrate the model. McDowell and Thornton (2008) performed an initial model calibration during the first year of operation, and additional efforts are currently under way to review and calibrate the model by comparing the results between measured and modeled energy performance results using measured weather and load data as inputs to the model.

[1] Based on gross area
[2] Apparent efficiency; does not account for year-to-year change in stored energy

3.2. Measured system performance

DLSC operation has been closely monitored since its commissioning in 2007 and a summary of the performance measurements between July 1, 2007 and June 30, 2017 is presented on Table 2. The annual collector efficiency has remained relatively constant over the period at approximately 34%, based on the gross area of the collectors and the collected energy measured at the heat exchanger in the energy centre. In the first year of operation, most of the collected energy (2610 of 4470 GJ) was sent to the BTES. Although the BTES only returned 152 GJ (6%) of the input energy for heating later in the first year, 1520 GJ of solar energy was also supplied directly from the STTS. Together, 1670 GJ of solar energy, out of a total of 3040 GJ was delivered to the district loop, giving a solar fraction of 55%. In the next 3 years, the BTES returned a greater fraction of the heat supplied to it, reaching 54% in the fourth year, allowing the solar energy contribution to the load to increase to 60% in year two, 80% in year three and 86% in year four. In year 5, the solar fraction increased to 97%, but the heat returned from BTES dropped to 36% of the heat supplied to it. Such low BTES contribution happened again in 2015-2016, when the system reached 100% solar fraction and the house heating loads were the lowest for the 10 years of operation. During the last 5 years, the average solar fraction was 96%, including 100% achieved during the 2015-2016 heating season.

[1] Based on gross area
[2] Apparent efficiency; does not account for year-to-year change in stored energy

Measured irradiation has been consistently lower than CWEC typical meteorological year numbers. Solar collectors have performed better than estimated through the simulations. Those discrepancies are currently under closer investigation. COP values have improved considerably since the beginning, mostly due to control strategies that reduced pump electricity consumption. Lower initial COP values were due to higher pump consumption and the fact that the BTES was being charged for the first time. The system has consistently produced COP results above 28. Moreover, the electricity consumption for pumps is almost entirely off-set by onsite PV generation. Unlike PV, however, the solar thermal system with seasonal storage delivers energy when it is mostly needed, without seasonal imbalances. Overall, the system has surpassed performance expectations and has operated with a high level of reliability.

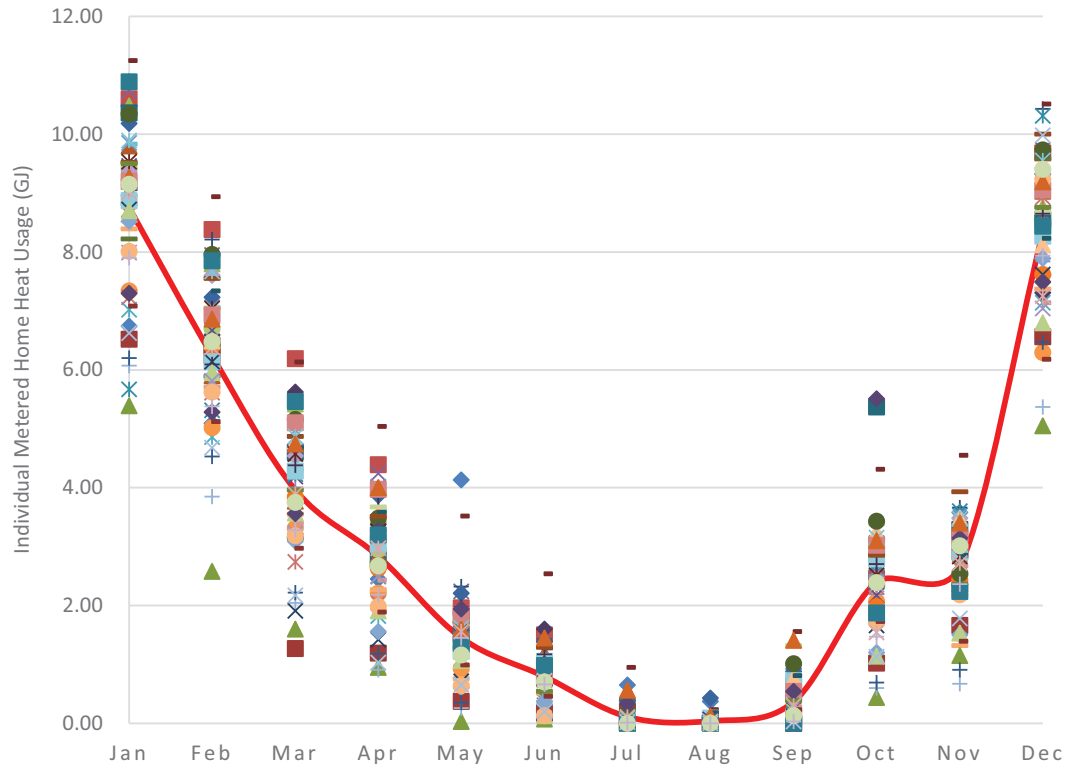

Fig. 5: Monthly metered heat usage for each one of the 52 houses for the calendar year of 2016

The individual heat metering results shown in Figure 5 show a large variation in heat usage among the 52 houses, even though there is not a significant difference in house sizes or construction. However, many other variables can lead to such variations, such as thermostat settings, and internal and solar passive heat gains. The original design heat load estimates showed that internal gain and passive solar represent about half of the contribution to the total heat load. It should be noted, however, that despite large individual variations, the average annual heat usage for the 52 houses is very close to the design value. For the initial 10 years, the average heating load for the 52 houses has been metered at 2370 GJ/year, compared to 2328 GJ/year simulated.

4. System Operation and Control

DLSC is controlled and monitored through METASYS, a building automation system (BAS) developed by Johnson Controls. Data is recorded every 10 min and the system operation is followed remotely by the project utility partner, ATCO and by researchers at CanmetENERGY Ottawa. There are no operators on site, and a number of alarms are set in the BAS, providing immediate awareness of operational issues. Figure 6 shows a functional diagram for DLSC with the system monitoring points.

The control system is designed to initiate and maintain collector loop operation whenever there is sufficient incident solar energy available. Initial operation each day warms up the collector loop, bypassing the glycol-water plate-frame

heat exchanger. When the collector loop fluid is hot enough, the flow is directed to the heat exchanger, transferring the heat to the water loop connected to the STTS. Thermal stratification is important in both the BTES and the STTS to allow the high temperature water to be available for space heating needs while supplying relatively low temperature glycol to the collectors. Both glycol and water collector loops utilize variable speed pumps. The control system was initially designed to vary the flow rate to achieve a 15°C temperature rise in the glycol loop and the water side pump would mimic the glycol side flow rate. This strategy enhances stratification in the STTS while reducing pump electricity consumption.

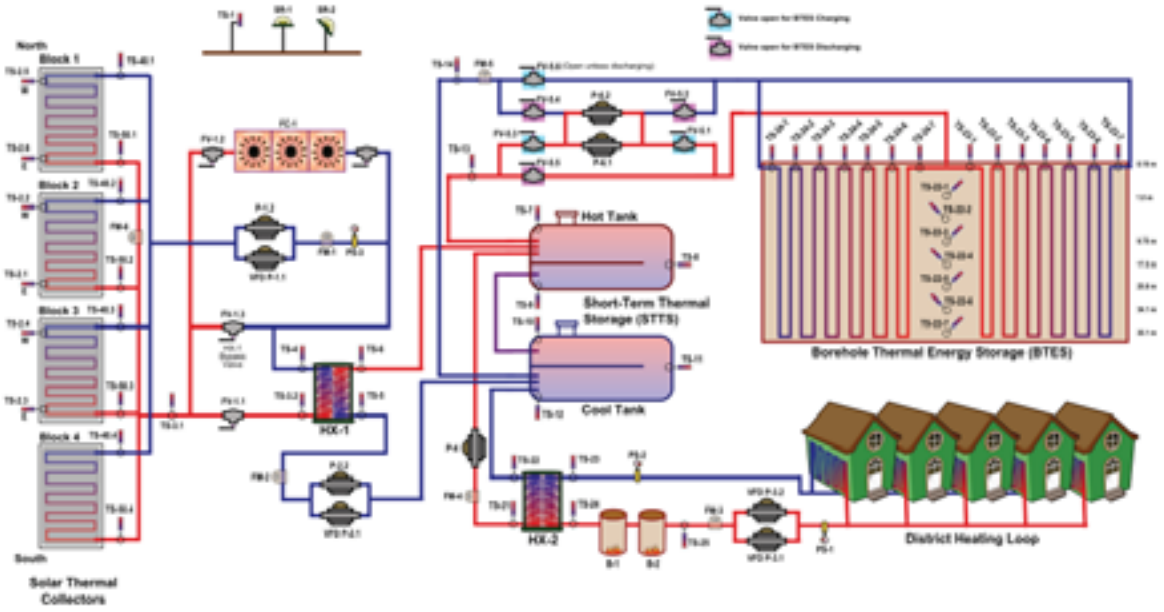

Fig. 6: Functional system schematic with monitoring points

One of the goals of the project is to evaluate control strategies that can optimize net energy production, maximizing the amount of collected energy and reducing power consumption for pumps. The solar collection pumps (primary glycol and primary water) account for more than 45% of all the electricity used for pumps (Table 3), despite the fact that the glycol loop was designed with a relatively low maximum flow rate of 25 l/hm^2. Therefore, during the years of system operation, a number of experiments were conducted to evaluate, through different control strategies, the impact of primary circuit flow reduction on electricity usage and thermal performance.

Tab. 3: Pump electricity consumption (GJ) for 2016-2017

Description	Pump					
	Primary Glycol	Primary Water	District Loop	STTS to HX	BTES	Total
Annual Consumption (GJ)	26.16	10.81	6.38	7.99	26.85	78.19
Percentage of Total	33.5%	13.8%	8.2%	10.2%	34.3%	-

Power consumption vs pump speed was measured for each one of the pumps equipped with variable frequency drives (VFD). Figure 7 shows, as expected, the marked increased in electrical power that follows an increase in pump speed.

The main strategy to reduce power consumption has been to increase the set temperature differential through the glycol loop, which leads to lower flow rates and pump speed. This effect can be observed on Figure 8. Compared to 2010-2011, both 2015-2016 and 2016-2017 show less hours of operation at high flow rates, which translates into a reduction of electricity usage. With negligible impact on collector annual efficiency, the electricity savings are calculate to be approximately 50% of the amount used with the original control strategy.

For the BTES pump the approach has been to use a predictive manual control, preventing energy from being moved from the STTS to the BTES if a cold front is forecasted, and only charging the BTES in the winter if the top temperature in the hot tank surpasses 60°C.

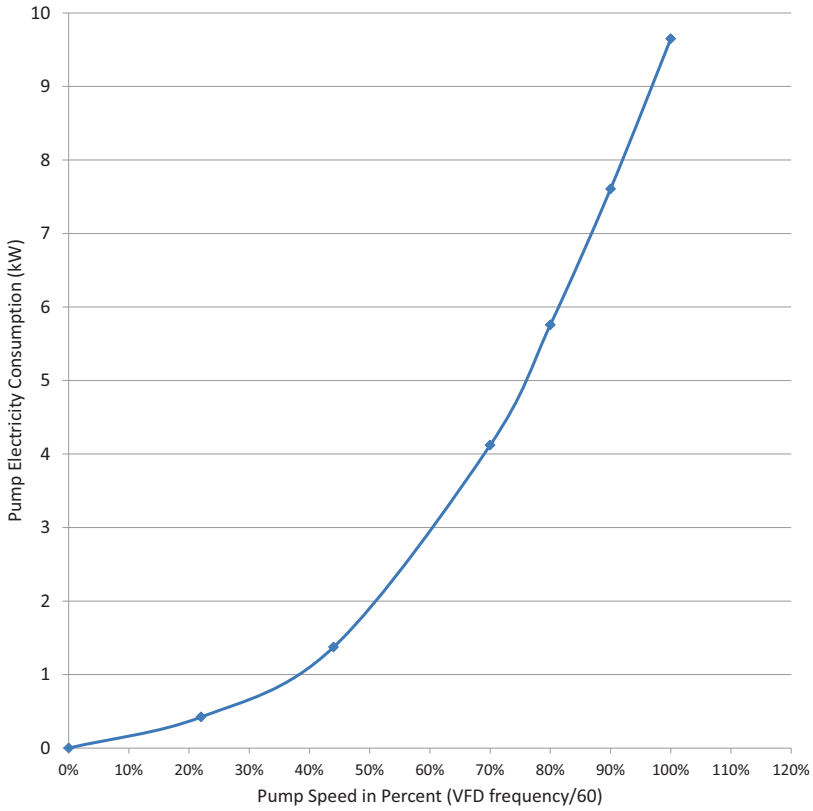

Fig. 7: Measured glycol pump (P1.1) electricity consumption as function of VFD setting

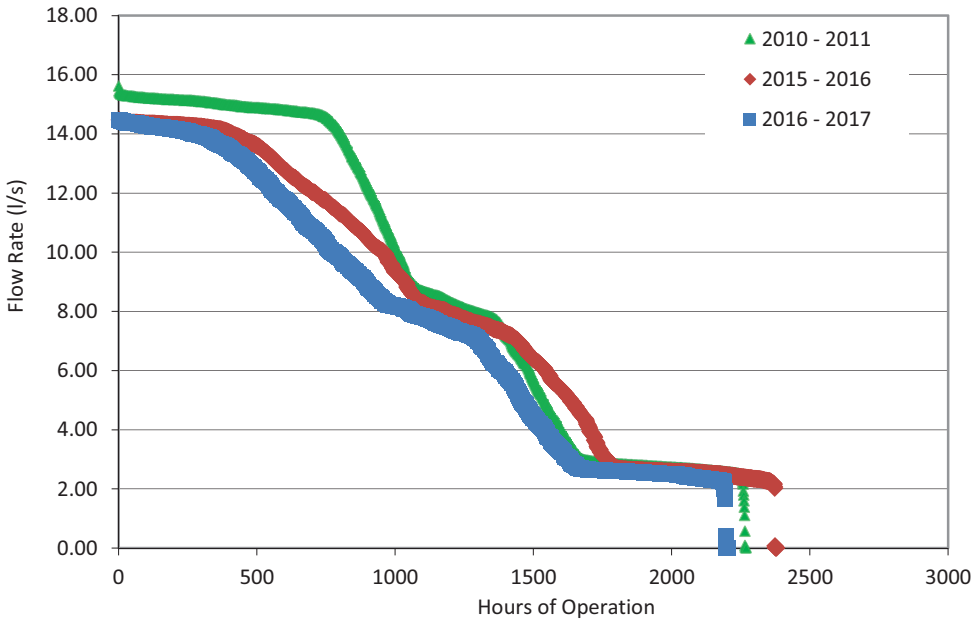

Fig. 8: Numbers of hours of operation at different flow rates for the glycol pump (P1.1) (selected years)

When space heating is required, energy from the STTS heats the district loop fluid through a second plate-frame heat exchanger. If there is insufficient energy in the STTS to meet the anticipated heating requirement, heat is transferred from the BTES into the STTS to meet the requirement. If the stored water temperature is insufficient to meet the current heating load, natural gas fired boilers raise the temperature of the district loop as required. When there is more heat in the STTS than is required for space heating in the short-term, water is circulated from the STTS through the BTES to store heat for later use. Figure 9 shows the heat supply to the system based on type of source for the

2016-2017 operational year. In this particular year, which was somewhat typical, direct solar was responsible for 48% of the energy supplied, while indirect solar, i.e., energy extracted from the BTES, accounted for 45% and the boilers for 7% of the supply.

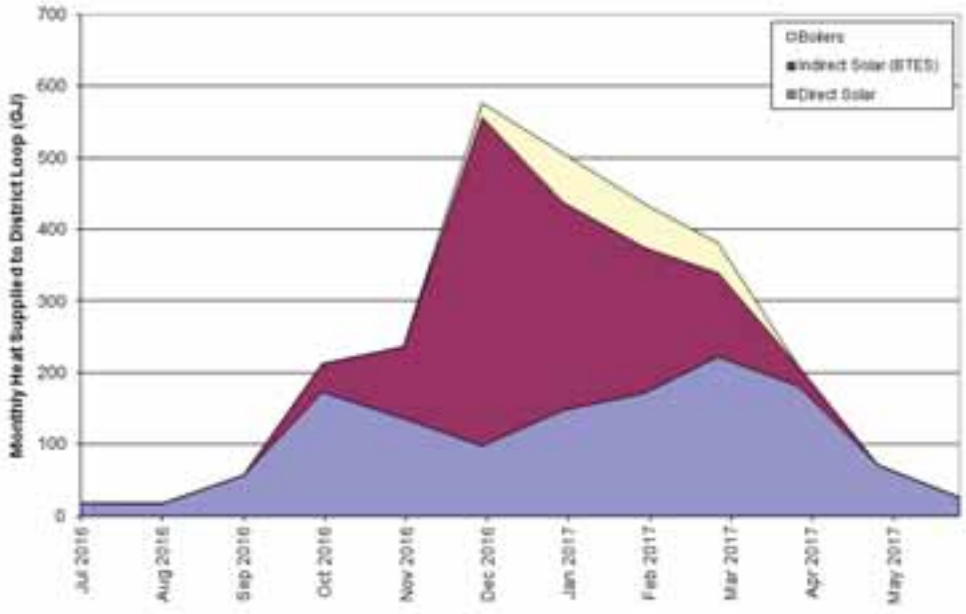

Fig. 9: Heat supply to the district loop in 2016-2017, according to the source

As mentioned previously, the home air handlers were designed to deliver the necessary amount of heat at a relatively low temperature. This, and the fact that the district heating system does not supply domestic hot water, allows the system to operate at low temperatures. The district loop supply water temperature is varied linearly from 37°C for ambient air temperatures of -2.5°C or above to 55°C for ambient air at -40°C. Variable water flow rates are also used in the district loop to allow a wide range of space heating loads to be met while facilitating efficient use of solar heat over a range of source and load temperatures, and limiting pump electricity consumption. Figure 10 shows the weekly average supply and return temperatures for 2016-2017. The slightly higher temperatures in the summer months are not indicative of operation set points. When the district loop is not operational in the summer, the surrounding air heats up the temperature sensors, which are located in the mechanical room close to the heat exchanger. Ambient temperatures in the mechanical room are usually close to 40°C in the summer.

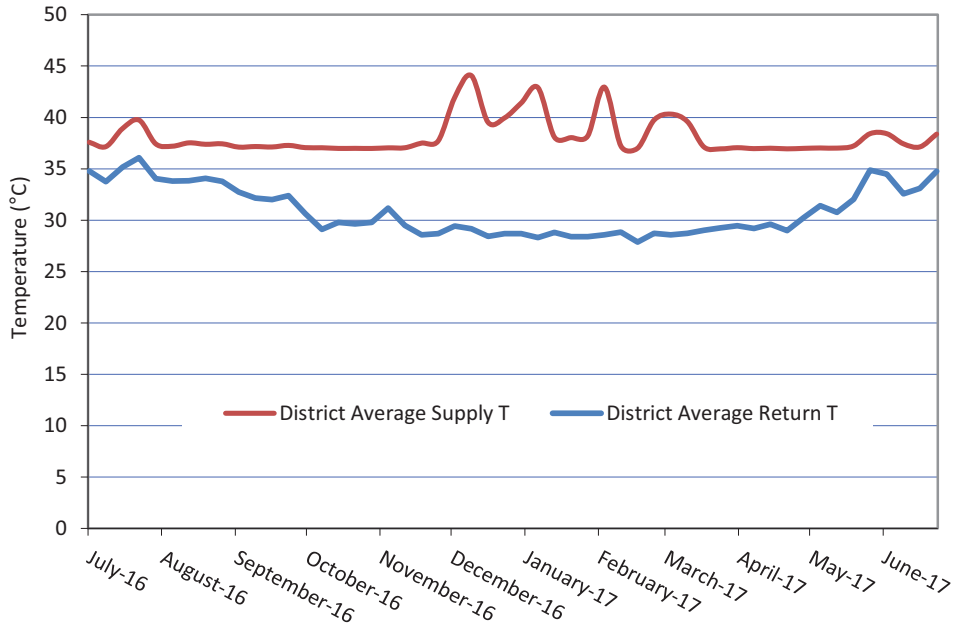

Fig. 10: Weekly average supply and return district loop temperatures for 2016-2017

Low supply and return district loop temperatures improve the effective thermal capacity of the BTES. In most cases, the BTES is able to meet the demand, with the exception of stretches of extreme cold days, which require higher supply temperature and thermal power. Figure 11 shows the maximum and minimum yearly temperatures for sensors located in the water piping at the top of the boreholes, with 24-1 and 23-1 being closest to the centre, and 24.7 and 23.7 being closest to the edge of the BTES (see Figure 6). Charging and discharging of the BTES is done in a way to promote thermal stratification within the BTES, with higher temperatures at the centre.

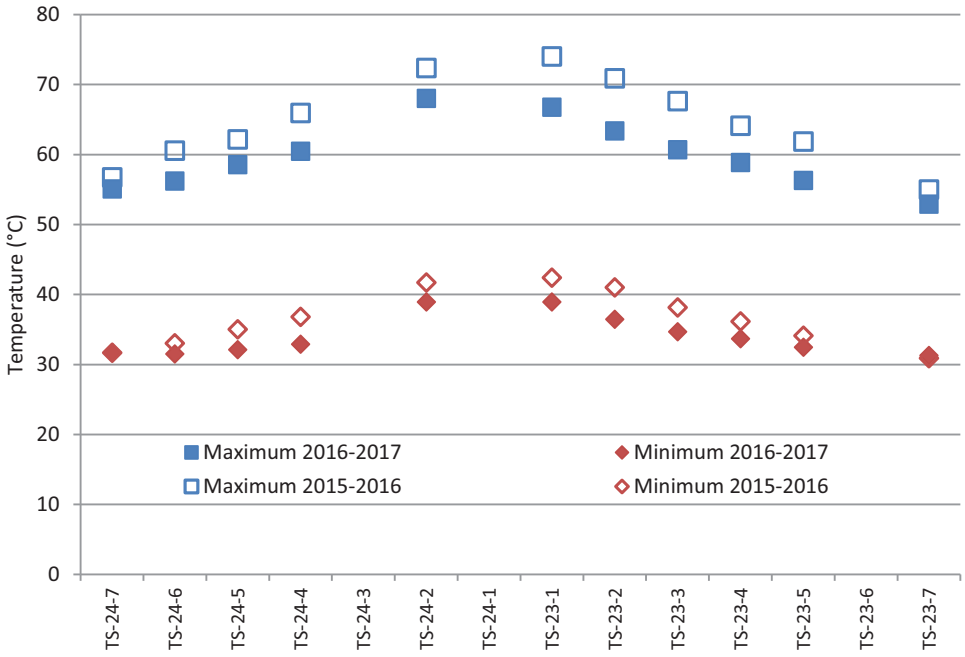

Fig. 11: Maximum and minimum yearly temperatures for sensors located at the top of the boreholes

During those 10 years of operation, DLSC has not experienced a stagnation episode in its glycol loop. This is mostly because there is enough capacity in the BTES to absorb all the energy produced. Nonetheless, the system is equipped with dry coolers that can reject enough heat to prevent the system from reaching a boiling state. The favourable conditions have resulted in longer glycol life and the fluid has not been replaced since the initial charge in 2007. Figure 12 shows the results of glycol pH and reserve alkalinity analysis throughout the last 10 years.

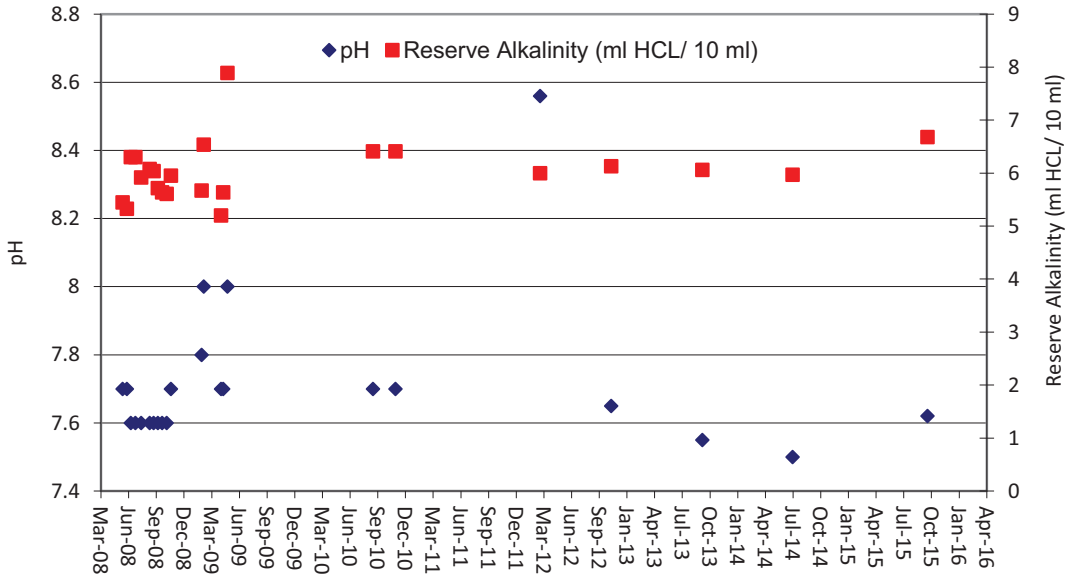

Fig. 12: Glycol pH and reserve alkalinity

5. Lessons Learned and Future Outlook

Overall, the system has successfully demonstrated the reliable operation of a high solar fraction solar district heating system with seasonal thermal storage in a very cold climate. In ten years of operation, only 2 of 798 solar collectors have been replaced and regular testing of the propylene glycol-water heat transfer fluid shows negligible deterioration, indicating many more years of service can be expected.

Adjustments and improvements have been implemented, such as better controls. Issues that could have led to significant performance and reliability problems were corrected early on. For example, a design oversight of the outlet ports in the upper half of one of the short term storage tanks led initially to lower thermal performance. It was promptly identified and corrected. This underlines the importance of technical and financial resources for monitoring and correction of eventual issues, common in pilot systems with this level of complexity. Careful design is seldom enough.

The DLSC builder, land developer and municipality were included in the project planning process from the beginning. This proved to be the right approach since their experience with and understanding of the home buyer's perspective had a significant positive influence on important design decisions throughout the process. It was also valuable in building confidence in the project regarding the market acceptance of the unfamiliar technologies being applied.

The homes were sold very quickly, with a long waiting list of potential buyers wanting to move into the community. People who live in the community are very pleased with it and they have adapted very well to the constant attention from outside, including opening their homes to people from over 20 countries around the world as far away as South Korea, China, and Chile. DLSC house values have increased in step with conventional homes in the area. The builder, the utility, the land developer and the municipality have all expressed interest in participating in the implementation of similar projects in the future.

As with the other utilities, district heating loop piping needs be installed before the houses are built. Shut-off valves in the utility easement near the street should be considered for subsequent projects to simplify the line installation and connection process for the builder.

It is essential to have committed partners. In significant projects, unexpected issues will almost certainly arise, however, with high levels of dedication and commitment, teams can identify acceptable paths forward which can be successfully executed. Some of the unexpected issues the DLSC team faced included severe construction site flooding, lower than expected reliability for some conventional equipment and some components that didn't actually perform to specification.

The ability to easily access and view detailed system operating data combined with the ability to compare actual operation against predicted is extremely valuable for the successful commissioning and the efficient operation of energy systems such as that used at DLSC. Going well beyond the obvious benefits of fine tuning control set points and identifying failed sensors and mechanical components, the availability of these data has identified inoperative control logic, inadvertent use of "temporary" set points, instances where plumbing modifications were warranted and opportunities to reduce electricity consumption with improved control logic. The performance and financial implications can be very significant if issues like these are not corrected.

Using the system data in conjunction with the TRNSYS design simulation has raised confidence in the ability to predict the energy performance of similar systems. Monitoring has proven the design simulations to be generally very accurate. Refined simulations have been subsequently used to perform feasibility studies for follow-on projects using similar designs. The simulation model has also been used to look for evidence of soil drying within the borehole field and conclude that no significant change has taken place in the bulk properties of the soil or in the performance of the seasonal storage.

Drake Landing system is too small to be economically competitive with the current very low price of natural gas in North America. However, subsequent feasibility studies show that larger systems of similar design can deliver solar energy at about half of the cost compared to Drake Landing, and additional work is underway to improve cost performance further. Current work includes model refining, O&M cost evaluation, and predictive control analysis and test implementation.

IEA SHC Task 55: Towards the Integration of Large SHC Systems into DHC Networks

Anna Katharina Provasnek,[1] Sabine Putz[1]

[1] R&D Department/SOLID, Graz (Austria)

Abstract

Solar thermal large-scale installations provide less than 1% of heat for DHC networks globally. The interest into solar thermal energy installations increases, but still strong measures are necessary to promote the technology across countries and energy policy frameworks. So how can the share of solar thermal energy be increased in district heating and cooling networks globally? Today, technical, economic, and policy measures still restrict a profound market development and limit the integration of large scale solar systems into different types of energy networks despite the huge potential of the technology to provide heat based on renewable sources. The new IEA SHC Task 55 extends research towards district heating and cooling networks, main system components and hybrid technologies. Additionally, the Task provides a new platform for scientists and industry partners to share their knowledge and solve pressing technical, political, and economic questions.

Key-words: IEA SHC Task 55, solar thermal large-scale installations, solar thermal systems, solar energy, district heating, district cooling

1. Introduction

Renewable energies such as solar provide promising business opportunities for companies. Innovation efforts at the right spot and at the right time can boost business success. Even international stock indices are aware of the economic strength of energy company efforts towards sustainability-oriented measures (Provasnek et al. 2015). However, increasing project dimensions require increasing technical capabilities and business model reliability. The cost competitiveness of solar thermal heating and cooling technologies is defined by several factors. Among these are initial costs of the solar thermal system, proper maintenance, or prices of alternatives. Solar thermal large-scale installations suitable to be integrated into district heating networks face these challenges on a much larger scale than well-established residential solar thermal systems. For decades, countries such as Denmark or Austria have paved a way to upscale solar thermal systems up to GW sizes, with a number of implications due to system sizes.

Several technical design characteristics determine the specific energy output of solar thermal systems, such as collector field losses, low temperature operations, or low return temperatures into solar collectors critical to storage losses. One major specific problem of regions with strong seasons are system and operational losses during winter times. The integration of solar thermal large-scale applications into district heating networks is problematic: Solar radiation is low while temperatures of the district heating networks are high (90°C – 140°C flow temperature). Additionally, the performance of collectors and their performance in field constructions do not correspond to their designated lab test results. Storages, hybrid technologies (industrial waste heat, heat pumps, or storage types) and optimized system components have to be aligned with all-year system requirements of district heating and cooling networks to guarantee a high solar fraction.

The IEA SHC Task 55 is a follow up Task of the successfully terminated IEA SHC Task 45. The former task provided research results on technical-economic parameters of large scale solar thermal plants (TASK 45, 2014). The new task integrates past findings and extends research towards district heating and cooling networks, main system components and hybrid technologies. Additionally, the new Task provides a new platform for scientists and industry partners to share their knowledge and solve pressing technical, political, and economic problems. It aims to provide options on how to best integrate solar thermal large-scale installations in combination with hybrid technologies (such as seasonal heat storages or adsorption heat pumps) into district heating and cooling networks. It is central to focus on the integration of solar thermal systems into network technologies, and on challenges which limit current integration efforts.

doi:10.18086/swc.2017.06.10 Available at http://proceedings.ises.org

2. IEA SHC TASK 55: Structure and Strategy

The international cooperation on the integration of solar thermal large scale installations into district heating and cooling networks is structured into four subtasks, A, B, C, and D. Subtask A focuses on district heating network requirements and options to integrate solar thermal heating or cooling installations. Economic analyses, hybrid technology applications, or control strategy challenges are major points of research. Subtask B elaborates on the specific components of such systems, testing and monitoring projects as well as quality aspects of integrated components. Subtask C emphasize the design of solar thermal systems. Projects elaborate on simulation tools, collector designs or modular conception and construction measures. Finally, Subtask D promotes and disseminates project results and know-how on SDH/SDC systems including hybrid technologies. It contributes business models, market analyses and best practice examples. Experts on Task 55 key research areas exchange their main fields of expertise in half-year cycles between 2016 and 2020, and aim to stimulate the growth and realization of a strong SDH/SDC industry. Strategic steps to reach set objectives are high attendance rates at Task 55 Meetings, active dissemination on most well-known industry platforms, increasing numbers of experts involved into Task 55 project work activities and active participation in the International Energy Agency on local and international levels.

3. Network Analyses and Integration

The overall district heating or cooling network and integration aspects are central as soon as the solar share of a DHC system reaches a level where the operation of the network and the other supply units is influenced significantly.

Best practice examples and case studies of existing, newly integrated and planned SDH and SDC systems with large (>5%) solar fraction (typically of > 0,5MWth up to GWth), including characteristics such as typical network temperatures, summer/winter load ratio, pressure level, collector fields, seasonal storages, hybrid-technology implementation, hydraulics and control strategies are central to analyze the network and integration strategies. Case studies, including potentials and barriers for the integration of solar thermal systems can show possible transition strategies from no to 100% solar thermal supply. System challenges in the network especially affect the hydraulics and the interaction with other supply technologies.

Technical and operational parameters of district heating systems differ across countries. In China, typical water supply temperatures range from 115-130°C, whereas in Denmark 66-115°C apply. In Germany, temperatures range from 90-113°C. Water return temperatures range from 50-80°C in China, 38-67°C in Denmark, and 30-60°C in Germany. Chinese networks show losses of 20-50%, whereas Denmark has 19.8% and Germany on average 13%. The volumes of networks in China have doubled since 2000 with rapid expansions, in Denmark networks are at the age between 24-54 years, whereas in Germany, some networks are close to 100 years old (IRENA, 2017).

The inclusion of solar thermal devices into diverse, complex heat distribution systems is ambitious, but doable. Solar thermal installations are based on renewable heat with minimal environmental impact. Disadvantages of the technology are the irregularity of solar irradiation (on which the heat yield depends) and the typically negative correlation between solar heat supply and heat demand. These disadvantages can be met by the use of storage tanks. Furthermore, heat production can be supported by the use of heat pumps. Complex heat generation and distribution systems incorporate many types of heat sources. The control of both the solar thermal systems and the heat distribution network constitutes a major challenge. Standard strategies of independent linear controllers for individual subsystems are not appropriate for control of transient modes. By disregarding the couplings between the systems, changes in operating conditions in one system can lead to oscillations and suboptimal behavior in others, which again can have repercussions on the first system. Unpredictable behaviors when integrating solar thermal systems into DH networks can be met by subordinate model-predictive control approaches.

Simple linear controllers do not account for dead time (delay), which is unavoidably present in large thermal systems fed by renewable sources. By a model-based approach, dead time can be explicitly taken into account in control strategies. Since the velocity-dependent throughput time corresponds to the heating time in the collector, one has some level of control over the outlet temperature by properly adjusting the mass flow. Adding an electrically operated heat pump to the system allows to decouple (to some extent) outlet temperature and heat flux. With a model-based control approach it is thus possible to independently prescribe target values both for outlet temperature and heat flux (within technical and physical limits). By setting the target values for critical system quantities, a superordinate predictive control system can make best use of all components and avoid unwanted situations, such as loaded storage tanks at a time when considerable solar yields are possible (Lichtenegger, et al. 2015).

Necessary conditions to use these predictive control measures to integrate a solar thermal system into a district

heating network are (Lichtenegger, Unterberger, 2015):

- Sufficient knowledge of the system,
- Reliable forecasts for solar irradiation,
- Reliable forecasts for ambient temperature and heat demand,
- Significant device for heat storage,
- The system has non-trivial heat demand characteristics.

International research projects on elementary components of the integration of solar thermal systems are heat portfolio, BiNe2+, UrbanDHExtended, OptENgrid, or BIGSOLAR. A switch to renewable energy sources for district heating and cooling can help meet rising urban energy needs, improve efficiency, reduce emissions and provide cost-effective temperature control. Under calculated conditions, DHC offers a cost-effective and energy efficient option. There is significant potential to upgrade existing systems and create new networks using solar thermal large-scale systems (IRENA, 2017).

4. Components testing, system monitoring and quality assurance

Operational conditions of components in large solar thermal plants usually differ from conditions under which components were originally tested in laboratories. Based on findings of IEA SHC TASK 45 Subtask C - which focused on system configurations, system performance, tools and guidelines for operating strategies, and models for ESCo services – the parameter are scaled up to much bigger sizes (Putz, Provasnek, 2016). Plant-specific characteristics, such as the azimuth, inclination, hydraulic effects, differentiated flow rates of parallel collector arrays, or characteristics of the heat transfer media determine how solar thermal systems operate. To reduce the uncertainty on the performance of solar thermal systems and to increase the planning reliability of systems to be integrated into DHC networks, current test methods have to be scrutinized and the actual operating conditions have to be put into consideration.

One major research project named `MeQuSo´ provides Task 55 with data on In-situ tests of the power output of large collector arrays to assess the thermal performance of the deployed collectors under real operating conditions in the field. By monitoring the performance of different collector types, assessments on the quality of individual products and external influences in the field are possible. Existing measurement data of solar thermal plants are not sufficient to improve current collector test approaches, since the needed quantities might not be measured and the accuracy might not be adequate. This is certainly true for radiation, since precise measurement of radiation is not always mandatory for control systems of solar thermal plants. A solar thermal plant called `Fernheizwerk´ was equipped with high precision measurement equipment to meet the data quality requirements of the project MeQuSo. Test results show that the field performance of a number of collectors differ highly from tests performed in the laboratory. Findings provide more accurate efficiency values under real operating conditions in the field, a higher reliability of the expected solar yield, and will lead to performance improvements of future collectors, collector arrays, and components of the total solar thermal system (Doll, Ohnewein, et. al 2016).

5. Design of the Solar Thermal System and of integrated Hybrid Technologies

The design of solar thermal systems defines their architecture, modules, and interfaces. The data on the design have to focus on the demand of specified requirements. Ideally, theory on system design and product development merge and are transported to the market, leading to innovative large-scale solar installations suitable for SDH. Core steps include the analysis, architecture and engineering of solar thermal components. Hybrid technologies can help to shape the change into DHC solar thermal innovation. Elements from new solar thermal system designs can be combined with technologies of the status quo. Hence, two technologies are combined with one another.

New systems can be based on a first simulation of solar thermal systems and their components, such as storage, piping, and hybrid technologies such as heat pumps. The project at hand elaborates on characteristics of collector array units, large and seasonal storages, hydraulics, and heat pumps within system operations. Large scale collector fields are simulated and compared to related measurements in field tests. Optionally, the simulation tool can be corrected. Next, parameters of seasonal storages are calculated and guidelines for the design and construction of different storage types identified. Hydraulics within systems are sensitive to a variety of parameters. These parameters have to be optimized. Piping within large systems and options for a modular conception and construction

of very large systems have to be investigated. The subsequently developed modes provide new findings for performance surveillance, system design, and system control measures.

Steps to evaluate and optimize the design of solar thermal systems include:

- Investigation of measured long-term field performance in relation to standardized collector test information
- Development of tools/models for annual performance predictions at different operating conditions and field designs
- Solar radiation modelling
- Assessment of different collector types for large collector fields
- Investigation of system performance and control for a collector field with series connection of different collector types
- Investigations on influence of the design of the solar collector loop on the thermal performance of solar collector fields
- Analyzing pressure loss and flow distribution in collector components, collectors, and collector fields

Focusing on renewable energy sources, solar thermal energy can be generated by more than one renewable source at a time. Examples are sources of solar, biomass, or geothermal. The hybrid energy generation module of solar and geothermal or solar and waste heat hybrid module are attractive, as they are abundant in nature and from the industry, and are very much environmentally friendly (TASK 55, 2017).

A component critical to solar thermal large-scale systems and their hybrid systems are thermal storages for achieving high penetration levels. It increases the capacity factors or value of such energy systems and are therefore core to any system design (IRENA, 2017).

6. Dissemination of SDH/SDC and of Hybrid Technologies in New Markets

Business activities on solar thermal energy are increasingly important contributors to the energy economy. Current firms on the market are major sources of innovation, business development, and of new jobs. Securing financial success for newly designed large scale solar thermal installations is still a challenge, as they are built upon intellectual capital rather than on physical assets, which are still to be built. However, several companies are willing to `go boldly where no one has gone before´ with solar thermal energy installations. For these companies it is central to identify sources of financing and new business models.

One instrument to assist in the availability of financing are promotion activities for large SHC installations coupled with existing DHC networks. Additionally, including industrial waste heating (and cooling) sources with the other technologies of heat pumps, geothermal heat and thermal energy storages are attractive, innovative combinations. Exemplary business models for these solar thermal and hybrid technologies are to be elaborated, as well as best practice examples of already existing installations.

Besides, promising are also new industrial markets for solar heating and cooling systems, which need training material in order to diffuse the technologies. Most countries could scale up renewable energy substantially in district heating and cooling. In a few countries, such as Denmark and Switzerland, renewable energy already provides more than 40% of district heat supply. Renewable energy such as solar thermal energy and hybrid technologies could theoretically satisfy all DHC demand in 2030. However, a realistic potential for deployment differs from country to country. China could realize a 24% renewable share in district heat generation, split equally between geothermal, bioenergy and solar. In Denmark, the already high renewable share of 42% could reach 73%. The country is and will remain a global leader in large-scale solar energy, which can be expanded to meet 13% of total district heat demand by 2030, complemented by hybrid technologies of geothermal and bioenergy. In Germany, solar heat could reach a share of 6% in DH networks by 2030.

7. Summary and Outlook

IEA SHC TASK 55 focuses on very recent efforts of a number of stakeholders to increase the share of solar thermal large-scale installations in district heating and cooling systems. District heating systems spilt the local production of energy and its consequences (such as CO2 emissions) from its consumption. Despite already being considers as more environmentally friendly than conventional single energy systems, district heating systems can still increase their

environmental performance by integrating renewable sources. Optimizing system operation, achieving economies of scale, integrating large scale storage and holistic system designs are essential to accelerate the deployment of cost-effective solar thermal assisted DHC systems. As the systems of solar thermal and geothermal large scale improve and grow, DHC systems will also offer increasingly attractive synergies.

Mismatches between load patterns and the supply from solar radiation can already be balanced to a great extent with thermal storage facilities. Storages are expected to become integral, with DHC systems coming to play a pivotal role in enabling variable renewable sources. Solar thermal large-scale applications are only used in a few places today but have significant potential. Countries such as China become increasingly dependent on variable renewables due to pollution crises. Next steps have to promote demonstration projects for the new technologies. Due to the limited number of systems already in place (despite in Denmark), the availability and suitability of renewable resources for DHC is often unclear. For solar district cooling technologies, demonstration projects will have a significant positive effect on investors´ and customers´ trust into the technology.

As installations in Denmark have shown for decades, large scale solar thermal systems are a promising technology. However, several challenges are still to be met: Which approaches are most promising in integrating such systems, how should the DHC systems be designed, which components fit best into the system and which business models actually meet most stakeholders´ needs? Examples of already existing installations and elaborations on promising new markets and market developments are much needed fields of expertise. IEA SHC TASK 55 tackles these challenges and will provide answers to all questions by mid-2020.

DH Networks - Concept, Construction and Measurement Results of a Decentralized Feed-In Substation

Toni Rosemann[1], Martin Heymann[1], Karin Rühling[1] and Bernd Hafner[2]

[1] Institute of Power Engineering, Professorship of Building Energy Systems and Heat Supply
Technische Universität Dresden, Dresden

[2] Viessmann Werke GmbH, Allendorf (Eder)

Abstract

The paper presents the concept and measurement results of a solar thermal pilot plant for decentralized feed-in to a 2nd generation district heating network. Ambitious conditions for both target temperature level and pressure difference are fulfilled with a return line to supply line feed-in (RL/SL) design. The use of water as solar liquid requires an active frost protection using return line district heating water. The stagnation state is investigated by the application of distributed temperature sensing (DTS). The measurement results include one frost protection and almost one feed-in season.

Keywords: solar thermal, decentralized feed-in, stagnation, frost protection, control concept, measurements

1. Introduction

Decentralized feed-in of solar thermal gains can contribute to the decarbonisation and flexibilisation of modern district heating networks (e.g. Heymann, et. al., 2017). The development of standards concerning network feed-in substations and their control concepts is the research goal of the ongoing research project "Kostenreduktionspotential beim Ausbau der Solarisierung von Fernwärmenetzen durch Standardisierung"[1]. These standards are derived from practical experiences of the planning, the commissioning and the operation of pilot plants – including the solar thermal system and the substation itself – as well as simulations studies.

In this paper the design and control concept of a pilot plant is presented which is in operation at the Centre for Energy Technology (CET) in Dresden since November 2016. The network feed-in substation is connected to a 2nd generation network (according to Annex X classification Rosa, et. al., 2014) and was developed in cooperation with the local network operator as part of a feasibility study for larger collector fields. The pilot plant is designed for the RL/SL feed-in into the district heating network - the most common and most flexible type of decentralized network integration.

This paper presents detailed measurement results and details of the control algorithms for the three main operation modes (hereafter referred to as states) of the network feed-in substation:

- *Feed-in* of solar energy,
- *Stagnation* and
- Active *Frost Protection* for the water-based solar circuit.

doi:10.18086/swc.2017.06.11 Available at http://proceedings.ises.org

2. Concept of the District Heating Network Feed-in Substation

The pilot plant is connected to the primary district heating network of the city with a nominal pressure stage of PN25 and the nominal target feed-in temperature is 110 °C. Therefore solar vacuum tube collectors working according to the heat pipe principle are used in the collector field (CF). The collector field consisting of six subfields C1..C6 has a total gross area of 84 m² (total aperture area 48 m²) and an inclination of about 31° facing south. The design heat flow rate is 30 kW based on a total incline irradiance $G_{t,i}$= 1000 W m^{-2} and collector field temperatures of 115/70°C. The subfields C1..C6 are connected in series (see Fig. 1).

The circulation pump in the solar circuit Pu_{STS} is a speed-controlled pump group where only one pump is used in main operation at a time and where the other pump is hold as a spare component. The redundancy is important to guarantee the functionality of frost protection. The compressor-based pressure maintenance is connected to the system in the supply line of the collector field through stagnation cooler. This cooler is built as a finned tube radiator which limits the maximum steam spread in case of stagnation, reduces the design volume of the common additional auxiliary vessel and thereby the design volume of the pressure maintenance expansion vessel.

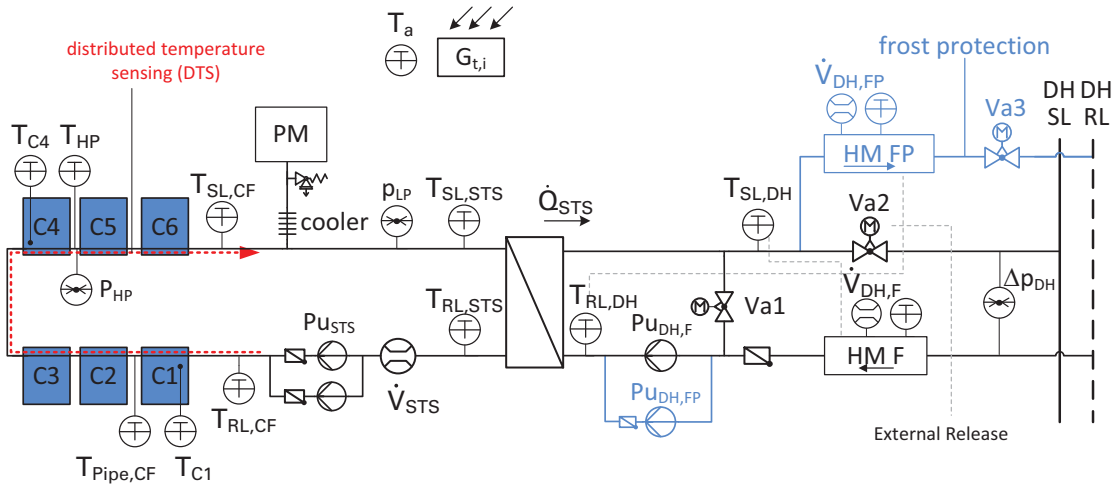

Fig. 1: Schematic of the feed-in substation (Ta – ambient temperature, C – collector, CF – collector field, DH – district heating, HM – heat meter, F – feed-in, FP – frost protection, HP – highest point, LP – lowest point, PM – pressure maintenance, Pu – pump, Va – valve, STS – solar thermal system)

The speed-controlled feed-in pump $Pu_{DH,F}$ is necessary to overcome the pressure difference Δp_{DH} in the DH network and generates the feed-in volume flow. The proper selection of this component is essential to assure the feed-in of the solar yields into the network. This is often complicated due to the lack of information about Δp_{DH}, $T_{SL,DH}$ and $T_{RL,DH}$ at the feed-in point for the course of the year and the future development of these values. Before feed-in the bypass valve Va1 will be opened to heat up the medium in the district heating side of the substation to prevent cold plugs in the network but will be closed during feed-in. It can also be opened during times of partial load/low irradiance to raise the RL temperature $T_{RL,DH}$ when the speed-controlled pumps reach their minimal flow rate. The valve Va2 is used to realize an external unblocking. If necessary the network operators can withdraw the release signal and prevent/stop the feed-in by closing the valve and shut of the pumps. The valves Va2 and Va3 are used to switch the flow direction between RL/SL in the state *Feed-in* (Va2 open, Va3 closed) and RL/RL for heating the STS in the state *Frost Protection* (Va2 closed, Va3 open). A separate frost protection pump $Pu_{DH,FP}$ is used because of different design parameter for the RL/RL frost protection heating (low discharge head) and due to redundancy.

A minimum sensor equipment is necessary for the plant operation. It consists of five temperature sensors ($T_{SL,CF}$ $T_{SL,STS}$ $T_{RL,CF}$ and $T_{SL,DH}$, T_a), the radiation sensor $G_{t,i}$ as well as two heat meters. The heat meter HM F measures the heat fed into the network. The volume flow signal $\dot{V}_{DH,F}$ of the feed-in heat meter is used for a control loop by an analogue module. There is a second heat meter HM FP, which measures the heat required for frost protection. These two separate heat meters are necessary as long as no bidirectional heat meter is available on the market that is certified for billing.

The monitoring package consists of additional temperature sensors, three pressure sensors (p_{HP}, p_{LP}, Δp_{DH}), a flow meter $\dot{V}_{STS}$, as well as a distributed temperature sensing system (DTS see Herwig, Rühling, 2014). The DTS uses an optical sensor cable, which is attached to the collector pipe of the system in order to measure the temperature distribution with a high spatial and time resolution. This is helpful for detailed analysis of the states *Frost Protection* and *Stagnation*.

3. State Feed-In

3.1 Controller

In order to operate the network feed-in substation in the *Feed-in* state a set of three controllers is used (see Tab. 1). The controller C1 is used for the matched-flow control of the collector field output temperature $T_{SL,CF}$ by adapting the pump speed of Pu_{STS}. This controller compensates changes mainly in the radiation $G_{t,i}$ and the return line temperature $T_{RL,STS}$. The objective is to keep the heat exchanger input temperature $T_{SL,STS}$ higher than the setpoint of the feed-in temperature $T_{SL,DH}$ – to guarantee heat transfer – and to keep the average temperature of the solar thermal system low to minimize losses.

Tab. 1: Closed-loop PI-controllers for state Feed-in

Name	Control variable	Setpoint	Output
C1	$T_{SL,CF}$	115..120°C	speed Pu_{STS}
C21	$T_{SL,DH}$	110°C	setpoint C22
C22	$\dot{V}_{DH,F}$	results from control signal of C21	speed $Pu_{DH,F}$

The two general main tasks of controlling the feed-in pump $Pu_{DH,F}$ are:

- to guarantee a stable volume flow $\dot{V}_{DH}$ despite the strongly changing pressure difference of the network Δp_{DH} but corresponding to the current solar yields and
- to operate with minimal power consumption.

A cascaded controller is used (see Fig. 2 left) to achieve both tasks. The temperature controller C21 finds a solution for the equation (eq. 1) by adjusting the volume flow setpoint $\dot{V}_{SP}$ of the controller C22 and thereby the volume flow $\dot{V}_{DH}$. The inner controller compensates any change of the pressure difference of the network $\Delta p_{DH.}$ This is energetic efficient, because the pump speed is changed to manipulate $\dot{V}_{DH}$ directly instead of using a throttling or bypass valve. The volume flow signal of the heat meter HM F can be used directly e.g. through an additional analogue module, depending on the kind of heat meter and the achievable update interval. The tested substation works well when controllers are updated every four seconds.

$$T_{SP} = T_{SL,DH} = \frac{\dot{V}_{SP} \cdot \varrho \cdot c_p}{\dot{Q}_{STS}} + T_{RL,DH} \quad \text{with } T_{SP} \text{..setpoint for } T_{SL,DH}, \dot{V}_{SP} \text{..setpoint for } \dot{V}_{DH} \qquad \text{(eq. 1)}$$

The compensation of the variable pressure difference Δp_{DH} by using the volume flow controller C22 (see Fig. 2 Right) is realized in three steps:

1. The setpoint volume flow is reached at the actual pressure difference $\Delta p_{DH,1}$ (steady state)
2. The volume flow $\dot{V}_{DH}$ differs from the setpoint as a result of the disturbing pressure difference $\Delta p_{DH,23}$. The feed-in temperature $T_{SL,DH}$ will differ from its setpoint as well. (instationary)
3. The controller C22 compensates the pressure difference variation and the feed-in temperature will not be affected. (stationary)

The volume flow signal $\dot{V}_{DH}$ of the HM F can also be used to find the right pump speed to overcome the pressure difference Δp_{DH} when the feed-in starts (Rosemann, et. al., 2017a). The integration of this signal into the plant control as described above is recommended because of the low additional costs for reading out this signal and the high advantages for solving the common technical pressure difference Δp_{DH} problems in district heating networks (Lennermo and Lauenburg, 2015).

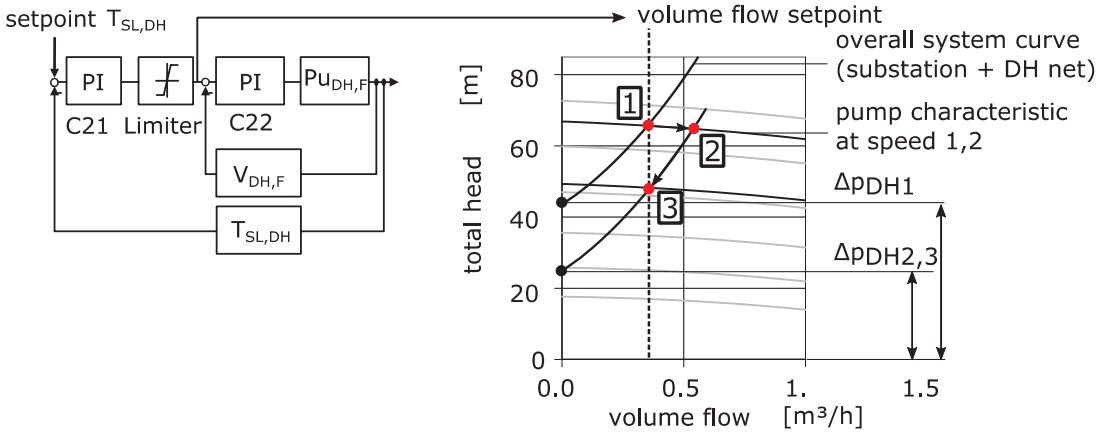

Fig. 2: Left: Cascade controller for the feed-in temperature TSL,DH

during the control action of C22 reacting on a step of ΔpDH
(1 – Starting point, 2 – after step of ΔpDH without reaction of C22, 3 – Final stage after correction of the pump speed)

3.2 State Machine

For the correct operation of a district heating network feed-in substation, the controller and actuators of the plant have to be de-/activated and set to corresponding values at the right moment. This task is solved with a state machine (see Fig. 3). A state is a set of actor and controller settings which structures the operation of the plant into sequential steps. The entry point of the state machine is "Start". There is always only one active state. The active state checks the criteria pointing to the connected states and starts a transition if the logical expression of all criteria is true. Global states are special states that always check their entry criteria because of their high priority, which is used e.g. for safety technology. States can consist of substates. This is used to cluster states to visualize their coherence (e.g. to heat up the solar thermal system is always a part of the feed-in).

A criterion is based on measurements of physical values and durations. A duration can be based on a physical criterion (additional time criterion, "How long is a physical condition met") or on the active time of a state (τ_{State}, "How long is a state active"). The parameters of the criteria depend on the concrete plant and its constraints.

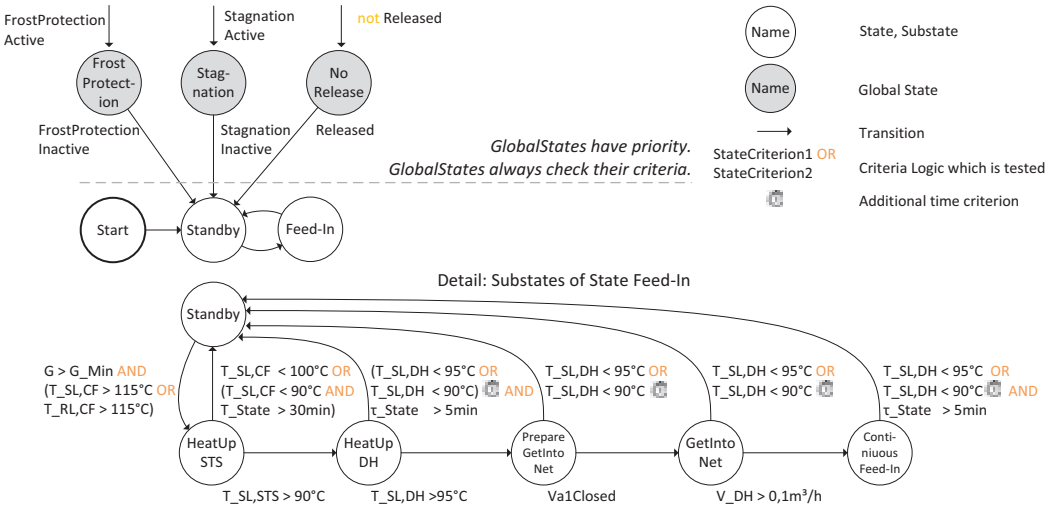

Fig. 3: State diagram of the net feed-in substation with detailed substates of the state Feed-in
Released – External release signal is true and feed-in allowed
G_Min – minimal radiation threshold calculated on basis of the collector curve
The criteria for Stagnation and Frost protection are discussed in the corresponding section.

Tab. 2: Description of the substates for the state Feed-in and controller activity (○ – inactive, ● - active)

State	Description	C1	C21	C22
Standby	Default State with no activity of the plant (night, cloudy day, winter day)	○	○	○
HeatUpSTS	When high temperatures are detected in the collector field, Pu_{STS} is activated and the hot fluid is moved into the network feed-in substation.	●	○	○
HeatUpDH	When the hot plug reaches the heat exchanger, the district heating side of the network feed-in substation is heated up by opening the bypass valve Va1 and starting the feed-in pump $Pu_{DH,F}$.	●	○	○
PrepareGetIntoNet	The bypass valve Va1 is closed.	●	○	○
GetIntoNet	The pump speed $Pu_{DH,F}$ rises until a volume flow $\dot{V}_{DH}$ is detected.	●	○	●
ContinuousFeed-In	Hot water heated by the collector field is fed into the district heating network	●	●	●

3.3 Measurement results

The exemplary measurement results of the state *Feed-in* (see Fig. 4) start at 8:00 of 22th of June and end at 18:00 with an average radiation of 530 W m^{-2} and an average ambient temperature of 31 °C.

The plant is operated according to the state machine described above with the substates from Tab. 2. In the morning, the system starts in *Standby* until $T_{CF,SL}$ or $T_{CF,RL}$ exceeds 115 °C. The collector field return line temperature $T_{RL,CF}$ is remarkable higher than the collector field supply line temperature mainly due to shading of C6. From 9:20 to 10:00 the active state falls back to *Standby*. The fallback is triggered by the low solar thermal supply line temperature $T_{SL,CF}$ < 90 °C criterion. This undesired behavior sometimes happens due to mentioned collector temperature variation during the heat up and is a specialty of the collector field design of the pilot plant. After reaching the state *HeatUpSTS* again the hot medium is transported to the heat exchanger and the district heating side gets heated up. During the *Continuous Feed-in* from 11:20 to 17:10 three different disturbances occur, which are well compensated. $T_{SL,DH}$ very accurately reaches its dynamic setpoint:

- 12:00, 15:50 – Peaks in the pressure difference Δp_{DH} are compensated by the pump speed adaption of the controller C22.
- 13:30 - The rising of the return line temperature $T_{RL,DH}$ by 10 K is compensated with a higher volume flow $\dot{V}_{DH}$ by the controller C21.
- 14:30 – The radiation starts to drop caused by clouds. The solar volume flow $\dot{V}_{STS}$ is reduced by the controller C1. The high thermal capacity of the collector and the medium as well reduces the sensitivity to radiation disturbances.

The continuous volatility of the district heating return line temperature $T_{RL,DH}$ is caused by the periodic opening and closing of the control valve of a district heating substation located in the long stub pipe to the district heating network.

In the evening the feed-in temperature $T_{SL,DH}$ falls below 95 °C and the feed-in is stopped by falling back to *Standby*. During the day 82 kWh solar thermal energy where fed into the district heating network mainly at the desired feed-in temperature of 110 °C. The current amount of heat fed into the network from January to September 2017 – without final optimization of the state machine and controller – is 8.556 kWh.

a) ambient, b) solar system, c) district heating side

4. State Active Frost Protection

4.1 Controller and State Machine

The frost protection has to prevent all parts of the installation from cooling down to a temperature near the melting point of the solar liquid. To achieve this, a lower limit for the medium temperature in the solar system of 5 °C is defined. If any of the temperature criteria goes below this threshold, the state *Frost Protection* is activated. This state is defined as a global and is checked in every iteration.

If activated, heating water from the district heating return line flows through the district heating side of the station and back to the return line via the frost protection branch with the heat meter. The separate pump $Pu_{DH,FP}$ (see Fig. 1), which is installed in parallel to the feed-in pump $Pu_{DH,F}$, is used for this issue. The frost protection stops and returns to the *Standby* state, when all observed sensors exceed the upper threshold value of 10 °C and a minimum runtime is reached.

The tested variants concerning the details of the state *Frost Protection* made during the winter season 2016/2017 are shown in Tab. 3. First tests were done with the activation of the pumps when any of the collector field temperatures falls below the lower limit. These temperatures are reported by sensors installed in the piping of the supply and return line ($T_{SL,CF}$ $T_{RL,CF}$) and sensors in the connection pipes of the collector field (T_{HP}, $T_{Pipe,CF}$). The pumps are stopped if all measured temperatures go above the upper threshold. It has been shown, that a minimum runtime of 13 min is necessary to assure at least one turn of the fluid through the solar thermal system. Furthermore detailed evaluations using the DTS showed that under some conditions the collectors cool down faster than the piping of the collector field (see Rosemann, et. al., 2017b). Therefore two collector sensors CS (T_{C1}, T_{C4}) had been included in the scanning routine to detect low medium temperature within the collectors.

Tab. 3: Tested criteria for the de-/activation of the state Frost protection (○ – on, ● - off, | - "or", & - "and")

Name	Frost protection	Criteria	Pump activity	
			Pu_{STS}	$Pu_{DH,FP}$
5 °C	Enter	$(T_{SL,CF} \mid T_{RL,CF} \mid T_{Pipe,CF} \mid T_{HP}) < 5$ °C	●	●
	Exit	$(T_{SL,CF}$ & $T_{RL,CF}$ & $T_{Pipe,CF}$ & $T_{HP}) > 10$ °C	○	○

4.2 Measurement results

In Fig. 5 the measurement data for the operation of the frost protection using the latest level of development are shown (5°C. 13min, CS). The measurement period starts at midday of the 8th of February and ends at midday the day after. The average ambient temperature was -2.7 °C, at minimum -4.7 °C and the sky was clouded. The upper chart illustrates temperature profiles gained from the sensors of the solar thermal system and the collector field. The lower chart contains the temperature values on the district heating side.

The temperatures in the collector field increase in the afternoon due to solar gains and are dropping constantly afterwards. The solar gains only effect the sensors located directly next to the collectors. The temperature in the 25 m long connection pipe between C1 and C2 $T_{Pipe,CF}$ is not raised. At 19:50 $T_{Pipe,CF}$ triggers the first frost protection period (#1). All other frost protection periods (#2 to #4) are triggered by the collector sensor T_{C4}.

The solar pump operates at its maximum speed ($\dot{V}_{STS}$) when the state *Frost Protection* is active. The volume flow on the district heating side $\dot{V}_{DH}$ is controlled in order to reach a supply line temperature of 20 °C in the

solar circuit. The temperatures on the district heating side $T_{RL,DH}$ and $T_{SL,DH}$ are very low, almost at room temperature.

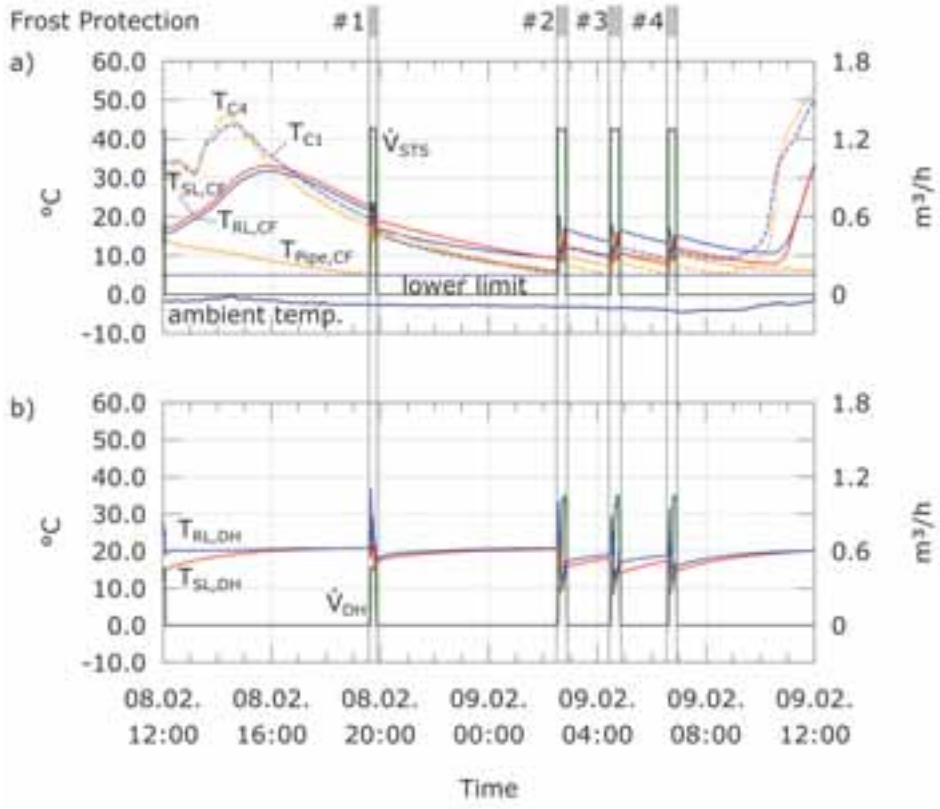

Fig. 5: Measurement data for state Frost Protection, a) solar system, b) district heating side

The solar thermal plant is connected to the district heating network via a long stub pipe. In the presented time period the connected consumers have no heat demand and the return line cools down. The frost protection can be guaranteed anyway, because it's little heat demand and the big transfer surface of the heat exchanger. Overall a heat demand for the frost protection of 4 kWh was measured at that day.

Fig. 6 shows the daily heat demand for the frost protection over the daily ambient temperature for the whole winter season. Days with a relatively high irradiation (> 1,2 kWh/m² in collector plane) are colored red, others blue. As expected the heat demand for frost protection increases with decreasing ambient temperatures. This demand is clearly reduced at days with high solar gains. The frost protection starts at daily average ambient temperatures of about 3 to 5 °C. The heat demand can go up to 14 kWh per day at very cold days with daily average ambient temperatures under -5 °C.

For the optimized and save variant of the state *Frost Protection* (✖ 5 °C, 13min, CS) only 9 days with a heat demand are available. The heat demand added up to 273 kWh for the whole winter season, which is about 2 – 3% of the annual heat output fed into the district heating system. This is in the range of known plants with active frost protection.

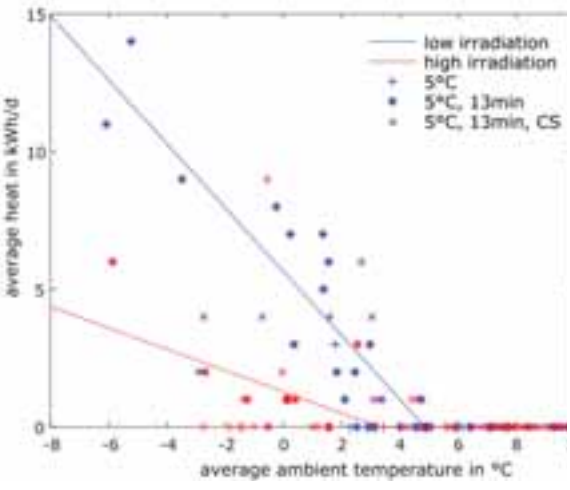

Fig. 6: Statistical evaluation of the frost protection season in winter 2016/17, daily average, low irradiation < 1,2 kWh/m² in collector plane per day ≤ high irradiation

5. State Stagnation

5.1 Controller and State Machine

The operation of a solar thermal system can stop during the day even though there is a solar irradiation. This can occur because of a case of damage, a plant maintenance or the operator of the district heating network withdraws the release signal. The stagnation concept has to ensure an intrinsic safety of the installation to handle this issue. Stagnation is detected by the state machine observing the collector field supply line temperature $T_{SL,CF}$. If it exceeds the limit of 138 °C for more than 5 min or if it exceeds 140 °C the state *Stagnation* is activated. This mainly stops the solar circulation pump. No other switching operation is necessary. The stagnation cooler should limit the produced steam volume and the compressor pressure maintenance should take this volume and keep the pressure in the tolerated range.

The state *Stagnation* is left when $T_{SL,CF}$ falls below 120 °C for more than 5 min or under 110 °C. The *Stagnation* state is implemented as global state.

5.2 Measurement results

Fig. 7 shows a test of the state *Stagnation* at the 5th of September 2017. It was a warm (up to 25 °C) and sunny day with some clouds during midday (maximum 1000W/m² in collector surface). Subfigure a) shows ambient conditions, Subfigure b) pressures at the lowest and highest point in the system (p_{LP}, p_{HP}) and the filling level of the expansion vessel (V_{PM}). Subfigure c) includes temperatures of the collector field (where T_{C6} is measured with the DTS), the calculated boiling temperature under the conditions at the highest point and the volume flow in the solar thermal system $\dot{V}_{STS}$. Subfigure d) is a carpet plot of the DTS with the time on the x-axis and the position in the collector field on the y-axis. The temperature is color coded (dark-blue means cold, light-blue means feed-in temperature, green means boiling temperature, red means superheated steam).

In the morning the system starts in *Standby* until one temperature of the collector field exceeds 115 °C. From 10:00 to 10:50 the solar and afterward the district heating side is heated up followed by the state *Feed-In*. At 12:00 the release signal is withdrawn manually and the system changes to *Standby*. At about 13:00 the state machine recognizes the state *Stagnation*. Using the DTS, which can measure the temperature not only at discrete locations, the boiling temperature is already reached at 12:30 in C5 and C6. The filling level sensor V_{PM} also recognizes a fast increase from 14 to 28% at this point in time, which means that first steam is produced here. Solar liquid displaced by the spreading steam bubble can only flow in the direction of the supply line into the pressure maintenance due to the plant configuration.

The equalizing of the pressure values at the highest p_{HP} and lowest point p_{LP} in the system between 12:30 and 13:00 is very interesting. This results from the falling water level when the steam fills the supply line and finally reaches the stagnation cooler at the lowest point. The pressure maintenance keeps the pressure level at the lowest point constant and thus increases the pressure at the top of the system p_{HP}. This behavior can reduce the dynamic of the beginning stagnation because the boiling temperature is slightly increased.

According to subfigure d) at about 13:00 the boiling point is reached in all collectors and all connection pipes between C2 and C6. When C1 is filled with steam a steam front fills about 8 m of the connection pipe between C1 and C2. The cool water in the connection pipe is pushed in C2 and C3 and temporary causes a condensation here. When the steady state is reached in C1 the steam front in the connection pipe condenses again and sucks in steam from C2 into the connection pipe. At first in C1 the steam is superheating, because here are the lowest dynamics. Shortly before 15:00 the superheating also occurs in C5 and C6 and at 16:00 in C4. In C2 and C3 there is boiling liquid for the whole measurement day.

At 16:30 the maximum filling level of the expansion vessel is reached with 65%. The stagnation cooler can safely limit the produced volume of steam. The solar irradiation is decreasing in the evening hours. Starting from 17:30 the steam front is declining, which makes the pressure at the highest point p_{HP} decrease again. At 18:15 subcooled liquid reaches the collector field and the steam condenses very fast and empties the expansion vessel. This causes a short and small underrun of the allowed pressure level p_{LP}. The state *Stagnation* is left.

The presented stagnation test (and several others) shows that the *Stagnation* state can be handled safely. Produced steam is condensed in the stagnation cooler. The compressor pressure maintenance can take all of the produced steam volume and can mostly keep the pressure in the desired range.

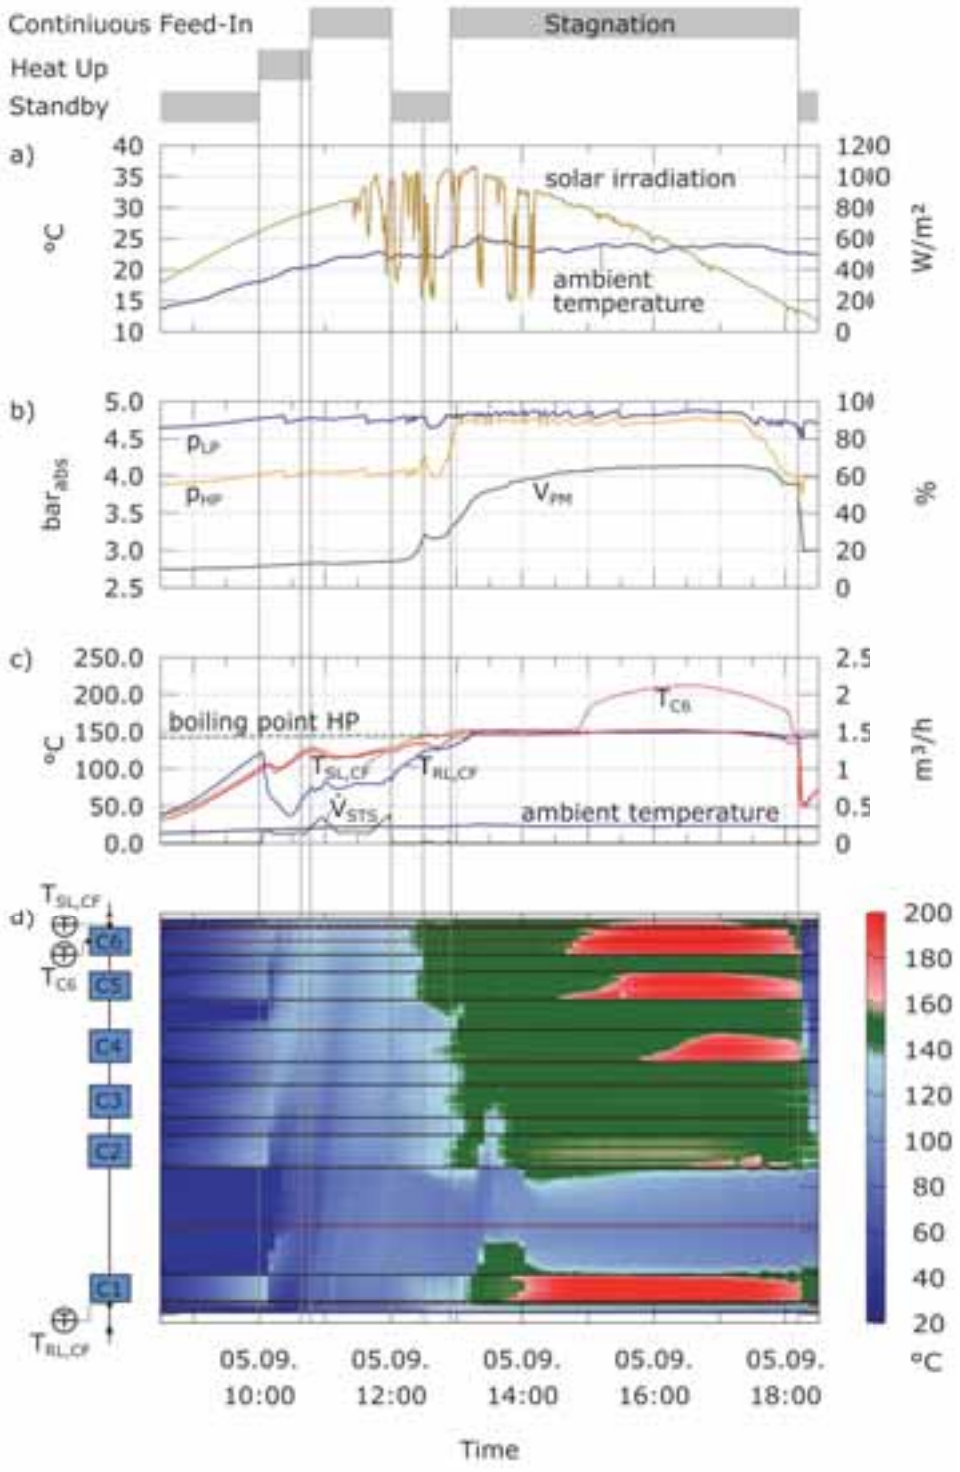

Fig. 7: Measurement data for stagnation, a) ambient, b) pressure maintenance, c) solar system, d) DTS of the collector field

6. Conclusions/Prospects

The planning of the pilot plant, the realization and the operating experience of almost one year have already provided valuable information which can be used for standardization of decentralized feed-in substations. There is a need for clarification with the district heating companies regarding the control accuracy of the feed-in temperatures. A high control accuracy of the feed-in temperature always is reached at the expense of a higher variation of the feed-in volume flow and vice versa. For solar thermal systems, a higher temperature tolerance especially in the morning during heat up or during phases of clouds would ease the general operation. Especially for district heating systems with a crucial solar fraction a high variation of the feed-in volume flow can cause hydraulic problems and interference.

The use of water as solar liquid is feasible with an active frost protection in the winter season. It is necessary to take the different cooling behavior of the collectors and the piping into consideration. A well designed separate stagnation cooler combined with a small additional auxiliary vessel can safely limit the steam spread and protect the membrane of the expansion vessel. This combination can reduce the design volume of the expansion vessel thus reduce investment costs.

Solar thermal gain prognoses will be possible after the validation of a simulation model for the decentralized solar thermal feed-in substations. It is intended to make simulations studies regarding the generalization of the current control concept (state machine) and a model predictive control concept. The commissioning of a combined supply and feed-in substation connected to a low temperature district heating network in Berlin Adlershof[1] is in progress. This will extent the monitoring portfolio of the research project.

Abstract

The integration of large and very large solar thermal plants in district heating (DH) networks gained increasing attention in recent years. However, the integration poses some challenges, especially for large shares of solar heat. This contribution gives an overview of the approach chosen within Subtask A of the IEA SHC Task 55 for assessing the impact of high shares solar thermal energy on the overall district heating and cooling network and different integration aspects in order to maximize the share of solar thermal energy. This includes:

- Collection and analyses of case studies for assessing the technical requirements of large shares
- Economic analyses of overall DHC networks, their supply strategies, transition strategies, heat demand and energy price scenarios
- Analyses of DHC network hydraulics, evaluation of hybrid technologies and possible supply points for large solar thermal installations
- Overall DHC network control strategies and other measures for increasing solar thermal fractions

This contribution describes the used approach and selected preliminary results

Keywords: solar district heating; case studies; integration aspects; transition strategies; network performance; hydraulics; control strategies; return temperature reduction.

1. Introduction

In recent years, megawatt-scale solar thermal (ST) supply to district heating (DH) or district heating & cooling (DHC) systems have gained increasing attention. This alternative energy is available almost everywhere (unlike e.g. deep geothermal energy or industrial waste heat) and thus it can contribute to satisfy the increasing energy demands of districts and cities. Further on, the use of solar thermal supported DHC networks has benefits on an environmental (reduced emissions and air pollution) and systemic level (e.g. DHC infrastructure and local economy). It can make use of synergies in the urban context (suitable integration into urban environment) and can increase energy supply security (reduced fuel imports, diversification of the energy mix).

A breakdown of fuel use in DHC systems worldwide shows that 43.2% are fueled by natural gas, 43% are based on coal and its products, followed by oil (4.3%), biofuel and waste (6.5%), or nuclear energy (0.2%). Solar based energy supply accounts for far less than 0.01% globally. Still, the share of energy based on renewable sources has been growing (IRENA, 2017). The presence of solar thermal supported DHC networks is highly diverse across countries. E.g. Denmark is well known for its integration of large solar thermal plants into local DH networks. Other countries, such as Austria, are about to implement even bigger solar thermal district heating systems.

In a simulation study[1] for Austria, Denmark, Germany and Italy, a technical potential between 3% and 12% solar share in 2050 has been estimated (*solar share = heat supplied by solar thermal collectors / overall heat supply to*

[1] http://www.sunwindenergy.com/solar-thermal/solar-thermals-role-2050-energy-mix

doi:10.18086/swc.2017.06.12 Available at http://proceedings.ises.org

the end customers). However, the integration of large solar thermal systems into existing and new DH networks faces several challenges, especially the high network temperatures and the seasonal mismatch between supply and demand, e.g. (BDEW 2017). This is especially relevant as soon as the solar share reaches a level, where the operation of the network and the other supply units are influenced significantly.

The solar heating and cooling (SHC) technology cooperation programm (TCP) of the international energy agency (IEA) was established in 1977 to promote the use of all aspects of solar thermal energy by international collaborative effort of experts from various countries[1]. Its primary activity is to develop research projects (Tasks) to study various aspects of solar heating and cooling. Task 55 of the SHC TCP provides a platform for practitioners and scientists to elaborate the benefits and challenges of solar district heating (SDH) and solar district cooling (SDC) systems[2]. Hence, SHC Task 55 elaborates options and measures to realize sophisticated SDH and SDC plants.

2. Methodology

The activities in IEA SHC Task 55 are funded through a task-sharing approach, where each participant contributes resources in-kind (for example personnel or materials)[3]. The task-sharing approach allows to connect existing national and international projects via the international platform and thus benefit from international experience and exchange. More than 25 international experts share their expertise on SDH and SDC systems, requirements and integrational challenges, existing district energy systems face when integrating large amounts of solar thermal energies. Task 55 is separated into the following 4 Subtasks: **A**: Network Analyses and Integration, **B**: Components Testing, System Monitoring and Quality Assurance, **C**: Design of the Solar Thermal System and of Hybrid Components and **D**: Promotion and dissemination of SDH/SDC and hybrid technologies in new markets.

This contribution describes the approach and selected preliminary results within Subtask A. It focusses on the assessment of the impact of solar thermal technologies on the overall district heating and cooling network and integration aspects in order to analyze barriers and opportunities for maximizing the share of solar thermal energy.

Subtask A is separated as follows:

1. Assessment of technical requirements of existing and newly integrated large scale Solar DHC networks. Aim is to understand the boundary conditions and parameters (technical, economical etc.) enabling high shares of solar thermal supply to DHC networks.
2. Economic analyses of overall DHC networks, their supply strategies, transition strategies, heat demand and energy price scenarios. Aim is to understand possible pathways from zero (or very little) solar shares to high or very high shares (e.g. 20-70%). Here, especially economic parameters should be analyzed.
3. Analyses of DHC network hydraulics, evaluation of hybrid technologies and possible supply points for large solar thermal installations. This part focusses on technical aspects of the integration, building upon existing analyses and case studies on solar thermal integration measures.
4. Assessment of overall DHC network control strategies and other measures that can support the integration of solar thermal energy and thus increase the solar thermal share.

Due to its interdisciplinary scope, activities in Subtask A will be performed in collaboration with other SHC Tasks (e.g. Task 52 on "Solar Heat and Energy Economics in Urban Environments"[4]) and the IEA TCPs on District Heating and Cooling (DHC) and Combined Heat and Power (CHP)[5]. For the later, one main cooperation will be established to the new Annex TS2 on "Implementation of Low Temperature District Heating Systems"[6].

3. Selected preliminary results

The runtime of Task 55 is from September 2016 to End August 2020. During the first year, the work in Subtask A focuses mainly on the set-up of the overall structure including a detailed work plan as well as analyzing and consolidating the international activities and projects from the Task 55 participants. Within this contribution, some selected preliminary results can be presented.

3.1. Assessment of technical requirements of existing and newly integrated large scale SDH/SDC – collection and analyses of case studies

Initially, best practice examples and case studies of existing, newly integrated and planned SDH and SDC systems with large (>5%) solar fractions (typically of > 0,5MWth up to GWth) will be collected. The case studies are collected via supporting projects from the IEA SHC Task 55 partners as well as through a dedicated internet research. A template for the data collection was set up with focus on:

- temperature and pressure ranges of both networks and solar systems
- solar thermal share
- storage size
- efficiency of the solar systems
- economic parameters (which will be used in the section 3.2)
- demand structure and possible additional summer demand (e.g. from adsorption chillers) .

Analyzing and comparing the existing case studies, potentials, challenges and barriers for the integration of solar thermal systems will be analyzed. The following aspects should be handled:

- What overall supply mix is the most economic/ ecologic for covering the heat demand in a given network?
- How to transform the DH network towards a maximum share of ST (and other low carbon sources?)
- What is the impact of different boundary conditions (energy prices, demand development …)?
- Evaluation of the system`s performance (e.g. Primary energy consumption and Socio-economic benefits)

3.2 Economic analyses of overall DHC networks, their supply strategies, transition strategies, heat demand and energy price scenarios

Based on the results of 3.1 and other case studies, possible transition strategies supporting a maximum share of solar thermal supply will be derived.

One very prominent example is the transformation strategy developed for the city of Graz (Austria). Fig. 1, left illustrates that current energy generation for district heating (DH) in Graz, Austria, is primarily based on waste heat from fossil-fired combined heat and power (CHP) plants. Due to low prices on the European electricity market, the operation of the CHP plants became increasingly uneconomic. Hence, the operator of the main CHP plant in Graz recently announced its closure in 2020. As a result, almost 80% of the overall heat production in the Graz DH network has to be replaced by new energy sources.

For developing future supply options, the city of Graz initiated a wide stakeholder process (Götzhaber et al 2017). This process resulted in a bunch of measures including the project “BIG Solar Graz” which is supposed to have a share of about 20% on the overall DH supply in Graz – see Fig. 1 right.

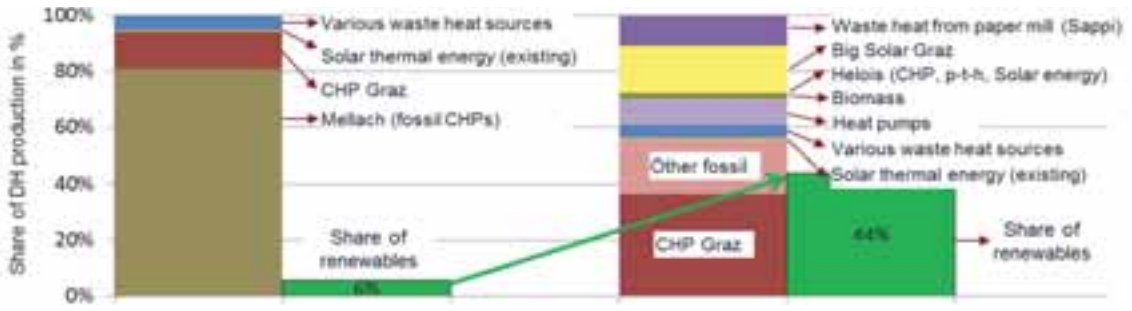

Fig. 1: Transformation strategies, example: Graz, left: current situation of the DH network in Graz, right: possible future supply mix (Prutsch 2017, translated, p-t-h = power-to-heat)

Current energy used for heating and domestic hot water in residential and service buildings in Graz is estimated at 2,400 gigawatt hours per year (GWh/a). In total, 1,100 GWh/a (2013) are provided by DH. While Graz receives 935 GWh per year, corresponding to 39% of the cities heat demand, the remaining 165 GWh/a are distributed beneath the southern communities around Graz, which are obtaining heat from DH mainly in winter. It is planned to further increase the share of DH up to 56% until 2030. Operating temperatures vary seasonally. The system is operated with flow temperatures up to 120°C in winter and up to 75°C in summer. The return flow temperature is on average 60°C. The DH network is operating all seasons throughout the year in Graz, whereas the southern communities are not supplied in summer.

The concept to integrate high solar thermal fractions into the DH network named "BIG Solar" aimed to investigate a maximum solar fraction applicable (e.g. (Poier 2017)). It is limited to the basic condition of having a competitive heat price compared to other sources of heat generation, such as from gas boilers for DH in Graz. Therefore, the size and capacities of key components, namely the collector field, the pit storage, and the absorption heat pumps (AHPs) were simulated in a certain range. Simulations aimed at identifying a system optimum for dimensioning each component and ultimately for the whole system.

First, for estimating the overall potential of the concept the heat load profile of DH in Graz was divided into two shares. A low temperature share for the basic heat load, provided either from solar and the storage directly and from the storage via the AHPs indirectly and a high temperature share, which is mainly for peak load especially in winter, provided by high temperature sources such as gas or biomass boilers. According to the calculation, the BIG solar share may be roughly at 55% of DH in Graz with current boundary conditions. Moreover, by taking into account that only one part of the energy is supplied by solar and the other part is supplied by the driving energy for the thermal AHPs from an auxiliary heating source, the pure solar output would be 33%. Therefore, detailed investigations of the concept were performed up to a solar fraction of 30%. TRNSYS, the transient system simulation software tool was applied to run multiple up to a maximum solar fraction of 30% in order to identify the technical and economic optimum. A series of simulations for collector field sizes between 20,000 m² up to 1 Million m², pit storage sizes between 100,000 m³ up to 2 Million m³ and 3 different sizes of AHPs (0, 50 and 100 MW heat output) were performed and evaluated. The multiple simulations with different parameter resulted in a techno-economic optimum of 450,000 m² collector field area, a seasonal heat storage capacity of 1,800,000 m³ and AHPs with a total heat capacity of 100 MW for the DH network of the city of Graz.

The use of AHPs is a key element in the system. On the one hand, AHPs are used to raise the temperature from the seasonal storage, when the storage is already partly emptied and temperature is lower than the minimum necessary 80 to 90°C for DH. On the other hand, AHPs accelerate the cooling down process of the seasonal pit storage, which means higher collector-efficiency at lower temperatures and therefore they lead to an essential yield improvement of the specific net solar heat production. The solar thermal concept also foresees an auxiliary heating component, which serves to power the generator of the AHPs and raises the temperature from the BIG Solar system up to the required 120°C for DH in winter.

Technical limitations such as the maximum capacity of the DH transport line, current heat and temperature loads, or future loads of waste heat from industries, were taken into account. Furthermore, a comprehensive cost evaluation was performed by using capital budgeting. The most important economic key performance indicators (KPIs) such as net present value (NPV), internal rate of return (IRR), discounted payback period (DPB) and levelized cost of energy (LCOE) were calculated and evaluated for different financing scenarios.

To sum up, simulations show that the BIG Solar concept is technically and economically feasible. The economic analysis shows that a heat price is comparable to other heating sources for DH in Graz. Although such a system has high upfront investment costs, the payback-time is moderate and economically reasonable, even in the light of neglected environmental benefits. Moreover, the project has flexible parameters. Given the boundary conditions in Graz such as land availability, the size of the solar thermal system can vary between 150,000 and 650,000 m² respecting the adaptation of sizes of the pit storage and the AHPs by feasible and economic sound price ranges (Reiter, Poier, et al. 2017).

The study on solar thermal large-scale installations integrated into the DH network of the city of Graz was one of the first analyses undertaken. Next to the study, a range of analyses named ´BSX-BigSolarX´ have been performed. Results indicated flexible parameters and techno-economically feasible collector field sizes similar to parameters identified in Graz. A number of study results will be available in upcoming Task 55 expert meetings.

3.3 Analyses of DHC network hydraulics, evaluation of hybrid technologies and possible supply points for large solar thermal installations

The technical integration options of the solar thermal energy will be evaluated from a hydraulic point of view. This is including the differentiation between central and decentral supply into existing networks as well as different local hydraulic connections and supply options. Also, the related challenges in the network performance will be evaluated considering the interaction with other supply technologies. Fig. 2 shows possible supply points for solar collectors in a DH network.

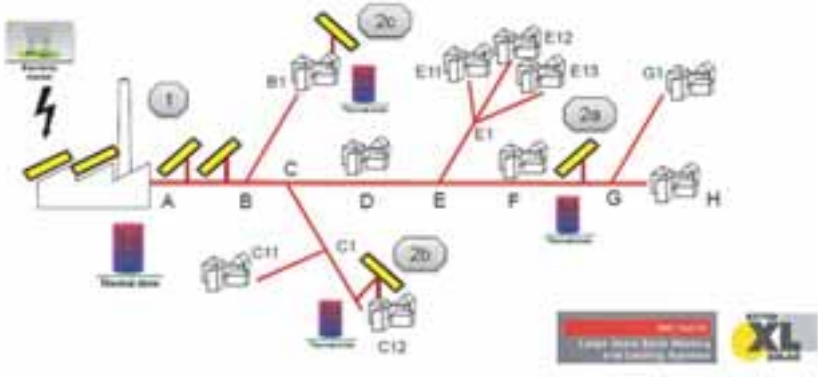

Fig. 2: Possible supply points for solar collectors in a DH network (from IEA SHC Task 45)

The *central* solar thermal systems are typically installed in combination with other heat-only or CHP plants and provided with a thermal storage unit, e.g. (SDH Guidelines 2012). As contribution to IEA SHC Task 55, the project partner PlanEnergi described the possible supply schemes of central solar systems; the most efficient solutions have to be identified in each case according to more parameters, among others:

- network supply and return temperature
- Solar system supply temperature
- Storage charge level and location of the possible storage charging/discharging points
- Boiler operational flexibility to return temperature fluctuations

The connection of *decentral* solar thermal systems is investigated in detail by (Schäfer et al. 2015), who analyzed the state of the art identifying 31 case studies in Austria, Denmark, Germany, and Sweden, and evaluated the potential and barriers for optimizing the integration. In the most cases (29), the connection is return-to-supply, in one case return-to-return, and in one case both options are possible. Contrarily to central collectors, the storage unit is not necessarily present in the decentral plants. Simulations allowed identifying the size of the existing users' connections as a possible hydraulic bottleneck limiting the solar share: in one case study, the solar collectors cannot entirely integrated into the network if the aperture exceeds 25% of the available roof area. Such issues can be faced adding new appropriate connections or/and storage units. As expected, the best solutions are highly case-sensitive.

However, while the network parameters considered in the existing studies are essentially the supply and return temperatures and the thermal load, a more complete investigation should take into account further aspects playing as well an important role in the integration of solar thermal systems. In particular, a solution-oriented approach to hydraulics cannot exclude the topology of the entire network and the (possible) supply points: the effects and the potential of the integration of decentral solar systems are in fact expected not to be the same in a linear, a ring, or a mash network, as well as they will vary according to the location of the supply point [Köfinger et al 2016]. For supply points outside the city center, hydraulic limitations might apply due to small pipe diameters in outskirt network branches. In some cases, the possibilities for bidirectional flows in line networks should be also investigated.

3.4 Overall DHC network control strategies and other measures for increasing solar thermal fractions

Another focus of Subtask A is on the assessment of measures for increasing the solar fraction. In doing so, the following measures should be considered:

Short term flexibility measures: In district heating networks, normally two distinct customer side heating load peaks occur at almost the same time of the day typically as morning and evening peaks (see Fig 3, right). This requires the intervention of additional peak boilers, usually operated with fossil fuels at high costs. Solar thermal energy has its supply peak usually directly in-between the morning and evening peak and therefore can only partly be used for covering the heating load, especially in summer times, when the solar thermal supply surpasses the heat demand. Short term flexibility measures for overcoming this mismatch include centralized and customer side storages, the utilization of the network as storage and customer side load shifting, with all measures mentioned being state-of-the art.

In (Schmidt and Basciotti 2014), those measures have been analysed and compered based on a literature review and network simulations of a typical rural heating network in Austria. The results can be summarized as follows:

- Centralized storage tanks are already used in many DH networks for various reasons (as back-up, for decoupling heat and electricity production in CHP and for peak load reductions) and represent a suitable measure for short term flexibility at a high economic viability.
- Smaller distributed storages at the customer side have a high storage capacity and the additional potential to reduce the pumping energy. However, they are very investment cost intensive and difficult to implement.
- The utilization of the network as storage is promising due to the very low investment costs and the resulting fast amortization, however, restrictions on the network side (i.e. the thermal expansion due to the additional temperature changes causes stress in the pipes and other system components) allow only limited number of temperature changes and lead to the risk of piping leakage respectively.
- Implementing load shifting for larger loads (e.g. hotels, swimming pools, shopping centre) is another conceivable measure resulting in a cost effective generation of short term flexibility. However, the practical implementation on a large scale needs further investigation.

In conclusion, for improving the supply of solar thermal energy in DH networks, the penetration of short-term flexibility measures and their cost-effectiveness need to be improved, including the development and integration of new technologies (e.g. storages, controls), services (including customer involvement) and business models. Also measures for forecasting the flexibility of the DH network need to be develop in order to be included in the overall system management.

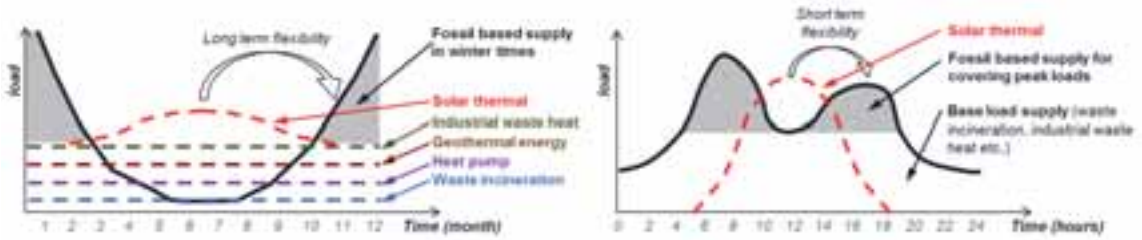

Fig. 3: Mismatch between the DH network demand and seasonal (left) and daily (right) behavior of different heat sources

Long term flexibility measures: Beside the short term mismatch, a major barrier for integrating solar energy and other renewable heat sources (such as geothermal energy and ambient heat) as well as waste heat in DH networks is their seasonal mismatch to the demand profiles (see Fig. 3, left). Here, two cases have to be differentiated: First, DH networks with very low operational costs in summer, i.e. the base load is covered by heat pumps, geothermal energy or industrial waste heat. For economic reasons, those sources should not be turned off or operated on part load for allowing solar energy to be integrated. As a consequence, every notable solar supply in summer times needs to be either cooled to the ambient or stored for transition times or winter. This applies also for a base load supply by waste incineration, having a “must-run” condition.

Second, DH networks where the base load is covered by supply units that consume fuels, e.g. fossil fired CHP plants or biomass plants. Here, the solar energy can actually safe operation costs and could be economically beneficial. However, subsidies and profits on the electricity markets from CHP plants might require those plants to run as well in summer times. Also very large shares of solar energy, i.e. exceeding 20% of the overall heat supplied to the network, need to be stored in a seasonal storage anyways, e.g. (Winterscheid et at 2017).

For this purpose, various seasonal storage systems are available nowadays, including aquifer, borehole, pit, tank storages, e.g. (SDH Guidelines 2012). However, these systems have up to now mainly been integrated in small/rural networks or building clusters in Germany, Denmark and Sweden. For increasing the long term storage capacity of larger, urban DH networks, the disadvantages of seasonal storages, especially the mismatch of the maximum storage temperature to the typical network temperature level, the high space requirements and the high investment costs need to be overcome.

One example for the integration of seasonal storages is the urban DH network Linz (Austria). Here, available industrial waste heat from a steel mill cannot be fed directly into the network during summer times since a waste incineration plant already covers the whole summer load and has a must-run condition (Pauli 2016). As a consequence, the integration of a seasonal storage was investigated for shifting the summer surplus waste heat into the transition time. Within a pre-study (Muser et al 2015) possible locations, geometries and costs of a seasonal storage for the Linz DH network have been analysed. Based on this study, two different operational scenarios for the integration of this seasonal storage have been analysed (Köfinger et al 2017): First, a "simple" operation strategy of the seasonal storage, where the storage is mainly charged in the summer and discharged in autumn/winter. Further on, a "strategic" operation strategy has been developed, allowing also short term charging/discharging and as a consequence also to enhance the operation of the existing CHP plants and reduce the use of the peak load boiler. Whereas the "simple" charging strategy the 1.8-fold storage capacity can be used, for the strategic charging strategy, this value goes up to 4.4 and therefore increases its economic feasibility. As a consequence, in a best case scenario a payback period of ~20 years could be achieved, although various uncertainties (especially electricity prices) apply. Together with high investment costs of about 100 mil. Euros, the investment risk for the storage is unacceptable high in the particular case. However, smaller DH networks with lower network temperatures and lower investment costs have already proven to be realizable.

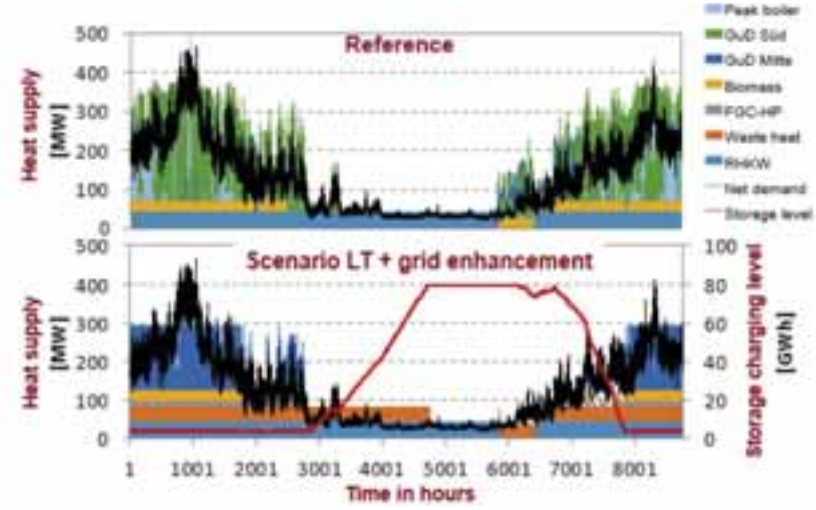

Fig. 4: Simulation based evaluation of the integration of a seasonal thermal storage in the DH network of Linz (Austria) for improved waste heat utilization, top: reference scenario without seasonal storage, bottom: integration of the seasonal storage in a low temperature scenario with enhancement of the network (Köfinger et al 2017)

Control strategies for an efficient integration of solar thermal plants into district heating networks: The operation of a district heating network incorporating different producers with at least one being a solar thermal plant and different consumers in any case goes along with several control problems to be considered.

At *first*, the scheduling (load respectively energy management) of the different producers and possibly also consumers has to be managed properly, i.e. a strategy which is able to plan ahead the use of the different components is necessary. This is especially important when slowly reacting and/or weather dependent heat

producers, such as solar thermal plants, or relevant energy storages, as it is the case in both the short and long term flexibility measures previously mentioned, have to be considered. Thus a high-level control has to decide the general mode of operation and adjust the reference values for different process variables, such as for example the required outlet temperature of the collector field. In most practical applications this high-level control is specifically adjusted to the particular heating network and bases on various standard controllers and additional expert rules. Within the last years it got increasingly popular to incorporate weather forecasts, however, with the control algorithms still basing on specific expert rules.

A very promising alternative approach is the application of a model predictive controller (MPC). MPC bases on mathematical models used to predict the future behaviour of the system for different courses of the manipulated variables. This allows to determine the optimal future course of the manipulated variables, thus in the specific case of a district heating network with different producers and consumers the optimal future operational strategy. This prediction is periodically repeated always using updated values for the state of the different components. The different approaches for MPCs for (bidirectional) heating networks mostly base on mixed-integer linear programs (MILP), since not only continuous states but also discrete states, e.g. for the activation and deactivation of specific producers, have to be considered, e.g. (Moser et al 2017). The resulting optimization problem of the MPC, formulated as mixed-integer linear program (MILP), has to be solved by appropriate MILP solvers. In order to provide the MPC with the future heat demand of the consumers or for example the future solar yield to be expected additional forecast methods have to be applied. Within the Task both control approaches, control strategies based on expert rules as and different MPC approaches, as well as forecast methods for the future heat demand or the solar yield to be expected are considered.

Second, it must be ensured that the heat produced by the different producers is properly fed into the district heating network and transported to the corresponding consumers. If there would be only one (central) heat producer in a network, this would be comparatively simple. In this case the pumps supplying the network would aim for setting the differential pressure in such a way that the supply is ensured even for the most distant consumer. However, in the general case, this is more complex, since it has to be ensured that the pumps of the individual producers do not work against each other. At first it has to be distinguished between producers which need to feed into the network immediately, since they cannot store the heat produced locally, and producers coupled with a buffer and consequently able to temporarily store the heat produced. One common approach is to use heat producers with buffer storages for maintaining the differential pressures, while the others regulate the mass flows of the feeds to ensure that their heat is properly transferred to the heating network. In detail, the finally applied approaches strongly depend on the actual heating network and there is also no systematic approach available in literature.

Third, the mode of operation of the collector field chosen by the high-level control (load respectively energy management) has to be realized by the respective low-level control at the solar collector site as efficiently as possible. Strictly speaking the outlet temperature of the collector field respectively the different sub-fields has to be controlled by adjusting the flow rate to the current radiation. This is in general done by varying the pump speed. Additionally, the individual fields are typically equipped with adjustable balancing valves in order to ensure an adequate flow distribution in the individual subfields. These valves can either be adjusted manually for nominal operation or be driven by a servomotor in order to achieve an adequate flow distribution for every operating condition and thus avoid exergy losses by mixing flows with different temperatures. The controllers applied typically are simple linear PID controllers, which in some are enhanced by a static feedforward control signal for the pump speed based on a static model for the heat output of a solar collector representing a static energy balance, where the parameters are determined in a standardized collector test (EN12975-2) and can be found in the datasheet. In research more advanced approaches can be found, e.g. (Camacho et al, 2007), but they have not reached a wide practical distribution up to now. A promising approach, also using mathematical models describing the collector field but explicitly aiming for practically manageable complexity, is presented in another article within this conference proceedings (Unterberger et al, 2017).

Measures for reducing the return temperatures: The potential for the utilization of solar thermal, but also other alternative heat sources such as industrial waste heat, geothermal energy and heat pumps, in DH networks is strongly correlated to the temperature level at which the networks are operated. Currently, many “traditional” existing DH networks are not designed for a significant share of solar thermal energy due to the relatively high network temperatures, often between 60°C (return) and 120°C (supply). Fig. 4 compares “traditional” high temperature DH networks with low temperature systems enabling higher shares of solar thermal energy.

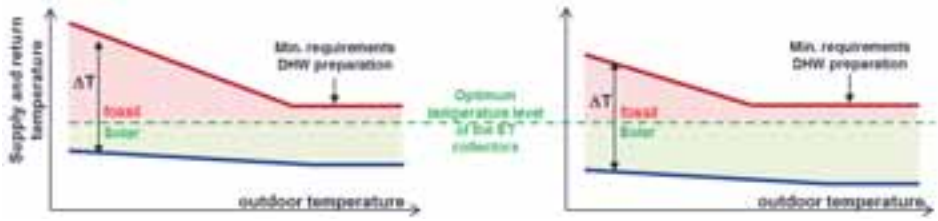

Fig. 5: Schematic description of the influence of the temperature level of the district heating network on the potential for the utilization of solar thermal energy (left: high supply and return temperatures in the DH network result in a limited potential of solar thermal energy, right: decreasing return and supply temperatures enable an increasing share of solar thermal energy)

Most of the technical measures for transforming traditional DH networks towards low temperature systems are well known, mature and in principle straightforward in their implementation. They can be distinguished in following areas:

- building side optimization such as hydraulic balancing and the correct use of thermostatic radiator valves
- Detecting and minimizing errors and faults in substations and domestic hot water preparation
- cascading (using the return flow of high temperature customers as a supply to low temperature customers)

Within Subtask A business models, existing strategies and the impact of different approaches from the participating parties as well as from literature should be analysed in detail within the Task. Here, a strong link to the currently starting IEA DHC Annex TS2 on low temperature district heating systems will be established.

4. Discussions

Based on the preliminary results, a literature review and stakeholder discussions, following analyses of the strengths, weaknesses, opportunities and threats (i.e. SWOT analyses) for the integration of solar energy into DH networks can be summarized:

Strengths: Besides being free of any emissions such as CO_2, NO_x or others (including noise), the main asset of solar thermal energy supply to DH networks is the good availability and the very low operation cost in combination with fuel independency and long term stability. Compared to other renewable sources, especially biomass, the required specific land use area is very low, e.g. (Poier 2017). The DH network temperatures in summer times are in general lower, supporting the efficiency of the collectors. Thermal driven adsorption chillers can increase the summer demand and thus absorb a possible surplus heat in summer times. The solar thermal components as well as different centralized and decentralized integration concepts are state-of-the-art and well proven in various DH networks already. Further on, producers of components for solar thermal collectors and system installers are often available regionally, resulting in high local added value.

Weaknesses: Additional to the high specific investment costs of solar thermal energy systems, the main disadvantage is the supply competition to other renewables (e.g. heat pumps, geothermal energy), waste heat (e.g. from industrial processes) and pants with must-run condition (e.g. waste incineration) in summer times. Seasonal storages for shifting the summer surplus heat to transition or winter time are available, but difficult to integrate in urban DH networks. Further on, higher network temperatures in winter times reduce the efficiency of the collectors. Also the integration of thermal driven adsorption chillers require higher network temperatures. For reaching significant solar shares, the systems require large areas that are limited and costly in an urban context. Larger and low-priced areas are likely to be far from the city center and thus additional investment costs for transport pipes and hydraulic limitations for supplying to outskirt network branches might apply.

Opportunities: For different reasons, many DH network operators are working continuously on the reduction of their network temperatures and this will increase the efficiency or solar thermal systems by trend. The utilization of large shares of other renewable or alternative heat sources (such as heat pumps, geothermal energy and waste heat) in DH networks supports the integration of seasonal storages. Finally, for accomplishing the COP21 targets, direct or indirect subsidies (e.g. CO2 taxes) for solar thermal energy are either already in place or are currently discussed in some countries.

Threats: One main threat are the long payback times of the systems, reducing the flexibility in the overall system. Further on, large and exposed collector areas might be damaged due to more frequent extreme weather events due

to the climate change, resulting in by trend lower heat energy supplied the network and higher maintenance cost. Finally, the price of the land for installing the collectors might increase, as soon as the land owner get aware of the aim of the intended land use and want to increase their own profit – especially if only limited areas are available.

5. Conclusion & outlook

Solar thermal energy is one of the few renewable heat sources, that is available almost everywhere and can bring multiple benefits to DH networks (on an environmental and systemic level) with very low operation costs and risks. However, the integration of large solar thermal systems into existing and new DH networks faces several challenges, especially the high specific investment costs, the mostly very high network temperatures and the seasonal mismatch between supply and demand.

Task 55 of the IEA Solar heating and cooling technology cooperation program provides a platform for practitioners and scientists to elaborate the benefits and challenges of solar district heating (SDH) and solar district cooling (SDC) systems. As part of Task 55, Subtask A focusses on the assessment of the impact of solar thermal technologies on the overall district heating and cooling network and integration aspects in order to analyze barriers and opportunities for maximizing the share of solar thermal energy.

During the first year, the work in Subtask A focuses mainly on the set-up of the overall structure including a detailed work plan as well as analyzing and consolidating the international activities and projects from the Task 55 participants. However, some preliminary results already show the strengths (especially small running costs), weaknesses (especially the high specific investment costs and a competition to renewable or must-run base load supply), opportunities (especially decreasing temperature levels and possible subsidies) and threats (especially long payback times) for a large scale integration of solar energy into existing and new DH networks. More results from Subtask A can be expected in the next years.

The international cooperation between IEA SHC Task 55, Subtask A and the IEA DHC TCP will lead to a more holistic understanding of integrated systems with a clear focus on achieving a high share of solar thermal supply in DH networks by following up on some best-practice examples from Denmark and the current discussions in Graz. Both TCPs show significant expertise, which in the past had mainly been focused on each system individually. In a future energy system, the different sectors have to be highly integrated to reflect developments not only in Task 55, but also in other IEA TCPs.

Finally, it should be mentioned, that the integration of solar thermal energy can trigger some significant synergies: most of the measures supporting the integration of solar thermal energy also support the integration of other renewable and alternative energy sources such as heat pumps, geothermal energy and industrial waste heat. Although being in competition to each other, especially seasonal storages are a key element for the other sources as well. Additionally, the integration of various heat sources and efficiency measures will require an overall management strategy, supporting also the integration of solar thermal energy.

Abstract

Two types of simulation software TRNSYS and Polysun are studied to check their suitability for solar district heating system planning. A reference case, a part of the Vallda Heberg district heating system is modelled in both tools and results are compared with available measured data and with each other. Models are successfully calibrated. TRNSYS and Polysun models have deviations in main key figures compared to the reference case less than 2% and less than 8% respectively. A sensitivity analysis of key parameters shows that the two tools give similar results.

Keywords: solar thermal, district heat, dynamic simulation, TRNSYS, Polysun,

1. Introduction

Approximately 10% from EU heat market is covered by district heating (Dalenbäck, 2011), thus giving solar district heating a good potential to also be implemented in existing networks.

Furthermore, there are examples where the employment of solar thermal technology in combination with biomass combustion can supply 100% renewable district heating (Faninger, 2000). However, there are a number of obstacles for the wide spread implementation of solar district heating (SDH) systems, namely: high investment costs, technological difficulties and lack of engineering experience (Dalenbäck, 2011).

Considering complexity of the systems, usage of new technologies and the lack of engineering experience, computer modeling of the solar district heating systems is a key to successful system implementation. It is achieved through market available computer simulation software or self-developed tools. Several studies have been made employing such tools, of which the scope and purpose vary.

Considering the wide implementation of simulation software for the design and the optimization of solar district heating systems, it is important to investigate how applicable available tools are. In the present study two different tools are compared TRNSYS 17 (Klein, 2012), originally developed at SEL, and Polysun (Rezaei et al., 2009), developed by Vela Solaris. The base case for this investigation is a part of the solar-assisted block heating system for a new building area in Vallda Heberg, Sweden.

1.1. Aims

The main aim of the study is to determine how applicable Polysun and TRNSYS are for simulation of block heating solar systems, which include advanced controlling strategies and/or complex hydraulics. In order to do this, different aspects should be considered. Available component models should be detailed and robust enough to build such system in the given boundary conditions. It should be possible to calibrate the model with the real system. Changing of the boundary conditions and sensitivity analysis of different components should lead to well-explained changes in the system model performance.

1.2. Methodology

As a base case, sub-station 1 (SS1) of the Vallda Heberg district heating system was chosen. The models, in TRNSYS 17 and Polysun, were constructed based on drawings, known properties and operational strategies of

Selection and/or peer review under responsibility of Scientific Committee
doi:10.18086/swc.2017.06.13 Available at http://proceedings.ises.org

the sub-station. The whole study is performed taking into perspective the boundary conditions, assumptions and limitations of the available data and models.

The system has been monitored to evaluate and fault-find the system. Based on data of the monitoring system and weather data of the Swedish Metrological and Hydraulic Institute (SMHI) for the monitoring period, input files have been constructed for the models in order to calibrate them using the measured energy, flows and temperatures. For the calibrated models, sensitivity analyses for key parameters were performed using Meteonorm weather data. The process and results of calibration as well as the models` reactions in sensitivity analyses were used to determine applicability, usability and limitations of the tools for the given case.

2. Description of the system

The local district heating system comprises one central heating plant (HP) for which the details are listed below in table 1 (the left part). It features a 250 kW wood pellet boiler (and an oil boiler for back-up) and four substations (SS1-4) connected to the primary culvert (PC).

Buffer storage tanks are installed in the central heating plant and in each substation. There are 108 m^2 evacuated tube solar collectors (ETC) on the heating plant and 570 m^2 flat plate roof-integrated solar collectors (FPC) in connection to the substations. Solar heat is targeted to cover 40% of the end-use of space heating and domestic hot water.

The focus of this study is SS1 with secondary distribution culvert and connected houses, of which the details are shown below in table 1 (the middle part).

Tab. 1: Details of the central heating plant (HP) and of substation 1 (SS1) at Vallda Heberg, Sweden

Heating plant (HP)		**Substation 1 (SS1)**		**Load (SS1)**	
Key characteristics	**Values**	**Key characteristics**	**Values**	**Key characteristics**	**Values**
Installed storage volume	15 m^3	Installed storage volume	15 m^3	Single family houses	19
Installed collector area	108 m^2 (ETC)	Installed collector area	142 m^2 (FPC)	Heating area per house	140 m^2
Collector Slope (β)/Azimuth(α)	70°/30°	Collector Slope (β)/Azimuth(α)	27°/30°	Heating area total	2660 m^2
PC design operating temperatures (S/R)	75°C/50° C	Load capacity solar HEX	85 kW	Specific demand heat	59 kWh/(m^2·yr)
PC pipe diameter ØPC	100 mm	Load capacity auxiliary HEX	165 kW	Specific demand electricity	34 kWh/(m^2·yr)
Load capacity solar HEX	65 kW	PC connection pipe diameter ØCP	50 mm	SC length (total)	938 m
Load capacity biomass boiler	250 kW			SC target temperature	58°C
Load capacity oil boiler (backup)	500 kW			SC pipe diameter Øsc	63 mm
Load capacity PC HEX	1000 kW				

The secondary heat distribution system between the substation and the buildings is a so called GRUDIS 2-pipe system (Zinko 2004) where hot water is circulated in plastic (PEX) pipes, similar to a standard DHW circulation

system. The pipes are located in an insulating (styrofoam) box buried in the ground, with fig. 1 showing the distribution to the houses and the placement of the sub-station as well as heat meter points.

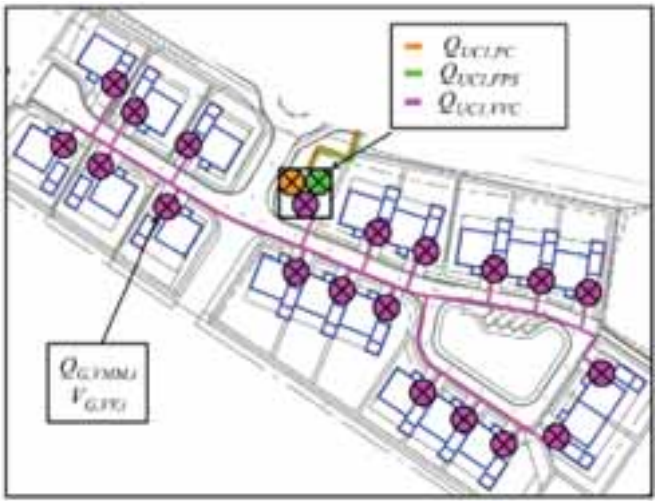

Fig. 1: Drawing of distribution network and houses connected to SS1 (Olsson and Rosander, 2014)

142 m^2 aperture area of flat plate collectors are connected to SS1. 38 m^2 on the roof of the substation, while the second field 104 m^2 located on multi-family buildings. The solar collectors deliver heat to the storage tanks via an external heat exchanger, as the collector loop fluid is a water-glycol mixture. One pump is controlled on each side of the heat exchanger by matched flow rate. The fixed solar collector flow rate is 0.38 l/min per m^2 aperture area. The pumps are controlled based on "sensors" in storage, collector outlet and heat exchanger outlet. To obtain stratification, two inlet heights to the storage are possible from the charging loop. Fig. 2 shows how the different loops are connected by heat exchangers.

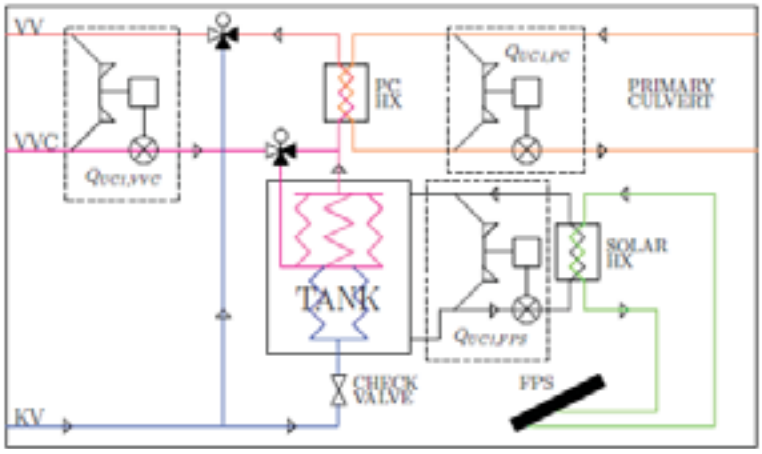

Fig. 2: Schematic drawing of SS1 with installed heat meters (Olsson and Rosander, 2014)

The circulation pump is running at constant flow. The cold water inlet of the loop is supplied through the storage to be pre-heated. If the storage temperature is high enough, the DHW circulation will pass through the storage as well. The primary culvert delivers heat to the secondary distribution loop via a heat exchanger when the solar heat of the sub-station is not sufficient to maintain 58°C outlet temperature. If the temperature after this heat exchanger is more than 60°C (due to high temperatures in the storage tank), cold water is mixed to lower the supply temperature.

The load is represented by a group of single-family houses and the DHW-circulation in the secondary culvert (SC). Details of the load are shown in table 1 (the right part).

All buildings are designed as passive houses according to the Swedish standards, i.e. well insulated buildings with air tight envelopes, and supply and exhaust ventilation with heat recovery is applied in all buildings (Jimmefors and Östberg, 2014). Roof overhang and balconies provide sun shading to reduce solar gains in the summer period.

Each house has two floors, and a total heated area of 140 m^2. The hot water circulation of the secondary culvert is connected to each individual building. The hot water is delivered directly for tapping and for heated appliances (e.g. washing machines). The circulating flow is passing through the floor heating loop in the bathroom and utility room without control (ie all year) as well as through a heat exchanger coupled via a thermostat controlled water-glycol loop that delivers heat to an air heating coil. Space heating is provided by the air heating coil to the supply air, which is pre-heated by the exhaust air using a rotating heat recovery unit.

2.1. Monitoring system

The monitoring system is logging every hour. Temperatures, flow rates and energy rates (and total quantities) are measured to evaluate the system performance of houses, distribution network and heating plant/substations. Incoming solar energy and auxiliary energy from heating central and hot water circulation losses are monitored at the substation, as shown in fig. 2. The DHW and space heating loads are measured in all houses. Temperature to and from houses are measured as well.

In 2014 the whole area of Vallda Heberg had a low heat demand, corresponding well to the design values. The measured yearly load of sub-station was 59 kWh/(m^2 living area) including circulation losses. Distribution losses are a large share of the yearly load (25 %), especially due to the low space heating demand of the buildings.

Solar fraction of SS1, SF (eq. 1), is calculated by the supplied solar (Qsolar) compared to load (Qload) as the relative saving of energy from the main heating plant:

$$SF = \frac{Q_{solar}}{Q_{load}} \qquad \text{(eq. 1)}$$

The actual solar utilization and solar fraction are larger than what is measured in the sub-station directly, due to the evacuated tubular collectors installed at the main heating plant. The specific collector performance of the flat plate collectors connected to SS1 was 297 kWh/(m^2·yr).

3. The models

The system models have been created based on known system properties and the available monitored data. Measured temperature levels and flow rates were used as a guideline when setting the controls of the model. Monitored data concerning energy consumption of the area has been used to calibrate the load parts of the model (space heating and distribution losses) and to create a load input file (domestic hot water). The monitored data for energy to the substation from heating plant and flat plate solar collectors are used to calibrate the supply parts of the models.

A hot water pattern input file has been constructed using DHWCalc (Jordan and Vajen, 2003) so that it matches the measured monthly demand data for all 19 houses of the network. The cold water inlet temperature variation during the year is based on information from the provider (8 to 16°C – January coldest) as this temperature is not measured.

Weather data of 2014 from SMHI has been collected on hourly basis as input file for the calibration process. This includes direct and global solar radiation data for horizontal surfaces for the area constructed by SMHI based on interpolation of values of other Swedish locations (SMHI, 2015).

The calibration itself has been based on monthly energy balances, due to the large uncertainties when combining short time interval interpolated weather data, limited measurement points and general assumptions.

3.1. TRNSYS and Polysun models

TRNSYS is a component based dynamic simulation tool, where the user combines component models and user defined equations and controls. The timestep used is 3 minutes. Integration and convergence tolerances are 0.001 relative.

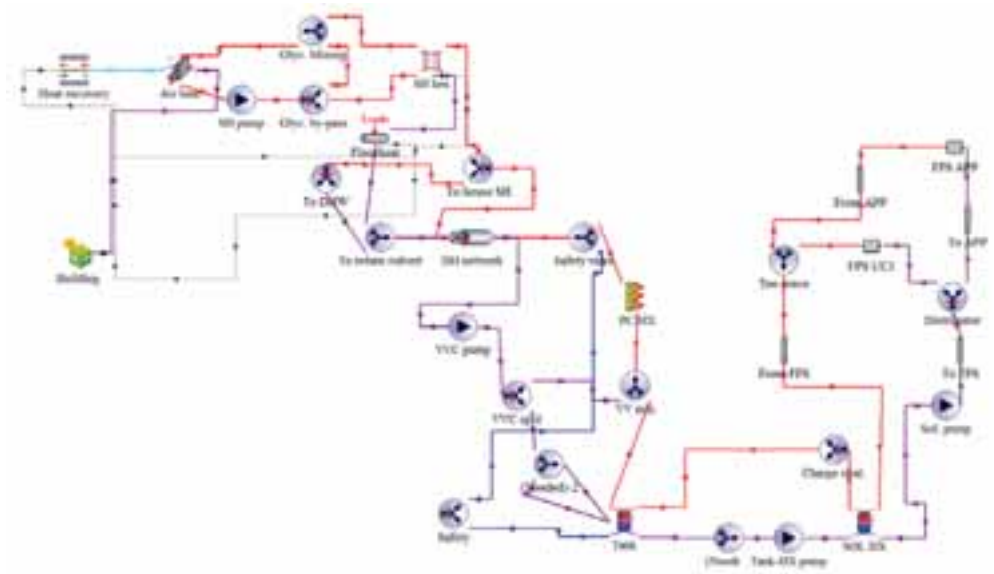

Fig. 3: System model in TRNSYS

Polysun is a dynamical simulation tool, which is used principally for design and planning of renewable energy systems. Polysun uses variable timestep. The largest timestep is chosen which satisfies convergence criteria, but not larger than 3 min and 12 min for day and night respectively.

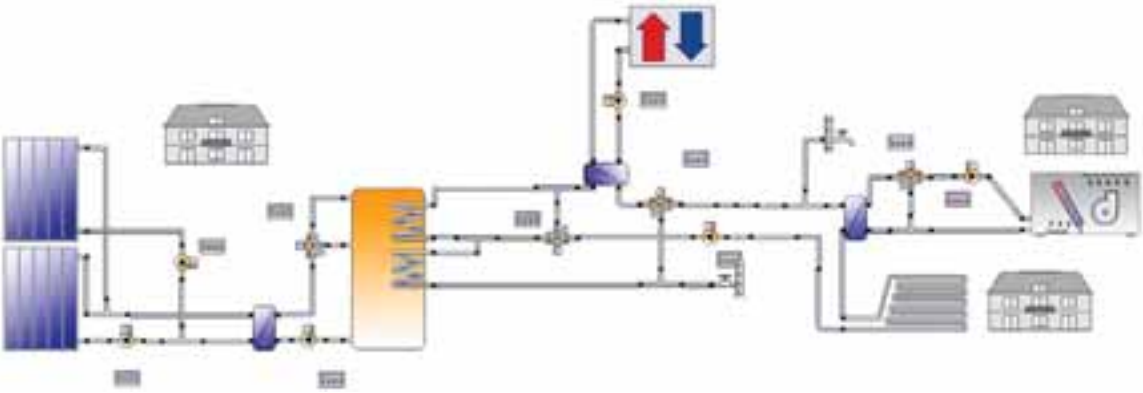

Fig. 4: System model in Polysun

The main components of SS1 are storage, heat exchangers and solar collectors. Other modelled components include pumps, valves and collector loop pipes.

The solar collectors are modelled as two flat plate collector components using the parameters for the installed collectors from Solar Keymark certificates. The pipe lengths to the two fields are included to simulate thermal capacity, time dependency and heat losses. The flow is distributed to the two fields dependent on collector area, so that the area specific flow rates are the same for both fields.

Even though the storage is cubic in reality, it is modelled as a vertical cylinder. Real inlet and outlet heights are used both for tank charge- and discharge.

In TRNSYS the distribution pipe is simulated using Type 951 buried twin pipe in the ground (Thornton 2012), comprising supply and return pipe inside one shell of insulation. In Polysun an existing pipe model was extended to simulate buried pipes. Each pipe has a separate shell. The models assume circular shape while the real twin pipe has rectangular insulation. The part of the flow which is due to DHW tapping is withdrawn from the flow at the end of the secondary culvert. The rest of the flow is for space heating with no flow bypassing the houses.

In TRNSYS one two-zone building is modelled to simulate an average of the 19 space heating loads of the 19 buildings. The flow rate to the building is thus one nineteenth of the total flow in the secondary culvert, after

DHW has been extracted. When the hot water returns to the network pipe the flow rate is multiplied by 19 again, while assuming that the return temperature is valid for the whole flow. In this way the space heating demand of the simulated building acts as average of all buildings in the network.

In TRNSYS inputs for outer area of walls in different directions and air volume of the two zones have been modelled based on drawings of the house. Windows and shading (provided by roof overhang and balcony) are accounted for. Internal gains are added to the main area (i.e. not bathroom) based on known electricity consumption (70 % is expected to be gained as heat) and the average number of inhabitants (4 seated at rest). The yearly measured average electricity consumption is 4700 kWh per house. One zone is bathroom including floor heating, and the other zone comprises all other indoor areas, which are heated by mechanical ventilation only. All of the hot water circulation initially passes through a glycol heat exchanger, then through the floor heating. The glycol loop heatsup the inlet air via a heat exchanger after it is pre-heated by ventilation heat recovery unit. There is a bypass valve in the glycol circuit that is controlled by a room thermostat, and thus varies the addition of heat to the inlet. The heat recovery efficiency is a function of the ambient air, and the unit is turned off at ambient temperatures above 16°C.

In Polysun the space heating load is modelled as two one-zone buildings. The first building model represents the living area with a fan-coil heating system. The second building model represents a bathroom and a floor heating system. There is no flow separation since the first building represents total load of living areas of all 19 buildings, the second building represents total load of bathrooms of all 19 buildings.

In Polysun the same boundary conditions for building as in TRNSYS are considered, but since one building represents 19 buildings it is scaled down. The actual size is chosen during model calibration. For the living room internal gains are increased. These gains represent gains from bathroom, since there is no connection between the living area and the bathroom in the model.

3.2. Assumptions / simplifications in the models

Pressure drops are generally neglected, as pressure is not the driving force of flows in the models. This causes issues when controlling valves, as the flows rates are controlled upstream. Thus hydronic diverting valves are controlled based on equations, which are working ideally. Pipes and valves without flow during normal operation have been neglected. The primary culvert heat exchanger is modelled to give constant outlet temperature (perfect flow control on primary side).

In TRNSYS external heat exchangers are modelled without thermal capacity and heat loss coefficients. Heat losses of the solar heat exchanger lumped together with the return pipe of the solar loop. The UA value is constant for the solar heat exchanger. Pipes in solar loop have constant loss coefficient.

In Polysun, the main simplification is the use of two one-zone building models instead of one two-zone building model. So heat gains from bathroom to living area are not modelled. Heat exchangers are modeled without thermal capacity. Two independent buried pipes are used to model secondary culvert, therefore pipe thermal interaction is not considered.

Only modelling one house and one distribution pipe is a big simplification, and it is only possible in this study because the dynamic effects of the space heating elements are not the focus of this study.

3.3. Calibration

A few unknown properties were found by parameter identification based on comparison with monthly heat balances.

For TRNSYS model room set-point temperature of air heating, maximum heat recovery efficiency (80 %) and maximum external shading share (80 %) were estimated in this way. External shading is activated when solar radiation on the wall surface is above 200 W/m^2 until it decreases to less than 120 W/m^2. Floor heating was simulated using an active floor layer. The parameters of the floor were calibrated to reach around 200 W all year from water circulation to bath zone. Heat loss coefficient of pipe in solar loop was calibrated to monthly values of solar gains.

For Polysun model sizes of buildings which represent living area and bathroom were defined by parametric identification. Set-point temperature of air heating was also estimated in this way. Thickness of insulation of buried pipe was defined based on losses in distribution system. Thickness of insulation of pipes in solar loop was

calibrated to monthly values of solar gains.

3.4. Simulated versus measured

Fig. 5 shows how the measured loads and solar gains of the block-heating system correspond to the simulated values on a monthly basis. Solar gains correspond very well, which is partly due to the calibration process. Considering loads, simulated values correspond well with measured values for simulations performed with TRNSYS. The simulated values obtained in simulations with Polysun show minor deviations due to the application of the one-zone model, as mentioned earlier.

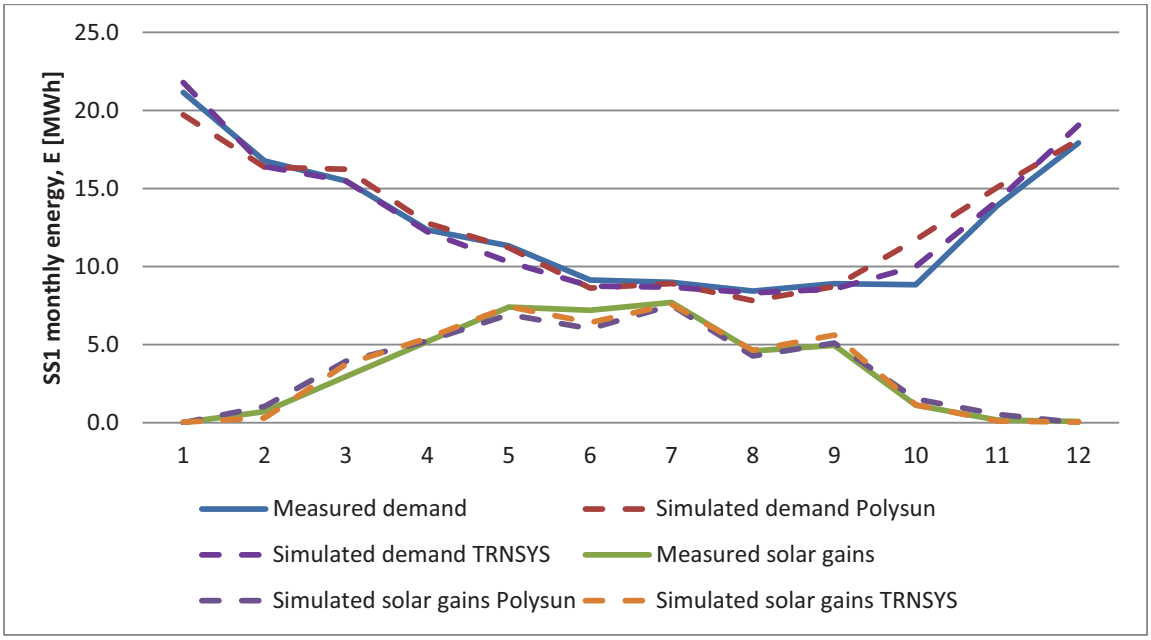

Fig. 5: Measured vs. simulated in TRNSYS and Polysun heat loads and solar heat to storage for SS1 in 2014

4. Model comparison

Table 2 and 3 below show comparison between measured and simulated values of key figures. The simulation results obtained with TRNSYS show very good agreement at production and load sides. Relative deviation on an annual basis for each key figure is lower than 1.5 %.

Polysun model has the highest deviation from measured value for space heating, which was partly compensated by calibrating distribution losses to achieve expected solar performance. Therefore, production side has very good agreement with measured data. Relative deviation on an annual basis is lower than 1.5 %.

Tab. 2: Monitored and simulated in TRNSYS yearly key figures, and the deviation between these values

Parameter	Monitored [MWh]	Simulated [MWh]	Deviation [MWh]	Deviation, %
Space Heating	71.9	72.6	0.7	1.0
DHW	45.2	44.7	-0.5	-1.2
Distribution losses	36.1	36.5	0.4	1.2
Solar to storage	42.1	42.5	0.4	0.8
Primary culvert heat	111.1	110.6	-0.5	-0.4

Tab. 3: Monitored and simulated in Polysun yearly key figures, and the deviation between these values

Parameter	Monitored [MWh]	Simulated [MWh]	Deviation [MWh]	Deviation, %
Space Heating	71.9	77.5	5.6	7.8
DHW	45.2	44.4	-0.8	-1.6
Distribution losses	36.1	33.5	-2.6	-7.3
Solar to storage	42.1	42.1	0	0
Primary culvert heat	111.1	113.1	2	1.2

5. Sensitivity analysis

For the sensitivity analysis weather data for a standard average year shall be used. For this purpose, Meteonorm data for this location is chosen. Therefore, the first study is sensitivity of the models to different weather data. Figure 6 and 7 show how simulated values for energy demand and solar gains vary according to the choice of weather data.

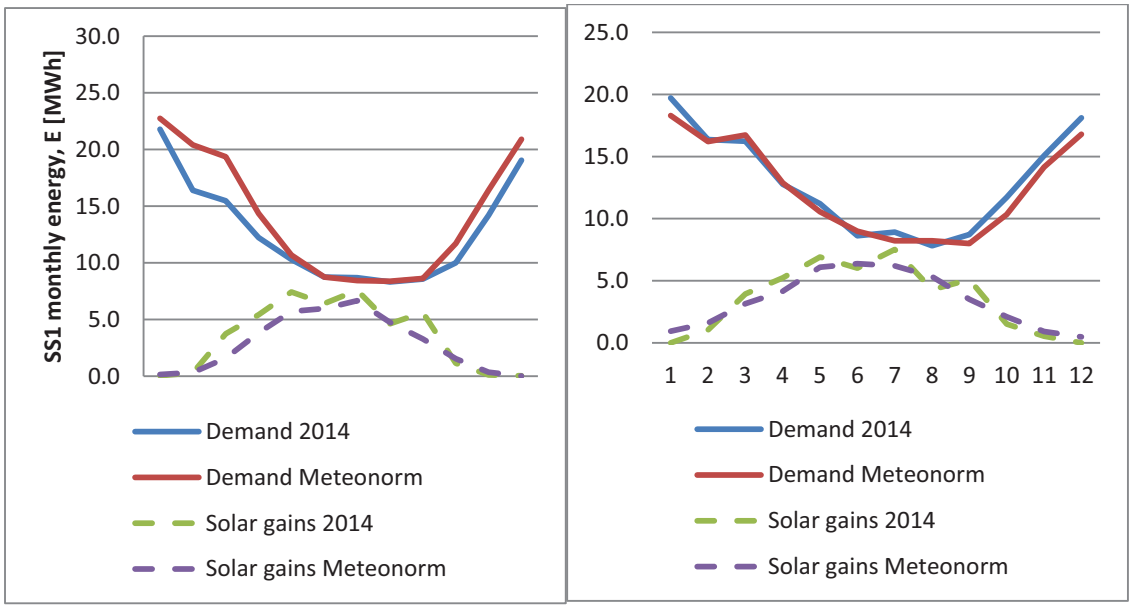

Fig. 6 and 7: Comparison of Polysun (left) and TRNSYS (right) simulated 2014 data with Meteonorm data: heat loads and solar heat to storage for SS1.

The Meteonorm average year is colder and has lower solar radiation level than 2014. It corresponds very well with TRNSYS results: annual total demand is higher and annual solar gains are lower with the weather data of the Meteonorm average year.

Polysun shows that even though shapes of the curves are similar to ones from TRNSYS, the absolute values do not reflect adequately the change of weather data. The main reason for it is an uncertainty in the building model, namely thermal performance of the one-zone model the size of which was calibrated according to thermal behavior of 19 multi-zone buildings.

Since the main focus of this study is to evaluate how Polysun can simulate the collector field and the substation as well distribution network and how close it can get to TRNSYS results, further sensitive analysis is done based on key figures normalized to the basic case simulated with the Meteonorm average year. In this way an influence of the uncertainty of the building model can be eliminated and other parts of the model can be studied.

Thus sensitivity analysis consists of two parts. The first part is a study of an influence of density of the heating network on the solar fraction of the sub-station and distribution losses in the system. The density of a distribution network is a relationship between the number of houses and the length of the distribution network. For the present

study the number of building is constant and equal to the actual number of buildings at the site. The length of the distribution network is varied from 0.5 to 2.5 times of the actual length. The study showed a good agreement between both tools, as shown in the fig. 8.

The second part of the sensitivity analysis is a study of the influence of different collector field sizes and storage tank sizes on performance of the system in terms of solar energy supplied to the system from the store. Collector field size is varied from 0.5 to 2 times of the basic case. A relative storage volume (storage volume / collector aperture area) is varied for each collector field size from 0.5 to 2 times of the basic case. In this way a matrix of 25 systems is built.

In the fig. 9 matrix results for solar energy supplied to the system from storage are shown. For all cases Polysun results are close to TRNSYS showing consistency between tools.

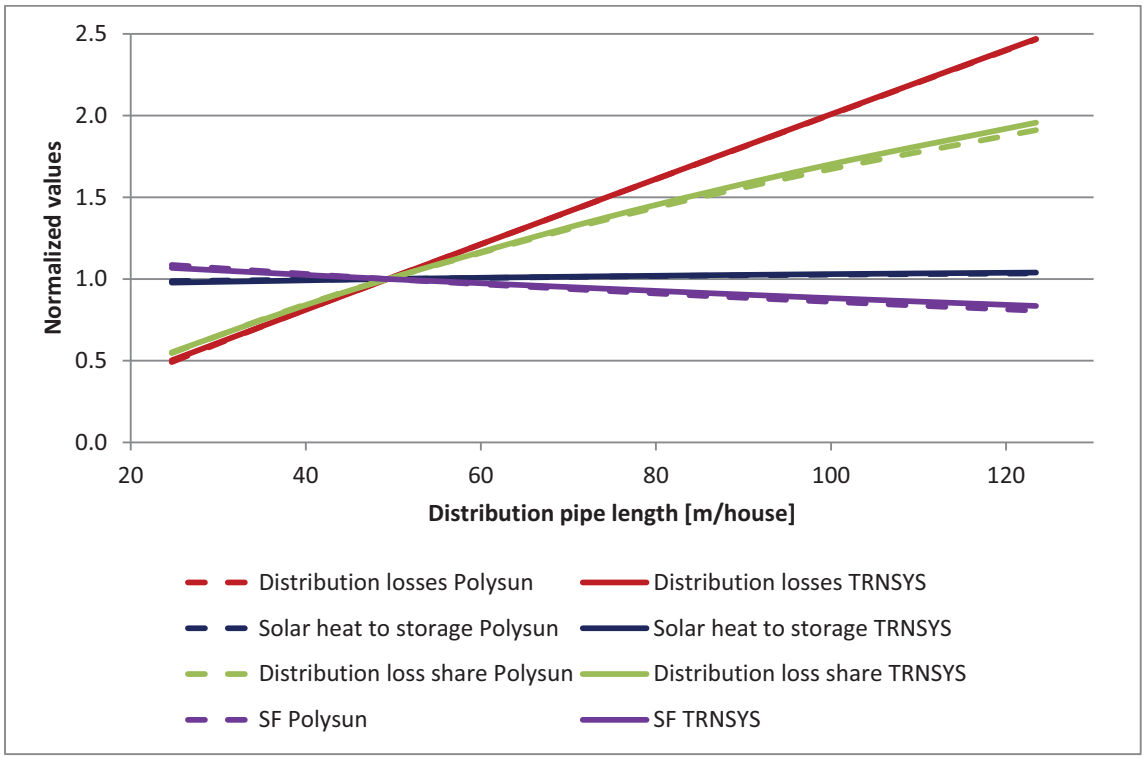

Fig. 8: Sensitivity analysis of influence of heating network density on district heating system performance (solar fraction, value of distribution losses, solar energy to the system and share of distribution losses in total demand) for TRNSYS and Polysun models

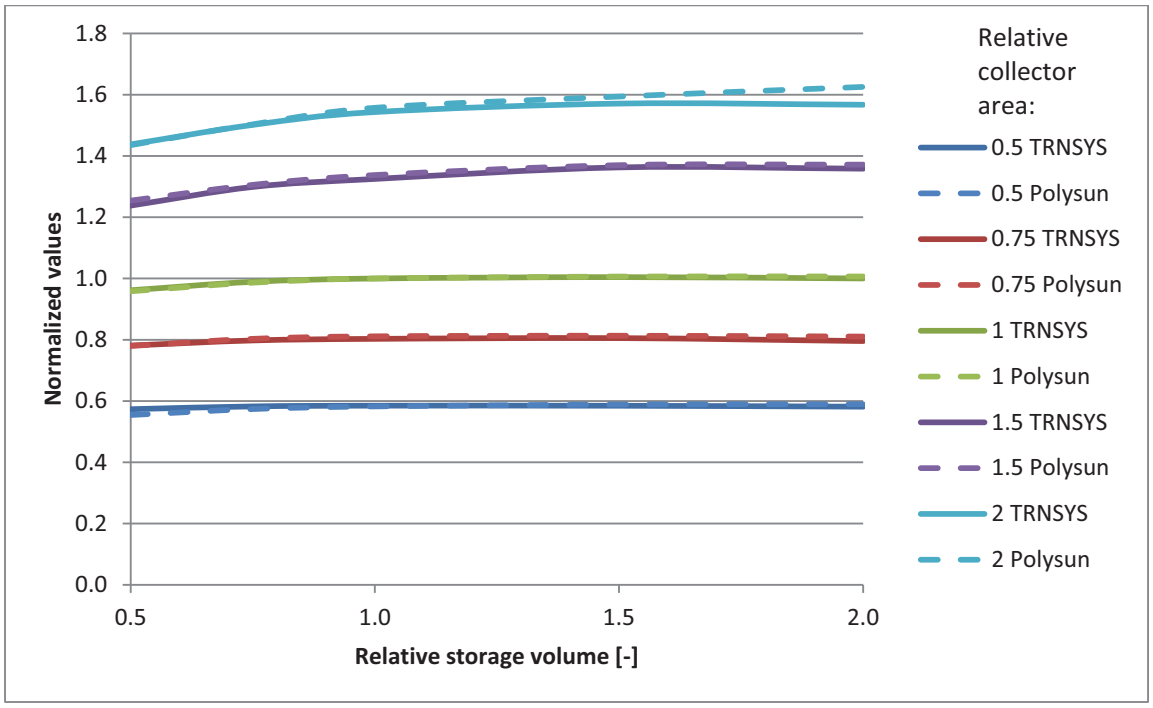

Fig. 9: Sensitivity analysis of influence of collector and storage sizes on system performance for Polysun and TRNSYS models.

6. Conclusion

Applicability of Polysun and TRNSYS for simulation of block heating solar systems was studied by comparison with measured data and performing a parametric study. As a reference case Vallda Heberg decentralized solar district heating system was chosen. It was proven that if enough measured data is available and controlling strategy as well as main system parameters are known it is possible to calibrate models in Polysun and TRNSYS with high degree of accuracy. Relative deviations of all annual key figures of both tools compare to the real case are low and monthly values are also in good agreement. Relative deviations of annual key figures for TRNSYS and Polysun are < 2% and < 8% respectively.

In order to compare model behaviors a sensitivity analysis was performed. First of all, instead of actual weather data Meteonorm average year data was used. With the new weather data TRNSYS showed expected performance. Since the year 2014 was rather warm, total demand for the average year is higher than for 2014. For the same changes in boundary conditions Polysun showed poor agreement – total demand for the average year approximately equals to the one in 2014 and is significantly higher than TRNSYS. It means that the building model in Polysun does not respond adequately to change in the weather data. The main reason is that the one-zone building model is not suitable to simulate such complex case (multi-zone building with complex interaction between zones).

Then two cases were studied; influence of a density of the heating network on a solar fraction of the sub-unit and distribution losses in the system; and influence of different collector field sizes and storage tank sizes on performance of the system in terms of solar energy supplied to the system and a solar fraction. In order to eliminate influence of the building model, key figures were normalized to the base case and plots were built based on these normalized values (fir. 8 and fig. 9). The plots show very good agreement between Polysun and TRNSYS. It means that Polysun simulates the changes in the same way as TRNSYS for collector and store sizes as well as pipe length/energy density of the network.

Performance and Optimization of a Novel Combined Solar Heating Plant with Flat Plate Collectors and Parabolic Trough Collectors in Series for District Heating

Zhiyong Tian, Bengt Perers, Simon and Jianhua Fan

Department of Civil Engineering, Technical University of Denmark, Brovej Building 118, Lyngby, 2800, Denmark

Abstract

More than 1.3 million m^2 solar heating plants are in operation in Denmark by the end of 2016. Most existing collectors in the solar heating plant are flat plate collectors. To maximize the advantages of flat plate collectors and parabolic trough collectors in large solar heating plants for a district heating network, a novel combined solar collector field with 5960 m^2 flat plate collectors (FPC) and 4039 m^2 parabolic trough collectors (PTC) in series has been constructed in Taars, Denmark. The design domain variables of the combined solar heating plant require to be considered in the optimization routine to get the optimal performance of such plant. A validated TRNSYS-Genopt model was set up to optimize key design parameters and investigate the potential performance of the combined solar heating plant. It is found that the design concept of hybrid solar heating plants with flat plate collectors and parabolic trough collectors in series can be feasible in Denmark. The results of optimal design parameters could guide engineers and designers in the design, construction and control of large-scale combined solar heating plants.

Keywords: combined solar district heating plants, flat plate collectors, parabolic trough collectors, LCOH.

1. Introduction

Large scale solar district heating plants have gained great success in Europe, particularly in Denmark. Denmark is the frontrunner country in the large scale solar district heating plants. Most solar collectors in the existing solar heating plants in Denmark are ground mounted flat plate collectors. A hybrid solar heating plant with flat plate collectors and parabolic trough collectors was put into operation in August of 2015. The aim of this study is to optimize the hybrid solar heating plant based on the Levelised Cost Of Heat (LCOH).

2. Case study

The Taars solar heating plant was put into operation in August of 2015, consisting of a 5960 m^2 flat plate collector field and a 4039 m^2 parabolic trough collector field in series [1]. Figure 1 briefly illustrates the basic principle of the plant. The solar collector fluid of the parabolic trough collectors is water, while that of FPC is a 35% glycol/water mixture. The return water from the district heating network is heated up to 70°C by the heat exchanger connected to the flat plate collector field. Then the water from the flat plate collector field is heated to the required temperature by going through the parabolic trough collector field. The orientation of parabolic trough collector axes is 13.4° towards west from south. The parabolic trough collectors track the sun rays from east to west when the collectors work during the daytime. There are six rows of parabolic trough collectors and the row distance is 12.6 m. The length of each row is about 120 m. The parabolic trough collectors were delivered by Aalborg CSP A/S. The orientation of the flat plate collectors is south and the collector row distance between flat plate collectors is 5.67 m. The tilt of flat plate collectors is 50°. The flat plate collectors consist of two types of flat plate collectors, namely HTHEATboost 35/10 and HTHEATstore 35/10, delivered by Arcon-Sunmark A/S. Half of flat plate collectors are HTHEATboost 35/10, while the other half is HTHEATstore 35/10. The backup heat resource is two natural gas boilers. Two tanks with a total volume of 2430 m^3 are used as heat storage for several days in the summer. The lessons from the operation are that the parabolic trough collectors have to be defocused in several sunny days in summer because of limited heat storages and heat demand. A validated TRNSYS model was developed to optimize the hybrid solar heating plant to reach the minimum nLCOH [2]. The yearly DNI and global

doi:10.18086/swc.2017.06.14 Available at http://proceedings.ises.org

radiation in the Design Reference Year are 1150 and 1030 kWh/m^2 respectively. The typical heat demand is 20167 MWh per year.

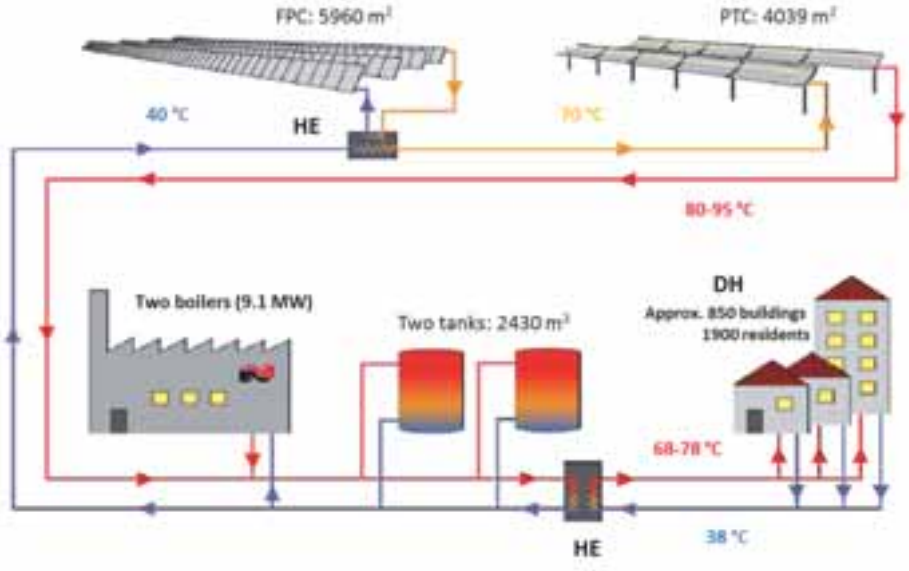

Fig.1.Illustration of the Taars solar heating plant [3].

3. Method

LCOH definition has two boundary conditions for the solar district heating network in this study. One boundary condition is elaborated only for the solar collector field and heat storage. Other boundary condition not only includes the solar collector field and heat storage, but also takes conventional heat supply into consideration. The former is called by net LCOH (nLCOH). nLCOH is used in this study and can be expressed as equation below: I_s is the initial cost, DKK; T is the lifetime, 30 years; r is the discount rate, 3%; P_s is the operation and maintenance cost, SE is the energy produced, kWh. The operation and maintenance cost of the flat plate collector field every year is assumed as follows: a) 2 DKK/MWh heat produced for maintenance fee; b) 1.5 kWh electricity/100kWh heat produced for operation (2.3 DKK/kWh electricity). The operation and maintenance cost of the parabolic trough collector field every year is assumed to be 0.8% of the initial cost. The initial cost of the flat plate collector field without foil was assumed as 2180-2400 DKK/m^2 (500-10000m^2). The cost of the flat plate collector field with foil was assumed as 7.6% higher than that of the flat plate collector field without foil. The cost of the parabolic trough collector field is 40-70% higher than that of the flat plate collector field. Detail information is shown in the reference [4].

$$nLCOH = \frac{I_s + \sum_{t=1}^{T} P_s \cdot (1+r)^{-t}}{\sum_{t=1}^{T} SE \cdot (1+r)^{-t}} \quad (1)$$

4. Results and conclusions

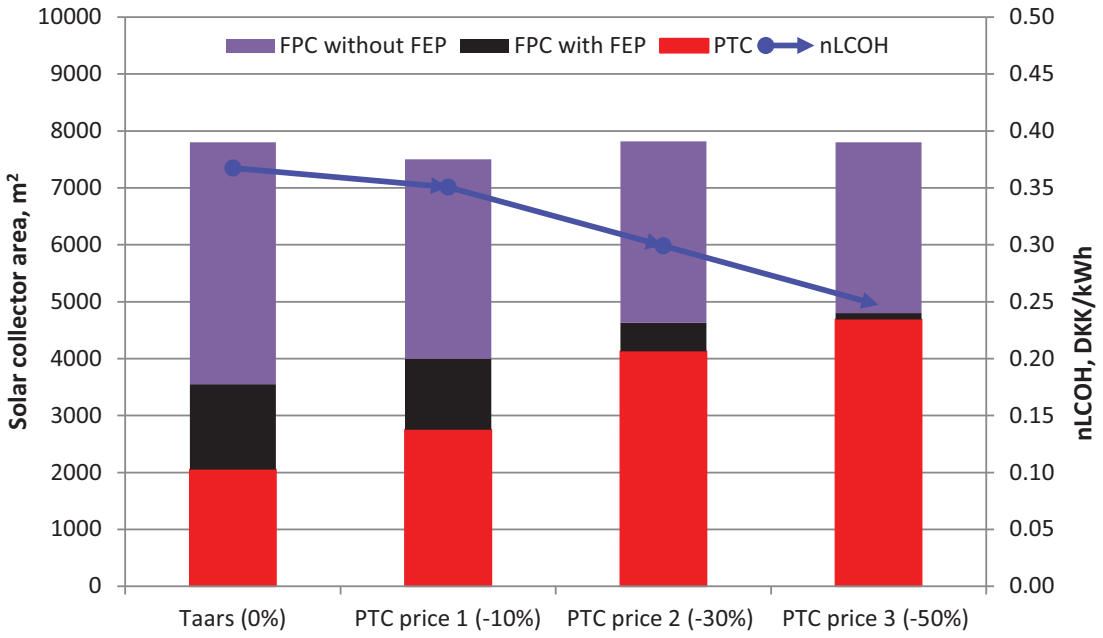

Fig.2. Minimum LCOH and optimal parameters based on different prices of the PTC [4].

Fig.2 shows the optimal solar collector area for different scenarios. The Taars bar shows optimal solar collector area for the reference case. Different scenarios for different parabolic trough collector price levels are also investigated, if the the price of the parabolic trough collector field decreases by 10%, 30% and 50% in the future. All the scenarios show that the design concept that the hybrid heating plant with flat plate collectors and parabolic trough collectors can be feasible in Denmark. Further information please find in the published papers.

Abstract

The integration of solar thermal plants into district heating grids requires advanced control strategies in order to utilize the full potential in terms of efficiency and least operating effort. State-of-the-art control strategies cannot completely fulfill this since they are not able to consider the physical characteristics of the different components, nor do they take information on future conditions and requirements into account properly. A promising attempt for improvement is the application of model-based control strategies together with practicable forecasting methods for both the solar yield as well as the heat demand. This contribution will present the results of several projects performed on the development of suitable mathematical models, forecasting methods and control strategies relevant for the integration of solar thermal plants into district heating grids.

Keywords: model-based control strategies, forecasting methods, solar thermal plants, district heating grids

1. Introduction

Modern large-scale solar thermal plants are increasingly used as heat sources for heating grids. In urban environments, they are also often set up with local buffer storages and the possibility to directly supply local consumers with heat. In this specific case an additional bi-directional transfer station can be used which allows the supply of the local consumers with heat from the grid in case there is too little solar energy available. The most beneficial operating strategy of such a configuration first of all depends on the point of view: For the operator of the solar thermal plant, who is responsible for the supply of the local consumers, maximizing the on-site consumption will be most beneficial, since the prizes for heat fed into and taken from the heating grid typically differ significantly. For the operator of the heating grid, generally a different operating strategy would be most beneficial, since all other components and parties have to be taken into account. This contribution will focus on control strategies for an efficient integration from the point of view of the solar thermal plant operator, but also parts relevant for the district heating grid operator will be outlined.

The most important part of the solar thermal plant is the collector field. In the most general case, this solar collector field consists of several subfields connected in parallel that can differ in size. These differences in size have their origin in the optimization of the collector area under the local constraints of the place of installation which are often encountered in urban areas. In order to ensure an adequate flow distribution in the individual subfields, and to avoid exergy losses by mixing flows with different temperatures, the individual fields are typically equipped with adjustable balancing valves. These valves can either be adjusted manually for nominal operation or be driven by a servomotor in order to achieve an adequate flow distribution for every operating condition.

There are two major challenges to be faced when controlling such plants. The first challenge is to use the generated heat in an economically optimal way. The price for selling heat to the grid is typically lower than the price for buying it back, so an effective buffer management strategy is necessary which ensures the heat supply to the consumers while maximizing profits. The decision whether the heat currently generated should be stored in the buffer storage or be fed into the district heating grid determines the required feed temperature. When feeding into the grid, a minimum feed-in temperature must be provided by the plant; when feeding the local consumers via the buffer storage, a lower feed temperature is normally sufficient and thus a higher efficiency in the collectors can be obtained, a point that needs to be considered in the buffer management strategy.

The second challenge is to keep the outlet temperature of the solar collector field within certain boundaries and

doi:10.18086/swc.2017.06.15 Available at http://proceedings.ises.org

adjust it quickly regarding the mode of operation (store the heat in the buffer storage vs. feeding it into the district heating grid) even for fast changing ambient conditions. This is difficult because of several factors: first, there are delays between the control actions and the resulting outlet temperature changes, and the actuators are usually slow. Second, the outlet temperature depends on the accumulated influence of the solar irradiation during the transition time of the water through the collectors, thus requiring control strategies incorporating some kind of memory to obtain a good outlet temperature control performance.

To deal with these challenges, state-of-the-art control systems of solar thermal plants are often hierarchically structured. On a high-level basis, typically a set of rules defines the general mode of operation (e.g. feeding the heat into a district heating grid vs. storing it in the local buffer storage). On the low-level basis, control tasks such as controlling mass flows and temperatures are mainly handled separately for each subfield using simple linear PID controllers, which in some cases are enhanced by additional expert rules and, for example in the case of controlling the solar collector output temperatures, by energy balance calculations. On both control levels typically neither the non-linear and coupled characteristics of the different components are considered, nor is information on future conditions and requirements taken into account. Thus the default strategies applied on both levels usually do not yet utilize the full potential of modern solar thermal plants, mainly resulting in efficiency losses, even unused solar energy and increased operating efforts due to the need of frequent re-parametrization by the operators.

For both control levels, the most promising alternative approach would be the development and application of appropriate model-based control strategies combined with a good forecast of the expected heat generated by the plant and the heat demand of the local consumers.

Model-based control strategies base on mathematical models describing the fundamental static or dynamic characteristics of the different components and systems and thus allow an explicit consideration of the physical characteristics of the different components. In the case of high-level control, the specific method of model predictive control can also take information on future conditions and requirements into account. The models for most of the components and systems of interest available prior to the beginning of the work underlying this contribution were either too complex (used for comprehensive simulation studies) or too simple (static mass and energy balances). For this reason, the development of mathematical models suitable to serve as a basis for model-based control strategies represents a necessary part of the overall control development.

Furthermore, the available forecasting methods for solar yield and heat demand were in most of the cases mathematically by far too complicated, tailored for a specific application and very often not adaptive. Thus, they cannot serve as a general basis for model-based control strategies, which is why the development of general, simple and adaptive forecasting methods for the solar yield as well as the heat demand is another prerequisite for the final application of model-based control strategies.

This contribution presents a summary of the results of several projects performed on the development and validation of mathematical models suitable for model-based control strategies (section 2), forecasting methods for both the load demand as well as the solar yield (section 3) and control strategies relevant for the integration of solar thermal plants into district heating grids from the point of view of the solar thermal plant operator (section 4). Finally, section 5 sums up the results and draws a short conclusion.

2. Mathematical modelling

The modelling for the low-level control focusses on the correlation of pressure differences and mass flows in hydraulic components as well as the heat transfer, i.e. the temperature levels especially at the outlet of the components or systems as functions of the inlet temperature, ambient conditions and mass flows. The modelling for the high-level control focusses on heat storage and heat loss and aims at mathematically more simple models usable in optimization problems such as those formulated in model predictive control. Appropriate models for all relevant components in a solar thermal plant (buffer storage, collector fields and all hydraulic components for the heat distribution such as piping, pumps and valves) respectively control levels were developed, of which the model of the buffer storage as well as the solar circuit and its components are described exemplarily in this section.

2.1 Buffer storage

Buffer storages are used in order to decouple the occurrence of heat production from heat consumption at least at a certain degree. The mathematical modelling of buffer storages is primarily important for the high-level controller in order to estimate the available heat in the buffer within the next hours.

The modelling of buffer storages can be conducted in different levels of detail. In literature, models ranging from three-dimensional partial differential equations used for computational fluid dynamic (CFD) simulations, to single ordinary first-order differential equations can be found. In the next section three model of different detail are described: a detailed model primarily useful for simulation purposes (PDE model); the simplest possible model that is usually used for high-level, optimization-based control purposes (single integrator model); and a new, purpose-built linear hybrid model that combines the advantages of both for more accurate prediction results (hybrid model).

PDE model

A reasonable compromise of complexity and accuracy when considering a typical cylindrical buffer storage is to neglect the radial temperature dependency and assume a constant temperature at a specific axial (vertical) position. This assumption is supported by the usual mechanical construction of inlets aiming at a good radial distribution of entering fluids and thus minimal axial mixing. This leads to a mathematical model of one partial differential equation with only one spatially dependent variable (typically the temperature), where all relevant mechanisms of heat transfer are considered, e.g. (Cruickshank, 2009; Hemmer, 2014; Zlabinger, 2017). In simulations, the differential equation should preferably be solved implicitly in order to increase numerical stability and reduce computational effort. Typically, all model parameters can be determined from geometrical data and data sheets, but if they are not available or if the geometries are exceedingly complicated, it could be easier to determine some model parameters experimentally. This typically also would lead to an improved reproduction of the energy losses to the environment.

Fig. 1 shows results of an exemplary experimental verification of the model described in (Hemmer, 2014) performed with a commercially available buffer storage with a capacity of 1500 l. In the beginning, the upper third of the boiler got heated up to 70°C while the two lower thirds remained at ambient temperature. In the next step the lower part got heated up via an internal heat exchanger. In order to evaluate the simulation results, 12 vertically distributed temperature sensors have been installed. Despite the challenging setup the model describes the measured behaviour sufficiently well.

A model like this can be used for simulation purposes and even in a predictive high-level control not based on linear optimization. However, such controllers typically are computationally expensive and cannot rely on standard solvers. A simpler prediction model for the future available heat is thus required.

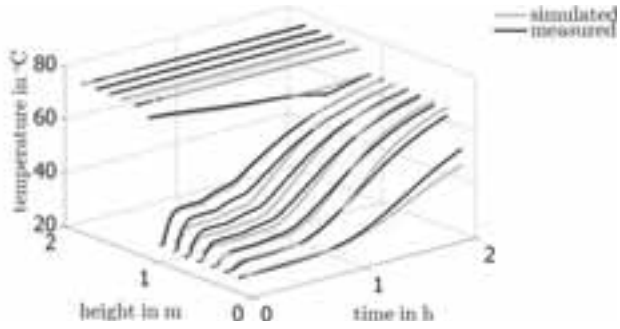

Fig. 1: Exemplary comparison of measured (black) and simulated (grey) vertical temperature distribution in a buffer storage while transferring heat via an internal heat exchanger in the lower third of the buffer.

Single integrator model

The single integrator model is the simplest approach for a linear model of a buffer storage and describes the dynamic behavior of the buffer storage on the basis of a simple energy balance

$$\frac{dE_{\mathrm{stor}}}{dt} = \sum \dot{E}_{\mathrm{in}} - \sum \dot{E}_{\mathrm{out}} \qquad \text{(eq. 1)}$$

with the stored energy as state variable E_{stor} and the in- $\dot{E}_{\mathrm{in}}$ and outgoing $\dot{E}_{\mathrm{out}}$ energy flows as inputs.

This model describes the energy content of typical cylindrical buffer storages sufficiently well to be used in model predictive control strategies with approximately constant inlet temperatures during the optimization horizon and comparatively quick charging and discharging cycles, where a detailed description of the losses is not crucial (Moser, 2017). But as soon as different, varying temperature levels or long-term operating cycles have to be taken into account, a more complex model has to be considered.

Hybrid model

In (Zlabinger, 2017) a more detailed but still linear approach is suggested, which is able to consider a finite number of different inlet temperatures and in- and outlets at different heights as well as all relevant mechanisms of heat transfer (convective heat input and output at predefined heights, axial heat conduction, environmental losses and natural convection). It is a hybrid, linear model that divides the buffer volume into different zones with constant mean temperatures and variable heights. The quantities of heat stored within these zones represent the continuous state variables of the system, and are described by simplified energy balances. The energy flows to the connected consumers and from the producers constitute the input variables. Depending on the heights of the zones in relation to the heights of the in- and outlets, different energy flows have to be considered. They are selected depending on additional discrete state variables that are used to distinguish between the different operating states. In the simplest form of the model, the consumers' return temperatures and the producers' feed temperatures are assumed to be constant, but through further case differentiation, varying inlet temperatures can be represented as well. Finally, the model can be described in the form of a mixed logical dynamic model (Bemporad and Morari, 1999), which is well-suited for the design of model predictive controllers for the high-level control as discussed in chapter 4.

2.2 Solar Circuit

The solar circuit in general consists of pipes, a pump, valves and several subfields, made up of multiple solar collectors, connected in parallel. It is connected to other hydraulic circuits via a heat exchanger. All these components have to be described through their thermal characteristics (heat transfer) as well as their hydraulic characteristics (correlation of pressure differences and mass flows) as described next.

Thermal characteristics

The thermal characteristics of pumps, valves and insulated pipes can be neglected for control purposes since no relevant heat transfer occurs. Only the thermal characteristics of the solar collector subfields are of major importance, for which several models of different levels of complexity already exist. On the one hand there exists a static model for the heat output of a solar collector based on a static energy balance, where the parameters are determined in a standardized collector test (EN12975) and can be found in the datasheet. This model is sometimes already used in today's control strategies in order to calculate a static feedforward control signal for the pump, and can be incorporated into solar yield forecasting methods (see section 3).

On the other hand there are more sophisticated dynamic models, such as models consisting of two coupled partial differential equations for the fluid and the absorber temperature of the collector, e.g. (Camacho et al., 2007a). Such more complicated models are often linearized in an operating point in order to obtain linear models. These linear models represent the dynamics of the outlet temperature of the collector field depending on the inlet temperature and the solar irradiation (Lemos et al., 2014) and can be used for model-based outlet temperature controllers. In several articles, the complicated models are used in combination with model-predictive controllers, e.g. (Camacho et al., 2007b; Lemos et al., 2014), but still more at an academic level or implemented in small-scale demo plants (Andrade et al., 2015).

Hydraulic characteristics

The hydraulic characteristics, namely the correlation of pressure differences and mass flows of the individual components in the solar circuit, play an important role for the low-level control. For pipes, valves and pumps simple models describing their static as well as their dynamic characteristics are summarized in (Unterberger et al., 2017). A turbulent flow regime can be assumed for all these components. When considering collector fields consisting of several large flat plate collectors this is different. The collector fields experience different flow regimes varying from laminar to turbulent as well as transition regimes between them. Thus, it is not sufficient to describe the correlation between pressure difference and mass flow through a purely quadratic equation. Another challenge in modelling the hydraulic characteristics of solar collector fields is the influence of the

temperature. Due to the significant rise in temperature of a fluid flowing through a collector, its viscosity and density are highly affected. This effect even increases further when an anti-freeze mixture is used. This results in varying hydraulic resistance values depending on the temperature levels and temperature increases.

These challenges can be dealt with by expressing the pressure difference over a subfield Δp_{subf} as a combination of the pressure difference in a laminar flow regime Δp_{lam} and the pressure difference in a turbulent flow regime Δp_{turb}:

$$\Delta p_{\mathrm{subf}} = \Delta p_{\mathrm{lam}} + \Delta p_{\mathrm{turb}} \qquad \text{(eq. 2)}$$

The pressure difference in the laminar regime Δp_{lam} is based on the friction along a straight pipe of constant cross section described by the Darcy-Weisbach equation (Rouse, 1946). This is a linear correlation between the pressure difference Δp and the mass flow $\dot{m}$ for a certain fluid temperature T. The correlation depends on the pipe parameters diameter and length and is proportional to the temperature dependent kinematic viscosity of the fluid $\nu(T)$. The constant parameters, diameter and length can be combined in a constant parameter $R_{0,\mathrm{lam}}$,which has to be determined experimentally for a specific temperature T_0:

$$p_{\mathrm{lam}} = \frac{\nu(T)}{\nu(T_0)} R_{0,\mathrm{lam}}\, \dot{m} \qquad \text{(eq. 3)}$$

The pressure difference in the turbulent regime Δp_{turb} is represented by an empirical formula usually used to describe the pressure drop due to an abrupt change in the pipe cross section as e.g. caused by a bezel. It is a correlation between the pressure difference and the square of the mass flow, with the constant parameter $R_{0,\mathrm{turb}}$, experimentally determined for a specific temperature T_0, and the density of the fluid ρ:

$$p_{\mathrm{turb}} = \frac{\rho(T_0)}{\rho(T)} R_{0,\mathrm{turb}}\, \dot{m}^2 \qquad \text{(eq. 4)}$$

In practical applications, using the mean temperature between inlet and outlet of a solar collector usually provides a sufficiently accurate approximation of the correlation.

If a balancing valve is installed at the entry of the collector subfield, it is useful to describe the hydraulic characteristics of the collector subfield together with the balancing valve. In this case, both the laminar as well as the turbulent temperature independent coefficients ($R_{0,\mathrm{lam}}, R_{0,\mathrm{turb}}$) are modelled as a function of the valve position. This in turn allows calculating the valve position necessary to obtain a desired mass flow through the subfield given a specific pressure difference provided by the pump, which is useful for feedforward control strategies.

A comparison of the model with measurement data for a single collector subfield with an overall size of 172 m² is shown in Fig. 2 for stepwise changes of the plug position of a balancing valve.

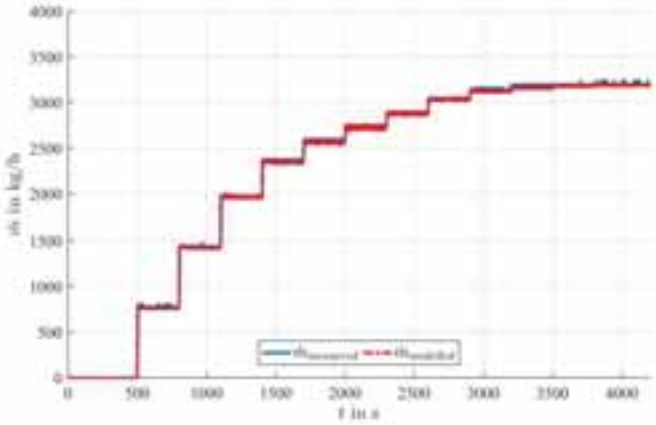

Fig. 2: Exemplary comparison of the measured (blue) and the modelled (red) mass flow through a solar collector field (172 m²) for stepwise changes of the plug position of a balancing valve at its inlet at a constant rotational speed of the pump.

3. Forecasts

The high-level controller, which is often called energy or load management system, of the solar thermal plant should incorporate forecasts for both the expectable solar yield and the expectable heat demand of the consumers in order to optimally plan generation, storage and consumption of heat.

Many different approaches for performing these forecasts can be found in literature, but almost all of them are highly academic and very complex. They are often tailor-made for specific configurations, require high computational effort and, due to their complexity, a comprehensive mathematical educational background of the implementing control engineers. Therefore, most of them are inappropriate to be widely used in practical implementations.

To be practical applicable, the forecasting methods first of all need to be general in order to cover a big variety of systems. Furthermore, the methods should be easy to implement and use little computational resources so that they can be integrated into the PLCs typically used for controlling solar thermal plants. Finally, the methods need to be able to adapt to varying conditions such as shading or changing consumer behavior. In this section, methods for predicting the future heat demand and the future solar yield are presented which fulfill these requirements and are thus usable in both solar thermal plants and district heating grids.

3.1 Forecasting method - heat demand

The method for forecasting heat demand presented in (Nigitz and Gölles, 2017) is based on the empirical analysis of the correlation between weather data and heat load data of several types of consumers. The analysis revealed that there exists an approximately linear correlation between load demand and ambient temperature and that there is a characteristic dependency of the heat load on the time of the day. Furthermore, it was also found that the individual days of the week do not have to be considered explicitly, but a distinction between working days and weekends/holidays turned out to be necessary.

The method predicts the heat demand of the consumers and corrects it by using the current prediction error as well as basic expert knowledge. The method itself is based on a linear regression model for each hour of the day describing the dependency of the heat demand on the ambient temperature. The parameters of the regression model are updated every hour taking into account the actual heat flow and the ambient temperature of the previous days, where only similar days are considered (work days or weekends/holidays). The only inputs necessary for the method are the measured heat flow supplied to the consumers and the predicted ambient temperature, provided e.g. from a weather service provider. This means that no parameterization is needed and no complex model of the connected buildings or the consumer behavior is necessary. Fig. 3 shows an exemplary forecast for the heat demand of a local consumer connected to the buffer storage of a thermal solar plant, compared to the actual load demand.

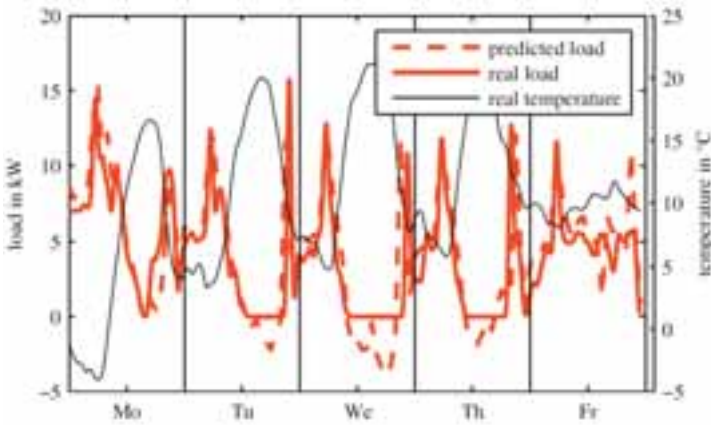

Fig. 3: Exemplary prediction of the load demand of an on-site consumer (connected load: 35 kW) compared to the actual (measured) load demand together with the (measured) ambient temperature for a representative work week.

3.2 Forecasting method - solar yield

The method developed to forecast the solar yield is based on an extensive analysis of weather data and measurement data from a large-scale solar thermal plant. The analysis showed that the static collector model

(see section 2.2) with the model parameters from the datasheet, determined according to European Standard EN12975, does not directly lead to satisfying results but represents a suitable basis to forecast the solar yield. This is because the model parameters are only valid for stationary conditions in the laboratory and not for the dynamic conditions occurring in the daily operation. Furthermore, these model parameters would have to change over time because of polluted collector surfaces decreasing the optical efficiency, or because of the decay of materials leading to higher convective heat losses of the collector.

For this reason the method developed is based on the static collector model, but continuously estimates the collector parameters based on previous data. Like the method for forecasting the future heat demand, the method to forecast the future solar yield is based on linear regression models for each five minutes of the day describing the dependency of the solar yield on the ambient temperature, the global solar irradiation and the absorber temperature.

The parameters of the static collector model are adapted every five minutes, taking into account the past values of the measured solar yield, the measured ambient temperature as well as the measured global solar irradiation. By doing so, the pollution of the collector fields, the decay of the materials as well as the influence of local shading is automatically considered. In addition, no manual parameterization efforts or complex dynamic models are necessary. The only inputs necessary for the method are the measured solar yield and both the predicted and measured values for ambient temperature as well as global solar irradiation.

Fig. 4 shows an exemplary forecast of the solar yield for a sunny summer day of a subfield with 172 m² built in 2009, compared to the expected solar yield calculated with the static collector model with the parameters taken from the datasheet of the manufacturer as well as the actual measured solar yield. For this verification, real weather forecast data from the company *meteoblue AG* (https://www.meteoblue.com) was used, which provides weather information world-wide. This method will be extended by a correction approach in order to react on prediction deviations, which is for example necessary in case of very cloudy days.

It can be seen that the static model with the parameters taken from the datasheet would indicate the solar yield before 8 am as soon as global solar irradiation is predicted, not considering the heating up phase of the collector subfield. Furthermore, most of the time the static model is overestimating the solar yield. Only in the afternoon the prediction of the static collector model seems accurate. In fact this has its origin in the course of the predicted global solar irradiation which in the afternoon is below the measured one compensating the general overestimation of the collector efficiency. In contrast, the predicted solar yield resulting from the developed forecasting method with the parameters based on previous measurement data describes the real generated solar yield of the subfield throughout the day very well.

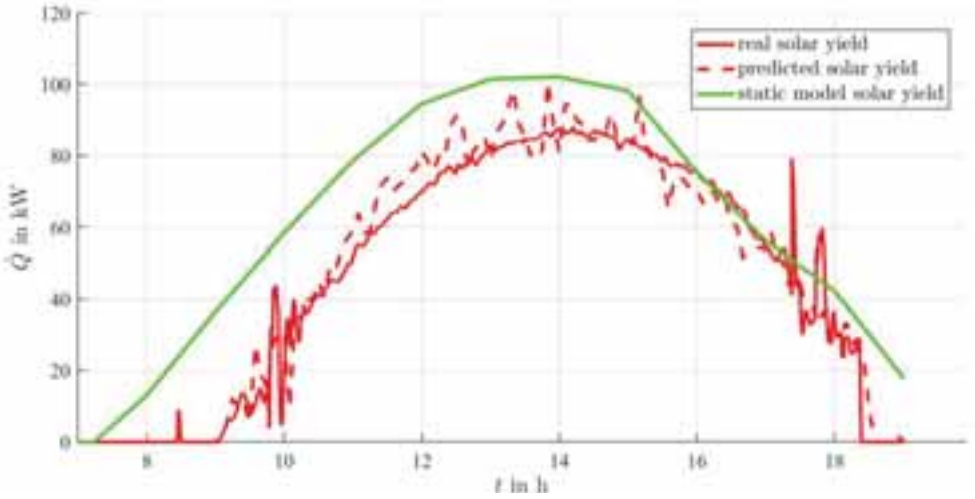

Fig. 4: Comparison between the measured solar yield, the predicted solar yield and the solar yield calculated with the static model and the parameters taken from the datasheet for a collector field of 172 m².

4. Control

The control of a solar thermal plant connected to a heating grid and local consumers must handle multiple aspects. Locally, a high-level controller must decide when to feed heat into the grid, when to store it locally and when to consume heat from the grid. A low-level controller must take care of temperature and mass flow control in the solar collectors, and of the heat distribution to and from the local buffer storage. At the heat transfer station, a grid controller must handle the feeding of heat into the grid or the transfer of heat from the grid to the local buffer storage. Such bidirectional heat transfer stations are still a matter of research, and often two transfer stations are operated in parallel, one for each task.

The different model-based controllers developed base on different methods from control theory. Fig. 5 shows the main idea of a model predictive controller used for the high-level control providing the reference values for all the underlying low-level controllers.

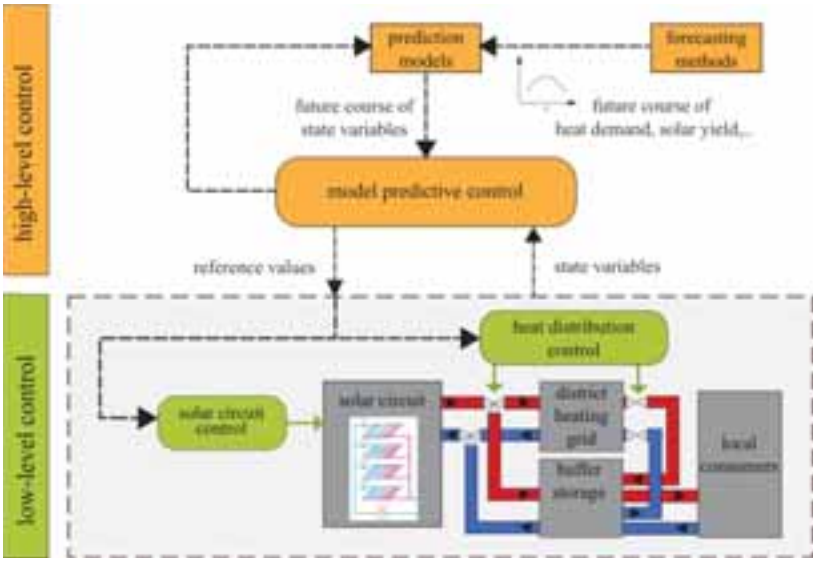

Fig. 5: Schematic overview of the interactions of the different control systems addressed

As an example for the different low-level controls to be considered, the control of the most important part, the solar circuit is discussed in more detail. The task of the low-level controller of the solar circuit is to realize the reference values given by the high-level control as efficiently as possible. In case of the solar collector circuit, this only influences the desired collector outlet temperature, which is different depending on the mode of operation of the plant - feeding the heat into the district heating grid requires a higher outlet temperature than storing it in the local buffer storage.

The desired outlet temperature of the solar circuit is realized by the model-based solar circuit control. It controls the pump in such a way that the mass flow necessary to achieve the desired outlet temperature is reached. In case there are motor-driven balancing valves installed in the subfields, these can be used to individually control the mass flows through the individual fields, and the controller has to adjust the valves appropriately. One possible control concept to accomplish this task will be described next, first for the case that controllable balancing valves exist in each collector subfield, then for the case where no motor-driven balancing valves exist.

In a first step, the mass flows through the N individual subfields ($\dot{m}_{1,\mathrm{des}}$ to $\dot{m}_{N,\mathrm{des}}$) necessary to achieve the desired outlet temperature $T_{\mathrm{out,des}}$ are calculated based on a thermal model of the solar collector field, e.g. the static collector model based on the energy balance mentioned in section 2. This requires the knowledge of (measured or predicted) influencing variables such as the global solar irradiation G, the ambient temperature T_{a} and the inlet temperature to the collector subfields T_{in}. The parameters of the thermal models for each subfield can be continuously estimated according to the forecasting method for the solar yield in order to consider shading, pollution of the collector surface or decay of materials.

In addition to this static calculation, the individual desired mass flows are continuously updated by a temperature controller. The temperature controller compares the current outlet temperatures of the individual subfields $T_{1,\mathrm{out}}$ to $T_{\mathrm{N,out}}$ with the desired outlet temperature $T_{\mathrm{out,des}}$. Based on this comparison, the desired mass

flows calculated in the first step are either in- or decreased. In the simplest case, the temperature controller consists of very slowly adjusting PI controllers, but also more sophisticated, model-based control techniques could be used.

In the second step, the sum of the desired mass flows, together with the nominal positions of the valve plugs φ^*_1 to φ^*_N are used to set the rotational speed of the pump n_P and, as a consequence, the differential pressure Δp_P. The nominal positions of the valve plugs are chosen between 80-100%, where 0% corresponds to a closed valve and 100% to an open valve. They should be chosen as high as possible in order to avoid unnecessarily increased pressure losses, but keeping in mind that controllability is reduced when the valve is opened too much because the valve will have less effect on the mass flow closer to the opened state.

The results of the two steps, the desired mass flows and the differential pressure of the pump, are used in a third step to determine the individual actual valve plug positions. In order to realize the adjusted desired mass flows, a feedforward controller for the valves is used. In this feedforward controller the valve positions φ_1 to φ_N necessary to accomplish the desired mass flows are determined based on the differential pressure provided by the pump and the hydraulic model of the solar collector subfield (see section 3). In the simplest case this feedforward control can be implemented neglecting the hydraulic couplings between the subfields, but even more extensive control techniques using graph-based algorithms, e.g. (Hassine and Eicker, 2014), could be used which take into account the hydraulic couplings by solving the equations simultaneously.

In case of larger model deviations, an additional slow controller could compare the actual valve positions (φ_1 to φ_N) with the nominal ones (φ^*_1 to φ^*_N) in order to adjust the rotational speed of the pump. Fig. 6 shows a schematic representation of the described strategy for the solar circuit control.

In case that there exist no motor-driven balancing valves in the solar circuit, the control strategy can be simplified to steps one (calculating the desired mass flows) and two (choosing the rotational speed of the pump), by adding a control loop comparing the overall outlet temperature of the solar circuit with the desired one, and adjusting the rotational speed of the pump accordingly.

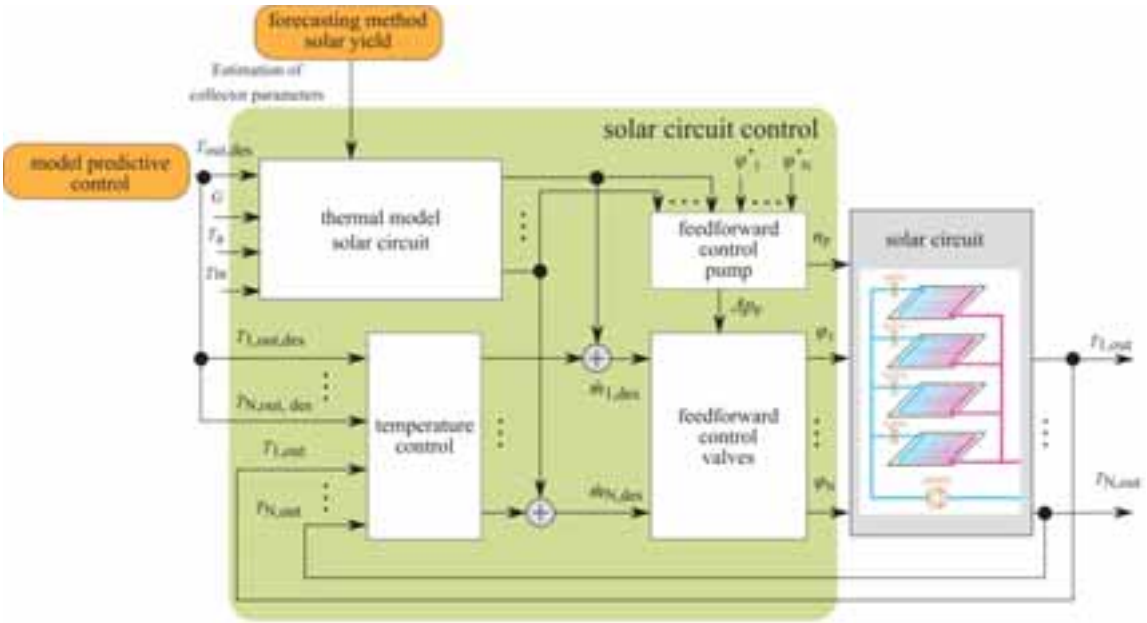

Fig. 6: Control approach for the low-level control of the solar circuit.

5. Conclusion and outlook

In order to efficiently integrate solar thermal plants into district heating grids challenges regarding the hydraulic control and the load management have to be dealt with. State-of-the-art control strategies cannot cope with these challenges in optimally since they are neither considering the non-linear and coupled characteristics occurring in such hydraulic systems, nor do they take into account future weather conditions and therefore cannot control the

systems in a predictive manner. Instead, they can only react when a control deviation has already occurred. A promising approach for improvement is the application of model-based control strategies together with practicable forecasting methods for both the solar yield as well as the heat demand.

In this contribution models, forecasting methods as well as control strategies for solar thermal plants were presented exemplarily and verified with either measurement or simulation data, already showing good results. Some of the presented approaches such as the forecasting methods can serve as a basis for developing similar methods for the heating grid as well. Future investigations have to address the cooperation of the solar thermal plant with the district heating grid: for example the interactions of the high-level controllers in charge of the respective load management. This issue is relevant for all kinds of consumers also acting as producers, and is still a topic of current research.

Abstract

In this paper, a novel approach for manufacturing cost effective polymeric solar-thermal collectors is described. The approach known as Twin-Sheet-Thermoforming (TST) is suitable for mass-production and enables a significant cost saving potential compared to conventional, metal-based collectors. Based on an absorber made of acrylonitrile butadiene styrene (ABS), a collector prototype was set-up and tested according to EN ISO 9806:2013. The results were compared to data available both from literature and market available polymeric collectors. The tested prototype shows a higher solar-thermal efficiency compared to market available polymeric collectors and a similar efficiency compared to laboratory prototypes recently described in literature. Against this background, the production and manufacturing costs of polymeric solar-thermal collectors become increasingly important, as these costs directly affect the Levelized Cost of Heat (LCOH) of a solar-thermal system equipped with such collectors.

Keywords: Solar-thermal flat-plate collector, Collector Efficiency, Polymeric Materials, Experiment

1. Introduction

Currently, solar-thermal systems are facing two challenges: On the one hand, the low commodity prices for oil and gas on the world market cause longer payback periods for solar-thermal systems. On the other hand, heating with other renewable energy sources (e.g. heat pumps in combination with photovoltaic systems) becomes economically more attractive. In order to remain competitive compared to other heat generation systems, prices for solar-thermal systems must be significantly decreased. According to Ivancic et al. (2014), current heat generation costs of solar-thermal systems have to be halved to become cost competitive with heat generated by fossil fuels (*fossil fuel parity*). To achieve this goal, different approaches are currently pursued, e.g. increasing the collector efficiency or decreasing the installation costs with so-called *plug-and-function* systems. Further cost reduction can be realized by utilizing cost-effective, polymeric materials on both collector and system level. In this study, the efficiency of a solar-thermal collector based on a polymeric absorber is investigated.

2. State of science and technology

2.1. Polymeric collectors described in scientific literature

The application of polymeric materials for solar-thermal collectors and systems has been subject of various scientific publications. Next to economic key figures like investment and operating costs, the thermal efficiency of polymeric collectors is of major importance for cost effective solar-thermal systems. However, the thermal efficiency of polymeric solar-thermal flat-plate collectors is limited by the physical properties of polymeric materials such as low temperature and pressure resistance.

Martinopoulos et al. (2010) determined the efficiency[1] of a polymeric collector (absorber area: 1.25 m^2) both experimentally and with a numerical flow simulation (CFD). A 10 mm thick honeycomb plate made of polycarbonate (PC) was the basis for the absorber. Two acrylic, rectangular, 8 mm wide pipes were used as header channels and connected with the absorber. The same 10 mm thick honeycomb PC plate was used for the backside insulation of the collector. To minimize the thermal losses to ambient, a special nanogel was used, enabling the overall heat transfer coefficient of the insulation to be lowered to 0.018 W $m^{-1}K^{-1}$. The authors used a 3 mm thick transparent PC plate as a front cover. A circumferential, 30 mm thick insulation made of extruded

[1] $\eta = \frac{\dot{Q}_{out}}{\dot{Q}_{in}} = \frac{\dot{m} \cdot c_p \cdot (T_{out} - T_{in})}{A \cdot I}$

doi:10.18086/swc.2017.07.01 Available at http://proceedings.ises.org

polyurethane (PUR) minimized the thermal losses towards ambient. Black colored water was used as the heat transfer fluid (HTF). The efficiency of this collector is shown in Fig. 4 **(**blue curve**)**. The authors point out the importance of a well-designed inlet of the absorber. In case of a poorly designed inlet, the HTF may not be equally distributed across the whole area of the absorber. As a result, the remaining air inside the collector will deteriorate the heat transfer from the absorber to the HTF, resulting in a decrease of the collector efficiency.

Based on the work of Martinopoulos et al. (2010), Missirlis et al. (2014) investigated different manifold configurations in order to determine the optimal position of both the in- and outlet. The highest efficiency could be obtained with a setup where both the in- and outlet pipe are aligned with the orientation of the honeycombed absorber sheet. The efficiency curve of this setup is shown in Fig. 4 (red curve).

Sandnes and Rekstad (2002) carried out experimental investigations on a combined photovoltaic and solar-thermal (PV/T) collector (absorber area = 0.48 m^2). The twin-wall shaped polymeric absorber made from polyphenylene ether (PPE) was filled with a ceramic granulate to increase the heat transfer between absorber and the HTF. A 4 mm thick sheet of glass was used ($\tau \approx 0.9$) as a front cover. The HTF was pumped to the upper manifold of the collector, from where it trickled down through the granulate-filled absorber due to the gravity. The efficiency curve of this collector is shown in Fig. 4 (grey curve).

Ariyawiriyanan et al. (2013) tested five different (unglazed) polymeric collectors to determine both the influence of the material and the aperture area on the thermal efficiency. Three absorbers had the same aperture area (1.30 m^2) but were made from different polymeric materials. The remaining two absorbers were made from polyvinyl chloride carbon black (PVC-CB) and had an aperture area of 1.8 and 2.0 m^2, respectively. According to the results from an outdoor-measurement, the authors suggest to choose an absorber material with a high thermal conductivity. In addition, a correlation between increasing aperture area and collector efficiency was found. The efficiency of the 2.0 m^2 absorber made from PVC-CB is shown in Fig. 4 (yellow curve).

Chen et al. (2015) also adopted the principle of extruded twin-wall sheets as the basis for a polymeric absorber. The absorber (aperture area: 1.16 m^2) consisted of an 8 mm thick twin-wall sheet. An additional 4 mm thick twin-wall sheet was used as a front cover, a 20 mm thick foam material was used as the backside insulation. Both the absorber and the glazing twin-wall sheet were made of transparent PC. In their study, the authors mention one general disadvantage of connecting extruded twin-wall sheets with header channels made from different materials: Due to different coefficients of thermal expansion, leakage may occur at higher operating temperatures. To absorb the incoming irradiation, a black coating was applied to the transparent absorber. The authors were able to demonstrate that the position of the coating (either top or bottom surface of the twin-wall plate) hardly affects the thermal efficiency. The efficiency of the absorber is shown in Fig. 4 (black curve).

2.2 Market available polymeric collectors

The approaches described above resulted in some market available polymeric solar-thermal flat-plate collectors. A honeycomb structure is used as an absorber (gross collector area: 0.95 m^2) in case of the *One Sun One World* solar collector. The structure is surrounded by a frame made from multiple polymeric parts which are welded together (Buchinger and Barek, 2015). In between the polymeric absorber and the transparent, polymeric glazing, a honeycomb matrix is inserted to mechanically support the glazing and to prevent large deflections of the glazing (e.g. in case of snow load). In addition to the support function of the matrix, the convective losses can be reduced by using such a honeycomb matrix (Hollands, 1965). An identical honeycomb matrix is used between the backside of the absorber and the backside cover of the collector. In this context, the encapsulated air inside the single cells of the honeycomb matrix acts like an insulator to minimize the backside losses to ambient. The efficiency curve of the *One Sun One World* collector was determined according to EN ISO 9806:2013 (One Sun One World GmbH, 2015) and is shown in Fig. 5 (blue curve).

The collector *Eco Flare 3M*, patented by the Israeli manufacturer *Magen Eco Energy*, is composed of a large number of individual plastic pipes (Sessler et al., 2011). The individual risers connect the two manifolds of rectangular cross-section. The efficiency curve of the collector (gross collector area: 2.25 m^2) was determined according to DIN EN 12975-2:2006 (Magen eco energy, 2011) and is shown in Fig. 5 (red curve).

The Norwegian company *Aventa AS* utilizes an extruded twin-wall plate of polyphenylene sulfide (PPS) as a basis for an polymeric absorber (Rekstad, 2012). A special feature of this collector (gross collector area:

2.65 m^2) is the arrangement of the two manifolds. Both of them are located below the absorber to ensure a proper self-draining when integrating the collector into a drain back system (DBS). The front-side glazing is made of a PC plate. The glazing, absorber and the backside insulation (mineral wool) are held together by a frame made of aluminum profiles. The efficiency curve of the collector was determined according to DIN EN 12975-2:2006 (Aventa AS, 2014) and is shown in Fig. 5 (grey curve).

In conclusion, the application of polymeric materials in solar-thermal collectors has been investigated in depth in scientific literature. Some of these concepts have been adopted by manufacturers of polymeric collectors and further developed. It is worth mentioning that all concepts presented in scientific literature as well as all market available polymeric collectors utilize pre-fabricated, semi-finished products (e.g. twin-wall-plates, pipes, etc.) as the basis for a polymeric absorber. The main advantages of this approach relates to the fact that these semi-finished products are widely used across several different industries (e.g. automotive or aerospace technology), yielding relatively low component costs. However, this approach also lead to some disadvantages. Firstly, the assembly of different parts yields higher production costs, either due to higher personnel or machine costs. Secondly, leakage problems may occur in case of insufficient sealing (e.g. welding) between the connection of single components or due to different coefficients of thermal expansion. Due to the lower raw material costs of polymeric materials compared to metals, the replacement of metallic materials (e.g. copper, aluminum, etc.) yields a cost saving potential. However, the manufacturing of polymeric absorbers and collectors should be linked with the materials applied to unleash the full potential of polymers. Some of the disadvantages described above can be compensated by utilizing a modern manufacturing technique for polymeric materials such as the Twin-Sheet-Thermoforming (TST) process. The manufacturing of a polymeric absorber based on this approach is described subsequently.

3. Setup of a polymeric absorber by means of the Twin-Sheet-Thermoforming manufacturing process

Deviating from common approaches described in scientific publications, a highly automated manufacturing process was chosen for mass production of polymeric absorbers. By comparing the respective advantages and disadvantages of several different polymeric manufacturing processes, the Twin-Sheet-Thermoforming (TST) manufacturing process was found to be the most suitable approach for manufacturing polymeric solar-thermal absorbers. The major advantages of the TST process compared to other processes such as injection molding, extrusion, blow molding or single-sheet-thermoforming are the low unit costs and the high reliability of the process (Ehrenwirth et al., 2016). The necessary process steps for manufacturing a polymeric absorber with the TST process are shown in Fig. 1. The major requirement for the TST is a molding tool that contains two halves. Starting from an initial position with both mold halves open (c.f. Fig. 1-a), two polymeric plates (e.g. made of PP, PC, etc.) are inserted and clamped by a mount (c.f. Fig. 1-b). In the next step, both the upper and lower plate are heated up by means of radiators (c.f. Fig. 1-c). The necessary temperature depends on the type of material used and the level of local deformation. Therefore, the temperature across the plate may vary. Prior to further processing, the radiators have to be removed out of the processing zone (c.f. Fig. 1-d). Subsequently, a vacuum is applied to both polymeric sheets (c.f. Fig. 1-e). The combination of the vacuum applied and the viscous material yields the plates to adopt the form of the mold halves (c.f. Fig. 1-f). Afterwards, the mold halves are closed, sealing together the upper and lower part of the absorber (c.f. Fig. 1-g). As soon as the final shape cooled down, the mold halves re-open (c.f. Fig. 1-h). Cutting away manufacturing remnants leads to the final polymeric absorber (c.f. Fig. 1-i). Applying both appropriate glazing to the front side and an insulation to the backside of the absorber finalizes the process (c.f. Fig. 1-j).

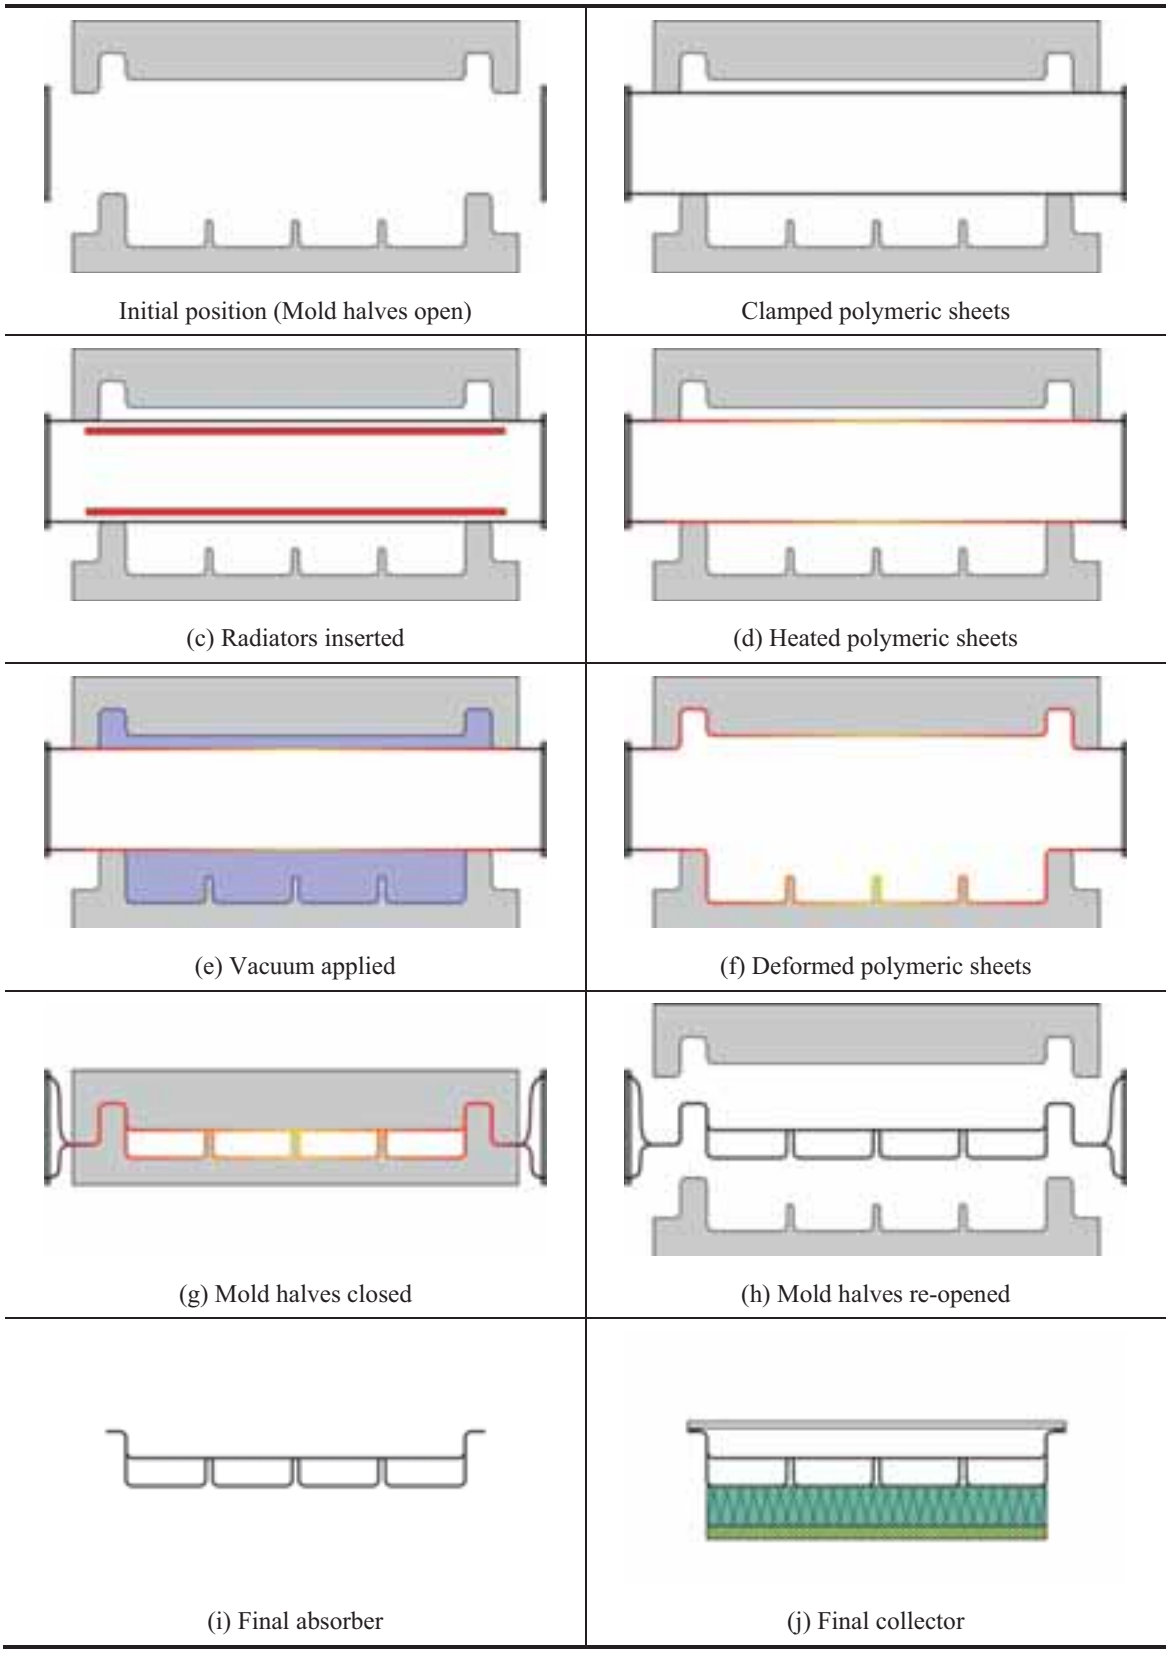

Fig. 1: Necessary process steps for manufacturing a polymeric absorber.

Based on the procedure described above, a prototype was set-up. A 4 mm thick front cover made of glass was glued onto the absorber (c.f. Fig. 2, grey part). A 30 mm thick insulation made from PUR minimizes the heat losses towards the backside (c.f. Fig. 2, crosshatched part). Special profiles made from aluminum were utilized to build a frame, encapsulating the glazing, absorber and the insulation (c.f. Fig. 2, dark blue parts). For both the back and side walls, 4 mm thick transparent walls made from poly(methyl methacrylate) (PMMA) were used. Temperature sensors were applied on the backside of the absorber ($T_{Absorber}$), the insulation ($T_{Insulation}$), the back wall ($T_{Backside}$), the outer side of the glazing ($T_{Glazing}$) as well as the side wall (T_{Side}) to monitor the temperature of these components during testing. Thermocouples (type T) were used, positioned in the center of each component and fixed with adhesive aluminum tape.

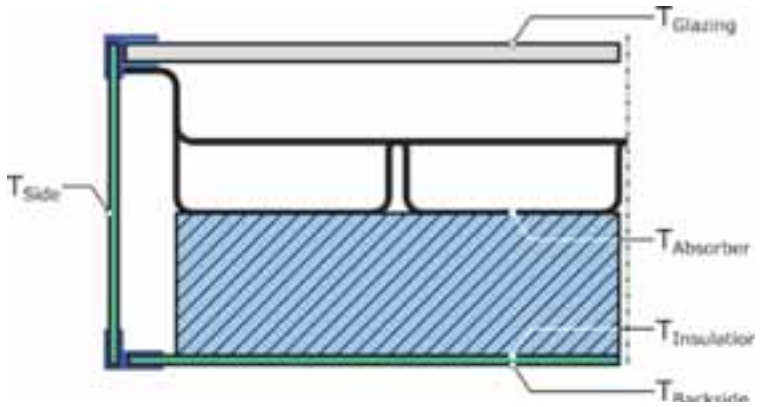

Fig. 2: Cross sectional view of the collector prototype.

The properties of this prototype are summarized in Tab. 1 (last column) and compared with information available from other studies. Comparing the different parts such as absorber, insulation and glazing reveals that the mounted prototype is similar to approaches described in recent studies.

Tab. 1: Properties of polymeric collectors described in previously cited studies vs. tested prototype (last column). Empty cells indicate that no information is available regarding the specific property. Crossed-out cells (—) indicate that the corresponding collector does not include the specific property.

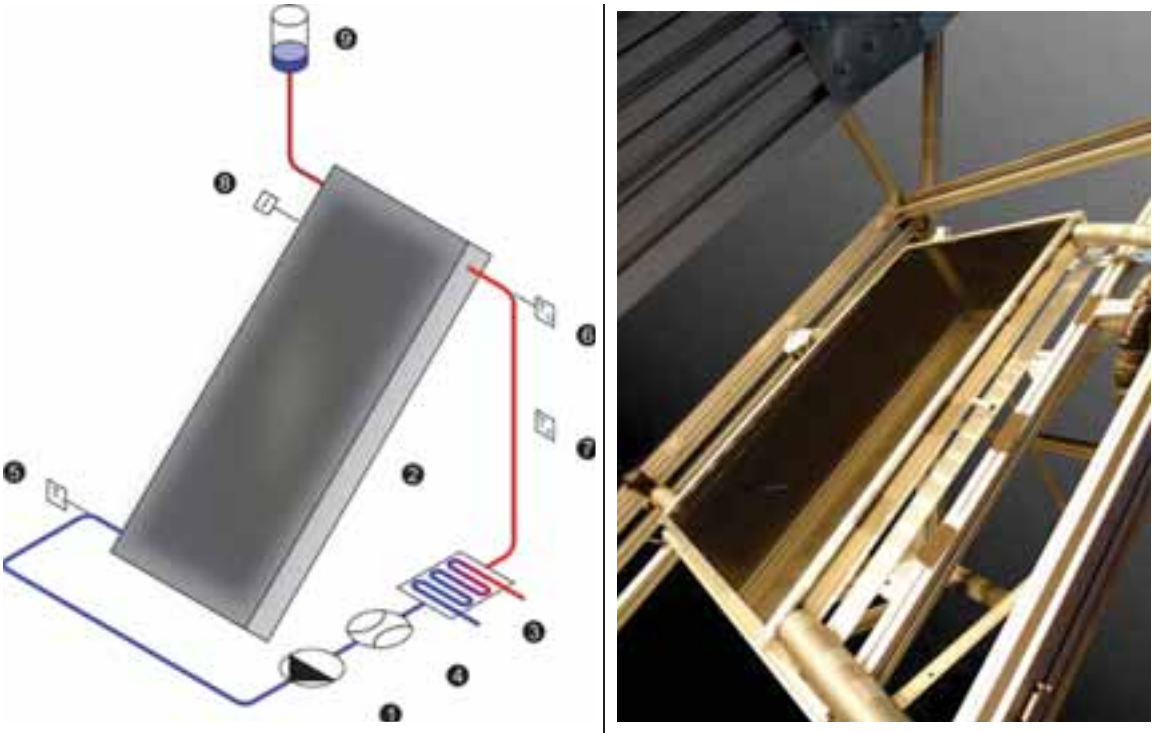
The efficiency of the tested prototype was determined according to EN ISO 9806:201 using the university`s solar simulator. Fig. 3-a shows the setup of the test rig. The HTF is pumped through the tested prototype (2) by means of a pump (1). An array of special lamps (not shown in the sketch) provides an irradiation with a spectrum similar to the sunlight towards the collector. The energy absorbed by the collector is removed w of a heat exchanger (3) to provide constant inlet temperatures. The volume flow rate is monitored with a magnetic-inductive flow sensor (4). Deviating from EN ISO 9806:201, an additional reservoir (9) was included to the system. As this reservoir is open to the atmosphere, the operating pressure inside the system is a function of the difference in height between collector and reservoir (Pascal`s principle). This setup was chosen to prevent damages to the prototype in case of over-pressure. During the test, the inlet (5) and the outlet temperature (6) as well as the ambient temperature (7) were monitored with temperature sensors. Furthermore, the in-plane irradiation is recorded by means of a pyranometer (8). A photo of the prototype during testing can be seen in Figure 5-b.



(a) Scheme of the collector test rig (b) Photo of the tested prototype

Fig. 3: Determination of the solar-thermal efficiency according to EN ISO 9806:2013.

4. Results and discussion

The efficiency curve of the tested prototype in relation to data available from literature is presented in Fig. 4 (green curve). The measured efficiency curve is well comparable with the results reported by Martinopoulos et al. (2010). Following the advices given by Missirlis et al. (2014), the efficiency of the prototypes could be improved by means of an arrangement of the in- and outlet pipe into and out of the manifolds. A comparison of the tested prototype with market available collectors reveals the highest solar-thermal efficiency of all polymeric collectors analyzed for temperatures $(T_{mean} - T_{amb}) / I < 0.07\ m^2KW^{-1}$ (c.f. Fig. 5). During measurement of the solar-thermal efficiency of the prototype, the temperatures of each component of the collector were recorded. Tab. 2 (first four rows) shows the steady-state temperatures for different inlet temperatures. Except for the lowest inlet temperature (24.2 °C), the absorber always reaches the highest temperature measured, followed by the glazing and the insulation. Between the insulation and the backside wall, only a small difference in temperature is observed (0.2 °C – 1.4 °C). The temperatures of the side walls are ranging at similar levels as the backside wall.

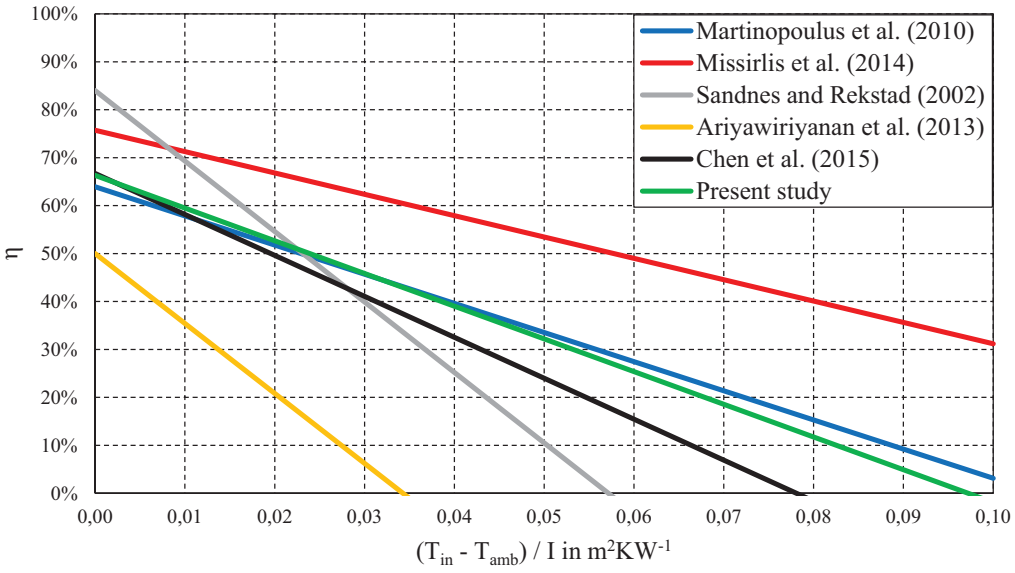


Fig. 4: Efficiency curve of the tested prototype (green curve) contrasted with data available from literature.

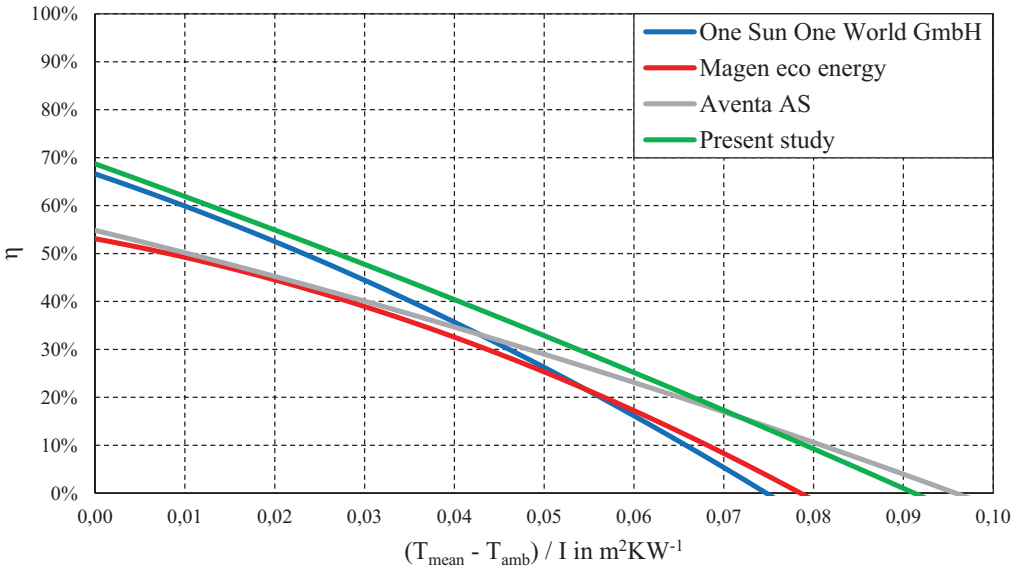

Fig. 5: Efficiency curve of the tested prototype (green curve) compared with market available polymeric collectors (data source: One Sun One World GmbH (2015), Magen eco energy (2011) and Aventa AS (2014)). The efficiency of *One Sun One World* solar collector was determined according to EN ISO 9806:2013, the efficiency of the collectors from *Magen Eco Energy* and *Aventa AS* according to DIN EN 12975-2:2006. For a comparability of the efficiency determined according to different standards, the ratios η_0, a_1 and a_2 were multiplied by the ratio of the aperture surface area to the gross collector area in the case of *Magen Eco Energy* and *Aventa AS*.

In addition to the case of HTF flowing through the absorber, the component temperatures were evaluated in case of dry stagnation for two different values of irradiation (c.f. Tab. 2, last two rows). Special attention is attributed to the maximum absorber temperature (93.6 °C), as this temperature is of crucial importance for the polymeric material used. In case of ABS, the maximum permissible temperature for permanent operation ranges between 95 °C and 105 °C (Bonten, 2014, p. 199).

Tab. 2: Measured component temperatures for different inlet temperatures in case of a filled absorber and for different values of irradiation in case of an empty absorber (dry stagnation).

5. Summary and Outlook

Within this paper, a polymeric solar-thermal absorber made of ABS was produced by means of the Twin-Sheet-Thermoforming manufacturing process. Based on a literature research, characteristic properties of both polymeric absorbers and other main components of polymeric solar-thermal collectors were identified and taken into account when setting up an appropriate prototype. The evaluation of the solar-thermal efficiency according to EN ISO 9806:2013 indicates competitive results compared to different concepts of polymeric collectors both described in scientific literature and market available collectors. Against this background, the production and manufacturing costs of polymeric solar-thermal collectors become increasingly important, as these costs directly affect the Levelized Cost of Heat (LCOH) of a solar-thermal system equipped with such collectors. As a technology capable of mass-production, the utilization of the highly automated TST for manufacturing polymeric solar-thermal collectors enables a significant cost-reduction. However, due to material limitations (such as low pressure and temperature resistance), polymeric solar-thermal collectors must always be considered as part of an entire solar-thermal system. Extending the application of polymeric materials to other parts of a solar-thermal system (e.g. pipes, heat storage, etc.) can therefore lead to further cost reductions. The determination of the LCOH of such a polymeric solar-thermal system is therefore subject of further research.

Simulation Study on the Optimization of Solar Water Heating System in Passive Solar House - Case Study

Tao Li, Yanfeng Liu, Dengjia Wang, Yong Zhou, Juan Li

Xi'an University of Architecture and Technology, Xi'an (China)

Abstract

The design of the active solar heating system is different in the passive solar room due to its passive additional heat. The passive additional heat affected the active solar heating system thermal performance. So the optimization of the system is necessary. In this paper, a solar heating building with active and passive combination as the object of study. The TRNSYS simulation model of solar heating system was established. The accuracy of the simulation model was verified by field test of indoor thermal environment for three consecutive days in the heating season. Under the condition of typical meteorological data, the indoor thermal environment of the whole heating season was simulated and compared under four different conditions. The results show that when the active and passive solar heating technology coexists, the indoor air temperature has been significantly improved. The design of the active system does not take into account the influence of the passive solar room. The design parameters and operating parameters of the system were analyzed by simulation in this paper. The research can provide the basis for the optimization of the active solar heating system in the passive solar room, which is beneficial to the popularization and application of solar heating technology.

1. Introduction

Almost all of China's heating areas are solar energy resources rich areas, with solar heating conditions. Therefore, solar heating should be the village buildings heating and energy conservation priority development direction. Active solar hot water heating technology has been correspondingly mature, many areas have formed corresponding demonstration buildings (Wang et al., 2014; Yu et al., 2014; Zheng and Han, 2013). The corresponding technical specifications and evaluation criteria have been formed (GB 50495-2009; GB/T 50604-2010; Zheng et al., 2012), to provide the basis for engineering application and construction. In addition, many studies on solar hot water heating systems at domestic and abroad, mainly in the system components optimization, operation control analysis and system evaluation research (Shukla et al., 2013; Wang et al., 2015). The research on system component optimization mainly included thermal collectors, water tanks and heat exchangers.

Although these studies provide a reference for the design and application of solar hot water heating systems, these studies are less concerned with passive solar construction. Due to the larger additional heat of the passive solar room, the heating needs of the building had significant difference between the day and night, and the heat storage capacity of the active system had a great influence (Liu and Wang, 2016). At the beginning of the design, the calculation method of the average heat consumption was used to determine the design parameters of the active solar heating system (GB 50495-2009). It shows that active solar heating system design in the passive solar building is not reasonable.

In order to obtain optimization design parameters of active solar heating systems in the passive solar rooms. The TRNSYS system simulation model was established in this paper. The influence of the design parameters and operating parameters of the typical meteorological year on the solar energy assurance rate and indoor thermal environment of the whole heating season were compared and analyzed. For the passive solar rooms' active solar heating systems to provided the basis for optimization. It was conducive to the promotion and

doi:10.18086/swc.2017.07.02 Available at http://proceedings.ises.org

application of solar heating.

2. The demonstration project

2.1. The demonstration project of solar heating system with passive solar house

The study object consists of two types of passive solar rooms, included thermal storage walls and additional sun-space. The photo of the exterior feature of the demonstration project was shown in Fig. 1. The external envelope of the building is a brick wall with 240mm thick. A 50mm thick XPS thermal insulation layer on the South wall, and 80mm thick XPS thermal insulation layer on other walls. The roof consists of 160mm thick Reinforced concrete and a 100mm thick XPS thermal insulation layer. The ground consists of a 150 mm thick Reinforced concrete and a 60 mm thick XPS thermal insulation layer. All of the windows adopt plastic steel material Insulating glass, on both sides containing 16mm thick air layer and 4mm thick glass. Southward, Northward and other directions to the windows with the height of 1800mm, 1500mm and 900mm respectively. The building plane is shown in Fig. 2. The basic parameters of the passive solar house are shown in Table 1.

The active solar heating system is designed for heating the demonstration building. Included 7 flat plate heaters modules with a total area of 14 m^2, a storage tank of 200 L volume, a thermal collector circulating water pump, a heating circulating water pump, water segregator and collector, controller and floor heating end etc. Radiant floor heating using DN15 coil, spacing 300mm.

Fig. 1: Photo of the exterior feature of the demonstration project

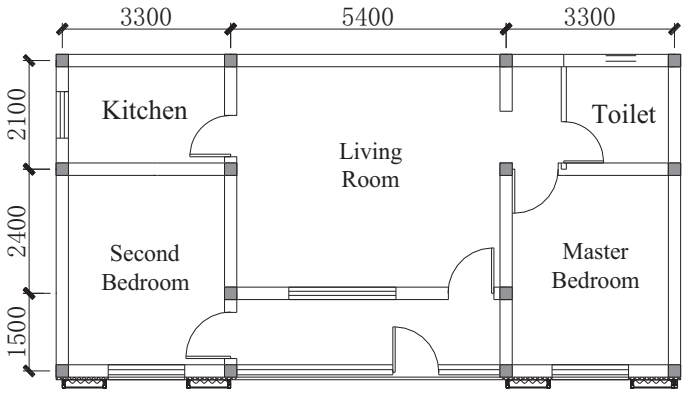

Fig. 2: Plane layout and size of the demonstration project (unit: mm)

Tab. 1: The components of the passive solar house

Types	Component	Descriptions
Trombe wall	Air vent	Size: 200mm×200mm, locate upper and lower three and two respectively
	Glazing	4mm thick simple glass
	Coating	10mm thick red corrugated sheet iron
	Air layers	100 mm thick

Attached sunspace	Sunspace	There are windows with a size of 1800mm×2100mm on the wall
	Glazing	The attached sun-space covered with 5mm wire glass

3. TRNSYS modeling and validation

3.1 Thermal performance simulation model

Used TRNSYS17.1 (TRNSYS 17.1) to build the simulation model of the combined active and passive solar heating system, as shown in Fig. 3. The building model in the system model was built in Google SketchUp according to Section 2.1.1. And imported it in the TRNBuild to set parameters, further as an external file for Type 56. There are two house connected forms in the actual building. The demonstration building has the same house type, so one house of the building was chosen to build model. Assume that the walls of the two rooms are adiabatic. Building adopted floor radiant heating. Living room, master bedroom and second bedroom belonged active heating room, other rooms were non-heating. The heating temperature of the heating room was set at 18 °C. The main TRNSYS components and parameters adopted were explained in Table 2.

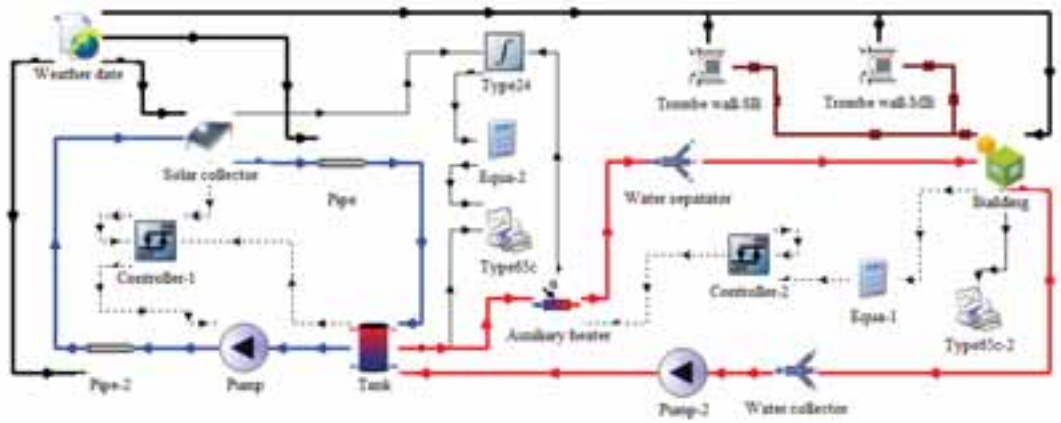

Fig. 3: TRNSYS modeling

Tab. 2: The main TRNSYS components and parameters

Name	Component	Main parameters	Descriptions
Weather date	Type 15-2	Number of surfaces: 2; slope of surface-1: 30°; slope of surface-2: 90°.	The external file contains the TMY-2 weather date of Gangcha. Used for the optimization analysis.
Weather date in test conditions	Type 99	The measured meteorological conditions during the test were inputted.	Used for the model validation.
Building	Type 56	The room air exchange rate: 0.5 h^{-1}; the active layer of 3 rooms were added.	The building model was built in Google Sketch Up, and imported to TRNBuild for setting the parameters. For the thermophysical properties please see Table 1.
Tank	Type534	Tank volume: 0.2m^3, tank height: 0.9m, number of tank nodes: 2, outer tube diameter: 0.025m, length of coiled tubes: 5.7m, HX cross sectional area: 0.45m^2, coil diameter: 0.3m.	There has a heat exchanger in the tank.
Controller	Type73	Collector area: 14m^2, collector slope: 30°.	The thermal performance parameters obtained from the manufacture.
Auxiliary heater	Type 6	Maximum heating rate: 10800 kJ h^{-1}, efficiency of auxiliary heater: 0.95.	Used for supplying the auxiliary heater

		Base case: set point outlet temperature: 40 °C.	
Trombe wall	Type 36b	Wall height: 2.9m, wall width: 1.5m, wall thickness: 0.33m, vent outlet area: 0.2m^2.	Used for calculating the energy of trombe wall flow to MB and SB.

3.2 Tests and model validation

A demonstration project of solar heating in Northwest China is taken as the research object. One dwelling with active and passive solar heating was test under the overall heating modes operating conditions. Conducted a three-day continuous test on April 25 - 27, 2016. Test contents had outdoor weather conditions, the indoor temperature of various function rooms of the two buildings and solar heating system operating parameters etc. The main parameters of the test included: the global solar irradiance on the inclined collector surface and the horizontal surface, ambient temperature, indoor temperature of various function rooms, the inlet and the outlet temperature of each device, flow rate of each system. Time interval of the data acquisition was 30 min. The measuring instruments and corresponding accuracies are listed in Table 3.

Tab. 3: Measuring instruments for the tests

Test instruments and type	Accuracy	Measurement parameter
Solar pyranometer (TBD-1) Recrding meter(QTS-4)	±8.789 W m^{-2} ——	Solar radiation intensity
Thermo recorder(TR-72ui)	±0.2 °C	Indoor and outdoor air temperature
Ultrasonic flowmeter(PH204)	±1.0% rdg	Flowrate of the pipes
Thermocouple thermometer(CENTER309)	±(1 °C+0.3% rdg)	Import and export temperature of main components

Meteorological conditions of weather data were tested as the input meteorological conditions for the model validation. According to the reference Denget al. (2016), the meteorological conditions were added to the input data in order to remove the initial thermal inertia of the building since the begins in the heating season in this area. Comparion of heating room master bedroom indoor air temperature test data and simulation data, as shown in Fig. 4. It can be seen that the overall correlation is good, although there is still a certain gap in temperature. It may be due to the following reasons: The opening and closing time of the ventilation holes of the heat storage wall was not set; residents and testers into and out of the room led to the actual increase in the amount of cold air penetration etc. During the test, the maximum relative error between the master bedroom test and the simulated temperature was 8.9% and the average of the relative error was 3.7%. Therefore, the simulation results show that the calculation error can be accepted, the simulated model can be trusted in the later analysis.

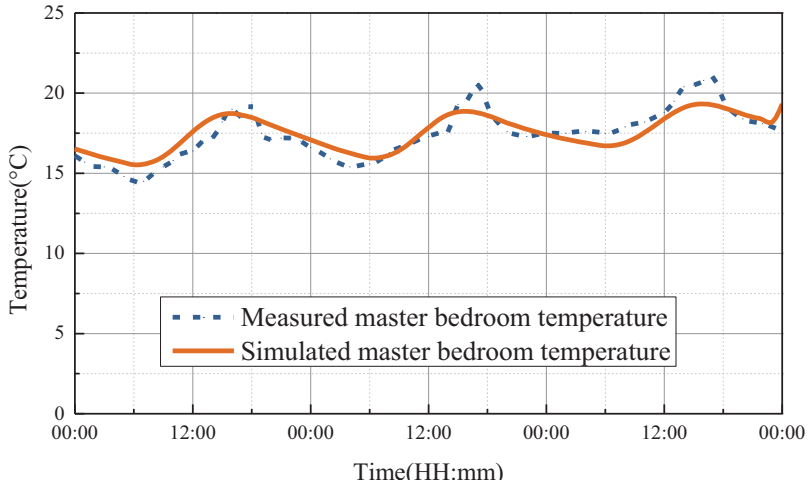

Fig. 4: Comparison of the simulated master temperature with the measured values during the test period

4. Optimizing the results and discussion

4.1. Comparison of indoor thermal environment during heating season

Simulated and compared the building with or without a passive solar room and active solar heating system, the master bedroom air temperature comparison shown in Fig. 5. It can be seen that the difference among the four types of indoor air temperature at the beginning and the end of the heating season was smaller. At the beginning and end of the heating season, the outdoor temperature was higher and the solar radiation intensity is larger, the heat load of the building was smaller, and the passive solar room had a higher additional heat. The passive additional heat can meet the heat required for the building basically. During the middle of the heating season, the indoor air temperature of the active system was significantly higher than that without the active system, the average temperature difference between the two is 14 °C or more. Because in the middle of the heating season, the outdoor temperature was lower, the building heat load was larger, the passive additional heat can not meet the heat supply of the building needs. The active solar heating system can provide a higher heat supply to meet the indoor temperature requirements. In addition, throughout the heating season, the active and passive combination of solar heating had the higher indoor temperature than other types, the average temperature can reach 19.8 °C. So the active and passive combination of solar heating technology is the most effective way to enhance the indoor thermal environment.

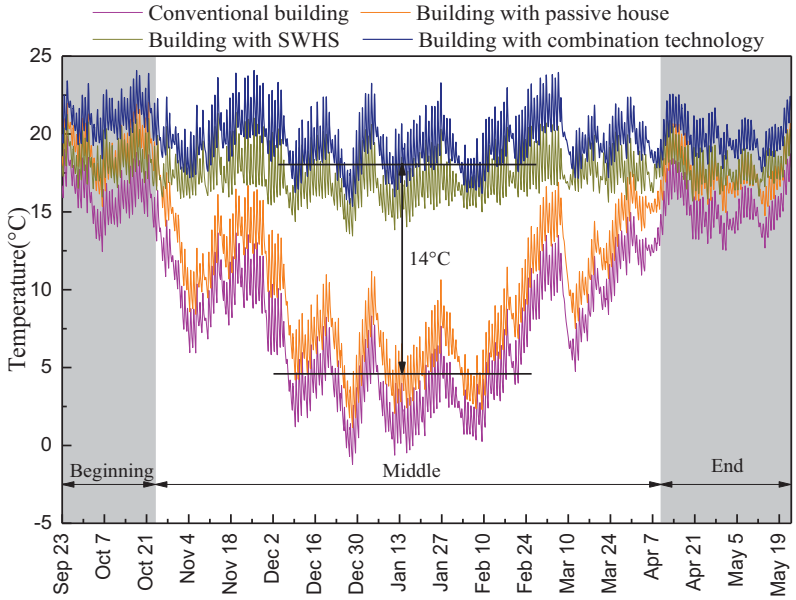

Fig. 5: Comparisonof air temperature in master bedroom

4.2. System design parameters optimization and comparison

(1) System capacity

In the building with or without passive components under different system capacity conditions (Solar collector area and storage tank volume). Compared the solar guarantee rate and indoor air temperature, as shown in Figure 6. It can be observed that the active and passive combination technoledge had more higher solar energy assurance rate and indoor temperature than the active solar heating significantly. Passive solar components for the building to provide a certain amount of heat, used to enhance the indoor temperature, and further reduced the amount of auxiliary heat, thereby enhancing the solar guarantee rate. In addition, in the active and passive combination heating technology, the solar energy guarantee rate increased with the system capacity increasing, the growth of initial stage was larger. When the system capacity reaches 49-700 (m^2-L), solar guarantee rate and master bedroom temperature increase gradually slow with the increasing in system capacity. At this point, the corresponding solar guarantee rate of 48.59%, master bedroom air average temperature of 20.16 °C. Therefore, a reasonable system capacity design is not only conducive to enhance the solar energy assurance rate and indoor thermal environment, but also to avoid blindly increase the system capacity and thus reduce the initial investment of system.

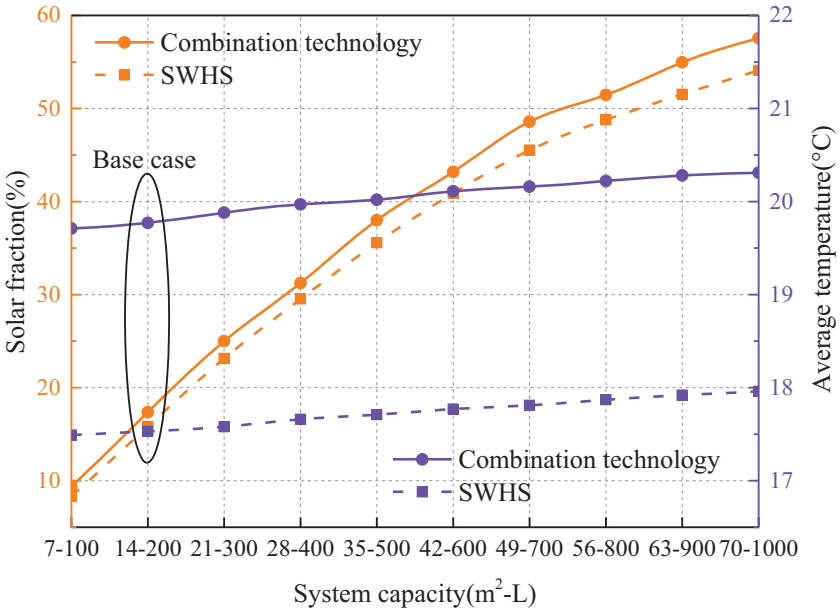

Fig. 6: Comparison of solar fraction and averagetemperature with the change of system capacity

(2) Tank volume

Under the condition of the building with or without passive components when the storage tanks had different storage capacities. The solar energy assurance rate and indoor air temperature had compared. Shown in Fig. 7. Similar to the system capacity change, the active and passive combination technolege can made higher solar energy assurance rate and indoor air temperature than only the active system. The average temperature of the indoor air increased slowly as the tank volume increaseing. The outlet temperature of the auxiliary heater was set to a constant value, affected the heating system inlet temperature directly, so the indoor air average temperature change was relatively small. The initial stage of changes of water tank volume , solar heating guarantee rate increased faster; with the further increased in the volume of the tank, solar heating guarantee rate growth rate gradually slow. It can be observed when the tank volume to a certain extent, although the storage capacity of the tank will become larger, but the system can gradually increase to the maximum heat storage capacity. Further increase the tank volume can not affect the stored heat amount of solar heating system. So the tank volume can be determined in a certain range. Do not have to increase the initial investment in the tank.

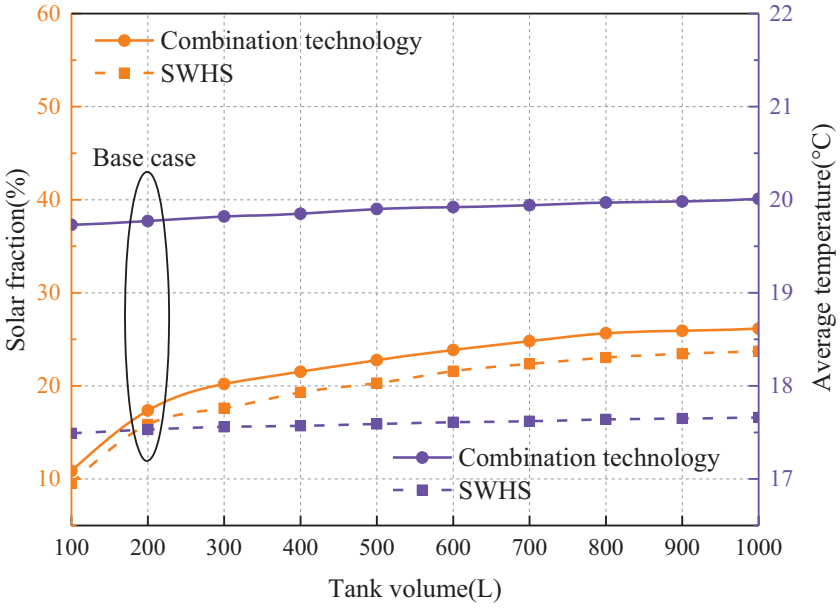

Fig. 7: Comparison of solar fraction and averagetemperature with the change of tank volume

(3) Solar collector area

Under the conditions of the building with or without passive components of different solar collector area. Comparison of the solar energy assurance rate and indoor air temperature shown in Fig. 8. When solar energy collector area changed, the average temperature of indoor air and solar heating guarantee rate changed similar to the changes of tank volume. With the increasing in solar collector area, the system heat collection increased. The heat of needed to store will increase gradually. But the tank capacity was limited, its thermal storage capacity was limited, and can not be stored excess heat of the system. Therefore, in order to meet the required heat supply in the night or rainy days of building. Need to increase the area of solar collectors also need increase the relative capacity of the system.

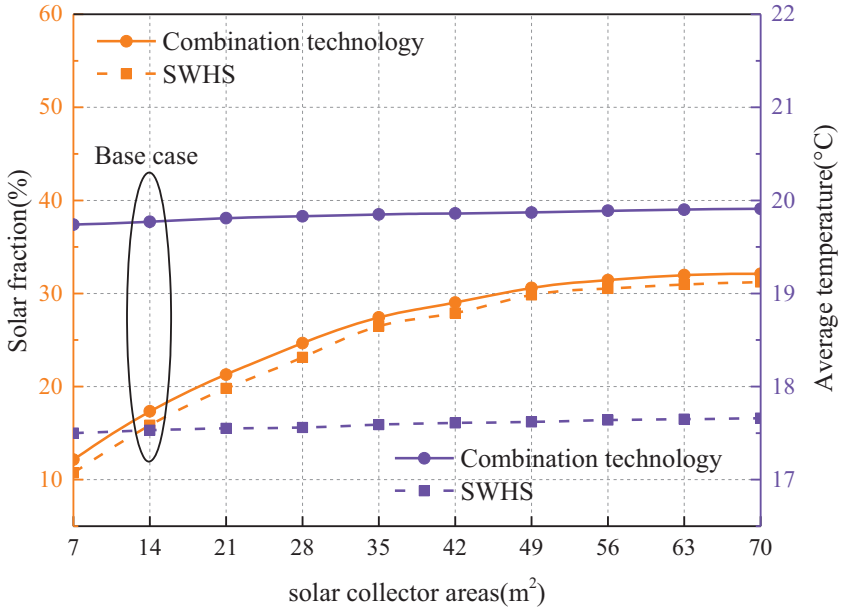

Fig. 8: Comparison of solar fraction and averagetemperature with the change of solar collector areas

Based on the comparative analysis of the above system design parameters. It can be observed that increasing the system's single component capacity can increase in the early play a certain effect. But blindly increased, will only increase the system investment costs, and not the relative gains. Should be combined with the system as a whole, while changing the design parameters of the system components to get more efficient solar heating system design. At the same time, should be combine with the system economic analysis in the follow-up study, and further evaluation of the system.

4.3. System operation parameter optimization and design

Under the conditions of the building with or without passive components of different auxiliary heaters set the outlet temperature conditions. Compared to the solar guarantee rate and the indoor air temperature, as shown in Fig. 9. The solar energy assurance rate decreased as the auxiliary heater sets the outlet temperature increasing, while the indoor average temperature increased as the auxiliary heater sets the outlet temperature increasing. When the tank outlet temperature can not reach the auxiliary heater set temperature, auxiliary heater operation will result in auxiliary heat increasing, resulting in reduce solar energy assurance rate. When the outlet temperature is set above 45 ° C, the indoor air temperature is almost unchanged. As the heating room has a set indoor temperature value, when the indoor temperature reaches the set value, the auxiliary heater to stop running. Auxiliary heat was no longer changed, solar guarantee rate remained stable.

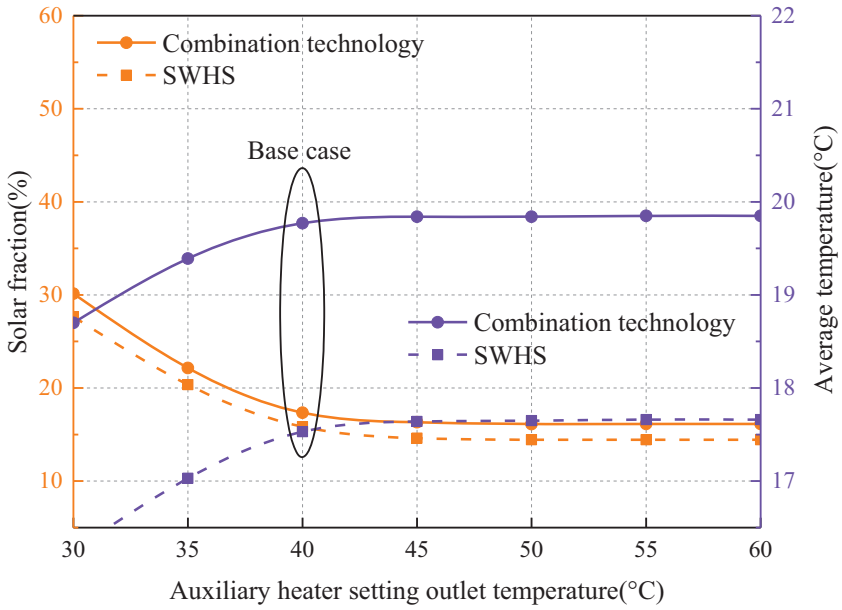

Fig. 9: Comparison of solar fraction and averagetemperature with the change of auxiliary heater setting outlet temperature

5. Conclusion

The indoor heating effects of SWHS in passive solar house were analysed, by means of dynamic simulation using TRNSYS software. The results have been well validated by comparison to the results of the demonstration short-term test in April 25-27. During the test, it was found that the maximum relative error of the master room test and simulated temperature was 8.9%, and the average relative error was 3.7%. Contrasted the four types of building indoor thermal environment, found that active solar heating technology had a significant role to enhance the indoor environment temperature.

Based on the simulation and optimization of the design parameters and operating parameters of the active SWHS in the passive solar building, it is found that: When the area of the solar collector and the size of the thermal storage tank are increasing in proportion, the growth rate of the indoor air temperature and the solar guarantee rate is gradually reduced. Only increased the capacity of the storage tank and solar collector area, can not enhanced the indoor thermal environment and increased the solar guarantee rate significantly. Reasonable outlet temperature settings of auxiliary heater had a greater impact on system performance. These findings can provide a basis for the application of active solar heating systems in passive solar rooms.

Education and Workforce Development

Example of an innovative initiative for education in thermal energy storage: INPATH-TES project

Gabriel Zsembinszki and Luisa F. Cabeza

GREiA Research Group, INSPIRES Research Centre, University of Lleida, Pere de Cabrera s/n, 25001 Lleida (Spain)

Abstract

Following the EC SET-Plan Education and Training Roadmap, the goal of INPATH-TES is to create a network of academia, research institutes and small and medium-sized enterprises (SMEs) to implement a joint PhD programme on Thermal Energy Storage (TES) technologies. The project consortium consists of 22 partners from academia, industry and SMEs from 14 different countries. The final result of such a network is to educate professionals on these technologies for the European research and industry institutions. Some of the main challenges identified so far consist of the development of the programme, the implementation of the programme in each country/institution, and to ensure the continuity of the programme after EU funding ends.

Keywords: Thermal energy storage, PhD programme, e-learning

1. Introduction

According to the European Commission (EC) SET-Plan Education and Training (E&T) Roadmap (JRC Coordination, 2014), there is a need for more efficient education in the area of thermal energy storage (TES). To meet the needs and fill the gaps identified by the SET-Plan E&T Roadmap, the project "Innovative Pathway for PhD research in Thermal Energy Storage" (INPATH-TES), coordinated by the University of Lleida, Spain, was launched in May 2015 (www.inpathtes.eu). The project is funded within the framework of the research and innovation programme Horizon 2020 by the EC.

The goal of INPATH-TES is to create a network of academia, research institutes and small and medium-sized enterprises (SME) to cooperate in defining and implementing a joint PhD programme on TES technologies. The final result of such a network will be the qualification of professionals for European research and industry institutions interested in hiring personnel with expertise in TES technologies. The specific objectives and outcomes of INPATH-TES project are:

- to establish a unique PhD programme in the field of TES starting year 2017,
- to develop at least 20 ECTS equivalent common training modules,
- to develop four technology oriented PhD courses,
- to establish one annual joint workshop for PhD students,
- to aim at graduating 28 PhD students per year at year 2021, and
- to exchange at least 14 PhD students per year between industry and academia.

The INPATH-TES consortium consists of 22 partners from 14 European countries, and has the presence of 14 universities, 3 research institutes, 3 industries, and 2 SMEs. Currently, they are the core of a future larger network of excellent R&D institutions, and industries for co-funding and industrial placement, sharing infrastructure capacities, and enhancing mobility of students.

doi:10.18086/swc.2017.08.01 Available at http://proceedings.ises.org

2. Approach for the PhD programme in TES and main results

The INPATH-TES work plan is divided in six work packages, being either coordination or support activities. Main coordination activities contain the development, maintaining and updating of the PhD programme in TES and the implementation of the PhD programme. Main support activities are stakeholder involvement, expansion of partnerships, framework for monitoring and evaluation of INPATH-TES as well as intellectual property rights, and regulatory issues.

A total of curriculum 14 courses are currently being developed by the consortium that can be implemented from a global perspective in ECTS awarding institutions. The courses can be grouped as follows:

- Basic common PhD courses: Research and PhD, Introduction to thermal energy storage, Thermal energy storage materials, Testing and characterisation of thermal energy storage materials, and Heat and mass transfer and sizing of energy storage devices.
- Common technology specialisation courses: Thermal energy storage applications for buildings, Demand side management concepts and energy storage, Large scale and industrial energy storage, and Energy policy and market development.
- Research management, dissemination, and communication courses ("soft skills"): Intellectual property and patenting ideas, Idea to product development, Dissemination and communication of R+D+I, Funding of research and project management, and Management and entrepreneurship.

2.1. Description of the courses

2.1.1. Research and PhD

The main objective of this course is to introduce the students to the basic aspects related to the scientific method, and provides the students with the details on the concepts of research, development and innovation (R+D+I). Specifically, the course provides an introduction to the different research methods and exposes the differences between the definition of PhD and industrial PhD. Concepts such as Responsible Research and Innovation (RRI), management of the research data, and the Intellectual Property Rights (IPR) are also dealt with in detail. The students also have the opportunity to learn how to correctly write a CV (academic and industrial one) and supporting statements.

2.1.2. Introduction to TES

The course will introduce students to thermal energy storage (TES), from thermophysical properties of materials used in TES systems to their implementation into the energy system. Thus, it will introduce the energy system and policy drivers, describing the technologies that can be used for storing energy, and focusing on fundamentals of thermal energy storage, its technologies, and its role in the energy system, while providing details on thermodynamic properties of materials. The learning philosophy of this course is to provide students enough information in order, for them, to be able to analyse a problem related to thermal energy storage and have a first idea on how to solve it by TES.

2.1.3. Thermal Energy Storage Materials

The purpose of this course is to provide an overview of thermal energy storage materials and their properties. It will also introduce a selection methodology as a tool for selecting TES materials performing the best for a certain application. Numerical models will be introduced for design and calculation of composite structures including TES materials, in order to perform an optimal selection regarding energy efficiency. Numerical models at micro/nano-scale for TES materials can provide better understanding of the heat and mass transfer phenomena on small scales. This knowledge can be applied to the design of new energy storage materials. A continuous learning philosophy is adopted in this course, with emphasis on problem solving through application of thermal engineering fundamentals - energy balances and thermodynamics. This course will be linked to other courses such as building or industrial applications.

2.1.4. Testing and characterisation of Thermal Energy Storage Materials

The course focuses on the characterization of energy storage materials and on the methods that could be used for testing them. It will provide the theoretical background and standard of characterization, describing also the

instrumentation and the parameters that have to be measured. Thermal and structural characterization technologies have been subdivided in conventional and "in house". Such technologies are the objects of the lessons of the course with the aim to offer a complete overview on: Differential Scanning Calorimetry (DSC); Thermogravimetric Analysis (TGA); T-history methodology and stability analysis for heterogeneous materials; technologies for measuring morphological, structural and specific solid properties, thermal diffusivity, thermal conductivity, thermal expansion, rheological properties, volatility and vapour pressure. Lab scale, experimental and in-situ procedures for thermal response, compatibility, flammability and mechanical testing will be given also.

2.1.5. Heat and Mass Transfer and Sizing of Energy Storage Devices

This course provides the INPATH-TES students with basic and advanced knowledge in heat transfer. It addresses such topics as multi-dimensional heat transfer, mass transfer, heat transfer with phase change, thermal design and component modelling. It is envisioned that since the PhD programme allows enrolling students with very different background, their entrance level knowledge in heat transfer may significantly vary. For this reason, the learning material includes such very basic items as fundamental heat transfer modes, thermal properties of materials, and heat transfer enhancement. On the other hand, students with an appropriate background would proceed directly to the lessons on basic numerical methods for thermal problems, analysis and modelling of heat transfer with phase change, and study of specific effects related to heat transfer in phase-change materials. Mass transfer by diffusion and convection is included as the theoretical basis for thermochemical energy storage. An advanced student will also acquire broad knowledge and practical tools in principles of thermal design, modelling and optimization of heat transfer equipment in general and sensible, latent and thermochemical energy storage devices, in particular.

2.1.6. Intellectual Property and Patenting Ideas

The purpose of this course is to provide the students enrolled in the INPATH-TES PhD programme with all fundamental aspects of Intellectual Property (IP) in general, and of patents in particular. The first part of the course is designed to provide an overview of IP and the reasons why it is considered an important economic and cultural asset in today's life and economy. Another important subject of the first part of the course is devoted to the definition of the dissemination, exploitation and communication plan. The second part of the course focuses on some basics concepts regarding patents, such as the relevant parts of the patent system and how to make use of patent information to encourage innovation and economic growth, patent classification, and the main tools available for patent information search. Besides this, the course also explains the different ways to apply for a patent, and presents some relevant case studies for a better understanding of the theoretical information presented.

2.1.7. Idea to Product Development

The objective of the course is to provide the methodology required to develop a product starting from the preliminary idea. The structure of the course starts with an introduction (with the need for innovation), then it describes the idea generation, idea screening, idea development and testing, followed by the business analysis, finishing with the technical implementation of a new idea.

2.1.8. Dissemination and Communication of R+D+I

This course aims at providing the students sufficient skills and information needed to locate and successfully apply for suitable sources of research funding, and to introduce them to the basics of project management, dissemination, exploitation and communication. Specifically, the course presents the different types of funding available and where these sources of funding can be found, how networking can help in locating funding, how to prepare and write a proposal, and how proposals are evaluated. Furthermore, the course also presents the different stages of the lifecycle of a project and explains the main skills required in managing a project. Finally, the purpose and definition of the research dissemination, exploitation and communication plan are also provided.

2.1.9. Funding of Research and Project Management

This course aims at providing the students sufficient skills and information needed to locate and successfully apply for suitable sources of research funding, and to introduce them to the basics of project management,

dissemination, exploitation and communication. Specifically, the course presents the different types of funding available and where these sources of funding can be found, how networking can help in locating funding, how to prepare and write a proposal, and how proposals are evaluated. Furthermore, the course also presents the different stages of the lifecycle of a project and explains the main skills required in managing a project. Finally, the purpose and definition of the research dissemination, exploitation and communication plan are also provided.

2.1.10. Management and Entrepreneurship

This course provides an introduction to Management and Entrepreneurship for course participants with a technical background. The topics covered in this course are prototype to market roadmap (business ideas), business planning (innovation concept), entrepreneurship (start-up company), managing firms for growth, and building soft skills in management and entrepreneurship. By the end of this course, participants will be able to generate business ideas, assess opportunities, formulate business strategies, find their first customers, procure funding for start-ups and manage firms for growth. Soft skills such as teamwork, leadership and communication for management and entrepreneurship are covered as well.

2.1.11. Thermal Energy Storage Applications for Buildings

In this course, the main building integration strategies of TES systems as passive and active solution for energy saving and indoor thermal comfort conditions are introduced and discussed. The key evaluation methodologies, e.g. experimental assessment and modelling-simulation approach, are also presented and deeply analysed. Then, the most significant research contributions are described and the uttermost promising future trends are outlined. Finally, the student is driven to select the proper TES solution with varying the main constraint of several research problems and also the district scale application is discussed, in cooperation with other two courses of the same PhD programme (Course 12 and Course 13).

2.1.12. Demand Side Management Concepts and Energy Storage

Demand side management (DSM) is based on two essential features, namely energy efficiency and of increasing importance, the role of demand side response. Energy efficiency is essential if we are to deliver zero carbon and low energy solutions for society. Changes to human behaviour and control systems are increasingly proving to be critical if energy savings, as a result of technological development, can be maximised. Often technology improvements are let down by the human involvement and hence it is important that those involved with research into the development and implementation of technologies understand demand side management. Demand side response addresses variable electricity and heat load management, whether driven by variable renewable energy or batch/cyclic demand and supplies. The course will cover the subject at macro – city level, down to buildings. It will outline legislative and incentive programmes, discuss the financial aspects and conclude with case studies of DSM.

2.1.13 Large Scale and Industrial Energy Storage

This course aims at providing the students with information about the use of thermal energy storage technologies in large-scale and industrial applications. The course begins with an introductory overview of examples of the integration of thermal energy storage in production and energy facilities, specifically in energy-intensive industries, concentrating solar power, and district heating and cooling. The students will be introduced to recent research progress in terms of innovative materials, container designs and concepts for systems integration for large-scale TES. Specific demonstration and operational, real-world projects as well as collection and analysis of in-field performance data will be discussed in detail. Different numeric simulation exercises give an introduction to the computer aided TES design and integration using realistic scenarios. The course will delve into environmental and economic aspects of large-scale TES installations, specifically introducing the use of LCA, LCC and further analyses in these studies, and will close with several real-world examples of applications in large-scale thermal energy storage. Common issues with industrial installations will be presented, including the scalability of R&D results.

2.1.14 Energy Policy and Market Development

The energy policy and market development course takes a holistic approach in looking at how thermal energy storage can solve issues identified at EU policy level. It commences by providing insights into energy policy

with particular reference to renewable energy policies, and examines this further by considering "good" and "poor" policies. Then in a heuristic fashion, it looks at the theory and real-life examples of how market development tools can be used to identify and develop new opportunities for TES in the context of energy efficiency and renewable energy technology policies. The course also examines how best to inform policy through key skills such as networking, influencing and communication, and how this can be enabled by being close to the customer and aware of predicted future market developments.

Each of these courses is composed of various topics, and each topic is then composed of different lessons. The lessons can then be “tailor-packaged” to meet the needs of each of the PhD supervisors for their PhD candidates. The developed learning material is implemented in the constructive alignment perspective in the EIT (European Institute of Innovation and Technology)/KIC InnoEnergy pedagogical methodology of student-centred learning, aligned teaching, and active learning (Biggs and Tang, 2011).

2.2. Online learning platform

An e-learning repository platform has been commissioned to host all the learning materials that will be delivered in the PhD curricula. The pedagogical methodology in student centred learning consists of careful design by the teachers of the intended learning outcomes (ILOs) assessed with the achieved learning outcomes (ALOs) assessment questions (EIT handbook, 2016). The online learning platform self-learning section consists of recorded learning videos, recorded lectures, automatically corrected exercise, remote lab, filmed study visits and online literatures. Randomized automatically corrected calculation exercises are to be programmed so that students may test their skills and knowledge at their convenience.

Based on the specific content generation and delivery needs of the project, as well as the demands of the consortium’s partners, the following main functionalities have been delivered: set of tools for content creation and co-creation between partners; server for content storage and indexation; tools for application of the agreed pedagogical methodology; system for achieving the 3 stages material review (content, methodology, IT) process; front-end, autonomous, self-operating content delivery system which allows the student to follow the courses with no needed for the professor to intervene for ensuring the due learning process; tracking mechanism of student progress, including completion of exercises and results, plus generation of a report; generation of certificate after completion of each course’s lesson; complimentary online manual and instructional videos for solution understanding and operation.

2.3. Web-based platform

The internet has become a powerful tool for reaching a wide range of groups of people and websites provide the best way of transmitting information. The website has been developed by one of the INPATH-TES partners, TCD, and the domain of the website is www.inpathtes.eu (see Figure 1). The website is a web-based platform designed for external communication and dissemination. This includes a general description of the project along with a more detailed explanation of its specific objective, partners’ logos and links to their own websites, a list of project results such as scientific papers and newsletters published during the project life-time, information related to how to enrol on the PhD programme, a description of the training material that is being developed, information regarding past and future events, links to other relevant European projects and international platforms, and contact information.

Currently, only students belonging to the core members of the INPATH-TES project can register and take lessons from the online learning platform. However, external people from academia or companies may also take courses from the platform in the near future. Enrolments will be possible by filling up the form that will be made available on the project website, and after paying the corresponding fees.

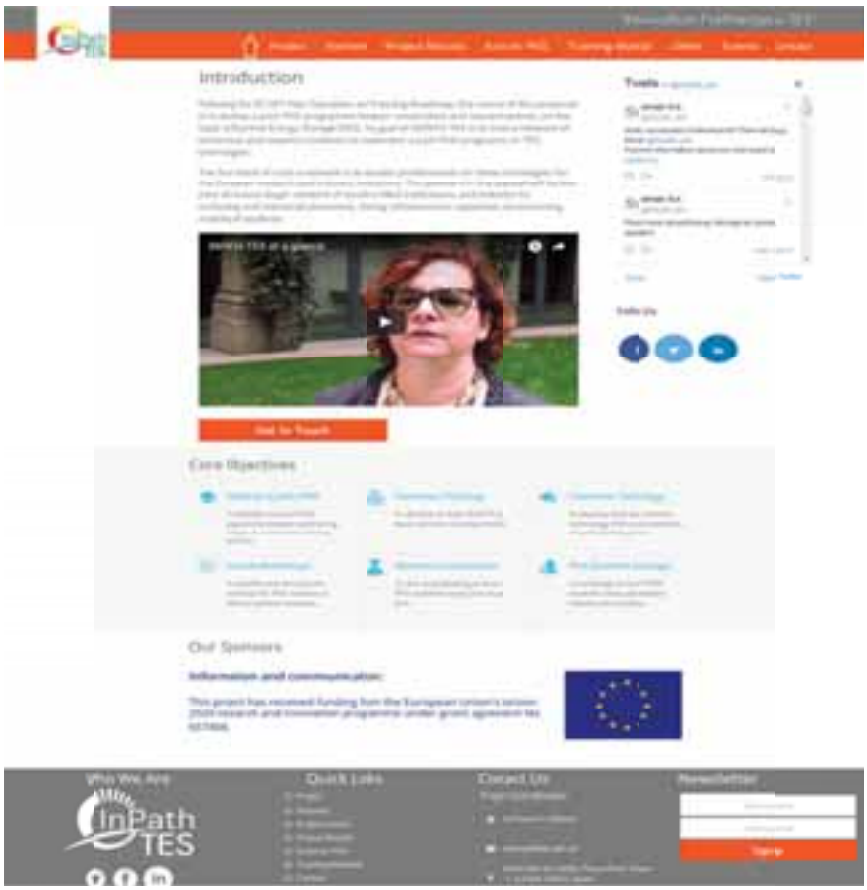

Fig. 1: Image of the website of the project

2.4. INPATH-TES label

The students willing to achieve the recognition of INPATH-TES label should contact two partner universities or institutions to join their own doctoral programme under joint PhD supervision, also called co-tutelle, and achieve the needed milestones. To be awarded the INPATH-TES label, the PhD candidate must fulfil the following requirements:

- To take at least 20 ECTS from lessons within the INPATH-TES programme.
- To perform at least 2 months of internship or secondment to a third partner from the INPATH-TES consortium for at least 2 months.
- To publish at least 1 scientific journal paper with co-authors from 3 institutions from INPATH-TES consortium.
- To have attended at least one annual INPATH-TES workshop/training school.

3. Main challenges

During the development of the project, some difficulties and challenges have been encountered, which can be summarized as follows:

- Development of the programme.
- The implementation of the programme in each country/institution.
- Two levels of work: PhD programme and Master of Science (MSc) programme.
- To ensure the continuity of the programme after EU funding ends.

The main difficulties regarding the development of the programme consisted in the fact that the contents of the proposed curriculum should respond to the needs and gaps identified by the SET-Plan, and at the same time they

must meet the needs of industry. On the other hand, the presence of many members who are not from academia required additional efforts to successfully adapt and implement the innovative EIT pedagogical methodology into the material developed. Last but not least, the development of a new e-learning platform for hosting the online learning material, and the need for 100% online assessment activities that does not require the presence of lectures, accounted for an additional degree of difficulty.

With regards to the implementation of the PhD programme, right from the beginning of the project the consortium collected the main information related to the PhD programme on the topic of the project in each of the academic institutions participating in the project, as well as others that are in close relationship with research centres also participating in the INPATH-TES project. After collecting all the information, the consortium reached to the conclusion that although there are some common items in all countries regulations, it is very difficult to define a unique implementation agreement for a joint PhD programme able to fit all requirements from each country. Consequently, the INPATH-TES consortium proposed to carry out doctoral theses in a co-tutelle regime as an alternative way to fulfil the main project objectives. A co-tutelle is an agreement on joint supervision at PhD level (also known as co-tutoring). Such agreements can be reached between the two cooperating universities, the PhD candidate, and the candidate's supervisors. The co-tutelle agreement regulates enrolment, supervision and the evaluation of the candidate's doctoral degree thesis. The PhD candidate must be enrolled in both universities, and must have at least one supervisor at each university. Furthermore, the PhD candidate must have a period of stay at both institutions. The thesis must have the logo of both institutions, and the cooperation agreement must be specified. Usually a single public presentation of the thesis is sufficient, which must comply with the rules that are in force at the institution where the presentation is to be given. The PhD candidate shall receive a diploma from each institution. This kind of PhD is well recognised in most of the partners' regulations. Therefore, at least 30 bilateral agreements are being negotiated between partner universities, and currently there are already a few students enrolled in co-tutelle PhDs.

Besides the development of a PhD programme, one of the aims of the project is to also implement a joint Master on TES. There is a big opportunity found in the fact that there is no other master on TES around the world, and that we have developed high quality material during the project. Unfortunately, today it is not possible to have an international joint Master programme outside the Erasmus Mundus programme, therefore the consortium decided to start by implementing a non-university Master programme, but apply in the near future for an Erasmus Mundus. Next step would be to apply for a university Master on TES by one of the universities members of the consortium. Here the biggest challenge would be to ensure its long term sustainability, but this is basically based on the number of students the Master would have each year, and the high specialization of the Master makes it difficult to convince the authorities of its sustainability. Therefore the first step would be to implement a non-university Master on TES at one of the consortium universities with the participation from the other consortium members as lecturers. We expect that after a short period of success of the Master will be the best way to go a step further to get a university master on TES or even a university joint Master on TES with participation of as many partners as possible in a joint-degree.

Finally, one of the main challenges of the project refers to the long-term sustainability of the project, once funding from the EU ends. INPATH-TES has the aim to continue as many years as International Network on TES with a joint-PhD programme and a joint-Master programme. Currently, the consortium is working on the development of a strategy to address this issue. The main problems to address consists in how to provide the funding necessary to meet the costs related to the e-learning platform and for maintaining, updating and reviewing the learning material, and also to establish an appropriate governance structure for the future network. The consortium is considering two possible options: continuing as network, based in one of the partners (now it is the University of Lleida), or creating a non-profit association. In any case, the membership is based on current partners that are the core of the future network of this project on the long-term. For the future sustainability of the project, there will be a membership fee applied to all members. However, the core members will avail a membership discount if they take responsibility of improving, maintaining and updating the learning material. New members are always welcome to join our network, under terms and conditions that will be agreed by the core members.

4. Conclusions

The INPATH-TES project was launched in May 2015 with the main goal to create a network of academia, research institutes and SMEs to implement a joint PhD programme on Thermal Energy Storage (TES) technologies. The proposed PhD curriculum aims to meet the needs and fill the gaps identified by the SET-Plan E&T Roadmap, through providing qualified professionals specialized in TES technologies for European research and industry institutions.

A curriculum consisting on 14 courses has been proposed, which are currently being developed by the consortium. Through active engagement with different stakeholder groups in the project, research and market oriented inputs to the PhD topics were set up in the training courses.

All the leaning material is being implemented in the "flipped classroom" perspective in the EIT/KIC InnoEnergy pedagogical methodology of student-centred learning, aligned teaching and active learning. An e-learning repository platform is being developed, which has the functionality of hosting recorded learning videos for efficient learning.

The main challenge that has been identified is the implementation of the joint PhD programme in each of the participating countries. Although all participating countries in INPATH-TES are within Europe, differences in the regulatory framework for establishment of PhD programme subsist. In order to overcome this problem, the consortium decided to define different bilateral agreements between partner universities for joint supervision of PhD students. Another important challenge of the project is how to ensure the continuity of the programme after EU funding ends. By creating further synergies between INPATH-TES and other global organisations and initiatives, extension of the partnership and exchange of students are foreseen.

Solar photocatalytic treatment of rain: from laboratory scale to real sanitary use in elementary school into economic unfavorable urban areas from Mexico City

Fabiola Mendez-Arriaga[1,2] and Rafael Almanza[2]

[1] Centro de Ciencias Aplicadas y Desarrollo Tecnológico (CCADET), UNAM, Mexico City, (Mexico).

[2] Engineering Institute, UNAM, Mexico City (Mexico)

Abstract

Important number of elementary schools in Mexico have not basic sanitary infrastructure: drinking water supply, sewer system or electricity service are not full available for the scholar community. On the other hand, hydric stress is remarkably worry in urban dense poor areas, as the case of the Iztapalapa municipality in Mexico City. In this condition, the development of sustainable technologies such the rainfall harvesting and solar photocatalytic treatment is a promising strategy against the water scarcity. This work shows the design, construction, installation and startup of a solar photocatalytic reactor as treatment of harvested rainfall for final use in an elementary school from an unfavorable economic urban area in Mexico City.

Keywords: Heterogeneous Solar Photocatalysis, TiO_2, rainfall, urban areas.

1. Introduction

The Mexico City metropolitan sector is one of the largest urban agglomerations in the world. With more than 21.2 million metropolitan population (18% of country's inhabitants), Mexico City has an unpredictable model of generation, carrying, supply and availability of basic public services such as drinking water, gas, transportation, food, hospitals, electricity, etc. In this big city, the social disparities and economic inequalities are strong remarkable among their residents. One of the most critical and detrimental situation is observed in the infrastructures of basic services in elementary schools predominantly into unfavorable economic areas. The most recent national census reflects 207,682 elementary schools attending more than 25 million of students among primary and secondary school age children (ages 2 to 15) (INEGI, 2014). Almost 50% of the elementary schools in México do not have drainage networks, 31% show deficiencies in drinking water accessibility, 11.2% express nonexistence of electricity facilities and 12.8% display entire absence of toilets.

Specifically in Mexico City there are 8,141 elementary schools attending around 13,151,297 students. More than a half of those schools (51.8%) belong to the public administration and 3.5% do not have drinking water facilities. Several students are used to return at home during the 30 minutes break between lessons in order to use the own toilets and lavatories if available in their houses. The inexistence of drinking water networks as well as the remarkable hydric stress are part of the sanitary problem for a large number of scholars and teachers. Figure 1 shows the availability´s coverage of basic facilities in elementary schools in Mexico City (INEGI, 2014)

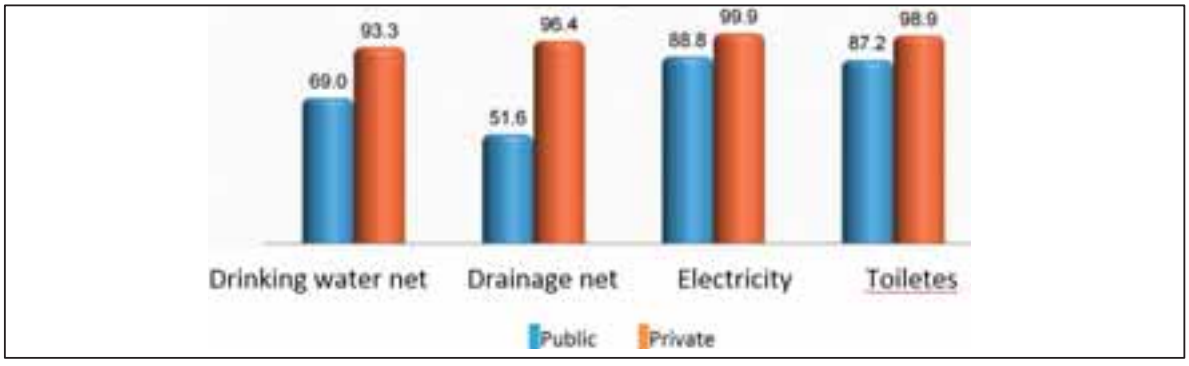

Fig. 1: Availability´s coverage of basic services in elementary schools in Mexico City (INEGI, 2014).

A rainfall-harvesting project is not under consideration as part of the public water supply in any governmental plan. Mexico City wastes approximately 1,000 million of m^3 of rainwater per year. In contrast, the Mexico city´s principal drinking water source, the Cutzamala system, has around 728 million of m^3 of capacity (SACM, 2017). Some estimations show that only 10% of the harvested rainfall is available and used within the same period of collection.

doi:10.18086/swc.2017.08.02 Available at http://proceedings.ises.org

On the other hand, the solar photocatalytic process has shown effective results as water treatment for effluents containing a huge variety of recalcitrant contaminants. Recent papers shows the increasing interest on this field applying the solar technologies to heat up, purify or pasteurize harvest rainwater at laboratory scale (Saran, 2018; Reyneke, 2017). Some of the most interesting goals for the scientific, engineering and academic community are to increase the efficiency of the harvest systems as well as to reduce the cost of the water treatment by means of sustainable solar technologies. This study shows the application of the well-known and mature solar photocatalytic process TiO_2 based at large scale in a real case of study inside of an elementary school placed into a high hydric stress zone in Mexico City.

2. Real case study: "Luis Braille" primary School

This school is located in Iztapalapa district, one of the most densely populated regions in the northeast of Mexico City as showed in Figure 2. This school belongs to the public administration. Twenty-six teachers attend around 550 students per each two timetables (morning, 8:00–13:00 and evening, 13:00- 18:00). The school has 4 bathrooms, 1 computer zone, 21 classrooms, 1 gymnasium or sport area, 1 parking among others facilities, etc. The Figure 2 shows the school localization and its physical boundaries.

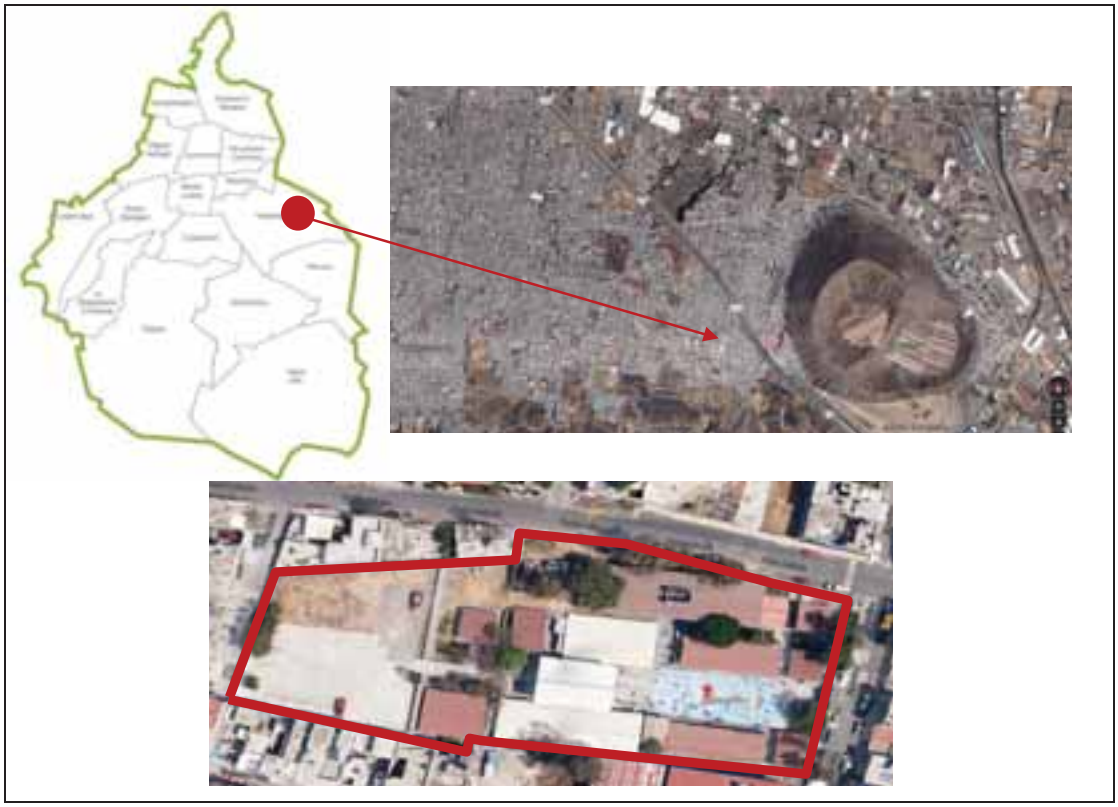

Fig. 2: Luis Braille elementary school in Iztapalapa district.

Municipal drinking water network is not available in this school. Acquisition of 10,000 liters of tap water shipped by a container truck or "pipa" is reach with around 50 dollars per week.

The water container truck does not offer any chemical/biochemical safe certificate of quality. The school has a cistern with capacity of 30,000 L as shown in Figure 3 (central photography). However, the maintenance of this reservoir is scarce and very often it remains empty or dirty.

Fig. 3: Sport area (left), cistern (center) and toilet building (right).

3. Design and on-field analysis

Initial step was the visual field inspection of the installations inside the school in order to evaluate the technical feasibility. Figure 4 shows the observations carried out in the parking area by technicians and researchers involucrate in this project. Noteworthy requirements taken into account during the on-field assessment were: a) accessibility of a south oriented large area; b) availability of solar free irradiated space without or as minimum as possible shades; and c) suitability of a large rainwater caption surface. Authorities, teachers and members of the Parents Association, whom showed deep involvement and interest amongst the research project, were also present during the field inspection.

Fig. 4: Parking area (left) and visual-technical inspection (right).

A crucial element of the school founded during the on-field analysis was a free large border wall (20 m length) south oriented in perfect conditions as supporter of the photoreactor. Figure 5 (left) shows this wall. The volcanic stones observed in the image were a “natural” stop limit to the occupation and self-construction progress of the neighborhoods (called in Mexico as “paracaidistas”) long time ago. Nearby this wall, there are no pedestrian cross or student presence due to the eventual occurrence of reptiles or arachnids adapted to the large accumulation of foliage. Thus, this isolated area was an excellent option for the operation of the photoreactor saved of damage for the football balls or other normal items used inside the school. On the other hand, the top roof cover of the playground was also a very important facility observed. Figure 5 (right) shows the roof cover of the playground. The long surface exposed for caption of rainwater allows harvest water previous filtration of dust and small particles following the photochemical treatment.

Fig. 5: Enclosing wall south oriented inside the school (left) and rainfall roof caption surface (right).

4. Rainfall treatment by solar heterogeneous photocatalysis

Advanced oxidation processes are based on the presence and reactivity of the hydroxyl radical (•OH) generated at

standard ambient temperature and pressure (25°C and 1 atm) with or without catalyst and/or presence of chemically reactive energy (Méndez-Arriaga, 2009). Among the AOP's, the heterogeneous photocatalysis with TiO_2, have shown highlighted efficiencies on removal of a wide type of persistent, recalcitrant, and emergent contaminants. Oxidation of organic compounds by means of TiO_2 is achieved by hydroxyl radical generation through the e^-/h^+ pair generated when the semiconductor is exposed to UV radiation.

On the other hand, contaminants present in rain are strong different in composition and content between annual season, stages or places. In an urban environment, most of the pollutant substances presents in rainfall are in relationship to the previous immediate quality of the air due to the "washing" effect during precipitation. In general, the direct employment of harvested rainfall is not preferable without previous physical and/or chemical treatment. Dissolved particulate substances and microorganism coming from the atmosphere are hazardous health compounds. In this project, an additional consecutive physicochemical conventional process (activated carbon and UV irradiation) follows the photochemical treatment train in order to guarantee the drinkable quality of the final effluent. Figure 6 depicts the full treatment train for both usages washbasin and drinking water.

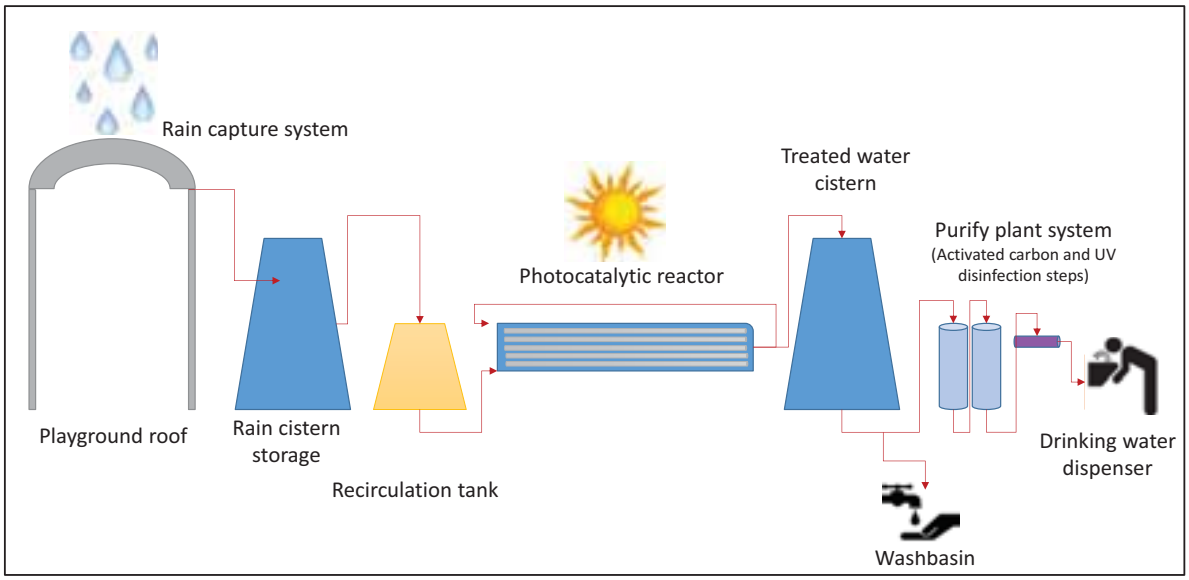

Fig. 6: Full treatment train (solar photocatalytic reactor and conventional physicochemical filters) for harvested rainwater

5. Solar photocatalytic reactor design

The solar photocatalytic reactor was designed with 10 compound parabolic collectors (CPC´s) disposed in parallel configuration. The basic components of the photoreactor are:

i) centrifugal pump (½ HP),

ii) storage cistern of harvested rainfall of 10,000 L of capacity (243 cm length, 238 cm extern diameter, 8.2 mm thick),

iii) sixty Duran glass pipes (5.08 cm inner diameter and 150 cm length) with TiO_2 (Degussa P25) thermally attached

iv) storage cistern of treated water of 10,000 L of capacity(243 cm length, 238 cm extern diameter, 8.2 mm thick).

Grupo Iddea Co. designed the layout of photoreactor and the virtual sketch (Figure 7a and 7b respectively), developed the hydraulic and electric systems and installed the full prototype.

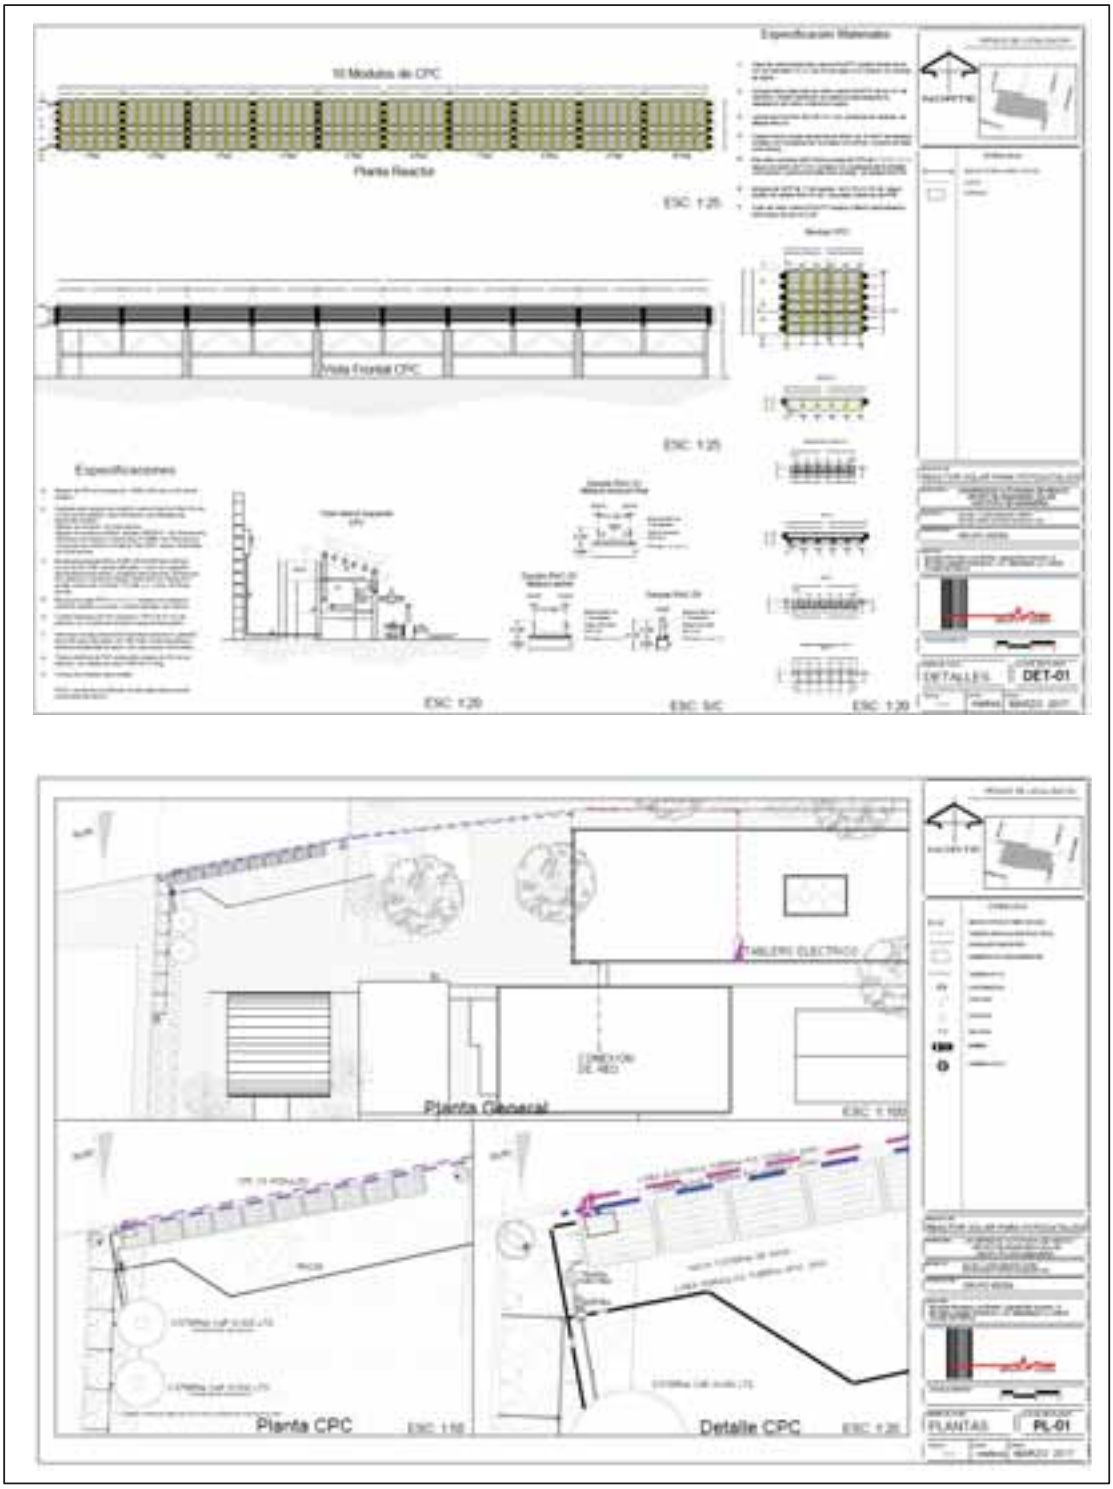

Fig. 7a: Layout and compound parabolic collector details

Fig. 7b: Digital sketch of the photocatalytic treatment system

6. Reactor construction, installation and startup

The photochemical reactor was constructed and installed in several stages per separated sections of the overall system following specific aims:

a) Fabrication of metallic structures for support and base of photo-reactors (see Figure 8);

b) Design of Compound Parabolic Collector and profile manufacture in fiber board outdoor material by jet stream water cutting system (see Figure 9 left and center);

c) Conformation of the high reflective mirror geometry through 99.5% aluminum film (see Figure 9, on the right);

d) Titanium dioxide (Degussa P25) thermal impregnation (150ºC, 4 h) on the internal pipe glass wall (5.08 cm ID Schott Duran glass);

e) Assembly of metallic structures and reflective aluminum mirror (see Figure 11);

f) Installation of hydraulic and pump system comprising the potable treatment system and final use (facet/dispenser) devices (see Figure 12);

g) Design of rain capture system on the roof of the outdoor play area (see Figure 13, left and center);

h) Installation of on-line measurement instruments (pH, OD, conductivity, salinity, temperature, total solids suspended, etc) and computational acquisition system (see Figure 13, right).

Figure 8 shows the manufacturing process for the construction of the metallic base of photoreactors including a finish detail of praimer and paint covering in order to avoid the outdoor damage.

Fig. 8: Metallic structures constructing.

Figure 9 depicts the one sun concentration geometry of the composed parabolic collector (CPC) of the photoreactor as well as the water jet cutting for construction of ribs to support the aluminum film along linear focus of the CPC.

Fig. 9: 1 sun CPC geometry (left), jet stream water cutting system (center), aluminum film adjust (right).

Figure 10 shows the shipping stage of all the premanufactured and separated pieces and devices from the laboratory at Engineering Institute in Coyoacan district until the elementary school in Iztapalapa municipality for the installation of the prototype. The Figure 10 also depicts the enthusiasm and collaboration of the students and academic community, which was interested to learn on the photochemical concepts and operation of the prototype.

Fig. 10: Transport of prefabricated pieces and helpfulness involvement of enthusiastic student in the school

Figure 11 illustrates the integration of one module consisted on the metallic base, aluminum reflectors and Duran glass pipes with catalytic activity. Ten modules with 6 glass pipes were hang on the wall south oriented making sure horizontal level and 19° inclination in each module.

Fig. 11: Parts joint and aliening-fastening on the wall

Figure 12 depicts a section of the hydraulic system including the harvest rain container, the closed recirculation tank and the treated water cistern together with the centrifugal pump and PVC pipelines to the photoreactor.

Fig. 12: Hydraulic system and pump test.

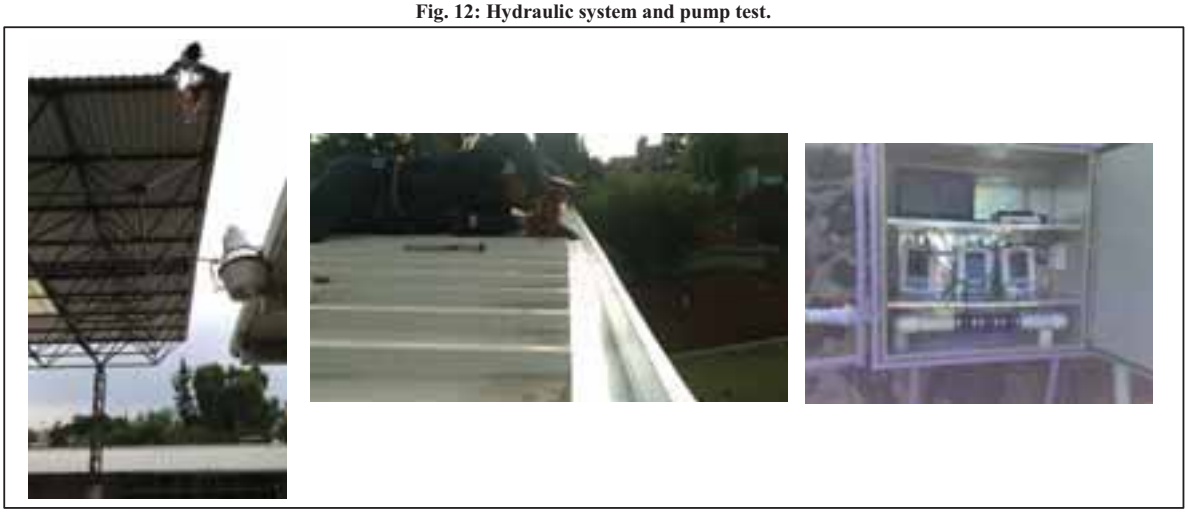

Fig. 13: Rainwater collection system (left and center) and on-line chemical measure instruments (right).

The harvest rain system was built with a semi-squared laminate canalization (20 m length) welding on the metallic top structure of the roof to 10 m altitude as depicted in Figure 13 (left and center). After that, the PVC pipeline reached connection to the storage tank with 45° inclination and previously crossing three cellulose glass paper filters consecutively attached.

The harvest rainwater flowed through the system till the pH, dissolved oxygen and conductivity sensors placed on the left side of the photoreactor. The measures during the photocatalytic treatment were recorded on line as well as the data of the UV-radiometer simultaneously acquired. Figure 13 (right) shows the chemical parameters measure system.

Fig. 14: Photochemical treatment system coupled to potable water train system and drinking water dispensers

Figure 14 shows the complete photocatalytic prototype including the conventional purification water system and the drinking water dispenser. The design, construction and startup of the prototype lasted 6 months. Following steps into the project consist on the assessment of the initial chemical quality of the harvest rainwater including the evaluation of inorganic ions (phosphorus, sulfates and nitrates among others), metals and organic compounds as well as the characterization of microorganism eventually presents. Effect of the photocatalitic treatment and optimization of residence solar irradiated time is also part of the goals during next rainy season during May, June, July and August 2018. Part II of this paper covers such results into the forthcoming ISES congress.

7. Conclusion

The solar photocatalytic science is a mature high efficient demonstrable knowledge applied for environmental remediation yet able to reach industrial scales and commercial proposes. However still there is a lack of examples with studies in real contexts to assess the potential scopes of this technology as the solar thermal and photovoltaic technologies did many years before. The solar photocatalytic research opens the opportunity to contribute against the water contamination and scarcity in unfavorable and marginal urban sectors.

Clustering methodology for defining a short test sequence for whole system testing of solar and heat pump systems

Diego Menegon[1], Anton Soppelsa[1] and Roberto Fedrizzi[1]

[1] Eurac Researc, Bolzano (Italy)

Abstract

Dynamic whole system testing methods are currently applied to evaluate the performance of heating and cooling system. One major obstacle to the implementation of such dynamic test methods is the cost connected to the experimental phase. To define a short test sequence, an original implementation of "k-medoid" clustering has been implemented. The paper investigates on the length of the sequence and how the days should be described to achieve effective results. A family of solar assisted heat pump systems has been generated by varying the collector field area and storage tank volume and studied via numerical simulations.

The results show that the days can be described as a function of average temperature and global horizontal irradiation. The simulation of different sequence lengths shows that a six-day sequence can be used to test the system with a possible deviation of results lower than 8% if compared to the annual simulation. The deviation is reducing with a higher number of clusters.

Keywords: Clustering; short test sequence, solar and heat pump system.

1. Introduction

In the contest of reducing the heating and cooling consumption, the system efficiency plays an important role. In a complex system composed by different energy sources and variable distribution, often driven by renewable energy, the performance of the entire system does not correspond to the "sum" of the single components performance, as the way the components interact among themselves has itself an impact on the performance and needs to be correctly considered. For this motivation, dynamic methods capable of assessing entire systems are used to characterize the system performance by different research institutes (Haller et al. 2013). The main advantage of this method is that the entire system is installed in the test chanber and realistic working conditions are used to study its performance. In this way, it is possible to perform a reliable evaluation of the system performance as-a-whole.

To reduce the cost of experimental phase, short test sequences (between 6 to 12 days) are defined to represent the seasonal boundary conditions. To arrange such short sequence, the literature presents different methodologies:

- Iterative definition of the sequence with the aim of attaining proportionality to the annual performance.
- Selection of days with temperature and radiation profiles corresponding to the monthly average conditions.
- Selection of days using some sort of weather data classification.

In the first approach, an optimization program reduces the deviation between the test bench data and the annual simulation of a system model. In addition to the fact that the method relies directly on a model of the system, it requires to perform a different optimization for every weather condition required to reproduce the weather pattern at the given location (unless the test it is referred to only one condition). The second approach is more easy to be implemented but in some cases it could not be able to perform a direct evaluation of performance, see for example (Haberl et al., 2009). For the last approach, different methodologies can be identified, i.e. classification into bins or classification with clustering. For example, the clustering has been adopted also for the definition of short sequence for the simulation of combined heat and power systems (Domínguez-Muñoz et al. 2011) and for heat pump systems (Huchtemann et al. 2016).

doi:10.18086/swc.2017.08.03 Available at http://proceedings.ises.org

In the development of the PLPE procedure (Menegon et al. 2017), we have investigated different methodologies. The first option was to create classes in according to the procedure developed for the test of components (Menegon et al. 2014). The method organizes the boundary conditions into multidimensional classes and a proportional part of the so-obtained distribution is selected. The good results obtained for the component test were not replicable when applied to the entire systems. Therefore, we decided to explore other techniques. Clustering, among the options we have considered, has the advantage that the weather conditions are classified without performing model simulations. In addition, the sequence corresponding to a certain climate can be easily be calculated. This study employs extensively numerical simulation of entire systems to verify the validity of the selections performed with clustering.

In particular, section 2 presents the clustering methodology while its application to the definition of test sequences of different duration is presented in the section 3. Different sequences are defined for the climate of Bolzano and Zurich. The section 4 presents the SAHP system to which the clustering procedure has been applied. The results and concluding remarks are finally given in section 5.

2. Method

The purpose of clustering is to group a set of objects in such a way the objects in the same group (called cluster) are closer, or more similar, to each other more than to those in other groups. In other words intra-cluster similarity is higher than inter-cluster similarity. In the case of this application, the objects to be classified are the days of a given weather file (long one year). The literature presents different algorithms and the authors have applied the Partitioning Around Medoids (PAM also called k-medoids) algorithm et al. 2007).

The user selects a number of clusters “N” and the algorithm classifies the objects into the “N” clusters. To apply the algorithm, the objects need to be described by a number of numerical variables, which are used to map every objects into a point in an M-dimensional coordinate space. Sometimes, the geometrical representation can be used to graphically represent the objects in the clusters.

The algorithm starts by defining randomly “N” initial medoids and the initial clusters are computed assigning every point in the cloud to one of these clusters. The clusters boundaries are then modified following an iterative process that tries all the possible combinations of point and cluster. The final clusters outline is obtained minimizing the total Euclidean distance between the cluster points and the medoid of the cluster they belong to. As the unit of measure used to characterize the objects along the dimension are different, data is usually moved (removing the mean) and scaled (by the reciprocal of the standard deviation) to avoid unit of measure bias. In this way, the object could be described by variables of different normalized physical quantities.

At the end of the iterative process, the “N” clusters are produced and the representative objects should be selected. Both the centroid and the medoid could represent the cluster: the centroid is the geometric center while the medoid is the nearest object to the centroid. For a discrete dataset, the centroid could not be part of the dataset. As in our case the points represent day of the years, the sequence is created selecting the medoids.

To understand better the application of the method, an example of classification of events with the clustering is given in Table 1: 15 objects, representing day of the year described by their mean temperature and irradiation, were randomly generated. Willing to select 3 representative days out from these 15, the method divides the objects into 3 clusters and then we select as representatives the clusters medoids.

Tab. 1: Example of clustering. 15 objects with their characteristics and cluster identity.

Day	Temperature [°C]	Irradiation [Wh/m^2]	Cluster
1	1.91	2376.85	0
2	9.90	2694.12	1
3	5.98	751.26	1
4	8.86	5.65	1
5	0.14	1048.74	0

6	2.57	1929.99	0
7	4.30	210.95	0
8	0.45	161.38	0
9	8.64	1454.36	1
10	0.58	5923.16	2
11	0.69	4057.67	2
12	3.77	6457.90	2
13	3.72	2715.89	0
14	6.00	4473.34	2
15	0.95	4764.96	2

Figure 1 shows the graphical representation of clusters indicating with different colors the different clusters. The centroids are indicated with a yellow point and the medoids are encircled. The centroids can be quite far or very close to a member of the dataset but usually they do not belong to the dataset. In this example, the sequence would be created with the temperature and irradiance profiles of objects 6, 9 and 15.

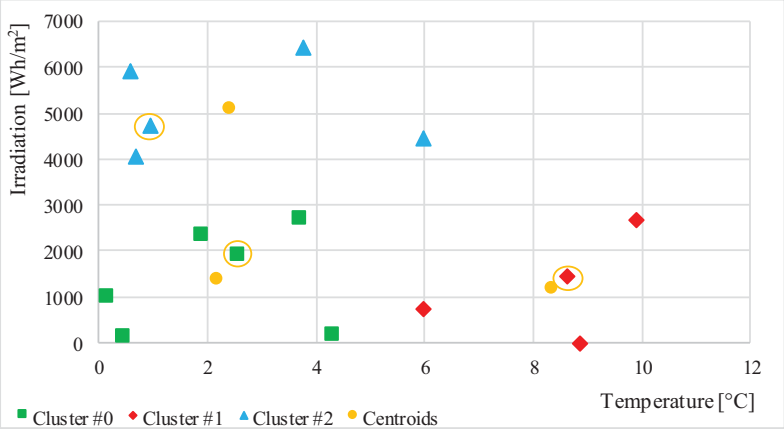

Fig. 1: Six-day and ten-day sequence defined with clustering of the climate of Bolzano.

In our procedure, the annual performance is directly extrapolated from the sequence performance, that is the performance of the tested system under the boundary conditions assembled from the short sequence. As the number of objects per cluster is usually not the same, the extrapolation of seasonal performance is done weighing the energy performance on the specific day by the size of the clusters it belongs to:

$$Q_{seas} = \sum_{i=1}^{n_{cluster}} n_{el,cluster,i} \cdot Q_i \qquad \text{(eq. 1)}$$

Where Qi is the energy measured during the event corresponding to the i-th Medoid and $n_{el,cluster,i}$ is the size of the i-th cluster, i.e. the number of objects it contains. The equation is valid for the thermal energies (SH, SC, DHW, collector and so on) and for the electric consumptions.

The medoid load is not equal to the cluster average load. In this way, the eq.1 does not give exactly the cluster load energy. In the PLPE method, the load is fixed and therefore we can apply a scaling factor to the medoid load. This factor (one value for each cluster) compensates for the deviation between the medoid energy and the cluster average energy.

$$L_{sc(i)} = \frac{E_{Simulations.Day(i)}}{E_{Simulations.Cluster(i)}} \cdot N_{Days.In.Cluster(i)} \qquad \text{(eq. 2)}$$

The scaling factor (Lsc) scales the space heating space cooling loads. The scaling factor is lower when a 3D or 4D coordinates are used then a 2D coordinate system.

The sequence defined with clustering would be closed to a correct representation of the whole year performances when the performances are linearly dependent from the boundary conditions. This because the days are selected considering the nearest object of geometric center of each cluster and the consumptions and loads are built through discrete integration.

As example, considering one-dimensional case where the consumption (W) is linearly dependent from the temperature, the consumption can be described as:

$$W = \alpha \cdot \mathrm{T} + \beta \qquad \text{(eq. 3)}$$

Where the parameters α and β are the coefficients of the linear dependence.

The total consumption is a sum of the "i-th" consumptions, and each "i-th" consumptions could be described as a function of the "i-th" temperatures with the equation:

$$W_{tot} = \sum_{i=1}^{N} W_i = \sum_{i=1}^{N} (\alpha \cdot T_i + \beta) = \alpha \cdot \sum_{i=1}^{N} (T_i) + \beta \cdot N \qquad \text{(eq. 4)}$$

In this case, the geometric center corresponds to the average temperature and the last summation could be substituted with the average temperature multiplied by the number of objects:

$$W_{tot} = \sum_{i=1}^{N} W_i = (\alpha \cdot \bar{T} + \beta) \cdot N \qquad \text{(eq. 5)}$$

The total consumption could be calculated directly from the geometric center of the boundary condition (in this case one temperature). The same demonstration could be performed with a multi-dimension problem when the consumptions are linearly dependent from more boundary conditions.

3. Short Sequence

As we have seen in the methodology section, the days have to be compared in terms of some characteristics that became the coordinates for the method. Days can be characterized by profiles of temperature, irradiance (with its different components), relative humidity, wind speed and so on. Not all these variables have the same influence on an heating and cooling system performance. For example, in a SAHP system the temperature and the irradiance profile have a higher effect than the wind speed. To reduce the number of variables that identify an object, the average ambient temperature and total irradiation on the horizontal surface are considered, describing a 2D coordinates. This classification is the simplest possible. Other solutions are given by adding the space load to the classification. Other options could be using 3D and 4D clustering where the 3D clustering considers the temperature, irradiance and heating and cooling load (in one vector using the sign to discriminate between heating and cooling), while the 4D considers the temperature, the irradiance and the heat and cooling loads separately.

In addition, the sequence length should be determined. The results presented in the literature show that longer sequences are more representative of the whole season. However, it is important to remark that the sequence length is a trade-off between accuracy and cost. To verify the influence of the sequence length in our application, we defined sequences of 6, 8, 10, 12 and 24 days.

In this study, we present the results for the climates of Bolzano and Zurich. The sequences are used as boundary condition of a family of reference numerical models of a solar assisted heat pump system (SAHP). The reference models were generated by varying, the collector area and the tank storage volume.

Fig. 1 shows the effect of changing the number of clusters: six clusters (green triangular points) and ten clusters (red diamonds points). With a different number of cluster, the shapes of the clusters changes and therefore different days are selected. It is possible that one specific day is selected by both classifications, although this is not generally the case (in the figure, one triangle - with coordinates 22°C, 7322 Wh/m^2 - is hidden by one diamond). With a larger number of clusters, a wider range of temperature and irradiation are covered. This happens because the dataset is relatively uniform and therefore medoids are quite uniformly distributed which means that increasing their number will cover better points at the boundary of the dataset. The other way round, with only few cluster the extreme conditions could not be reached.

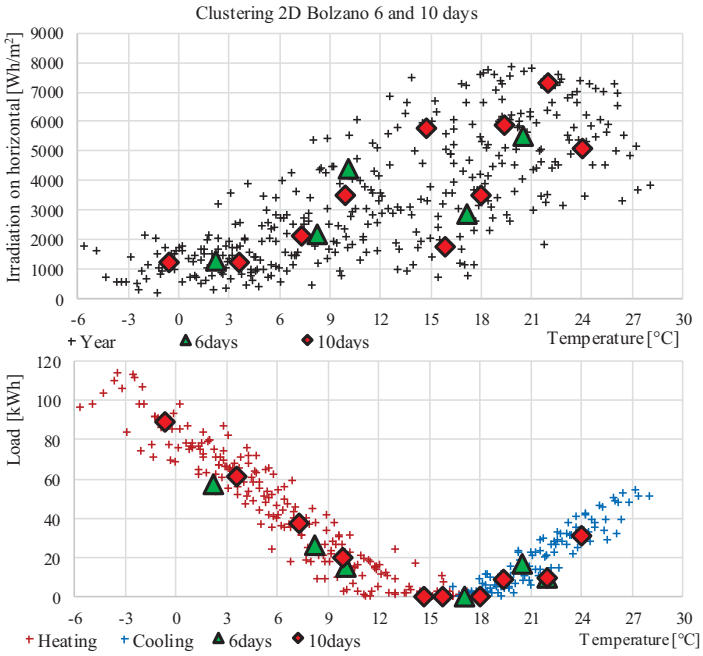

Fig. 2: Six-day and ten-day sequence defined with 2D clustering of the climate of Bolzano.

Fig. 2 shows the identification of the sequence for Zurich. The green triangular points identify the selection with 2D coordinates (T and GHI), the red diamonds points identify the selection with 3D coordinates (T, GHI and Load) and the blue circle points identify the selection with 4D coordinates (T, GHI, Heating and cooling load). The figure in the left shows the days of the year as function of the average temperature and global horizontal irradiation while the right figure shows the days as a function of the average temperature and the space load distinguished into cooling (blue points) and heating (red points).

The different coordinates of the days (2D, 3D, 4D) modify the geometry of the problem and therefore the selections are different.

In the climate of Zurich, the 2D clustering does not considers days with space cooling load. The 3D clustering selects only one day with very low load (1.6 kWh) while the 4D clustering selects two days with cooling load (one with 1.6 kWh and the other one with 25.5 kWh). The reason for this fact is that only few events require cooling. Using the 2D clustering, the load is more influenced by the temperature and irradiation while the 3D clustering gives more importance to the load. The 4D clustering gives equal importance to the cooling and heating load since the coordinates are normalized. This means that in a climate like Zurich where the heating load is about 30 time the cooling load, this selection would give the same number of days to the heating and to the cooling season, resulting in an unbalanced selection.

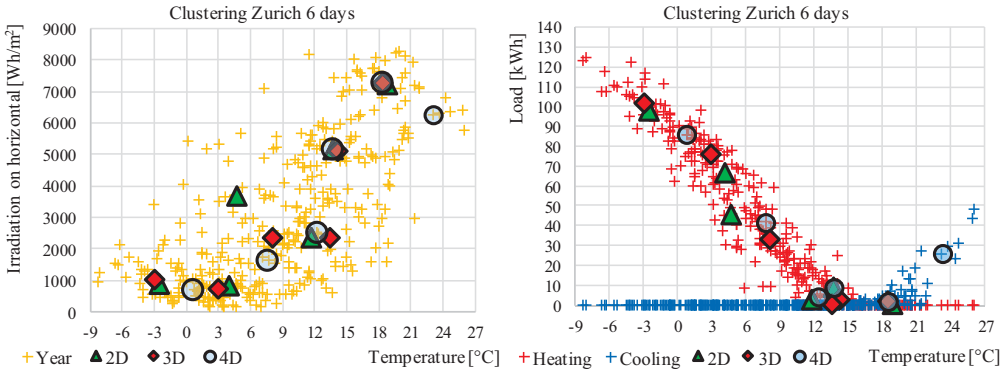

Fig. 3: Identification of six-day sequences defined with different coordinates. Zurich climate.

In addition to the information given with previous figures, Fig. 4 shows how the 2D and 3D coordinate systems affect the boundary conditions profiles. The figure present the two six-day sequence defined in the climate of

Bolzano. The 2D clustering presents the temperature profile higher than the 3D clustering and as consequence the heating load is lower and the cooling load is higher. The temperature profiles are smoothed between two days.

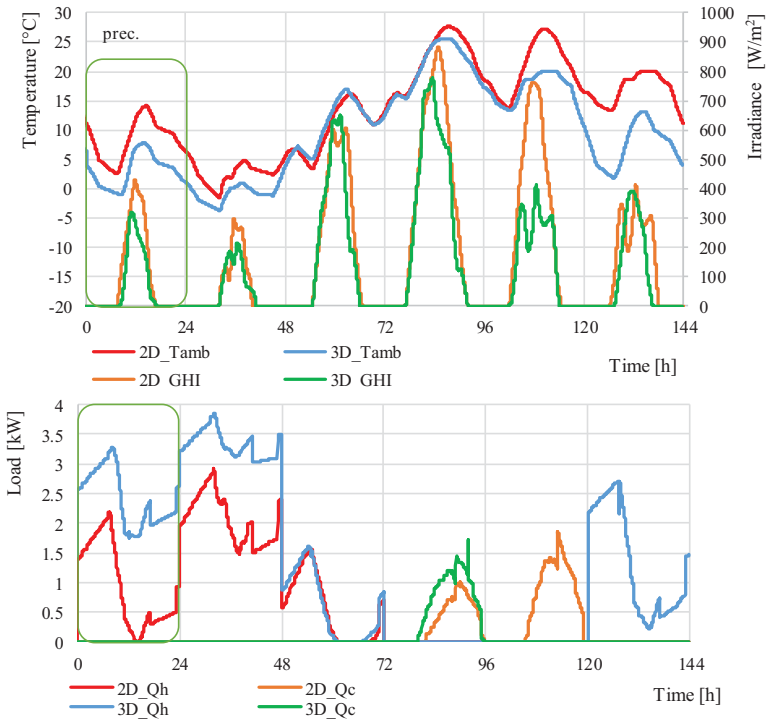

Fig. 4: Comparison of six-day sequences profiles defined with different 2D and 3D coordinates. Bolzano climate.

4. Simulation

The clustering was tested simulating a family of SAHP systems (see figure 5). The study considers different configurations of collector area (8 m^2 or 16 m^2) and storages volume (700 l or 1500 l). The volume of 700 l is obtained connecting in series a 500 l and a 200 l storages while the 1500 l volume is obtained with the combination of a 1000 l and 500 l storages.

The system was modelled with Trnsys (Klein and et al. 2012) and the components were validated with laboratory tests or with monitoring data (Bettoni 2013). The figure presents the layout and the models of the system:

- The heat pump model (type 847) is based on a performance map (as a function of inlet temperatures and flows).
- The collector model (type 1) considers the collectors' parameters calculated in the certification test of one commercial collector. The type 1 is coupled to a moving average to introduce inertia effects.
- The Storages model (type 340) is a commercial type (Drück and Pauschinger 2006).
- The building model is type 56.
- The weather file is read with the type 109 for the simulation of the whole year. The sequence' weather data is read with type 9.
- The dry-cooler model (type 880) was developed by (Besana 2009; Bettoni 2013).
- Other traditional models are the pipes (type 31), circulation pump (type 110), mixing and tempering valves (type 11) and heat exchanger (type 5b).

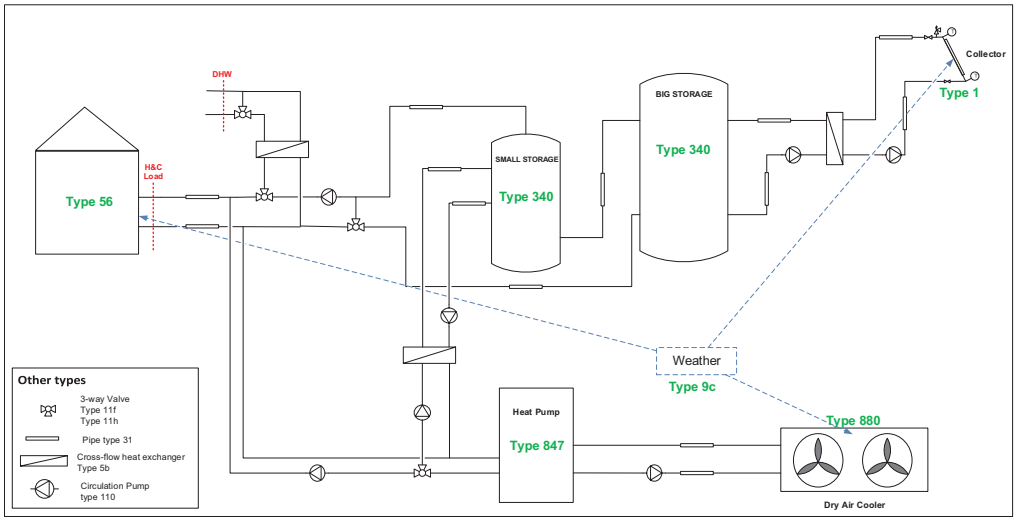

Fig. 5: System layout and component models.

The sequences are the boundary condition for the simulation of this system. The selection with the clustering method does not give any advice on the order of the sequence. The days are ordered in the same order as they occur in the year starting from the winter and ending the sequence with the autumn conditions. The last day of the sequence is used to precondition the whole sequence.

The simulation set-up considers the combination of:

- Climates of Bolzano and Zurich.
- 6, 8, 10, 12 and 24 day.
- 2D, 3D and 4D coordinates.
- System configurations (collector area and storage volume).

In parallel to the sequence simulation, also the whole year was simulated. The values extrapolated from the short sequence are compared with those calculated from annual simulation. The deviation between the values extrapolated from the short sequence and the annual simulation with:

$$\delta X = \frac{X_{short\ sequence} - X_{annual\ simulation}}{X_{annual\ simulation}} \qquad \text{(eq. 6)}$$

Where X represents one of the selected performance figures among thermal energy (load or source), electrical consumption, seasonal performance factor and solar fraction.

Six-day sequence are defined also for Rome and Gdansk.

5. Results

Figure 6 and Figure 7 show the SPF deviation (eq.6) as a function of the number of clusters for the climate of Bolzano and Zurich for the different plant configurations. The figures show the total SPF value calculated with the annual simulation. In general, the deviation of SPF decreases as the number of clusters increase. Table 2 and Table 3 report the SFP deviation RMSD and span (the difference between the maximum and minimum value). These values help to understand how much the trend could variate by selecting a different number of clusters. The cells of the two tables are colored in order to highlight in green the smallest values (best case) and in red the highest values (worst case).

The first outcome, is that the 4D clustering presents the highest deviation. As it was noticed before discussing the points in figure 3 (section 3), the 4D coordinate system gives an unbalanced selection (the days with heating load have the same weight as the days with cooling load also if the two loads are different). The 2D clustering represents better the selection in the climate of Zurich while the 3D represents better the selection in the climate of Bolzano.

The second outcome is that the configuration with the 700 l storage has a lower deviation than that with the 1500 l storage while the configuration with 8 m^2 of collector has a lower variation than the case with 16 m^2. In general,

we expect the sequence to be less accurate in case of high collector area. In the short sequence, more consecutive days with high irradiation could not be present while it occurs during the summer season. In this case, the stagnation could be neglected by the short sequence because the storage does not have enough energy to stagnate. Besides the effect of collector area, also the effect of the storage volume has to be considered. If we examine the extreme case of high collector area and very low storage volume, the system would use the solar energy by the end of the day when it has been produced since the solar energy cannot be stored. Therefore, a short sequence could be representative since no stagnation occurs due to consequent days with high irradiation. Increasing the volume, this effect starts to be noticeable. In fact, all the sequences simulated for the case of system with 700 l are more accurate than those with 1500 l.

ZU	**700**	5.6%	6.3%	6.5%		5.5%	5.7%	5.5%

Tab. 3: RMSD in the different coordinate systems.

		2D	3D	4D		2D	3D	4D
Climate	**Stor.\Size**	**8m²**	**8m²**	**8m²**		**16m²**	**16m²**	**16m²**
BZ	**1500**	0.35	0.14	0.6		0.5	0.53	0.62
ZU	**1500**	0.21	0.39	0.55		0.24	0.45	0.42
BZ	**700**	0.24	0.16	0.46		0.16	0.3	0.4
ZU	**700**	0.21	0.39	0.34		0.22	0.19	0.38

The system considered in this study presents the possibility to satisfy the space heating and domestic hot water loads with the solar energy or the heat pump, while the space cooling is satisfied only with the heat pump. The cooling SPF does not depends from the collector area and the storage volume and in the climate of Bolzano is quantified in 4.22. The figure 8 presents the trend of the deviation of the cooling SPF. This figure presents the same scale of the ordinate axis of figure 6 to show that the variation of cooling SPF is much lower than the total SPF and the deviation could be considered not dependent from the number of clusters. The reason is that the performance of the heat pump is close to be an affine dependence of the air temperature. We have shown with eq.3 to eq.5 that the clustering is nearly optimal in such a case.

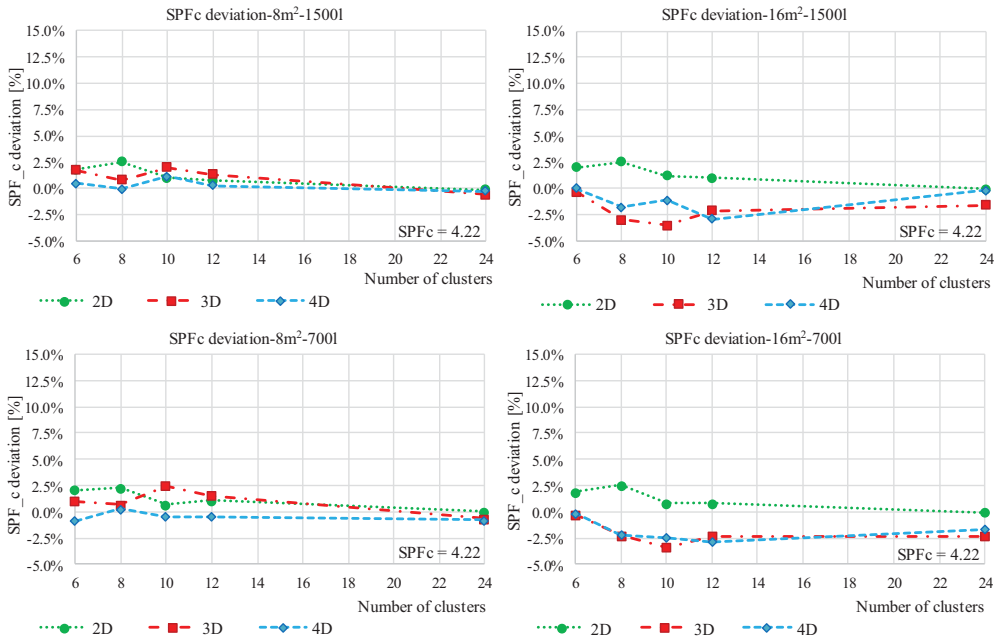

Fig. 8: Total seasonal performance factor as a function of the number of cluster and M-dimensional coordinates. Simulation of a SAHP system with different collector field and storage volume. Bolzano Climate.

Regarding the solar fraction, figure 9 presents the result of Zurich. The solar fraction is well reproduced for lower storage volume or collector area. The clustering with a 2D selection represents better the solar fraction with the only exception of Zurich with 16 m^2 and 1500 l (the sequence deviates from the annual simulation about 10 %). The cooling solar fraction is 0 since the plant uses only a compression chiller and not thermally driven chillers.

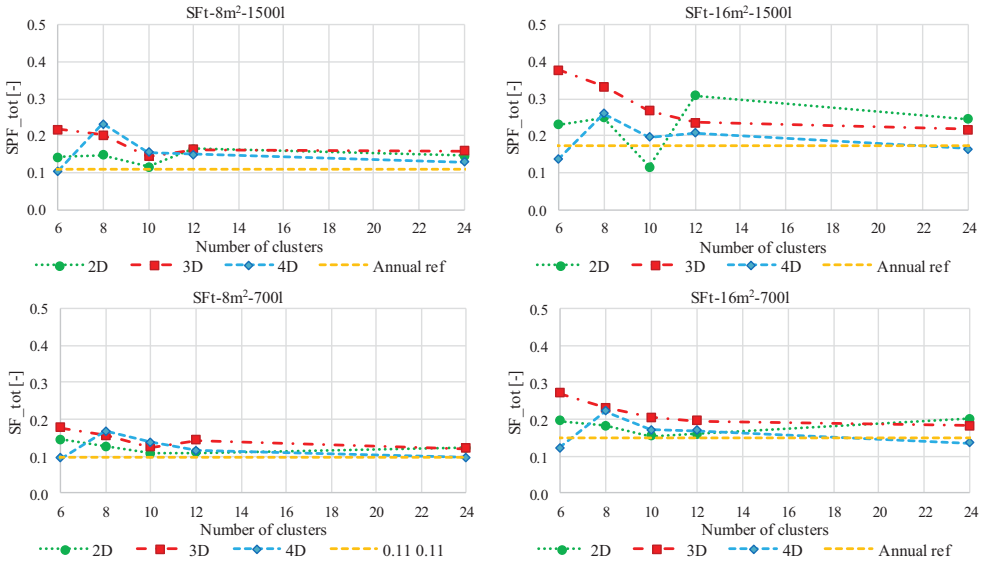

Fig. 9: Total solar factor as a function of the number of cluster and M-dimensional coordinates. Simulation of a SAHP system with different collector field and storage volume. Zurich Climate.

A shorter sequence is more attractive in terms of the cost connected to the testing phase but presents the highest uncertainty. In any case, the results presented previously showed that 2D or 3D coordinate system have a deviation lower than 10% with respect to the annual simulation. The 2D clustering was used to define a six-day sequence for other climates. Table 2 presents the total seasonal performance factor calculated with six-day sequence and with the annual simulation. The climates considered are Bolzano, Zurich, Gdansk and Rome. The highest deviation is 7.85% obtained for the climate of Zurich while the lowest deviation was obtained for the Roman case. This lower deviation could be also explained by the smaller collector area (16m^2 were not considered in this case since it would have not represented a good system design).

Tab. 4: Deviation of total SPF of six-day sequences defined with 2D clustering.

	Bolzano 16m²-1500l	**Zurich 16m²-1500l**	**Gdansk 16m²-1500l**	**Rome 8m²-1500l**
Six day	4.43	4.12	3.85	4.79
Annual	4.21	3.82	3.62	4.82
Deviation [%]	5.22%	7.85%	6.35%	0.62%

6. Conclusion

The purpose of this paper is to clarify the methodology used in the PLPE procedure to define a short test sequence starting from the annual weather data. The PLPE procedure is a method to perform dynamic test of entire heating and cooling systems in an objective way which is easily applicable to different climates and that allows a direct extrapolation of the seasonal results from the short test.

The underlying tool at the heart of the procedure is clustering. The days are grouped into clusters wherein each object is more similar to each other than to those in other clusters. To build the sequence, for each cluster, the

medoid, i.e. the closest object to the geometric centre, is selected. The days can be described with different quantities and the optimal solution is to consider the daily average temperature and the daily irradiation on horizontal surface. In the sequence, the days are ordered with the same order they occur in the year starting from the winter days and concluding with the summer days.

The sequence defined with clustering represents correctly the seasonal performances when those are linearly dependent to the boundary conditions; this could be a good approximation of heat pump system while for solar system the performances are not linearly dependent from boundary conditions.

Different system configurations have been simulated with sequences of different sizes. The deviation of the seasonal performance figures calculated with the short sequence and compared with the ones calculated with an annual simulation decreases as the number of clusters is increased. To that, we have noticed an influence on the accuracy given by the collector area and the storage volume. The deviation between the short sequence performance and the annual performance increases with increasing the collector area and the volume of storage.

A six-day sequence defined with 2D clustering has been defined for the climates of Bolzano, Zurich, Gdansk and Rome and the expected deviation is lower than 8%.

The main advantage of adopting the clustering is that the simple application of the methodology does not require any iterative simulation and therefore a test sequence can be defined for each climatic condition where the test would be performed.

The clustering could be used also for reducing the computational time for large parametric simulations. In that case the user can chose the proper number of clusters.

Abstract

Worldwide, around more than one billion people are without access to electricity and around three billion people use solid biomass for cooking, water heating and heating their homes. Majority of the developing countries of the world receive more than 5 kWh/m^2 of global solar irradiation per day, which can be utilized for a variety of applications such as providing electricity, cooking, drying, water heating, space heating etc. Use of solar energy can provide pathways for social and economic development of communities without triggering climate change but it requires consistent growth and efforts in providing solar energy education and skill development. The paper discusses the inclusion of solar energy education at school level and in higher education, the solar awareness programs and establishing a skilled chain for installation, repair and maintenance of solar systems at regional/community level. It also discusses some of the initiatives being taken in India.

Keywords: Solar education, solar awareness, skill development, socio-economic development, employment.

1. Introduction

Energy is linked to almost every aspect of life in one form or another. According to the report of World Energy Council worldwide more than one billion people are without access to electricity (WEC 2016). Around 3 billion people use solid biomass for cooking, water heating and heating their homes and over 4 million people die prematurely from illness attributable to the household air pollution from cooking with solid fuels as per World Health Organization (WHO 2016). For sustainable development of communities in developing countries it is essential that clean, safe and affordable energy is made available. In order to provide clean lighting source and clean fuel for cooking to billions of people in this world, apart from technical and financial support, awareness and knowledge dissemination is important. The implementation of policies and schemes can only be successful if people are willing to accept the technology. Majority of the developing countries of the world receive more than 5 kWh/m^2 of global solar irradiation per day, which can be utilized for a variety of applications such as providing electricity, cooking, drying, water heating, space heating etc. Use of solar energy can provide pathways for social and economic development of communities without triggering climate change but it requires consistent growth and efforts in providing solar energy education and skill development. Solar energy education at school levels can help in enhancing the awareness and increasing the acceptability of solar systems into the society for various applications. Inclusion of solar energy education in technical courses in higher education may provide the deeper understanding of solar technologies, enhance the research and development and produce innovations for use of solar energy to solve local problems. Further, there is need for awareness programs for communities and development of chain of local persons who can install, repair and maintain solar systems. These measures may help to a large extent in improving the quality of life of many communities through solar lighting, solar cookers, dryers, distillation stills etc. and at the same time provide employment opportunities to many. According to a study by Karakul (2016) during last two-three decades there has been rise in unemployment as the links between education system and economic system has been loosened. The links between education system and economic system may be strengthened by educating according to the needs of the economy. Though solar and wind energy accounted for only 4% of power generation in 2014, but it is estimated by

doi:10.18086/swc.2017.08.04 Available at http://proceedings.ises.org

2060 it will account for 20% to 39% of power generation as per World Energy Council (2016). According to Ciriminna et. al. (2016) with the prospective rise of solar economy it becomes important to think on solar energy education. They have discussed about a multi-disciplinary graduate course on solar energy.

With the above aspects in mind, the present paper discusses the course structures for inclusion at school level and in higher education, the solar awareness programs and establishing a skilled chain for installation, repair and maintenance of solar systems at regional/community level. The basis has been taken as the educational system in India, it may be replicated in other developing countries as well.

2. Solar energy for improving lives

Worldwide many communities are still struggling for basic facilities from which clean and affordable energy supply is one. According to World Bank (2015), more than one billion people are living without electricity and another one billion face the problem of unreliable and inadequate supply of electricity. Mainly kerosene lamps are used for lighting lamps which provides dim light and is polluting. Around three billion people use polluting fuels like wood, charcoal, coal, dung and kerosene for cooking and heating applications. It is estimated that around four million deaths take place each year due to indoor and outdoor air pollution caused by use of polluting fuels. Most of this population lives in rural areas of developing countries of sub-Saharan Africa, Pacific region, south and east Asia and are poor. Energy availability is closely linked with social and economic development. Absence or inadequate availability of clean energy affects health care, availability of clean water, education, information, communications, environment, agricultural or industrial growth and productivity. Most of the time of women and children is spent is picking wood and carrying water. It deprives them of quality time for studying, recreation, leisure and following creative interests. It hinders their productivity and economic growth also. Access to affordable, clean and adequate energy is essential to reduce poverty, promote welfare and meet the goals of climate change mitigation.

Here solar energy can play an important role as solar energy can directly or indirectly meet most of the energy needs for electric power, heating, cooling, cooking, drying, desalination, transportation etc. Further, it is interesting to observe that most of the developing countries facing the problem of energy access lie in high solar radiation receiving areas of the world. According to Renewables global status report (2016) many countries have started programs for installing off grid and on grid solar PV home lighting systems. Countries such as Kenya, Uganda and Tanzania in Africa; China, India, Bangladesh and Nepal in Asia; Brazil and Guyana in Latin America are seeing rapid expansion of small-scale renewable systems. Solar PV systems with battery storage or grid integration can provide clean and reliable supply of electric power to most of the countries. Further, solar thermal applications can be used for cooking, drying, heating, water treatment, distillation etc. Major global energy use for heat is fossil fuel-based, so solar energy has a huge potential to be used for providing heat. With deployment of solar technologies deep to the rural communities in developing countries, the pace of socio-economic growth can be increased.

3. Solar education

Among many challenges in penetration of solar technologies is reluctance and hesitation of the people. This requires more involvement of people at local level in designing, installation, operation and maintenance of the solar systems. Involving local communities will result in better support, developing region based solutions and sustainability of the projects. Here role of solar education becomes very important. The penetration of solar systems will be smooth and very fast if the new generation as student gains knowledge about the principle, working and maintenance of the systems. Solar education in itself involves application of various scientific and technological principles which will make studies more practical and interesting.

3.1 School level

At school level some theory and experiments on solar energy may be included in the science/physics laboratory, after the student has learnt basics of heat transfer and electricity. The instruments and equipment to be used in the experiments need not be expensive and of very high accuracy. These should be meant to provide students with the fundamental knowledge and inculcate an interest in use of solar energy. The theory and experiments may include

- Observing photovoltaic effect through small solar panel
- Types of solar cells
- Study of I-V characteristics of solar panel
- Estimation of maximum power point and fill factor
- Charging of battery by solar panel
- Effect of shading on power of PV panel
- Effect of tilt on power of PV panel
- Study of PV power during different times of a day
- Differentiating between flat plate and concentrating solar collectors
- Study of box type solar cooker
- Study of parabolic solar cooker
- Study of solar distillation still
- Study of solar dryer,
- Study of Fresnel lens, etc.

The solar PV based experiments involve basic principles of electricity and the learning outcome will be greater understanding of these principles. These experiments mainly require a small size solar panel, a multimeter or voltmeter and ammeter, a resistance box and connecting wires. The students will learn the use of voltmeter and ammeter, understand about dc electricity provided by solar panel, plot I-V characteristics, concepts of short circuit current and open circuit voltage, maximum power point and fill factor. Study of variations of PV power with shading, tilt and time of day will help the students understand the effect of varying solar radiation on the panel.

Fig. 1: A simple experiment to study characteristics of solar cell

The solar thermal experiments give insight to the students about green house effect of glass, transmission, reflectance and absorbance of different materials. The students can learn about beam, diffuse and global solar radiation, optical and thermal properties of materials in a simple manner through solar collectors. A simple hot box solar cooker involves explanation of optical property and heat trap property of glass, black absorber coating on a good thermal conducting material and reduction of heat losses through thermal insulating material. Like this, numerous experiments can be designed according to age group of the students for explaining them various principles. The experiments are generally very simple and safe, and cost of the experiments mainly lies between $20-70. Teachers and students may be motivated to design the systems and study them. Most of the systems may be made from inexpensive materials. Some of the entrepreneurs may

also come up with suitable low cost experimental kits for the schools so that the students learn the fundamentals of science in a more effective way through experiments on solar systems.

3.2 Higher Education

Inclusion of solar energy education in scientific/technical courses in higher education may provide the deeper understanding of solar technologies, enhance the research and development and produce innovations for use of solar energy to solve local/regional problems.

At the level of higher education many institutes in India offer B.Tech. and M. Tech. courses in renewable energy and recently some have started courses with specialization in solar energy. As solar energy is an extensive field covering materials, power generation, thermal applications, building design, modeling, simulation etc. it is required that a full- fledged master's course specialized in solar energy is run. In India M.Tech. is a two years course of four semesters, which includes a research project of around six months to twelve months. The course on solar energy consists of theory, experiments, seminars and project work mainly on

- Solar radiation –Physics of the Sun, solar constant, spectral distribution and variation of extraterrestrial radiation, air mass, beam, diffuse and global solar radiation, irradiance, solar insolation. Solar radiation on the earth surface - spectral energy distribution of solar radiation. Depletion of solar radiation - Absorption, scattering, atmospheric attenuation. Measurement through pyranometer, pyrheliometer, albedometer. Solar radiation geometry - Earth-Sun angles – Solar angles. Sunrise, sunset, solar day length, tilt factors, solar radiation on horizontal and tilted surfaces. Angles for tracking surfaces. Average and clear sky radiation, beam and diffuse components of hourly, daily and monthly radiation, radiation on sloped surfaces- isotropic and anisotropic sky, radiation augmentation, beam radiation on moving surfaces, effects of receiving surface orientation, utilizability.
- Fundamentals of materials- Electronic and atomic structures, atomic bonding in solids, structure of metals and ceramics, density computations, polycrystalline and amorphous materials. Polymeric structures, thermosetting and thermoplastic polymers, copolymers, polymer crystallinity, semiconductors, imperfections in solids. Diffusion mechanisms, factors affecting diffusion, diffusion in ionic and polymeric materials, phase diagrams, solubility limit, phase, microstructure, phase equilibria. Mechanical properties, concepts of stress and strain, Hooke's law, tension, compression and shear. Stress-strain diagram and thermal stresses, elasticity, effect of temperature, fracture and failure. Electrical, optical, thermal and magnetic properties of materials.
- Fundamentals of power generation- Power scenario-world and India, thermodynamic cycles, their importance and use, Carnot, Rankine cycle, modified Rankine cycle, Brayton cycle, Stirling cycle , Binary cycles, Combined cycles, reheat, regeneration and supercritical. Load duration curves, location of power plants, types of power plants- Steam, hydroelectric, diesel, gas, nuclear, biomass, solar and wind, relative advantages and disadvantages of different modes of power production, energy conversion and losses, power plant economics.
- Heat and mass transfer- One dimensional energy equations and boundary conditions – Three dimensional conduction equations - Extended surfaces – Critical thickness of insulations – Overall heat transfer coefficient. Convection-Momentum and energy equations, turbulent boundary layer heat transfer –Mixing length concepts, turbulent model – K - ε model. Analogy between heat and momentum transfer – Reynolds, Colburn and Von Karman. High speed flows. Radiation - Gases and vapour. Solar radiation – Sky radiations, solar radiation through fenestrations – Estimations. Phase change heat transfer, heat exchanger. Finite difference formulation of steady and transient conduction problems. Application of heat transfer in solar thermal system and its components.
- Energy audit and management- Role of energy conservation and energy efficiency. Energy Conservation Act- 2001, Electricity Act, Bureau of Energy Efficiency, energy and exergy analysis. Energy management and audit-need, objectives, types, methodology and phases, instruments used and report preparation. Material and energy balance, energy action planning, financial management, project management. Electrical system- losses, demand side management, factors affecting energy efficiency and minimizing losses in compressed air system, motors, fans and blowers, pumps and pumping systems, lighting system. Fuels and combustion, efficient utilization and energy saving opportunities. Thermal systems, cogeneration, heat exchangers, waste heat recovery, energy performance assessment of buildings and commercial establishments, financial analysis.
- Solar collectors- Radiation transmission through glazing, optical properties of cover systems, transmittance transmittance-absorptance product and its angular dependence, spectral dependence of transmittance. Flat Plate Collectors- components, basic energy balance equations, temperature distribution, collector overall heat loss coefficient, collector efficiency factor, collector heat removal factor, flow factor, critical radiation level, collector tilt and orientation, mean fluid and plate temperatures, effective transmittance- absorptance product, effect of dust and shading, heat capacity effects, liquid heaters, air heaters, measurements of collector performance, collector characterization and tests, practical considerations. Concentrating collector configurations, concentration ratio, thermal and optical performance of concentrating collectors, cylindrical absorber arrays, optical characteristics of non-imaging collectors, orientation, absorbed energy and performance of CPC collectors, linear imaging concentrators, ray trace method, incidence angle modifier, energy balance, paraboloidal concentrators, central receiver collectors, practical considerations.

- Solar photovoltaics- Semiconductors, charge carriers, carrier concentration, drift, diffusion, light absorption, recombination of carriers, solar cell design for high fill factor, properties of efficient solar cells, lifetime and surface recombination effects, efficiency and band gap, spectral response, parasitic resistance effects, temperature effects, efficiency limits for photovoltaic conversion. Crystalline silicon solar cell- manufacturing process, multicrystalline solar cells, photovoltaic modules, thin film silicon solar cells, high efficiency III-IV multijunction solar cells, amorphous silicon, Cu(InGa)Se_2 solar cells, Cadium Telluride solar cells and modules. Dye-sensitized solar cells, introduction, fabrication, new developments, approach to commercialization. measurement and characterization of solar cells and modules, rating PV performance.
- Solar thermal applications- Active and passive systems, auxiliary energy, natural and forced circulation systems, integral collector storage systems, testing and rating of water heaters, solar cookers-types, design components, factors affecting performance, Indian and international testing procedures. Solar process loads, energy storage, sensible, latent and chemical energy storage systems, solar dryers- types, direct gain, indirect gain, design components, application areas, solar distillation- design fundamentals, efficiency and practical considerations. Solar cooling: Fundamentals of refrigeration and air conditioning, solar absorption cooling, combined solar heating and cooling, solar industrial process heat. Solar thermal power plants: low, medium and high temperature power generation systems, thermal conversion systems, solar chimney power plant, central receiver power plant.
- Energy efficient buildings- Thermal comfort, factors affecting thermal comfort, comfort parameters, Climatic conditions, climate zones, heat flow calculations in buildings. Building heating and cooling- active methods, solar heating systems- liquid and air systems. solar energy- heat pump systems, phase change and seasonal storage systems, solar and off-peak storage systems, solar air-conditioning. Passive and hybrid methods for heating and cooling, insulation, shading, sunspace, storage walls and roofs, ventilation, evaporative and nocturnal cooling, earth–air tunnel, solar chimney, active collection-passive storage hybrid systems, heat distribution in passive buildings, Energy conservation building code. Building integrated photovoltaic systems.
- Solar power generation- Photovoltaic systems: Configuration and applications, grid –independent for small devices, PV systems for remote consumers of medium and large size, decentralized grid-connected PV systems, central grid connected PV systems. Components of PV systems-battery storage, charge controller and inverters. Design methodology for SPV system, system sizing. Installation, troubleshooting and safety, Economic analysis.
- Modeling and simulation- system, experiment, model, simulation - definition, importance, application areas, advantages, disadvantages and difficulties, types of models. Steps of modeling process-problem analysis, model formulation, model abstraction, defining variables, solving, execution, verifying, analysis of results. Verification and validation, Solar energy modeling techniques-, Brief introduction to the software used for simulation in solar energy field, comparative review of software for solar photovoltaics, solar thermal systems and buildings. Use of software such as TRNSYS, PVSYST, PVSOL, SAM, SOLTRACE, HOMER, Meteonorm etc.

The seminars focus on advancements in solar technologies, research and development, policy changes and their impact on industry and society. During project work student has to opt for a problem related to research depending on technical, industrial or society requirement.

At master's level students need to learn the principles and technologies with more depth and accuracy. More practical trainings, hands-on workshops and industrial collaborations improve the quality of the course and learning by the students. In order to improve the engineering education Royal Academy of Engineering,UK and FICCI, India have started Higher Education Partnership Project. This scheme involves partnership between Indian and UK universities and industry. In this scheme University of Kota has been awarded a project entitled "Enhancing teaching and research and development in Solar Energy Materials and Technologies through Capacity Building and Collaborative Research Projects" for its M.Tech. (Solar Energy) course. During this project instead of taking one major research problem, it was decided to carry out several minor research projects with involvement of students. This helped the students in gaining the skills. Solar based systems have been designed and developed through use of mainly locally available materials. The systems have been tested on-field for their performance and their economic analysis has been done. The

systems have been developed after analysing the requirement of the lower and middle income households and cottage industries of developing countries like India, which face the problem of availability of fuel in adequate amount and pollution due to solid fuel use. The system designed and tested are- solar cookers, solar distillation stills, solar dryer, solar PV cooler, solar PV induction cooker and solar water heater. The research projects aim at providing a solution to some regional/community level problem through use of solar energy. This promotes innovation, entrepreneurship and spin-out companies.

4. Solar awareness and skill development

The Government of India has set a target of renewable energy capacity of 175 GW by 2022. 100 GW of this

is planned through solar energy, 60 GW through wind energy, 10 GW through small hydro power, and 5 GW through biomass-based power projects. Out of the 100 GW target for solar, 40 GW is expected to be achieved through decentralized rooftop projects, 40 GW through utility-scale solar plants and 20 GW through ultra-mega solar parks. For achieving this target it is necessary to address the availability of skilled manpower and capacity building.

In 2015Government of India announced the National Policy for Skill Development and Entrepreneurship. It envisages a major role of private sector as shared responsibility for skill development in the country. The Ministry of Skill Development and Entrepreneurship has been creating Skill Councils in various domains. The initial funding for the Sector Skill Council is by the government through National Skill Development Corporation (NSDC) with 10% contribution from the industry. It becomes a self-sustainable body over a period of 3-5 years. Skill Council for Green Jobs (SCGJ) has been created in 2015, promoted by the Ministry of New and Renewable Energy (MNRE) and Confederation of Indian Industry (CII). In a report by SCGJ the skill gap is assessed as around 0.4 million for solar engineering, procurement and construction, 0.2 million for solar operation and maintenance, 36 thousand for solar off-grid and 16 thousand for solar thermal applications. SCGJ is offering various courses related to solar PV installations such as solar PV installer (Suryamitra), solar PV installer (Electrical), solar PV installer (Civil), solar PV rooftop entrepreneur, solar proposal evaluation specialist and rooftop solar grid engineer etc. for reducing the skill gap (SCGJ reports, 2016)

Apart from government initiatives, many not for profit organizations are also working for solar awareness and skill development such as Barefoot College. Barefoot college is exemplary as it involves women from rural areas, train them in solar technologies and empower them. They have trained more than 750 engineers in more than 1300 villages worldwide and have provided light 0.5 million people with light. Some companies are using their corporate social responsibility fund to disseminate solar systems which is also promoting solar awareness. Academic institutions and departments of science and technology hold workshops, exhibitions and competitions for spreading the knowledge.

5. Challenges and suggestions

Solar education and skill development are important for sustaining the deployment of solar systems deep into the regions waiting for access to clean energy. The various schemes and projects die out if proper measures are not taken. It is important the training should focus on both the technical aspects as well as engaging community, explaining and managing finances, knowledge of policies and project implementation. There can be several challenges in the way of solar education and skill development, overcoming those require following steps

- Understanding local needs
- Engaging communities and women
- Maintenance of quality of training programs
- Development of specialized solar courses
- Research and development as per local problems
- Involving industries as partner with academic institutions to enhance skills
- More hands-on training
- Monitoring and assessing the skills
- Support for entrepreneurship
- Reducing bureaucracy and corruption in implementation of skill development schemes
- Motivating rural communities to be self-reliant
- Sustained effort by government, academic institutes, industries and society.

Terrapon-Pfaff (2014), Dóci (2015) and Bossink (2017) have stressed on continuous evaluation and learning to develop sustainable prototypes as per need and engagement of the community and following chain of up

scaling and making it commercial with industry. So, solar education and skill development will be a continuous process involving evaluation and improvements.

6. Conclusions

Solar energy holds the potential to improve the quality of life of people in developing countries. Solar energy education and skill development are important for promoting the solar energy technologies to the communities without access to clean energy in developing countries. Solar energy education can easily form a part of school curriculum with simple theory explaining scientific principles involved and simple low cost experiments for practical understanding. In higher education, advanced and in-depth study of solar energy will help students get equipped with designing, improving and innovating new solar systems as per the need of local communities. Skill development initiatives can form a part of government's action plan, and industries and academic institutes can play a significant role in it. With these measures, it will be important to monitor, evaluate and assess the quality and need of programs. Further, involvement of local communities is essential for sustainability of the projects.

Abstract

Awareness raising and education regarding the use and application of renewable energy systems is a key issue in many development projects. The goal of this practice-based research was to explore the potentialities of locally developed instructional videos on tablet PCs to create awareness about renewable energy systems and to train mostly illiterate communities in extremely secluded areas to operate and maintain these systems. To do so, a case study was carried out in the Nepalese Himalayan Mountains. The observational mixed-method evaluation indicates (a) that, upon initial instruction, local people were able to handle videos on tablets PCs well. In addition, (b) after studying the tablet-based videos, small groups of workers were able to carry out concrete manual and analytical tasks regarding the development and operation of renewable energy systems; the findings also suggest that villagers' understanding of more complex tasks was enhanced significantly by showing videos a second time; and (c), the facilitated screening of instructional videos with a battery-charged handheld projector in public areas allowed the whole community to participate, watch, and engage in awareness raising and learning processes.

The pilot study supports the tentative conclusion that videos, which are produced locally and shared via mobile technologies, can serve as viable means in raising awareness and creating learning opportunities regarding the use of sustainable energy systems in extremely remote communities with a predominantly illiterate population. Further research is needed to corroborate the findings of this exploratory and small-scale pilot study.

1. Introduction and background

1.1 Challenges in the introduction and maintenance of renewable energy systems

The importance of implementing, operating and maintaining renewable energy systems is widely recognised. It is, perhaps most prominently, reflected in the sustainable development goals: Goal 7 highlights the access to affordable, reliable, sustainable and modern energy for all (SDG Goals, n.d.). The health-related, economic, educational and social benefits of sustainable and renewable energy systems are particularly important in low-income contexts. For instance, solar-based lighting would provide extra time for families to generate income and would allow children to do homework in the evening, let alone the health and ecological benefits of banning lighting sources such as open fire or kerosene lamps (The World Bank, 2016). However, the reality is still bleak for 20% of the global population who lack access to modern electricity and the 3 billion people who rely on wood, coal, charcoal or animal waste for cooking and heating (SDG Goals, n.d.).

The implementation of renewable energy systems in low resource contexts and elsewhere goes far beyond the introduction of new technologies. A change affects the overall system and often results in a novel configuration of actors, organization and practices which is in many cases, not a straightforward but a lengthy and dynamic developmental process (Negro et al., 2012). Accordingly, it is key to not only work together with local communities, but also to make them fully understand and drive these changes (Reid et al., 2009, Jerneck and Olsson, 2013). To do so, local people need to acquire the technical knowledge of building and maintaining renewable and sustainable systems. In addition, they also need to understand the underlying ecological, health-related and economical motives for this transformation.

A change in beliefs and practices requires systematic awareness raising, exposure and education. The organisation and realisation of these measures in the settings under investigation, i.e., the remote, underdeveloped and high-altitude villages in the North-West Nepalese Himalayan Mountain districts of Humla and Jumla, is a complex and challenging endeavour for a number of reasons. Yet the logistics of organising training events in the scattered villages are problematic, as it takes days of walking to reach these villages. This condition is further aggravated by the fact that many of the local people have very limited or no literacy or numeracy skills, which inhibits the value of written instructions and operation manuals. To address these contextual constraints, extended time and effort is needed, which, as past projects have shown, often exceeded budgets and time frames of smaller initiatives. Conventional training can be also problematic because it can reinforce existing power imbalances. Tensions can be created for example by community leaders who prioritise friends and relatives in the recruitment process (i.e., groups who are often more interested in receiving the per diem than in the training content) at the expense of the actual target group, as prior research has shown (Zossou et al., 2009).

1.2 Producing local videos to share local knowledge in community development context

One way in which awareness raising and training activities can be supported are videos. Video is seen as a powerful tool in development work, because it can attract people's attention, addresses barriers of illiteracy and it is reflective of the narrative culture and the oral traditions which are conspicuous characteristics in many rural contexts (Lie and Mandler, 2009). In addition, it can reach many people at the same time (Zossou et al., 2009). Although video has been applied in development cooperation for more than 30 years, recent developments, such as decreased costs and improved usability, have resulted in an increase in the use of this technology (Lie and Mandler, 2009). Advances in mobile and portable technologies have also widened dissemination and screening opportunities, for example by using handheld, battery-powered projectors (Cai et al., 2013, Kumar et al., 2015), or by directly distributing videos on users' personal mobile devices (Vashistha et al., 2016).

In development and low-resource settings, videos are being used for manifold purposes including capacity building and awareness raising (Lie and Mandler, 2009) across a wide range of disciplines, such as agriculture (Gandhi et al., 2007), health (Kumar et al., 2015) and climate change (Plush, 2013). In context of the present research, both training and awareness raising were of relevance. The idea was to use short videos to support the technical training regarding the implementation, operation and maintenance of a community-owned village drinking water system. Other videos were aimed at educating and raising the awareness of local communities regarding the underlying causes and benefits of this transformation.

However, despite the identified opportunities and potentialities, there is still relatively little systematic research on the use of videos in very marginalised and remote settings. Yet, there are a number of good-practice principles that

can guide and inform practitioners in the development and deployment of persuasive, educational and awareness raising videos.

In the video production process, it is recommended to follow the principles of participatory design, which requires the close involvement of the target group from the very beginning (Kumar et al., 2015). Local participation is important because it ensures the appropriateness of the verbal and visual language and it enhances the persuasiveness of the video (Lie and Mandler, 2009). For example, in an Indian agricultural extension service context, videos which featured farmers who spoke the same dialect and accent and who had similar levels of education as the target group were much more trusted by the audience than the ones which involved educated and outside experts. In the same vein, farmers were more convinced to adopt a new agricultural technique if they realised that peers to whom they could relate had already endorsed and implemented this practice (Gandhi et al., 2007). Another influencing factor was the type of content. It was witnessed that videos which featured engaging forms of content such as concrete demonstrations, testimonials and entertainment were clearly preferred over videos in classroom-style lectures (Gandhi et al., 2007).

In the training itself, it is important not to conceive videos as self-explanatory and standalone tools. Instead, it has been suggested to combine them with hands-on practical tasks and printed materials to help increase the understanding of the video content (Lie and Mandler, 2009). For example, a quasi-experimental study found that although both video training and traditional lecture-based demonstration increased agricultural knowledge of men and women, only the combination of these two methods decreased the pre-existing gender knowledge gap (Cai et al., 2013). In addition, the screening of videos should be facilitated, for example in the form of moderated group training sessions at the community level. Facilitators should seek to trigger reflection and enhance learning by highlighting the main points, moderating the discussions, raising questions and collecting feedback (Lie and Mandler, 2009). The value of facilitation is confirmed in the empirical literature: Whereas the screening of videos alone was received poorly and resulted even in people leaving the events, yet minimal facilitation positively impacted their interest (Gandhi et al., 2007). If need be, the facilitator can also screen the whole video or specific sequences a second time (Lie and Mandler, 2009), which is relevant because it was found that the audience frequently required a second viewing to better grasp the contents (Gandhi et al., 2007).

An emerging body of studies has confirmed the instructional value of videos, and especially of participatory videos, in sensitizing and educating local communities. For example, the facilitated screening of participatory videos in an agricultural extension project in rural India increased the adoption of certain agricultural practices by a factor seven while being 10 times more cost-effective in comparison to common training and visit-based extension services (Gandhi et al., 2007). The authors emphasised that it was not the technology but the people and social dynamics which ultimately triggered the change (Gandhi et al., 2007). Positive effects were also achieved through the facilitated screening of farmer-to-farmer videos of a rice parboiling process to communities in Benin. The video caused 95% of the audience to improve their practices compared to about 50% who received the conventional training (as a 2-day community workshop). No differences were found between people who only watched the video and people from a third cohort who watched the video and attended the training. This underscored the value of video as the most effective instructional means.

Open video screening is also considered a more democratic form of education compared to closed training sessions. Research from Benin has shown that neither ethnic group, age, number of dependents in the household, education level, perceived importance of and motivation for the topic, experience, religion and membership in a farmer organization influenced the participation in the viewing practices (Zossou et al., 2009). However, not all studies confirmed the superiority of facilitated video screening over traditional training methods (Cai et al., 2015, Cai et al., 2013). Although a participatory video on nutrition, which was shown to smallholder farmers in Malawi, increased the participants' knowledge as much as the control group with the conventional demonstration, it was less effective in changing the farmers' nutrition practices in the short term. Reasons were seen in the video cohorts' inability to taste and smell the food (Cai et al., 2015).

2. Approach and evaluation methods

2.1 Research question

The research questions were centred on the feasibility of using locally produced, participatory videos in very remote areas of the Nepalese Himalaya region. Concretely, they were formulated as:

(1) Whether, and if so how, can poorly literate and illiterate people in extremely secluded areas access and handle videos on tablet PCs?

(2) Whether, and if so how, can poorly literate and illiterate people in extremely secluded areas use participatory videos on tablet PCs to learn and perform concrete manual and analytical tasks regarding the installation, operation and maintenance of renewable energy systems?

(3) Whether, and if so how, can the screening of videos with battery powered handheld projectors during community meetings engage and raise the awareness of poorly literate and illiterate people in extremely secluded areas?

2.2 The setting: an extremely remote and poor Nepalese mountainous area

The practice-based research was carried out in the remote Nepalese mountain village of Syada (210 families and at 2'750 meters above sea level). It can be reached either by an 8-10 day trek from the nearest road or by a one-hour airplane flight to Simikot from Nepalgunj in the South and an additional one-day trek. The research site is in the district of Humla, which ranks among the country's three least developed districts regarding poverty, gender inequality and deprivation (CBS and ICIMOD/MENRIS, 2003). The Swiss-Nepalese NGO RIDS-Nepal/Switzerland has been working and partnering with the Syada village community since 2003 in small scale community development projects. The request of the village community to build a village drinking water system in 2015 in partnership with RIDS-Nepal formed the jumping-off point for this practice-based research project.

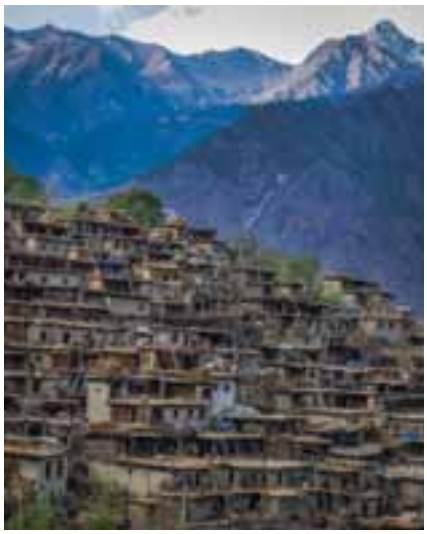

Fig. 2: Syada Village in northern Humla with 210 farmer families 2750 meters above sea level.

2.3 The production and use of the videos

The design and use of the videos was informed by the findings of the literature described in the previous sections. The videos were filmed and cut by RIDS-Nepal/Switzerland, a Swiss-Nepalese NGO. The local cameraman and video editor, who was from one of these remote villages, was trained and supervised by the NGO. The training and production took place in the form of face-to-face working phases, e-mail communication and Skype calls from the RIDS-Nepal head quarter in the Jumla district, when Internet was available. A number of 23 videos was produced (RIDS-Nepal/Switzerland 2017). The videos featured local actors directly from the communities who explained the rationale for and benefits of implementing renewable energy systems in story-like narratives and demonstrated specific tasks. The task-oriented videos adhered to the following design principles: providing a brief verbal overview of the process; an itemization of the required resources; step by-step instructions in which the local actors

demonstrated how a task was carried out (Gandhi et al., 2007). The use the videos was combined either with practical instructions and follow-up hands-on tasks, or in the community setting in which it was actively facilitated by a member of RIDS-Nepal/Switzerland, as specified in the following.

2.4 Task 1: Accessing and handling of videos on tablet PCs

First, local people were instructed regarding how to handle and use the tablet PCs. The RIDS-Nepal/Switzerland staff invited small groups of 4-6 people to participate in this learning event. Each group was informed about the activity. Then the staff member demonstrated the handling of the tablet to the group, which included the following steps: (1) switch on the tablet and log in; (2) navigate to the video folder; (3) select the correct video; (4) adjust volume (5) start playing the video (see Task 2). Then the tablet was switched off and handed over to the group with the task to repeat this step-by-step process. Each of the steps was evaluated on a scale from one to five. One signified that the step was not accomplished and great difficulties were experienced. Five meant that the step was very well accomplished. This procedure was carried out two times, i.e. with two groups in each of the four villages involved.

Fig. 3: Task 1: people handling the tablet PC

2.5 Task 2: Videos to learn and perform manual and analytical tasks

The second task consisted of the evaluation of the extent to which the groups were able to perform concrete manual and analytical tasks after watching short, tablet PC-based instructional videos. The first video (Task 2a) explained the evaluation of the suitability of a village owned water source. The goal was to learn how to determine systematically whether or not a spring provides sufficient water throughout the year so that it can be used as the village's central water source for their village drinking water system. This process involved several steps ranging from organizing and collecting the necessary items (two different sized buckets and a stopwatch) to measure the water source and calculating the water flow per minute.

Fig. 4: Task 2a: Village-owned water source measurement

The second video (Task 2b) required a group of female and male participants from the respective villages to moderate a process to identify suitable positions for tap stands in their village. First, a video was shown to the groups regarding how to organize and moderate this procedure. Water tap stand identification is a complex process, which requires the consideration of several infrastructural, social and cultural aspects. The final decision needs to be taken and supported by all community members. For example, a certain distance to houses and fields needs to be maintained to ensure that excess water would not flow into the people's premises. Upon viewing the video, the group moderated this process. Together with the community they developed a social map of the village on a rooftop of one of the houses (Figure 5). They used diverse items (e.g., stones, wooden sticks, charcoal, and leaves) to map the major infrastructure such as houses, walking paths, temples, fields and forest in and nearby the village as accurately as possible. On this basis, the community discussed locations for each of the water tap stands. The selection of the location of each tap stand was organized in the form of a democratic decision-making process.

Fig. 5: Task 2b: Social Mapping - Village water tap stand identification led by one of the participants

In each of the tasks, the video was shown to a group of about 4-6 people. This was followed by a question-and-answer session moderated by a facilitator from RIDS-Nepal/Switzerland. Then the participants performed the task. The task water measurement was more complex and thus the participants watched the video and carried out the associated hands-on water source measuring tasks two times (evaluated as a first and second trial). The accomplishment of steps and other criteria, for example the involvement of a sufficient number of female participants in the tap stand identification process, was evaluated according to a predetermined schedule on a scale of 1-5.

2.6 Task 3: Videos publically screened through a handheld, battery powered projector to raise awareness and educate communities

Also Task 3 was managed by an NGO staff who organised a community meeting. The video featured messages on the importance of a holistic community development (HCD) approach, the "Family of 4", which included the four basic and most often identified needs of the local village communities to be addressed as part of a long-term village development process. The four pillars of the "Family of 4" HCD are: (1) a toilet for each family; (2) a smokeless metal stove in each household; (3) basic indoor lighting powered by tapping into one of the locally available renewable energy resources and transformed through a contextualised renewable energy technology (such as solar PV, wind turbine or small hydro power plant; (4) clean and sufficient drinking water from the village-based water tap stands. After watching the video, facilitator asked the community the following questions: (1) name the four different "Family of 4" programs; (2) list the sequence of implementation, (3) explain the rationale behind the sequence, and (4 a to d) explain how the short- and long-term impact on families and community differ if 4, 3, 2 or only 1 of the "Family of 4" programs would be implemented. The video screening took place (see Figure 6) in the evening, using a tablet PC, a battery-powered handheld projector and an improvised screen (a white cotton sheet). After screening the video, the NGO staff asked up to 6 people (each 3 women and men respectively) the predefined questions. Apart from the answers elicited from the persons who were explicitly addressed, further discussions were stimulated and a number of additional people shared their opinion or experience. In this sense, the level of knowledge was evaluated as a collaborative product of the community.

Fig. 6: Task 3: Public video screening, awareness raising and educating the whole village community

The evaluation of all of the three tasks was carried out according to a predetermined assessment protocol. The participants' responses and actions were evaluated based on a set of previously developed criteria. For example, the step "collecting items" in the task water measurement was evaluated according to the following scheme: 5 points if all 4 items were collected, 4 points if 3 items were collected etc. The evaluator also took field notes, which were collected and analyzed in addition to the quantitative data.

3. Results

3.1. Task 1: Accessing and handling of videos on tablet PCs

The evaluation regarding the handling of the tablet was carried out in four villages with two pilot groups each. The results indicate that, in total, the small groups managed to handle the tablets well, with an average (mean) of 3.9 out of 5 points (Table 1). The more difficult tasks appeared to be the navigation to the video folder and the adjustment of the volume. It was also observed that women had more difficulties in using tablet PCs and they needed more support and repeated instructions. However, the most remarkable differences were found between villages and not between tasks. One village (4) scored particularly low. This might be explained by the fact that this village had an especially high number of poorly literate and illiterate people. According to RIDS-Nepal/Switzerland's evaluation, Village 4 could be also qualified as the least developed village from the cohort involved.

Tab. 1: Task 1 Accessing and handling of videos on tablet PCs

	Group 1				**Group 2**				
Steps / Villages	**Village 1**	**Village 2**	**Village 3**	**Village 4**	**Village 1**	**Village 2**	**Village 3**	**Village 4**	**Means**
Switch on tablet	5	5	5	2	5	4	4	3	**4.1**
Login	5	3	5	2	5	3	5	4	**4.0**
Navigate to video folder	4	4	5	1	4	4	4	3	**3.6**
Select correct video	5	5	4	2	5	5	4	4	**4.3**
Adjust volume	4	3	3	1	5	4	4	3	**3.4**
Play video	4	4	4	2	5	4	4	3	**3.8**
Means	**4.5**	**4**	**4.3**	**1.7**	**4.8**	**4**	**4.2**	**3.3**	

3.2 Task 2: Videos to learn and perform manual and analytical tasks

The video instructions on tablet PCs were regarded highly by the involved participants and, with a few exceptions, the tasks were carried out well (Table 2). It was observed that the group which found the videos particularly useful was illiterate women. This could be explained by the fact that their illiteracy and social position excluded them otherwise from similar participatory learning and community events.

Table 2 shows the participants' performance regarding the individual steps of the task water source measurement. As indicated, this task was more complex and the participants thus watched the video and carried out the associated tasks two times (labelled here as trial 2). In comparison with the first trial (Mdn = 3), showing the video a second time significantly enhanced the performance of the participants (Mdn = 5), as determined through a Wilcoxon signed ranks test ($Z=-3.704$ $p<.000$).

Tab. 2: Task 2a Water Measurement

	Trial 1				**Trial 2**				
Steps / Villages	**Village 1**	**Village 2**	**Village 3**	**Village 4**	**Village 1**	**Village 2**	**Village 3**	**Village 4**	**Means**
Organize equipment	4	4	4	4	5	5	5	5	**4.5**
Measure time	4	3	3	1	5	5	5	3	**3.6**
Measure water flow	4	4	3	2	5	5	4	3	**3.8**
Calculate water flow	3	3	3	2	4	4	5	3	**3.4**
Means	**3.8**	**3.5**	**3.3**	**2.3**	**4.8**	**4.8**	**4.8**	**3.5**	

The most difficult step was the calculation of the water flow (in litres per second), as it involved the solving of an arithmetic problem. This required the facilitator to demonstrate the task in addition to viewing the video at the measuring site in the second trial. However, after this demonstration, participants were able to calculate this measure rather easily, as some of them had a mobile phone with a calculator. In general, it was observed that younger men who had mobile phones and were familiar with the calculator app understood the calculation task better than elder people and women.

In the task water tap stand identification (Task 2b), the participants organised a group of villagers to develop a map of the village and to discuss and agree on the distribution of the water tap stands. In this task (like in the task water measurement), differences appeared to be more pronounced between groups (villages) than between steps, as can be seen in table 3. In particular in Village 1 and Village 2, the people and spokespersons were more actively engaged than in Village 3, which resulted in better results (Table 3).

Tab. 3: Task 2b Water tap stand identification through social mapping as a whole community

Steps / Villages	Village 1	Village 2	Village 3	Village 4	Means
Organise people & materials	5	4	4	4	**4.3**
Correct mapping	4	4	2	4	**3.5**
Identification of tap stand locations	5	5	2	4	**4.0**
Justification of tap stand locations	4	3	1	3	**2.8**
Means	**4.5**	**4.0**	**2.3**	**3.8**	

3.3 Task 3: Videos on handheld projectors to sensitize and educate communities

The public screening of the videos in each of the four communities raised considerable interest and the events were very well visited - with a total of approximately 380 participants (about 140 in Village 1, 120 in Village 2, 60 in Village 3 and 60 in Village 4). The video was received very well and participants requested to watch it at least two times. Again, illiterate women in particular provided positive feedback. They indicated that the spoken and visualised instructions helped them understand the rationale behind and the benefits of the "Family of 4 " HCD project concept, thus overcoming their illiteracy constraints and being active members of the village's awareness and knowledge building processes. As can be seen in Table 4, the quality of the responses from the community participants was found to be satisfactory. The importance and prioritisation of each of the "Family of 4" HCD programs was explained well. However, the participants had more difficulties in explaining the relation of the individual programs, and even more so, the possible synergistic benefits of the "Family of 4" programs (Questions 4a to c). The observations also point to helpfulness and persuasiveness of additional testimonies provided by some people who described their personal experience and especially the benefits that they experienced with the "Family of 4" programs.

Tab. 4: Task 3: "Family of 4" Holistic Community Development Concept Video

Questions / Village	Village 1	Village 2	Village 3	Village 4	Means
Q1: Name all four "Family of 4" programs	3.5	2.7	3.0	2.0	**2.8**
Q2: Describe implementation prioritization	3.5	2.7	3.0	2.0	**2.8**
Q3: Describe importance of each measure	4.0	3.3	3.3	3.0	**3.4**
Q4a: Describe benefits 4 measures	3.5	2.0	2.0	2.5	**2.5**

Q4c: Describe benefits 2 measures	3.5	2.7	2.7	2.5	**2.8**
Q4d: Describe benefits 1 measures	3.5	3.7	3.3	3.5	**3.5**
Means	**3.5**	**2.7**	**2.8**	**2.5**	

4. Discussion and conclusion

The findings of this practice-based study point to the feasibility and value of using locally produced awareness raising and educational videos for poorly literate and illiterate people in very isolated and secluded mountainous areas in the design, implementation and use of sustainable renewable energy systems. The videos were received very well by the individual study participants and the community as a whole. The public screening produced considerable effects in terms of interest, and increased awareness and collectively building up new knowledge. It was observed that the people in the community frequently wanted to view the video more than one time (as in the study of Gandhi et al., 2007), which, as the findings of the present study indicate, enhanced their understanding of the content significantly.

The findings also suggest that, upon initial instruction, local people were able to handle videos on the tablet PCs well. In addition, the tablet-based videos enabled small groups of workers to carry out concrete manual and analytical tasks regarding important community development measures for their village. The increased levels of knowledge and practical skills resonate with results from prior studies (Cai et al., 2015).

Perhaps the most genuine value offered by the videos was to allow groups of people, especially females and older people, with otherwise severely constrained educational and participatory opportunities, to acquire knowledge and to engage in central social processes in the community. This confirms previous research, for example from Benin, which revealed the democratising potentialities of public video screening, especially in comparison to closed training sessions (Zossou et al., 2009).

The qualitative observations indicate that one key to success was the incorporation of story-like elements (Lie and Mandler, 2009), which was regarded highly by the viewers. It was also observed that the testimonies and the local "good practice" examples demonstrated in the videos, such as a clean and hygienic kitchen, had a persuasive impact on the participants who appeared to transform their practices as could be often seen in the follow-up visits. However, this aspect was not measured systematically. Another practice-based observation was that, in the cultural context under investigation, the use of songs in the videos allowed the creators to highlight delicate and critical issues in the respective communities, such as the importance of gender equality, e.g. with regard to firewood collection, and the damaging exposure of women to indoor air pollution. Drawing on this insight, the project team has decided to film and incorporate songs about individual developmental measures in the production of future videos.

Although this study points to the feasibility and potential of using videos in highly secluded areas, the validity of the findings is constrained by a number of limitations which were mostly tied to the particularities of working in an extremely remote area. Firstly, only the immediate reception and knowledge output was measured and no longer-term transformation or knowledge effects were considered in the research design (for practical and logistical reasons). This is a constraint because prior research has shown that increased knowledge does not automatically amount to changes in local practices (Cai et al., 2015). In addition, the measurement was carried out on a group level, which causes bias with regard to the performance of individual members and needs to be viewed critically in terms of reliability. Moreover, although a detailed evaluation framework was developed a priori, the measurement was constrained in that only one observer, though experienced in the local culture and language, evaluated the tasks and no interrater-agreement could be taken into account. These constraints mean that the findings can only be considered preliminary in nature and further and more robust research is warranted. Finally, any generalization has to be treated with caution, given the socio-cultural particularities of these communities. Yet, we believe that future research can draw on these insights and this work can provide a jumping-off point for future investigations.

Abstract

This paper introduces a energy saving solar wall ventilation heating system.We measure the temperature of each part of the system and analyze the performance of the system.Results indicate that,Under the same conditions, the solar wall system has a high efficiency in the high volume of air delivery, while in the case of low air supply, the heating efficiency is lower;The air volume of the system is inversely proportional to the temperature rise.;The solar wall system has good energy saving effect and good economic benefit.

Keywords：Solar wall system，Energy conservation，Economy

1.Introduction

With the rapid development of the economy ,the energy and environmental pressure which people are facing is increasing.Solar energy as an ideal renewable energy is applied in the construction field.Solar wall system is effective integration of solar air heating technology and building integration,which provides an ecnonmic and applicable solution for heating and ventilation,and is with such prominent advantages as low cost,low energy consumption,low maintenance cost and high air quality.The paper investigate the thermal performance in actual building,application results and benefit analysis by experimental research and theoretical analysis.

2.Overview of solar wall research system

2.1. System introduction

The solar wall ventilation heating system studied in this paper is located in lianyungang, jiangsu province(Fig.1), which is the office of sunrain solar energy Co.,Ltd.The office heating area is 97.5m^2, office wall toward the south, with 25m^2 to install solar wall system, metope is exposed.

Fig.1 solar wall testing system

Fig.2 90°irradiation

Fig.3 wind speed and ambient temperature

doi:10.18086/swc.2017.09.01 Available at http://proceedings.ises.org

2.2. Principle of system operation

The system adopts the automatic control mode, when the cavity temperature reaches the set temperature , then the fan is started, and the air supply air temperature is set at 20℃

2.3. Data collection and testing methods

2.3.1. Measurement of irradiation strength

TBQ - 2 to measure Solar radiation(Fig.2).

2.3.2. Measurement of wind speed and ambient temperature

EC-1A to measure wind speed and pt100 to ambient temperature(Fig.3).

2.3.3. Solar wall system temperature measurement

The internal wall temperature and indoor temperature were tested respectively(Fig.4).

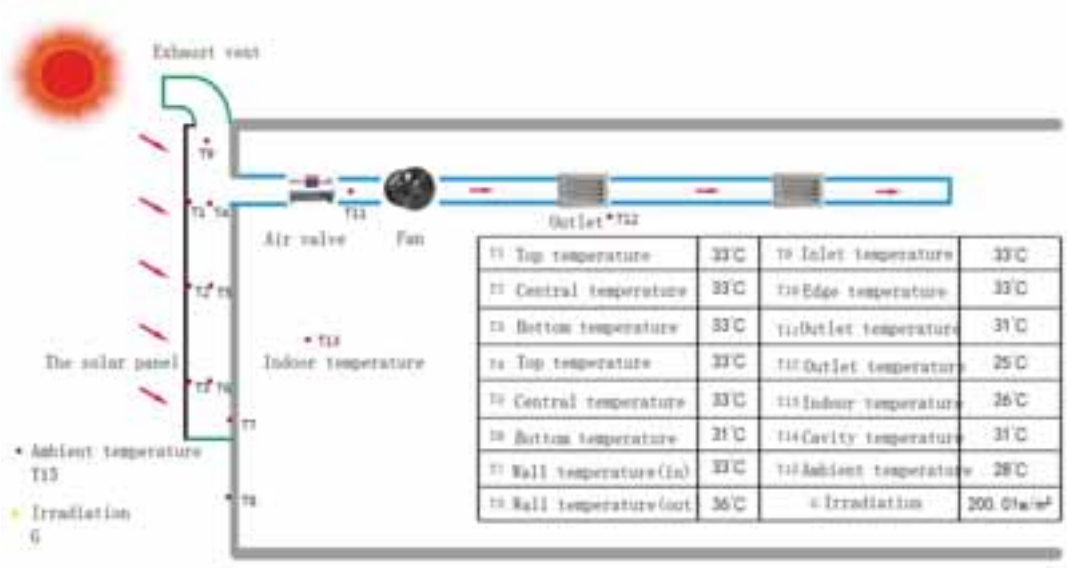

Fig.4 Temperature distribution of solar wall test system

3.Thermal performance of solar wall test system

3.1. Solar panel and cavity temperature

Figure 5 shows the change of cavity temperature and the surface temperature of solar wall panel during the solar wall system operation.From the diagram, the temperature of the solar panel and the temperature of the cavity are consistent with the variation of solar radiation.When the solar radiation intensity is greatest at noon, the temperature of the solar wall panel and the cavity temperature reach the maximum.In the morning and evening, the temperature of the cavity is low due to the small amount of solar radiation.During the operation of the system, the temperature of the cavity is up to 40℃, which is 30℃ higher than the outdoor environment, and the effect of temperature rise is obvious.

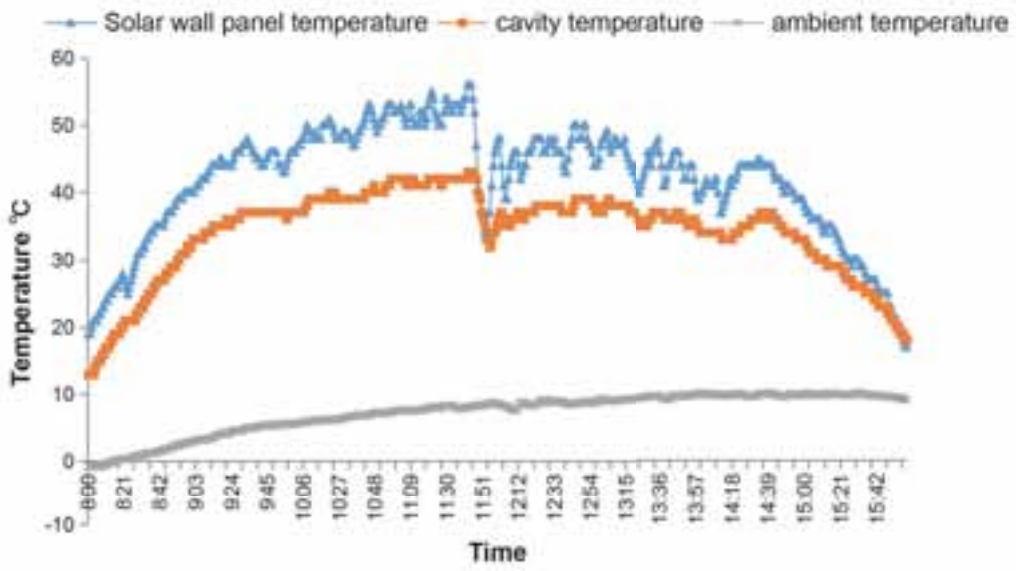

Fig.5 cavity temperature and the surface temperature of solar wall

3.2. Deliver temperature

Figure 6 shows the change of deliver temperature during the operation of the solar wall system in local heating period(Nov 14, 2016 ~Mar 27, 2017, total 134 days [1]).Figure illustrates the deliver temperature up to 48℃ during work, and the average working time from 8:30 ~ 16:00, with an average of seven hours.The results show that the solar wall heating system is stable and reliable in the better working conditions.

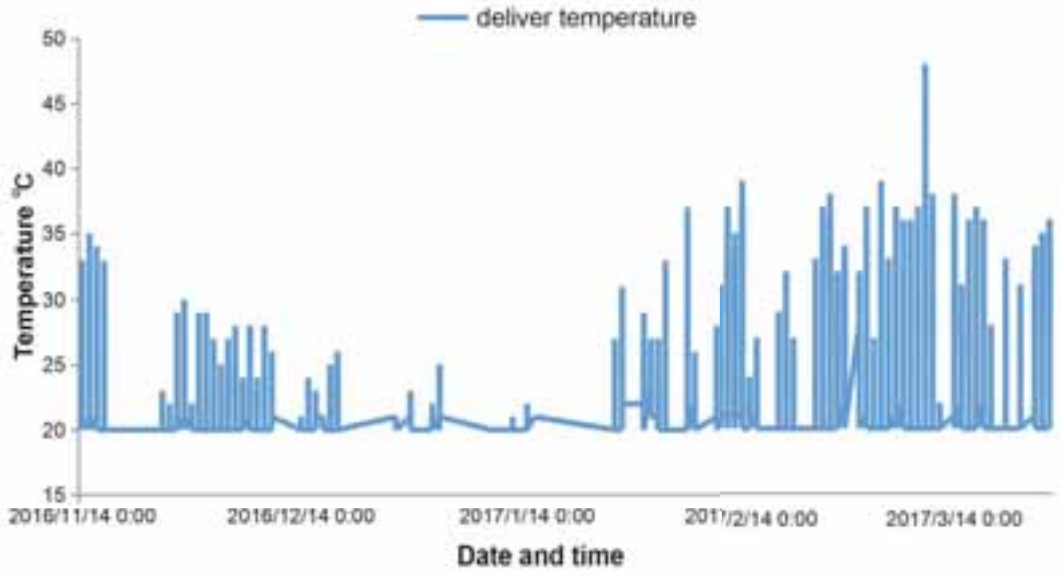

Fig.6 deliver temperature during heating period

3.3. Performance analysis

The save energy Q refers to the heat provided by the solar wall during a heating period

The heat provided by solar wall system in unit time：

$$Q = c * \rho * mv * \Delta T \text{ (eq. 1)}$$

The heating efficiency of solar wall heating system in unit time is calculated by

$$\eta = \frac{Q}{A * H} \text{ (eq. 2)}$$

As shown in figure 7, when the radiation is high, the instantaneous heat efficiency of the system decreases, and when the radiation intensity decreases, the instantaneous heat efficiency of the system is increased.Because the heat efficiency is proportional to the temperature rise and inversely proportional to the radiation intensity,When the magnitude of the decrease of radiation is greater than that of temperature rise, the efficiency will be increased. While when the amplitude of radiation rise is greater than that of temperature rise, the efficiency will decrease.

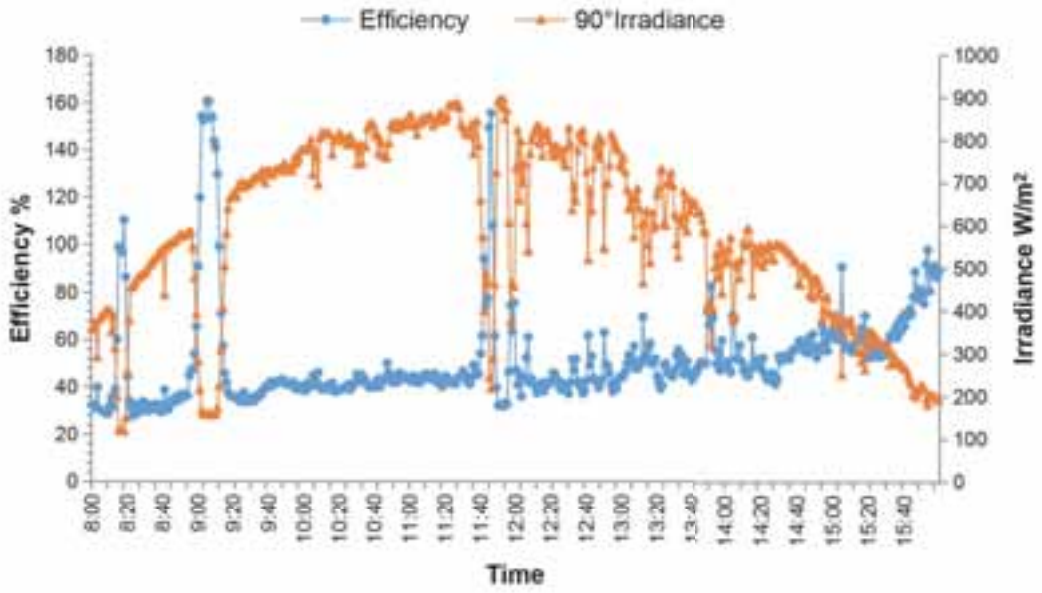

Fig.7 Efficiency and Irradiance

3.4. The effect of air flow on the system

It can be seen from figure 8 that under certain conditions, the heat efficiency is high in high air flow and low heat efficiency in low air flow.This result is consistent with figure 9.In this way, we can use the efficiency curve to calculate the energy of the section through irradiation

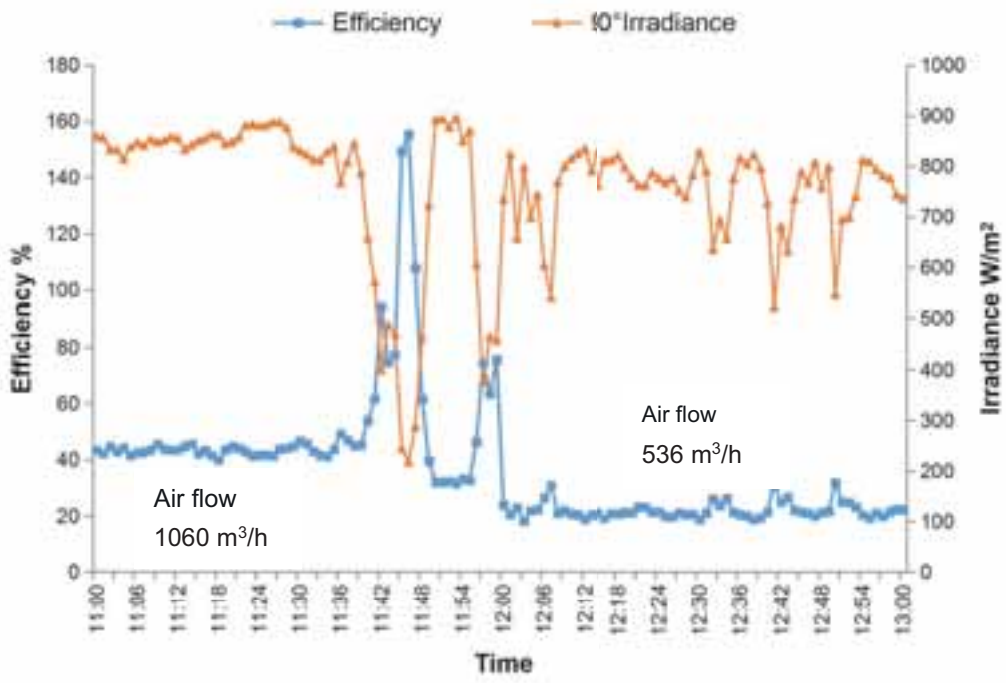

Fig.8 Efficiency for solarwall at various wind speeds

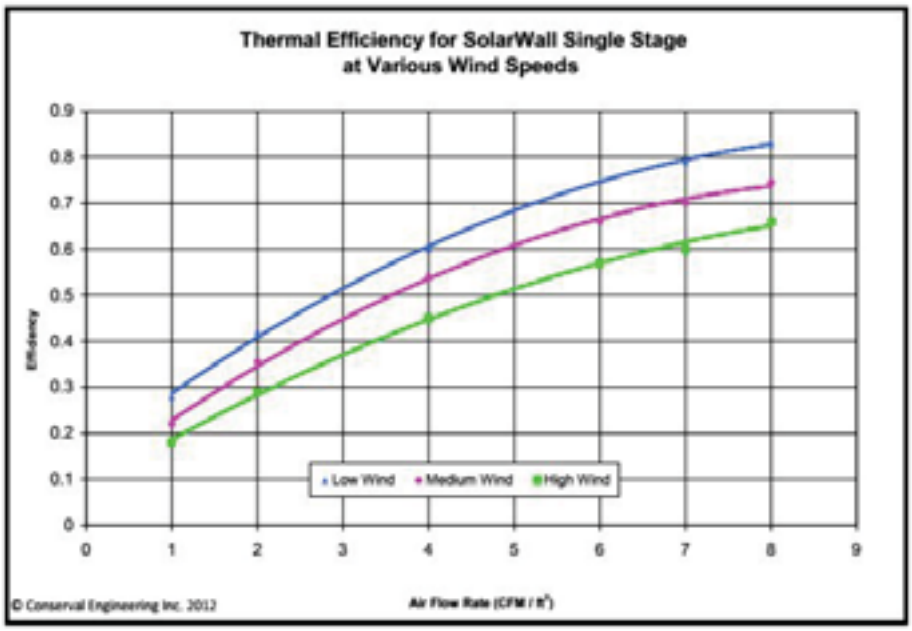

Fig.9 Efficiency for solarwall at various wind speeds[2]

According to the figure 10 analysis, under certain conditions, the solar wall system under the condition of high air flow, the deliver temperature rise is smaller, and under the condition of low air flow, the deliver temperature rise is larger. You can compare the temperature rise certification curve, as shown in figure 11.

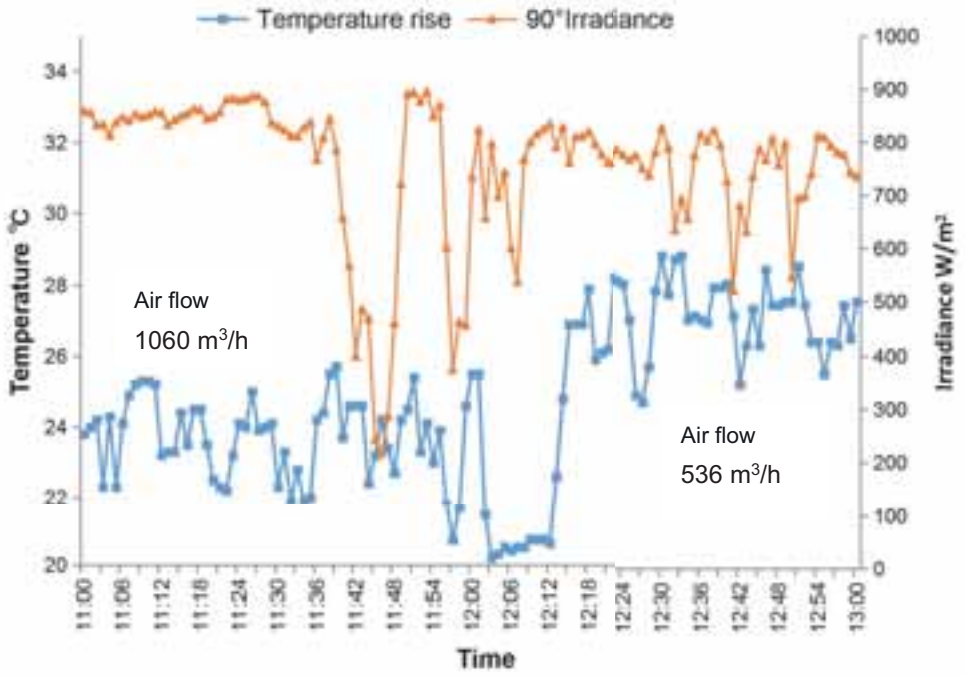

Fig.10 Temperature performance for solarwall wint wind variance

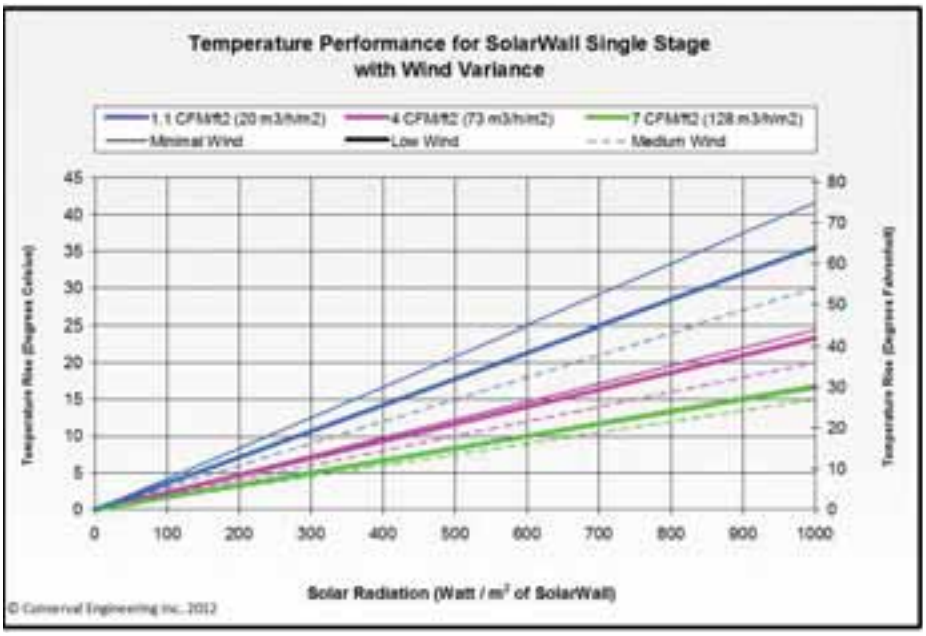

Fig.11 Temperature performance for solarwall wint wind variance[2]

Practical application can not blindly pursue high efficiency and increase the air volume, it will lead to the deliver temperature is low, thereby reducing the body's comfort, so in the later application according to different types of engineering deal with the relationship between air flow and temperature rise, maximize the benefits.

4.economy evaluation

The economic evaluation index of solar wall system includes the fund saving in life span and the payback time N[3].The two methods are calculated as follows：

$$SAV = PI * (\Delta Q_{SAV} * C_C - A * DJ) - A \quad \text{(eq. 3)}$$

$$PI = \frac{1}{d-e}\left[1-(\frac{1+e}{1+\mathrm{d}})^n\right] \quad \text{(eq. 4)}$$

payback time N，That is, when the formula SAV is equal to zero, the value of N,the calculation formula is as follows:

$$N = \frac{\ln\left[1-\frac{A(\mathrm{d}-e)}{\Delta Qsav - A \bullet DJ}\right]}{\ln\left(\frac{1+\mathrm{e}}{1+\mathrm{d}}\right)} \quad \text{(eq. 5)}$$

The above formula can be used to calculate the payback time N=2.3 years.

5.Conclusion

This paper studies the solar wall system in lianyungang,the following conclusions can be obtained by statistical analysis of the application of solar wall system

1.The solar wall system has good thermal performance, and system efficiency is inversely proportional to irradiation;The air flow is proportional to the efficiency, inversely proportional to the temperature rise.

2.The solar wall heating system can provide 48℃ heating air in the heating season, with an average working time of 7 hours per day, and 13640MJ energy in the heating season.

3.This solar wall heating system has good economic benefits and the payback time is two to three years.

Abstract

A numerical model was developed to study the coupling of heat transfer in the PCM and the air inside the enclosure. The solidification of the initially melted PCM induces a natural convection of air flow inside the cavity. We present in this work the heat transfer behavior between a chosen phase change material (PCM) incorporated in a thin right wall and a square enclosure filled with air whereas the left one is kept at ambient temperature. The solidification of the PCM generates a latent heat inducing a natural convection air flow inside the cavity and compensating the heat loss. The numerical analysis leaded to a Nusselt number correlations depending on constant Stefan number. Nusselt number is given as a function of a Rayleigh number and dimensionless temperature difference between hot and cold sides. These correlations have been established since there is a lake in the literature to evaluate the natural convection heat transfer coefficient between air and a PCM wall. The parametric domain covered the range of Rayleigh number between $3.4\ 10^5$ to $4.\ 10^7$ with Prandtl number Pr = 0.73 and Stefan number Ste=0.41.

1. Introduction

The adaptation of large-scale energy storage solutions are a prerequisite for the development of renewable energy. Thus, to achieve an efficient energy mix, it is necessary to manage the balance between production and demand to ensure optimal service. Except in very specific cases, it is difficult to store electricity directly. It must therefore be transformed into another form of energy more easily stored. One of those ways of storing thermal energy consists in using a phase change material (PCM). The energy is then stored in the form of latent heat through the melting of these materials and then released through the solidification process (Dinçer and Rosen 2002, Zalba et al. 2003). The Thermal Energy Storage (TES) method is commonly used to save energy and to improve the comfort level in buildings. This explains the growing interest of the scientific community to elucidate both numerically and experimentally the thermal performance of a PCM layer incorporated in a part of the building envelope.

The configuration of an enclosure with one side integrating a PCM layer has been rarely addressed despite its wide application such as in optimal utilization of energy (Tan et al. 2002, Ho et al. 2005) and thermal protection (Cao and Faghri 1990). The solidification of the PCM will provide a latent heat inducing a natural convection air flow inside the cavity. In this way, the study of the influence of the PCM wall on the coupled flow and heat transfer in the cavity provides both scientific and practical interests. An issue may arise in the study of this problem. Are the existing correlations applicable to describe the heat transfer between the PCM wall and air in the cavity?

Buoyancy-driven flow in a closed cavity without PCM wall has been studied widely because of the applications in nature and engineering. Many heat transfer correlations have been proposed for imposed temperature or boundary heat flux of the most common cases of rectangular, cylindrical or other regular geometries (Davis1983, Ostrach 1988, Shilei 2014, Gracia 2015). However, there are few studies regarding the solidification/melting effect of a PCM integrated in a boundary on the convective heat fluid inside the cavity. (Zhang and Bejan 1989) reported experimentally and analytically, the melting process of enclosed paraffin heated at a constant rate from the side with an air space 30 mm left at the top of the enclosure. They predicted overall Nusselt number relationship agrees reasonably well with the existing empirical correlation. (Wang et al. 1999) investigated experimentally the melting process of polyethylene glycol in a rectangular enclosure heated from vertical wall. An air gap of 12.7 mm was maintained between the assembled unit and all sides of the container. It was shown that the temporal Nusselt number variation distinguishes three different heat transfer regimes during the melting process. (De Gracia et al. 2013) have studied the convective heat transfer between an air flow and a phase change material plate. They found that the correlation used in the literature to determine the heat transfer coefficient in the case of the PCM is no longer valid. They introduced a correction coefficient in the correlation expression to account for the presence of the PCM.

(Lipnicki and Weigand 2012) studied experimentally and theoretically the natural convection and ice solidification in an annular enclosure. They found that the influence of the contact layer between the frozen layer and the cold surface is of significant importance for the solidification process. To predict the heat transfer coefficient, they used a conventional correlation given by (Vahl Davis and Thomas 1970). A previous work has been conducted to highlight the thermal performance of a Keeping Warm System (KWS) incorporating a PCM wall (Ait lahbib and Chehouani 2015). The studied configuration demonstrated the effect of the PCM discharge where the solidification plays a great role on the heat transfer in the KWS cavity.

As latent thermal energy storage represents smart efficient thermal energy storage, such technique can be used in many domestic and industrial sectors depending on PCM thermophysical properties such as latent heat, melting point and conductivity. During the development of useful applied PCMs, many different groups of phase change materials have been studied, including inorganic compounds (salt and salt hydrates), organic compounds such as paraffin's, fatty acids and even polymeric materials. In comparison to inorganic PCMs, organic substances could serve as important heat storage media because of their several advantages including their ability to melt congruently, their self nucleation and the fact they don't have a problem of separation on melting. A relevant aspect is the useful life of this category of PCM and the number of cycles they can withstand without any degrading of their properties. (Hadjieva et al. 1992) used three paraffin mixtures and confirmed that there was no effect of the cycles on the properties of paraffin. (Gibbs and Hsnain 1995) also

verified that neither the cycles nor contact with metals degrade the thermal behavior of paraffin thus they have excellent thermal stability.
The aim of this work is to propose useful heat transfer correlation in a widely used configuration of air cavity incorporating organic paraffin side. In this way both experimental and numerical studies have been carried out for the given configuration. The developed numerical model treats the coupling of the natural convection inside an air square enclosure with only conduction in the PCM side aiming to provide a comprehensive evaluation of the effectiveness of PCMs wall in industrial applications. Nusselt number was calculated as a function of the Rayleigh number, the temperature difference between both sides of the cavity in PCM during the solidification process.

2. Experimental setup and methodology

Experimental setup consists mainly of an enclosure cavity, electrical resistance, insulation material, PCM package, thermocouples and the data acquisition system (Figure 1).

In this study, the enclosure cavity has (10x10x10) cm^3 as geometric dimensions. It was differentially heated across two vertical walls; while the remaining side walls were thermally insulated. The hot wall was heated by an electrical resistance. The cold wall consists of an aluminum plate kept at the temperature T_C by controlled circulating water from a constant temperature bath. All the external surfaces of the test apparatus were insulated with polystyrene insulation material of 4 cm thickness to reduce heat losses from the sides to the surroundings. Four K-type thermocouples with accuracy of 0,2 °C were assembled in the hot and cold walls at various locations along the length, and two others were placed in the center of the gas cavity and the layer of PCM respectively. Temperature was constantly monitored for loading data every 5s via data acquisition system (Fig. 2 and 3).

Fig. 1: Experimental setup. 1) The enclosure cavity. 2) The cold wall. 3) Temperature regulator. 4) Data acquisition, 5) Heating system, 6) Computer.

Experiment have been undertaken to evaluate the numerical model validity. In our disposal, we selected the PCM60 provided by KAPLAN ENERGY-France which is a carboxylic acid that has the properties given in Table 1. We have no data on the thermal conductivity of the solid and liquid states. Their values are measured by the method of transient hot wire. This method is the best known and most widely used for measuring the thermal conductivity of fluid and solid medium because of its rapidity and ease of implementation. The principle of this technique is to heat by Joule effect a filiform element (probe) of very small radius immersed in the fluid to be characterized and measure the temperature rise in the vicinity of the probe versus time via a sensor associated therewith. Indeed, the transfer to the sample center is assumed to be unidirectional.

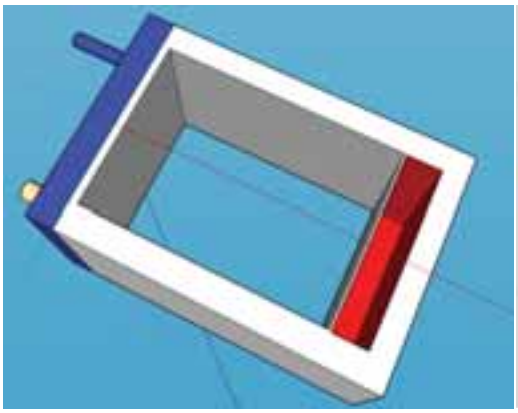

Fig. 2: Inside of the experimental square cavity.

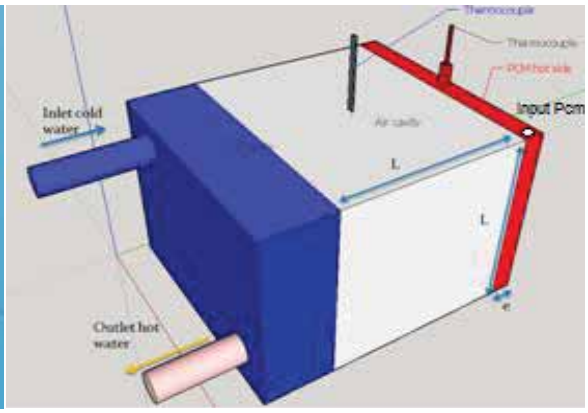

Fig. 3: Experimental square mode.

3. Model formulation and Numerical Solution

The 2D geometry used in the present study is shown in Figure 4. The thickness of PCM is equal to e and the cavity length is L. We define the aspect ratio parameter as A=e/L. The square enclosure is filled by air, cooled from the left side at T_C, insulated from the bottom and the top and heated from the right side by the PCM which is initially at T_H. The PCM is insulated from the top, bottom and right sides.

The following assumptions are made in the present study:

- The natural convection within the melt part of the PCM is negligible and can be ignored.
- All the thermophysical properties of the air are assumed constant except the density giving rise to the buoyancy forces (Boussinesq approximation). These thermophysical properties are taken at the reference temperature T_C.
- The thermo physical properties of the PCM are different for the solid and liquid phases and dependent on phase fraction.
- The PCM behaves ideally and is homogenous and isotropic.

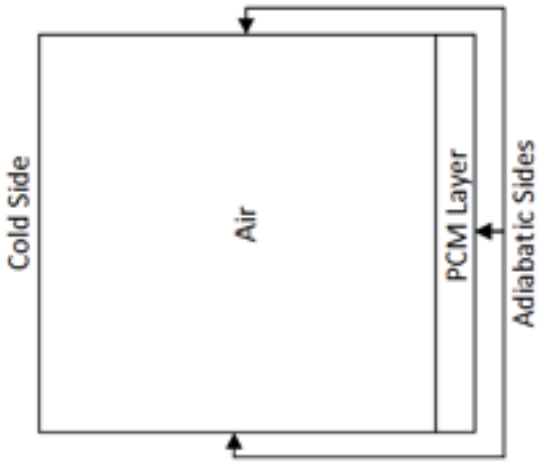

Fig. 4: Physical model

For the air inside the cavity, the equations describing the flow and heat transfer are written as follows:

- Continuity equation

$$\frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} = 0 \quad Eq.1$$

- Momentum equations:

$$\frac{\partial \mathrm{U}}{\partial \mathrm{t}} + \mathrm{U}\frac{\partial \mathrm{U}}{\partial \mathrm{x}} + \mathrm{V}\frac{\partial \mathrm{U}}{\partial \mathrm{y}} = -\frac{1}{\rho_g}\frac{\partial \mathrm{P}}{\partial \mathrm{x}} + \nu_g\left(\frac{\partial^2 \mathrm{U}}{\partial \mathrm{x}^2} + \frac{\partial^2 \mathrm{U}}{\partial \mathrm{y}^2}\right) \quad \mathrm{Eq.2}$$

$$\frac{\partial V}{\partial t} + U\frac{\partial V}{\partial x} + V\frac{\partial V}{\partial y} = -\frac{1}{\rho_g}\frac{\partial P}{\partial y} + \nu_g\left(\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2}\right) - \left[1 - \beta\left(T_g - T_C\right)\right]g \quad Eq.3$$

- Energy equation

$$\rho_g C_{pg}\frac{\partial T_g}{\partial t} + \rho_g C_{pg}\left(U\frac{\partial T_g}{\partial x} + V\frac{\partial T_g}{\partial y}\right) = \lambda_g\left(\frac{\partial^2 T_g}{\partial x^2} + \frac{\partial^2 T_g}{\partial y^2}\right) \quad Eq.4$$

Using an enthalpy-porosity method with the previous assumptions, the energy equation in the PCM wall reads as:

$$\rho_{pcm}\, C_{pcm}\,\frac{\partial T_{pcm}}{\partial t} = \lambda_{pcm}\left(\frac{\partial^2 T_{pcm}}{\partial x^2} + \frac{\partial^2 T_{pcm}}{\partial y^2}\right) - \rho_{pcm}\, H\frac{\partial f}{\partial t} \quad Eq.5$$

The properties of the PCM are updated following the values taken by the liquid fraction after each time step. Thus:

$$\rho_{pcm} = f\rho_l + (1-f)\rho_s \quad Eq.6$$

$$\lambda_{pcm} = f\lambda_l + (1-f)\lambda_s \quad Eq.7$$

For the density in the PCM layer was modeled by (Labihi et al. 2017). These authors proposed a new formula, ρ_{eff}, takes into account the PCM and the air layer resulting from volume contraction.

$$\rho_{eff} = \frac{\rho_{pcm}\, L^* + \rho_g \delta}{L} \quad Eq.8$$

where ρ_{pcm} is calculated using the Eq. 6

The governing equations are completed by the following initial and boundary conditions:

- $\mathrm{t} = 0$, all the intial values (U,V,T) in the gas are in steady state natural convection inside the closed cavity with differentially heated vertical walls. $\mathrm{T_{pcm}} = \mathrm{T_H}$ and $\mathrm{f} = 1$ (the PCM is liquid).
- $\mathrm{x} = 0, \mathrm{T_g} = \mathrm{T_C}, \mathrm{U} = \mathrm{V} = 0.$
- $\mathrm{x} = \mathrm{L} + \mathrm{e}, \frac{\partial \mathrm{T_{pcm}}}{\partial \mathrm{x}} = 0, \frac{\partial \mathrm{f}}{\partial \mathrm{x}} = 0, \mathrm{U} = \mathrm{V} = 0.$
- $\mathrm{y} = 0$ or $\mathrm{y} = \mathrm{L}, \frac{\partial \mathrm{T_g}}{\partial \mathrm{y}} = 0, \frac{\partial \mathrm{f}}{\partial \mathrm{y}} = 0, \mathrm{U} = \mathrm{V} = 0.$
- $\mathrm{x} = \mathrm{L}, \mathrm{T_g} = \mathrm{T_{pcm}}, \mathrm{U} = \mathrm{V} = 0, \lambda_g \frac{\partial \mathrm{T_g}}{\partial \mathrm{x}} = \lambda_{pcm} \frac{\partial \mathrm{T_{pcm}}}{\partial \mathrm{x}},$
- $\mathrm{f} = \frac{\mathrm{T}-\mathrm{T_s}}{\mathrm{T_l}-\mathrm{T_s}}$ with the correction f $\begin{cases} 0 \text{ if } \mathrm{f} < 0 \\ 1 \text{ if } \mathrm{f} > 1 \end{cases}$.

The time discretization is performed using the simple first-order Euler implicit scheme. The sets of algebraic equations resulting from the numerical scheme were solved iteratively using the Gauss-Seidel method.

- ***Mesh grid analyses***

In order to ensure grid independent solutions, a series of trial calculations were conducted for different grid distributions with an uniform mesh cells in both PCM and Air cavities.

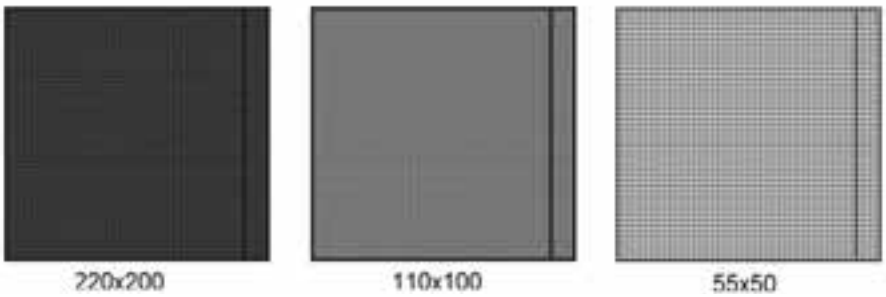

Fig. 5: Different Mesh grids sizes

To evaluate the grid size effect on numerical results, we conducted a series of trial calculations with 50X55, 100X110 and 200X220 nodes (Fig. 5) for a cavity with L=10cm and e=1cm. we calculated for each case the average Nusselt number at hot and cold side and the relative error issues between the different grid size chosen. Table 1 shows the thermophysical properties of RT55 product by RubiTherm used in this study.

Tab. 1 Thermo-physical propreites for RT55

T_m (K)	324.15 - 329.15
ρ_l ($kg\ m^{-3}$)	770
ρ_s ($kg\ m^{-3}$)	880
λ ($Wm^{-1}K^{-1}$)	0.2
H ($kJ\ kg^{-1}$)	170
C ($J\ kg^{-1}K^{-1}$)	2000

Table2 presents the different results founded of this comparison. We can note that the solution is very sensible when we use 50X55 mesh grids cells (up to 6%of difference) contrariwise, the obtained by 100X110 and 200X220 are practically the same.
The mesh 100X110 was adopted on the numerical computations in this study.

Tab. 2: Grid evaluation results

	$\overline{Nu}$ Hot Side	$\overline{Nu}$ Cold Side			Hot Side	Cold Side
55x50	13.15	13.135	Relative Error (%)	55x50 Vs 110x100	5.17	5.16
110x100	13.82	13.81		55x50 Vs 220x200	6.03	6.02
220x200	13.94	13.928		110x100 Vs 220x200	0.81	0.81

- ***Validation of the initial state***

In order to validate the initial flow and heat transfer in the cavity with PCM melted at constant T_H, we used two correlations for the average Nusselt number defined as:

$$\mathrm{Nu} = \frac{\mathrm{hL}}{\lambda_g} \quad \mathrm{Eq.9}$$

Where h is the average convective heat coefficient through the hot side of the cavity.

Table 3 compares the obtained Nusselt number with those calculated using the empirical correlations established respectively by (Eckert and Carlson 1962) and (Lankhorst 1991) for $\mathrm{Ra} = 5.32\ 10^6$. Since the relative error is less than 3%, our numerical model adopted in this study could be considered valid.

Tab. 3: Validation of the numerical model.

	$\overline{Nu}$	Relative error
This study	13.82	-
(Eckert and Carlson 1962)	14.139	2.3%
(Lankhorst 1991)	13.517	2.19%

4. Results and discussion

The experimental results were presented in our previous work (Labihi et al 2017). We found that the numerical simulation results match well with the experimental measurements. For that we conclude that the numerical model be considered valid along the process.

Due to the lack of empirical information about the heat transfer coefficients in the same studied configuration, authors used to use differentially heated wall cavity literatures correlation which is not representing the real physical processes of heat exchange between PCM and air cavity. In order to obtain correlations capable of characterizing the transient heat transfer process inside such cavity a simulation runs were carried out to obtain correlations of heat transfer rate via Nusselt number, with Rayleigh number Ra and the differnce dimensionless temperature between the hot and cold sides Θ.

In this study we define Ra number by the following formula $R_a = \frac{\rho g \beta L^3 (T_H - T_c)}{\alpha \mu}$ and $\Theta = \frac{T(t) - T_c}{T_H - T_c}$
Where $T(t)$ is the average temperature at hot side in each time.

In order to get a significatif range of Ra number we have chosen to vary L and not $(T_H - T_c)$ always keeps the same aspect ratio $A = \frac{e}{L} = 0.1$. Heat transfer at the hot interface between air and PCM is thoroughly inspected in the defined range $3.4\ 10^5 < Ra \leq 4.3.10^7$ with $Ste = 0.41$, $T_H = 50$ °C and $T_C = 20$ °C.

A simulation series was carried out with L=6, 10, 14 and 18cm. Figure 6 present the liquid fraction as a function of Θ for different Ra numbers. Despite the fact that we have the same formal report we can see that the solidification process (Θ from 0.6 to 0) is not the same when we change L. whereas the curves are very close to one another for Θ greater than 0.6. That can be explaining by the fact of volume contraction due to the difference between the density liquid/solid.

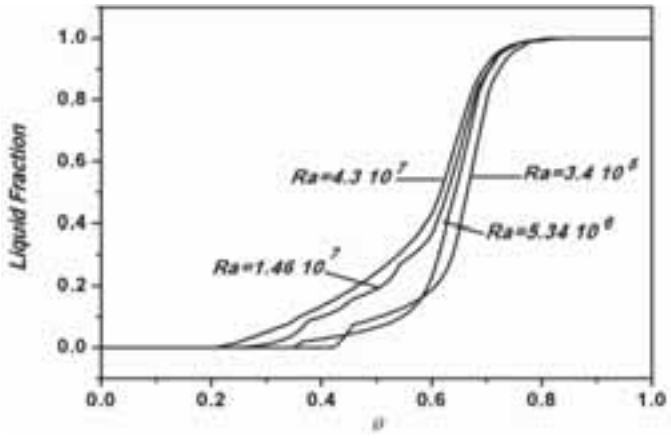

Fig. 6 Liquid fraction as function of Θ

The figure 7 shows the methodology that we use to find the correlations. to find an equation Nu as a function of Θ for different Ra number. We can see that the Nu number have a non-linear curve as function of Θ also we have some perturbation in the curves. The Nu perturbation becomes important when Ra increase.

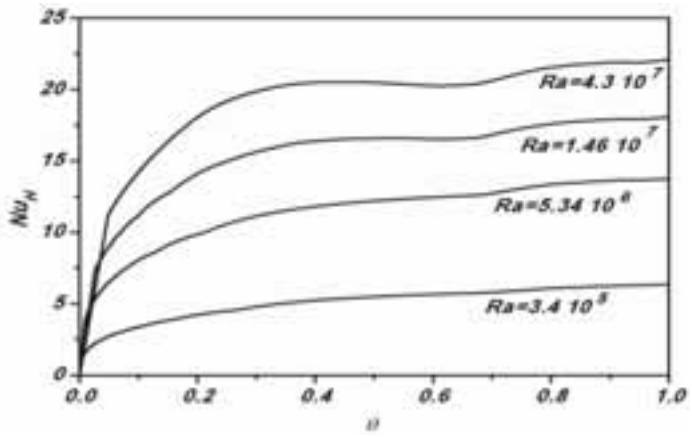

Fig. 7: Nusselt number evolution with dimensionless temperature for Ste=0.41

By using a non linear fitting for the curves issued in Figure 7.A new correlations between the dimensionless Nusselt number as a function of dimensionless Temperature Θ were made and presented in table 4.

Tab. 4: Nusselt number correlations at hot side as function of θ for different Rayleigh numbers

L (cm)	Ra	$\overline{Nu}$
6	$3.4\,10^5$	$6.7\,\theta^{0.3}$
10	$5.34\,10^6$	$14.88\,\theta^{0.283}$
14	$1.46\,10^7$	$19.67\,\theta^{0.254}$
18	$4.3\,10^7$	$23.50\,\theta^{0.213}$

5. Conclusion:

It is generally agreed that the intensive investigations undertaken in the last decades have given latent heat significant advantages especially organic PCM. We choose for this study a Rubitherm RT55 paraffin We conduct a numerical simulation where several assumptions had to be made in order to create a correlation model as close as possible to the realized experiment such as the invariability of PCM volume. Also knowledge of all the properties of the paraffin and the experimental validation would obviously provide more accurate results. Nevertheless, the coupling of convection of heat transfer in a cavity with solidifying PCM was successful and proposed correlation can be definitely used as a prediction in industrial or engineering fields. Hence, it can help for material selection step during design providing an economical advantage in saving time and money.

Based on the Numerical results and the correlated equations, the following conclusions could be drawn:

- The solidification process accurse early in time and tend to begin from the bottom to the top by following convection air loop.
- To have more Ra values we heed to vary L not the temperature difference between hot and cold side
- The contraction of volume in PCM layer affect the heat transfer processes from a Ra number to another despite the same aspect ratio in all cases.

For Ste=0.47 we see that we can write a new correlation for Nu number as function of Θ and Ra as the following formula:

$$Nu = aRa^n\theta^m$$

In future work we will exanimate a range of Ste values in order to write a general correlation of Nu number as a function of Ste, Ra andΘ.

Grid Integration of Variable Renewable Energy Systems

Reliability Analysis of Photovoltaic Systems with LEDs Integrated in Lighting Applications

Laurentiu Fara[1,2], Dan Craciunescu[1], Paul Sterian[1,2], Andreea Bobei[1] and Florin Dragan[1]

[1]Polytechnic University of Bucharest, Bucharest, Romania

[2]Academy of Romanian Scientists, Bucharest, Romania

Abstract

This paper is dedicated to the analysis of a PV system based on LEDs application from the point of view of its qualitative and quantitative reliability. This reliability study was conducted based on: 1) the RAMS (Reliability, Availability, Maintenance, and Safety) model applied to a PV system by using a simulation SYNTHESIS platform developed by ReliaSoft, and 2) the simulation of the LED lighting system using the SYNTHESIS platform and TM-21 Calculator software developed by ENERGY STAR. The purpose of the reliability analysis was to obtain a more stable and long-lasting operation of a PV system regarding reliability, maintainability, availability and degradation of the system.

Keywords: Reliability, Maintainability, Availability, Degradation, PV system, LEDs, simulation tools, RBD

1. Introduction

Due to various incentive programs and local market conditions in several European countries, as well as around the world, the PV systems represent a widespread solution for residential houses and other autonomous applications. This approach raises new and important issues related to the efficiency, reliability and safety of the PV systems, either autonomous or integrated in the electrical grid (Huffman and Antelme, 2011; DeGraaff et al., 2011).

In the case of grid-connected PV systems, the occurrence of system failures may affect the operation of other interconnected systems, that is why a thorough reliability analysis of such systems should be carried out (Kececioglu, 1991; IEC International Standard, 1995; Ishii et. al., 2011). The reliability analysis also makes it possible to establish an acceptable maintenance plan for both the user and the system as efficiently as possible (Crow, 2003, 2004). However, a reliability analysis is often missing from the feasibility study of photovoltaic systems or is treated superficially due to an incomplete methodological approach or lack of specific simulation tools (Herrmann et. al. 2010), (Hoffmann and Koehl. 2012). A PV system for LED lighting applications has been analysed (Popescu et al., 2009; Stanciu et al., 2015; Sterian, 2000, 2012), (Handbook, 2010). To overcome the reported inconveniences, it is envisaged the reliability analysis, using RAMS (Reliability, Availability, Maintainability, and Safety) statistical models through accelerated testing and application of stress levels (Nelson 1998; Kijima, 1989; Mettas, 2000; Holley et al., 1996). Starting from ground studies, the failures of PV systems have shown that manufacturers do not correctly perform reliability analysis of their PV modules' lifetime. For this reason, a small part of the PV modules fails before the lifetime specified by the manufacturer (Meydbray et. al., 2008). Reliability analysis applies to both PV systems, and simple systems, such as LED-based lighting lamps (Collins et al., 2009).

The authors proposed and carried out the reliability analysis of solar cells for specific meteorological conditions (Meydbray et al 2008; McMahon, 2004; Aoki et. al. 2010; Dhere et. al. 2010) To assess the reliability of the integrated PV system with LED lighting applications, its operating characteristics have been used for a time period (Wohlgemuth, 2011), and in the case of the simple LED lighting system there were used thermal characteristics of the studied LED lamp (Kim et al., 2006; Handbook, 2007) .

The most relevant analyzes proposed by the authors in this paper are based on Reliability Block Diagrams (RBDs) required for development of RAMS for studied PV systems. RBD diagrams have been developed for: 1)definition of PV systems, 2)description of interdependence between components, 3)identification of how they degrade / fail, and 4)appreciation of how the PV system reliability is influenced.

2. Background, state of the art and simulation tools

2.1. Background

The reliability of a product can be defined as the probability of performing its tasks without incidents within a specified time, under previously established conditions. On this basis, the quality of a product is determined, the reliability concept being applied in almost all areas of engineering, in the preventive maintenance of systems and their components. It is envisaged the modeling of the product's lifetime, represented by the time it has worked successfully or its time until the moment of failure. For the purpose of accurately determining the lifetime, it has been proposed an accelerate product testing (qualitatively or quantitatively during its lifetime) (Wohlgemuth, 2003; Dhere, 2005).

Qualitative accelerated testing only provides information about system malfunctions or ways of failure. Qualitative tests do not quantify the system's life (or reliability) characteristics under normal conditions of utilization, but provide valuable information on the type and level of demands to use during a later quantitative test. In qualitative accelerated testing, the expected result consists in identifying deficiencies and ways of failure without predicting the life of the product under normal conditions of utilization (Crow 2008; DeGraaff, et. al. 2011; Copper, 2016).

Accelerated quantitative testing involves the estimation of product lifetime characteristics, obtained under normal conditions of utilization after an accelerated test. High Accelerated Life Test (HALT) provides various information about the product and its failure mechanisms. Accelerated quantitative testing consists of tests designed to quantify the life characteristics of a product, component or system under normal conditions of utilization, and to provide information on determining the reliability of the system (probability of system failure under various conditions, life expectancy, average lifetime). It can be used to carry out risk assessments or for comparison of different design methods (Hoffmann and Koehl, 2012).

Two acceleration methods were designed (Hoffmann and Koehl, 2012) for use of: 1) acceleration rate and 2) stress acceleration, in order to obtain time data on product failure at an accelerated rate. For products where use of acceleration rate is impractical, a second method can be applied, in which the normal stress level of a product is exceeded.

2.2. State of the art

The reliability of photovoltaic systems and their components/elements (solar cells, PV modules, electrical storage systems, inverters, regulators, etc.) are the key issues in manufacturing performance and financially competitive photovoltaic installations. For this purpose, a number of methods for testing and improving the reliability of PV products have been studied (Nelson, 1998; Mettas, 2000), such as: 1) the accelerated test method for solar cells (Desombre, 1980); 2) analysis of defect detection and degradation mechanisms detection for solar cells (Kijima, 1989), as well as PV systems and their components (Vazquez and Rey-Stolle, 2008); 3) energy production forecasting based on the rate of failure and degradation of PV systems and their applications (Holley et al., 1996).

In this paper the authors proposed in this paper to integrate some of these methods by using a specialized complex simulation platform, namely SYNTHESIS, which allows a physical and statistical approach for PV products; it is envisaged the development of a highly useful RAMS methodology, both in research and in the efficient design of PV systems and their applications (Wohlgemuth, 2003; Van Weeran, 2013; Granata et al., 2009).

2.3. Methodology

In order to perform a fairly accurate reliability analysis of the PV systems and their components, the authors of this paper have chosen to use the SYNTHESIS simulation platform developed by **ReliaSoft (**Synthesis Platform, 2017)**.** The simulation methodology is intended to explain how the simulation platform modules work. On this basis the obtained results regarding: 1) solar cell, 2) PV system, including its components, 3) LED lighting system and 4) integrated PV system can be understood. The following modules of the simulation platform were used in the analysis:

a) The **Weibull++ software tool** is the industry standard in life data analysis (Weibull analysis) for many companies around the world. This software performs life data analysis using multiple lifetime distributions with a clear and concise, reliability-oriented interface. The features of Weibull++ provide the most comprehensive set of tools available for life data reliability analysis. The software supports all types of data and all distributions commonly used throughout the product's lifetime.

b) The **ALTA software tool** provides an intuitive way of complex and powerful mathematical models for quantitative analysis of accelerated life tests. Accelerated lifetime testing techniques, combined with powerful data analysis methodologies, reduce testing time for the product, thus providing faster product launch times, lower product development costs, as well as lower warranty costs.

c) The **BlockSim software tool** provides a comprehensive platform for the reliability, availability, maintenance and related products analyzes. The software provides a graphical interface that allows modeling of both simple and complex systems and processes using reliability block diagrams (RBDs), failure tree analyzes (FTAs), or combinations of both approaches. Using accurate calculations and / or discrete events simulation, BlockSim facilitates a wide range of analyzes: 1) system reliability analysis, 2) identification of critical components (important for reliability), 3) optimal allocation of reliability, 4) system maintenance analysis (determining the optimal intervals for preventive maintenance); 5) analyzing the availability of the system (determining the operating time, availability / unavailability), 6) performing calculations for obstacle identification, production capacity estimation, etc.; 7) estimating the cost of the life cycle.

d) The **RENO software tool** is a platform that allows complex analyzes for any probabilistic or deterministic scenario. Chart models can be created for complex reliability analyzes, risk and safety analyzes, decision making, or maintenance planning. The Monte Carlo simulation methods offer a number of definitions and constructions that allow modeling of the examined situations. Simulation results can be applied to estimate/optimize risk analysis, complex modeling of reliability and maintenance planning.

e) The **RGA software tool** allows the application of reliability enhancement models for data analysis from both development tests and on-site repair systems. In the development phase, the software allows to quantify the increase in reliability achieved for each product prototype and also provides advanced design, planning, and reliability enhancement management methods. The software also offers opportunities for ground-based system analysis, including a test utility for system reliability.

For a deep understanding of LED PV applications, the authors used the TM-21 Calculator software developed by ENERGY STAR to study the reliability of LED systems. The main feature of this software is the application of temperature stress levels that allow the establishment of lumen maintenance degradation during the lifetime of these products.

3. Modeling and numerical simulation of PV system components using RAMS analysis. Discussion of the results

3.1. Basic concepts

The studied integrated PV system is defined as a PV application, which uses a consumer for LED lighting application (see Fig.1). The implementation of the RAMS analysis of the PV system was performed using the modeling and simulation SYNTHESIS platform for system reliability (Craciunescu et al., 2017). When it is analyzed the reliability of studied solar cells, the simulation module used in the SYNTHESIS platform was Weibull / ALTA. This module statistically addresses reliability issues through statistical repartitions and together with the ALTA module contributes to the accelerated life tests. For the analysis of the PV system / LED lighting application studied in the paper, the BlockSim simulation module was used within the same platform. The simulation of the PV systems is based on the RBD diagram, as well as on the component types and the way they are arranged in the system.

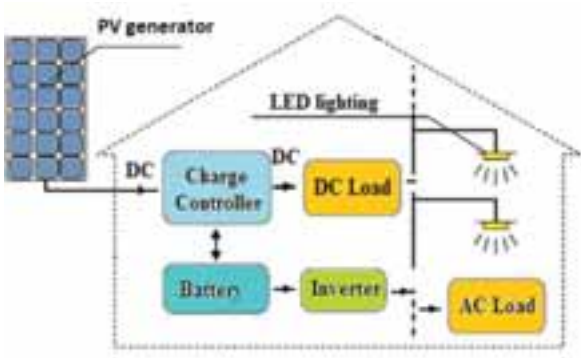

Fig. 1 PV integrated system concept

For a rigorous understanding of the RAMS analysis for the PV integrated system, it was analyzed the highlighting of solar cell degradation. By performing a statistical analysis based on the Weibull, Exponential and Normal repartitions, it was possible to estimate the most frequent events (characterized by main meteorological parameters: solar irradiance, temperature and humidity) that contribute to the most probable degradation of solar cells during their lifetime. The statistical approach was correlated with the accelerating lifetime method by stressing solar cells using different meteorological parameters (Fig. 2). The present study considered only the three meteorological parameters mentioned above, which have an essential role in cell degradation.

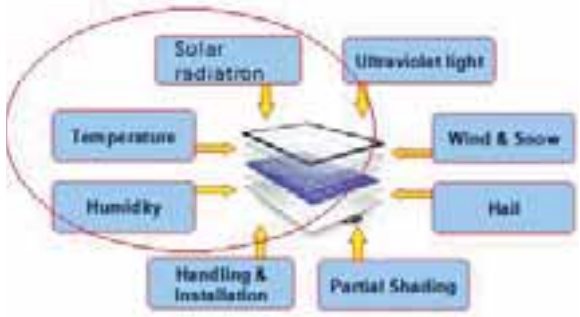

Fig 2. Accelerated stress test diagram

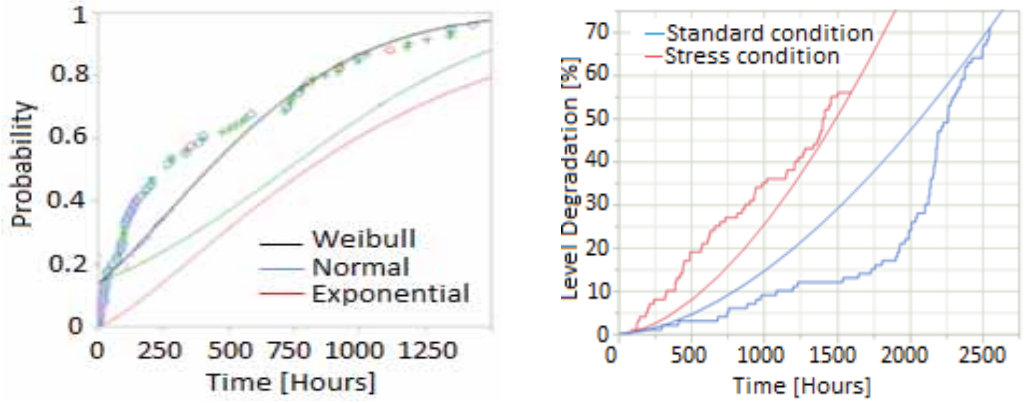
3.2. Reliability analysis of solar cells

Reliability analysis of solar cells has been developed based on the accelerated testing method, which has certain advantages: 1) avoiding testing in real and more severe conditions that can lead to cell degradation / failure, 2) determining the frequent reasons that determine cell failure. Highly Accelerated Stress Screening (HASS) aimed at identifying defects in as short time as possible compared to the standard method (based on cell monitoring and results analysis), which may take several months / years. Accelerated testing (HASS) can be performed with either a weather parameter (e.g. temperature / solar irradiance) or combined with few weather parameters (such as temperature, humidity and solar irradiance). Within this paper the HASS analysis was implemented in the version of the three key meteorological parameters.

The authors' study also looked at establishing the best statistical reparation used to make the most accurate predictions of the of solar cells life time. Three types of statistical repartitions, namely Weibull, Exponential and Normal, were evaluated using the SYNTHESIS software, and based on the correlation cause (determined by one of the three main meteorological parameters) - occurrence (characterized by the degradation degree of the solar cell) it was possible to obtain the probabilities for the three repartitions (the black curve defines the Weibull repartition, the green one defines the Normal repartition, and the purple one defines the Exponential repartition), using the HASS test. In Fig. 3a the curves of the mentioned statistical repartitions were obtained. It can be seen that Weibull repartition is the closest to the values of the three main meteorological parameters. The accelerated test has highlighted that the most influential meteorological parameter in solar cell degradation (characterized by most occurrences) is temperature, followed by humidity and further by

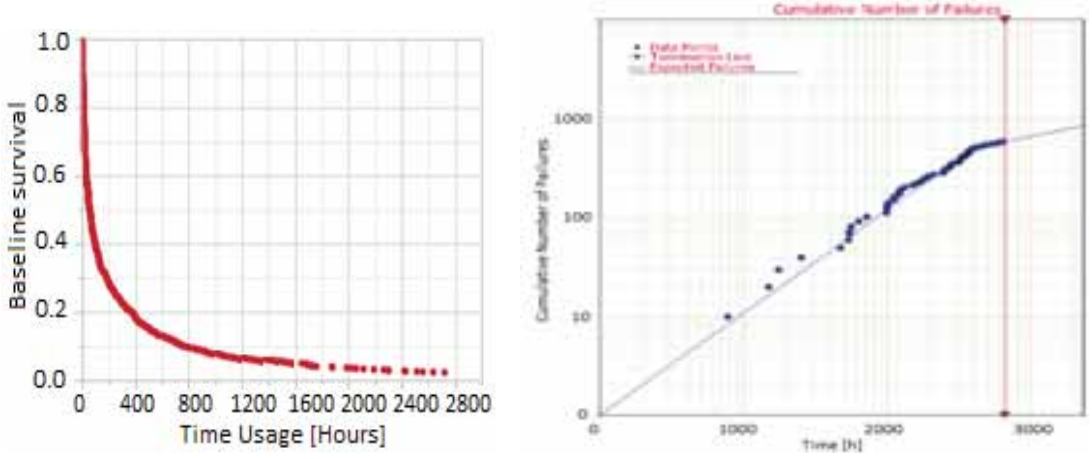
solar irradiance. Fig. 3b shows the temporal evolution (in hours) of the degradation level of solar cells for two operating modes: under stress conditions (purple continuous curve) and in standard conditions (blue continuous curve).



a) b)

Fig.3 a) The life distribution of solar cells for different distribution function b) Degradation level of solar cells simulation in different conditions (standard and stress)

Using the stress results of the HASS test (purple curve in Fig. 3b), it was possible to determine by numerical simulation in the SYNTHESIS platform, the limit value of the cell operating time in normal conditions, respectively 1600 hours, according to the curve in Fig. 4a. The accelerated test also enabled the probable number of solar cell failures (see Fig. 4b) within the range of 1000-2800 hours, with a higher concentration between 1500-2800 hours according to the results from Figure 4a; the linear dependence defines the expected failures curve based on Weibull repartition.



a) b)

Fig. 4 a) Baseline survival of solar cells module simulation in stress conditions b) Cumulative number of failures as function of time

3.3. RAMS analysis of the PV system

The analyzed PV system consists of a set of components, arranged to achieve the established performance and to provide acceptable reliability. The reliability characteristics of the PV system and its components can be presented in RBD-type diagrams illustrating their possible failures. These failures are due to a facile analysis of the failures risk.

The RAMS analysis for the photovoltaic system aimed to determine how the system and its components worked over a 5000-hour period (about 5 months). For this purpose, it was analyzed the time evolution of the PV generator efficiency, as well as of the PV system's battery efficiency. There were noted high fluctuations for the efficiency of PV generator, slower fluctuations in battery efficiency based on Fuzzy Logic Controller (FLC) and Maximum Power Point Tracking (MPPT) methods (see Fig. 5). The LED lighting system (electric consumer) will be discussed further in section 3.5.

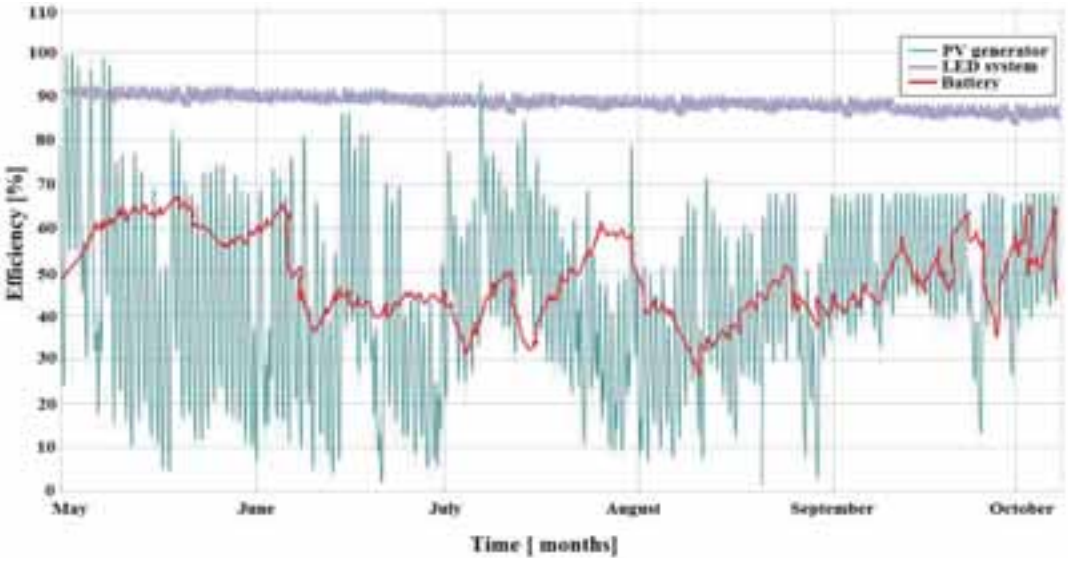


Fig. 5 Efficiency and functionality of a PV system for its main three components: 1) PV generator 2) battery and 3) electrical load

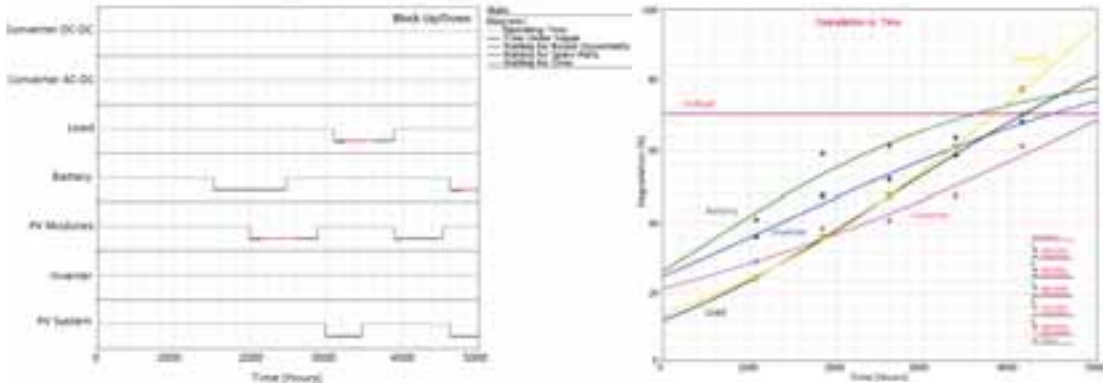
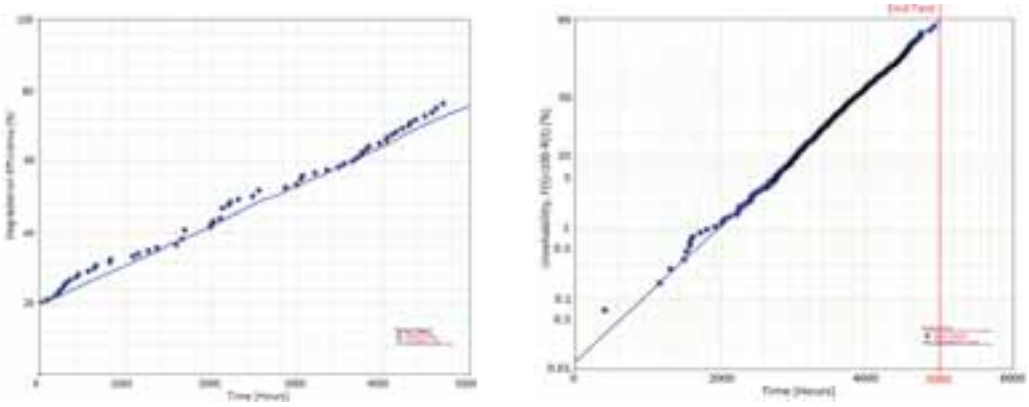
Using the results obtained in Fig. 6a we could establish the availability diagram of the PV system giving the operation time and unavailability periods (when the PV system is not working). The unavailability periods are usually small; after 3000 hours of operation there is a 500-hour period when the PV system has to be repaired due to different failures. In Fig. 6a there are also analyzed the main components of the PV system (PV modules, battery and load) to be maintained. The complex analysis of defect risks and preventive planned maintenance of the components aims at avoiding spontaneous malfunctions and premature degradation of the PV system.



a) **b)**

Fig. 6 a) PV system availability / unavailability diagram b) Degradation of system components based on availability / unavailability diagram

In Fig. 6b the level of degradation for each component of the PV system is presented. Although, excepting the inverter, all other components exceed the critical threshold to the end of the test (3500-4500 hours); however, two components, respectively the PV modules and the storage system, are the most vulnerable to failure (exceeding the critical level much earlier). The simulation tools allowed to obtain the efficiency degradation analysis of the PV system (see Fig. 7a). A good PV system is characterized by small fluctuations of the time evolution of efficiency, determining a usual degradation based on normal operation requirements for the analyzed simulation period (5000 hours).



a) b)

Fig. 7. a) Time degradation of PV system efficiency b) Statistical unreliability of the PV system in time

The probability of non-functioning of the PV system over time is sensitive after 2000 hours of the product use (see Fig. 7b). It is noted the role played by this diagram in RAMS analysis; when the components of the PV system start to degrade, the number of failures increases, that leads to the need for more frequent interventions (repairs) on the PV system.

The RAMS approach, based on the SYNTHESIS simulation platform, was able to obtain preliminary information on the time behavior of the PV system and its components (from the point of view of its reliability and maintenance) which could be very useful for its proper design.

3.4. Failure analyses for the LED lighting system

The operation of LEDs is strongly influenced by the thermal conditions that can cause LED degradation. The evaluation of LED degradation is performed by the lumen degradation method, in which higher internal temperatures are produced without heat sink. The RAMS analysis of typical LED lamps, as the one in Fig. 8, is possible with the help of two software environments, namely: 1) TM-21 Calculator developed by ENERGY STAR - to determine LED lamp degradation, and 2) SYNTHESIS simulation platform - to assess the failure of each component of the LED lamp (TM-21 Calculator, 2017; Synthesis Platform, 2017).

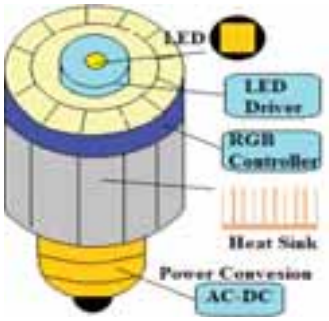


Fig 8. Concept of a typical LED lamp

According to Fig. 9a, at a test temperature of 140 ^{o}C, the lumen flux reaches 60% of its total value; it corresponds to a 2200 hours operation (based on a 5000-hour range for which the simulation was performed). It is remarked that the life duration of the LED lamp was reduced by roughly 1500 hours in the temperature range of 80-140 $^{\circ}$C.

The SYNTHESIS platform, in particular the BlockSim software tool, was used to obtain the degradation diagram of the LED lamp, as shown in Fig. 9b, useful in testing of several efficient cooling systems, which can help to increase the reliability of the LED system. It is noticed that, under standard operating conditions, the LED lamps are getting closer to the critical degradation limit, while using the Heat Sink the LED lamp component functioning is removed from the critical area.

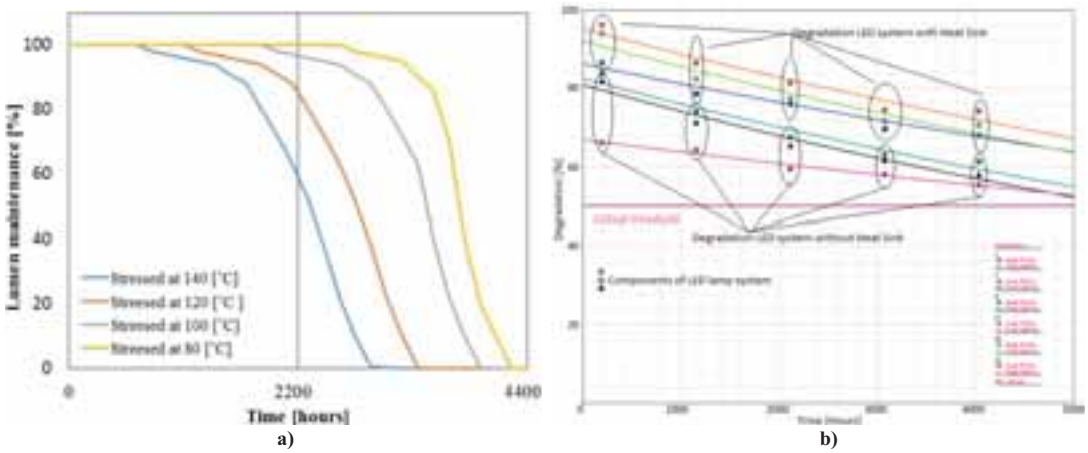

Fig. 9: a) The degradation curve of lumen maintenance [%] for the whole LED lamp, represented by life duration (hours) depending on four values of test temperature (stress). b) Degradation diagram of the LED lamp components

3.5. RAMS analysis specific to a PV system

A PV system based on LED lighting application has been studied. Analysis of the PV integrated system was possible using the availability / unavailability diagram of its components (Fig. 10). This diagram describes the interdependence between the components and defines how the system works. An important parameter of the availability / unavailability diagram is the power load LED system that is influenced by the operating mode (using either serial, parallel or mixed type configurations). Each component of the PV system is characterized by a repairable block, parameterized in the BlockSim simulation module.

A feature of the Up / Down diagram is the planning of the PV system maintenance; thus, as a result of prompt interventions in order to repair its components, spontaneous or irreversible failures are eliminated, the system thus becoming functional over the entire lifetime.

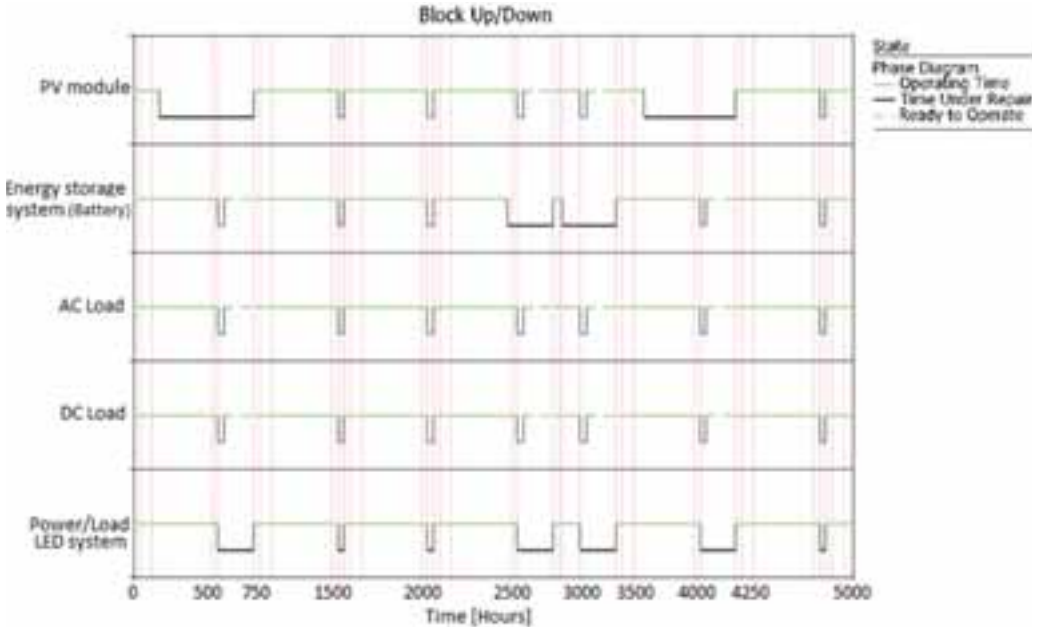

Fig. 10: Diagram of the availability / unavailability (Up / Down) of the PV integrated system

The failure rate for each component of the PV system was also being studied. The highest failure rate is presented, by the PV modules, respectively LED systems, according to the results in Fig. 11. This is due to

the specific configurations for these components (series, parallel or mixed) that increase their failure rate compared with other components (battery, inverter, regulator, etc.).

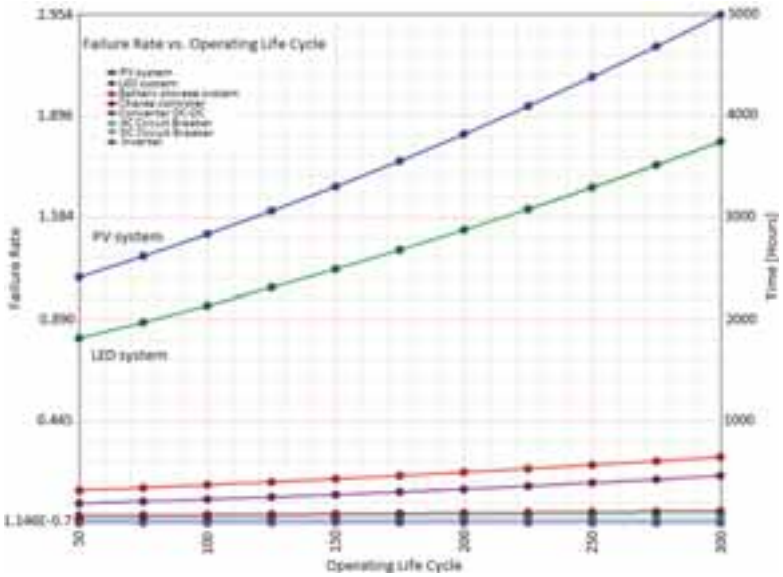

Fig. 11: Time evolution (in hours) of components failure rate of the PV system depending on operating life cycle

4. Concluding remarks

The authors have proposed the reliability analysis of a PV system for a LED lighting application using a performance SYNTHESIS simulation platform, which allowed the system to function more accurately by identifying probable defects in certain components of the system.

This contribution is based on an original approach of RAMS reliability analysis. It was considered the adaptation of Up / Down reliability block diagrams (RBD) from *the reliability theory and applications* for a photovoltaic system in order to determine its functionality and availability and to establish its duration of non-functionality (required to implement the PV system maintenance). The obtained results of this study are in good agreement with the reliability published studies from the point of view of the methods used (Huffman et al., 2009; DeGraaff et al., 2011; Crow 2004; Crow 2003; Collins et al., 2009; Copper et al., 2016; Vazquez et al., 2008).

The main results obtained by the authors in this article could be synthesized as follows:

- the simulation of the solar cells operation on an accelerated test basis (under the influence of three essential meteorological parameters: solar irradiance, temperature and humidity) allowed to put in evidence the normal operating time under normal / stress conditions, defining the initial degradation time of stressed solar cell (determined by a possible degradation of the cell's I-V characteristics). The Weibull most probable statistical repartition has also been identified using a proper solar cells testing; on this basis, the operating duration in which a significant concentration of defects is achieved, was determined.

- the simulation of the PV system operation allowed to obtain information on the availability / unavailability of the system, based on a RBD diagram. Using this diagram, PV components that may exhibit a higher rate of degradation (PV modules, electrical battery) during operation are identified. Also, useful information on degradation of the PV system was obtained (based on the efficiency degradation curve and the non-functional curve).

- the simulation of the LED lamp allowed to study the temperature influence on the lifetime and the degradation of the lamp components.

- the simulation of PV system operation for the LED lighting application allowed also to use the Up/Down diagram as maintenance schedule for elimination of spontaneous or irreversible failures,

The results obtained by the authors were partially validated by other authors research studies, regarding the availability and degradation of analyzed systems (Mahdi et al., 2017; Lavrova et al., 2015).

In order to increase the reliability of the PV system and its components, it is necessary to develop an elaborated failure management strategy that involves knowing the initial level of reliability and developing efficient solutions for planning and assessing the probable risks of failure. The essential directions for such a strategy could be as follows:

- experimental accelerated testing of the PV system under the influence of possible degradation factors;

- identifying the cause of failure in experimental conditions, that is intended to isolate possible failures occurring in the PV system;

- implementing effective corrective actions to significantly reduce the failures of the PV system.

Abstract

Decentralized surplus feed-in of solar heat into a District Heating Network (DHN) is here addressed. The heat collected from solar panels located on rooftops of DHN connected buildings may either be used locally for domestic hot water and space heating or fed into the heating network. Two-way substations able to transfer heat from and into the network seem then to be required utilities of future DHN. In that context, two equally important questions were identified: i) what should be the specifications and architecture of such solar fed bidirectional substations? and ii) what is the impact of decentralized reinjection on the network operation? The former is addressed in the present paper while the latter is an ongoing study not presented here. In the present work, first a discussion on the specifications and architecture of such bidirectional substations led to the conclusion that architectures for which the solar heat is entirely reinjected into the DHN without local consumption seem more feasible. Second, a Modelica-based modeling framework of the bidirectional substation is presented and preliminary results highlight the potential of reinjection on the DHN. The results presented here are part of the first year work in the frame of the European project 'THERMOSS'.

Keywords: Solar Feed-In, Decentralized, Substation, District Heating, Dynamic Modeling, Modelica, Prosumers

1. Introduction

In the "2way District Heating" course of action from the 4GDH concept (Lund et al., 2014), decentralized feed-in of solar heat from prosumers, i.e. customers reinjecting heat into a district heating network (DHN), seems to be a promising solution to increase the share of renewable energy of DHNs. The latter is especially true in dense urban areas with limited ground surface. Reinjection of solar heat will maximize the use of well-exposed customers' rooftops while minimizing the cost by mutualizing the equipment via the DHN.

However, when scattered heat reinjections occur in a DHN, new problematics arise. Among the most decisive ones, prosumers must decide whether it is interesting to consume or feed-in the collected solar energy, they must control their reinjection temperature in a context of variable differential pressure and the DHN operating company must deal with distributed reinjection points.

Among the various reinjection principles (see Fig. 1), the Return to Supply line (R/S) variant highlighted in Fig. 1a, seems to be the best option since it leads to the lowest temperature in the solar panels without modifying the network return temperature (Lennermo and Lauenburg, 2016; Schäfer et al., 2014). However, R/S feed-in implies to overcome the local differential pressure between the return and supply lines, which usually exhibits significant variations due to rapid load fluctuations. Moreover, the feed-in temperature must be superior or equal to the local network supply line value. The latter constraints on the local differential pressure and the local supply temperature involve at the bidirectional substation level the use of at least a variable speed pump and a finely tuned control strategy.

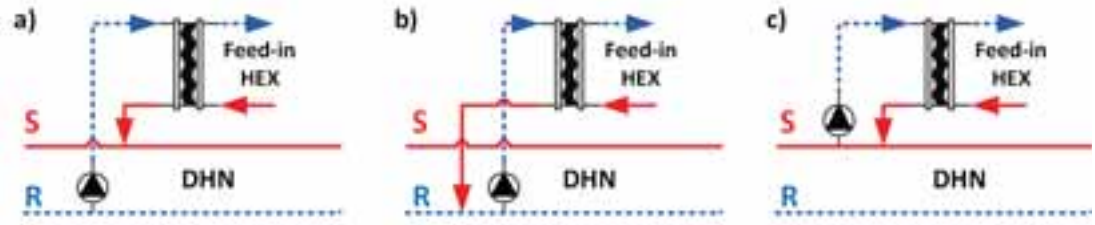

Fig. 1: Schematic of two-way substation feed-in strategies into a DHN – a) Return/Supply (R/S), b) Return/Return (R/R) and c) Supply/Supply (S/S)

doi:10.18086/swc.2017.10.02 Available at http://proceedings.ises.org

More than only considering decentralized reinjection like in Brange et al. (2016) or Heymann et al. (2017), it is of great importance to consider both the local consumption and reinjection of the excess heat as in Paulus and Papillon (2014) and Pietra et al. (2015). The local consumption possibility together with the local differential pressure and supply temperature constraints presented previously lead to the requirement of innovative control algorithm at the substation level (Rosemann et al., 2017). At the network level, the operation with multiple prosumers also becomes more challenging with the creation of new pressure cones for example (Brand et al., 2014) that may lead to flow stagnation in some parts of the network and even possible flow reversal at the main generator (Heymann et al., 2017). Additionally, the traditional critical differential pressure driven operation becomes more difficult to implement (Hassine and Eicker, 2014).

In this context, it seems necessary to address the question of bidirectional substation at both the substation and network levels. Thus, on the one hand, the present study addresses the specifications, architectures, and modeling of a two-way substation for a multi-family building including the possibility of local consumption. On the other hand, work on the influence of decentralized reinjection on the network's performance is ongoing but not presented here. These two studies are meant to be connected in future work by implementing the model developed in the first task into the network of the second task.

The present paper thus addresses the problem at the substation level. It firstly deals with the specifications and architectures of bidirectional substations. Features such as the location of the hydraulic separation between the network and the building, local consumption of the heat or total feed-in and control strategies are combined to build an exhaustive list of possible configurations. Secondly, a promising setup is chosen from that table based on a multi-criteria analysis. Finally, a modeling framework for the simulation of bidirectional substations is presented with preliminary results. Contrarily to most publications on this topic in the open literature, Modelica programming language is here used rather than TRNSYS (Paulus and Papillon, 2014), NetSim (Brand et al., 2014) or in-house tools (Pietra et al., 2015) since it has native multi-physical modeling capabilities (i.e. thermo-hydraulic) and allows for implementing new components. Both the details of the two-way substation and the impact of these prosumers on the network are thus studied using the Modelica "Standard" Library, together with the "Buildings" (Wetter et al., 2014) and the "DistrictHeating" (Giraud et al., 2015) libraries.

2. Bidirectional Substation Specifications

2.1. Initial Considerations

As previously discussed, the problem here addressed is the decentralized reinjection of solar heat on a DHN using R/S feed-in (see Fig. 1). The solar collectors are assumed to be on the rooftop of a multi-family building, equipped with a unique bidirectional substation (see Fig. 2). Variants relying on individual bidirectional stations at the apartment level have been discarded from this study due to prohibitive cost and increased complexity. Indeed, solar bidirectional substations seem more appropriate for multi-family buildings rather than for individual apartments (Rosemann et al., 2017) since it simplifies the hydraulic connections at the building level while reducing the costs. It also reduces the number of reinjection points in the DHN, aggregate heat inputs and thus simplifies the operation of the network.

Fig. 2 Two-way substation in multi-family building prosumers

The multi-family building considered in the present study consists in 3 floors with 2 apartments of 3 people per floor. Each apartment has a height, width and length of respectively 2.5m x 10m x 7m leading to an overall footprint of the building of 7.5m x 10m x 14m. A preliminary calculation leads to an overall space heating (SH) nominal power of about 42kW based on a consumption of 100W/m² (poorly insulated buildings built in the 80's in western European climate) and an overall domestic hot water (DHW) nominal power of 60kW. The latter is obtained using the daily draw-offs from COSTIC (2016), i.e. about 150 liters for an apartment of 3 people, and the "DHWcalc" calculator (Jordan and Vajen, 2005) to obtain distributed daily or yearly profiles. The maximum 10 minutes average from this profile is 16kW/apartment leading to the 60kW for the entire building when accounting for a simultaneity coefficient of 0.62. The solar collector field has an area of 80m², which covers one side of the rooftop with a 30° of inclination angle. The building solar production would reach 56kW with an assumption of 700W/m² of production based on IEA SHC recommendations (IEA SHC, 2004).

The rest of the present section is dedicated to the question of the architecture of such two-way substation. Fig. 3 summarizes schematically the challenge posed here with the bidirectional substation connected to the DHN, to the SH and the DHW loops, and to the solar collector field. The question to address in the following parts is how to do so.

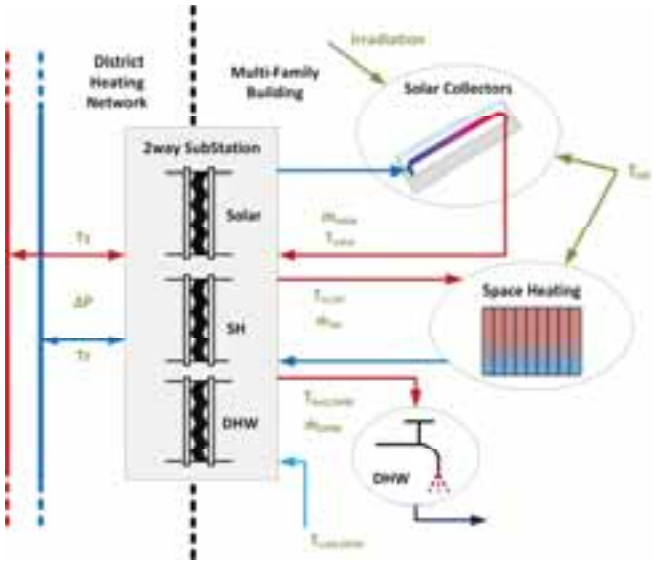

Fig. 3: Overview of the boundary conditions to account for in the design of the two-way substation

2.2. Selection of Features

In the present section, an exhaustive list of possibilities regarding the architecture of the substation will be established through the combinations of three features. Then, the purpose will be to select the most promising ones based on various criteria. The three selected features to characterize the bidirectional substations are the following:

- Feature 1: Type of connection to the DHN, i.e. location of the hydraulic separations for SH and DHW
- Feature 2: Possibility or not to reuse the heat locally, i.e. connection with the solar field
- Feature 3: Control strategy associated to the reinjection of heat.

Tab. 1 presents the three possibilities listed for Feature 1 'Network Connection', Feature 2 'Local Usage' and Feature 3 'Control Strategy'. In this Table, the substation is represented by a grey rectangle. More specifically, the section of the substation dedicated to SH and DHW production is highlighted by a 'SH/DHW' tag while the section dedicated to the solar heat is referred by a 'Solar' tag. The different features will be combined in the next section.

Feature '1', referred as C for Connection, deals with the location of the hydraulic separation between the DHN and the consumer (SH and DHW). Here is the list of possibilities for Feature '1':

- C0: There is no hydraulic separation between the DHN and the consumer inside the bidirectional substation;
- C1: A single heat exchanger in the bidirectional substation performs the hydraulic separation between the DHN on one side and the DHW and SH loops of the consumer on the other side. C1' indicates that

DHW production is then collective for the entire building while C1'' indicates that DHW production is decentralized at the apartment level;

- C2: Two heat exchangers in the bidirectional substation perform the hydraulic separation respectively between the DHN and the DHW loop and between the DHN and the SH loop of the consumer.

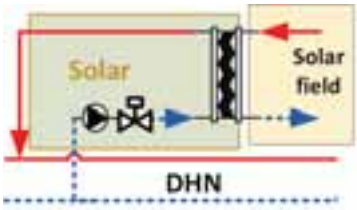
Feature '2', referred as U for Usage, deals with the local consumption of the produced heat, i.e. the connection between the consumer and the solar field. It is worth mentioning here that the hydraulic separation between the solar field and the DHN will always be performed with a heat exchanger in the two-way substation:

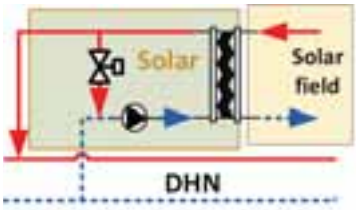
- U0: The produced heat is entirely reinjected into the DHN;
- U1: The produced heat is partly used locally for DHW preparation and partly reinjected in the DHN;
- U2: The produced heat is partly used locally for DHW preparation and SH and partly reinjected in the DHN.

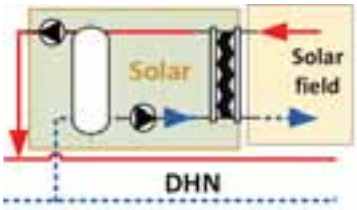
Feature '3', referred as S for Strategy, deals with the strategy/control associated to the reinjection (feed-in), i.e. the link between the substation and the DHN. The following possibilities are further detailed later:

- S0: A pump and a 2-way valve in series;
- S1: A pump and a 2-way valve as bypass;
- S2: Two pumps and a hydraulic separator.

Tab. 1: Possibilities for Features 1, 2 and 3 - The gray rectangle represents the bidirectional substation perimeter, the 'SH/DHW' tag represents the substation part dedicated to SH and DHW while the 'Solar' tag represents the substation part dedicated to the solar heat

FEATURE 1: HYDRAULIC SEPARATION between DHN and SH+DHW (Network Connection)		
C0	**C1**	**C2**
		FEATURE 2: SOLAR FIELD CONNECTION (Local Consumption)		
U0	**U1**	**U2**
		FEATURE 3: FEED-IN ARCHITECTURE (Control Strategy)		
S0	**S1**	**S2**
		






2.3. Features Combinations

As a first step, the two Features ('C' and 'U') are combined resulting in the configuration table Tab. 2. Fig. 4 Fig. 5 show examples of such combined configurations with the two parts 'SH/DHW' and 'Solar' inside the bidirectional substation. Additionally, here are the considerations to account for when combining these first two features:

- If there is no hydraulic separation between the DHN and the building in the bidirectional substation (C0), then each apartment is equipped with an individual small scale one-way substation with a DHW heat exchanger and a SH heat exchanger in parallel, as highlighted in configuration C0U0 of Fig. 4
- If there is no hydraulic separation between the DHW and SH loops in the bidirectional substation but they are themselves separated from the DHN (C1), then if the DHW production is individual, each apartment is equipped with an individual small scale one-way substation with only a DHW heat exchanger (C1''), as highlighted in configuration C1''U0 of Fig. 5

Tab. 2: Possible configurations for solar source bidirectional substation based on Features 1 and 2

DHN Connection	Local usage		
	U0	U1	U2
C0	V	X	X
C1'	V	V	V
C1''	V	X	V
C2	V	V	V

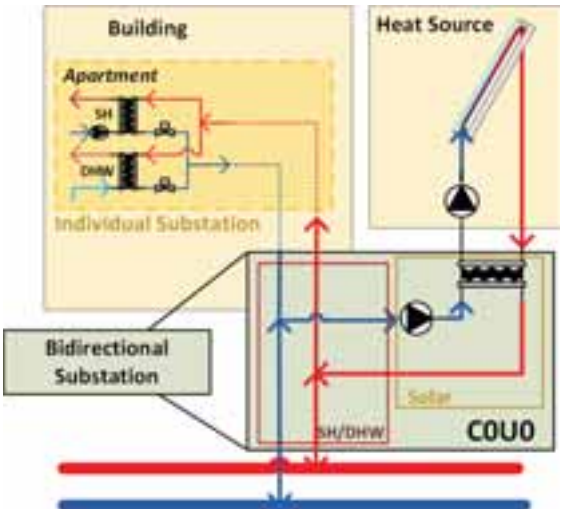


Fig. 4: C0U0 configuration with individual SH/DHW substation in each apartment

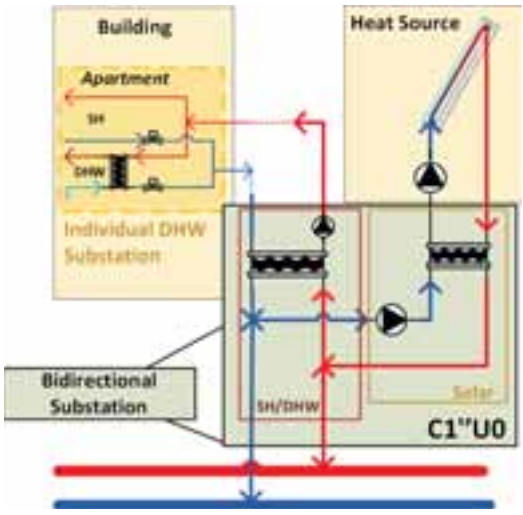

Fig. 5: C1''U0 configuration with individual DHW substation in each apartment

It is observed in Tab. 2 that three configurations, namely C0U1, C0U2 and C1''U1 are unrealistic. Indeed, for the first two, since in configuration C0 the bidirectional substation has no heat exchanger separating the network from the building, individual one-way substations (from network to consumer) are needed in each apartment. Thus, if local usage is implemented, it means that each individual substation needs to handle the solar heat produced. The latter seems inappropriate as explained in Section 2.1 (cost and complexity issues). Similarly in configuration C1''U1, since DHW is not separated from SH at the substation level and is produced individually in each apartment, it means that in order to be able to reuse the solar heat for DHW preheating, an extra heat exchanger is needed in each apartment, which is again rather costly.

For all the other feasible combinations, various criteria listed below have been considered and Tab. 3 summarizes the performance of each of these configurations for these criteria:

- Cost: Related to i) the pressure and temperature levels in the building (lower if hydraulic separation present in the substation), ii) the necessary equipment in the two-way substation (amount of pumps, valves, heat exchangers), and ii) the necessary equipment in the building (extra individual substation for DHW production or indirect space heating)

- Operation: Related to the operation of the solar field with respect to the DHN and the consumers. Simpler if the solar production is decoupled from the consumer part (U0 solutions)
- Ownership: Related to who owns what in the overall system, i.e. is the barrier between the DHN operating company and the consumer clear? In the case of local consumption (U1 and U2), it is clear if the solar field belongs to the consumer but not clear if it belongs to the DHN company.
- Extra DHW production in the apartments: Related to the requirement of an extra hydraulic separation between SH or DHN water and DHW water outside of the two-way substation. This is linked to the location of the hydraulic separation.
- Sanitary loop Requirement: Related to the requirement of a sanitary loop for DHW production. If individual DHW substations are used, sanitary loop is not needed.

Tab. 3: Performance criteria for the selection of the most promising architecture

	C0U0	C1'U0	C1''U0	C2U0	C1'U1	C2U1	C1'U2	C1''U2	C2U2
Cost	+/-	+/-	-	+	+/-	+	+/-	--	+
Ownership	+	+	+	+	+/-	+/-	+/-	+/-	+/-
Operation	+	+	+	+	+/-	+/-	+/-	+/-	-
Extra DHW production needed	Yes	Yes	Yes	No	Yes	Yes	Yes	Yes	No
Sanitary loop required	No	Yes	No	Yes	Yes	Yes	Yes	No	Yes

In general, operation and ownership are easier if there is no local usage of the produced solar heat (U0 solutions) since the DHN could then own the decentralized solar fields and operate them at wish, as common generators (but of small size). Solutions involving additional individual substations (C0 and C1'') are more costly but do not require sanitary loops and allow for individual metering. C2U1 also seems interesting since it does not increase drastically the number of components while allowing self-consumption of the locally generated heat. However, that configuration is more complex to operate.

2.4. Selected Architecture

For the continuation of the present study, configuration C2U0, i.e. with the hydraulic separation for both the space heating and the DHW performed in the bidirectional substation and with no local consumption, has been selected for the following reasons:

- In this configuration, the DHN operator could rent the building's rooftop to install the collector field and would then operate it at wish to suit the entire DHN operation;
- In this configuration, the operation of the consumer part of the substation remains as usual;
- It is cost efficient since the hydraulic separation is performed at the building scale and thus individual one-way substations are not necessary. Additionally, since the hydraulic separation is performed at the building scale, the building's piping would run at lower pressure and temperature;
- It presents the simplest operational scheme / control strategy.

The selected configuration C2U0 is shown on Fig. 6. On this Figure, control strategy S0 (see Tab. 1) of the last feature, i.e. Feature '3', has been superimposed to the C2U0 configuration. In general, the main objective of the control strategy is to obtain a feed-in temperature level above the local supply temperature in the DHN, while fulfilling the following constraints:

- Obtain the lowest temperature in the solar field to reach high efficiencies;
- Overcome the strongly varying local flow resistance, i.e. differential pressure drop;
- Well adjust the feed-in flow rate so that the feed-in rate matches the strongly varying heat rate produced by the solar field.

As highlighted in Schäfer et al. (2014), the challenge here lies in the combination of two parameters with strong and fast variations, i.e. the solar heat production and the local differential pressure drop. In general, if a speed controlled pump alone is used to maintain the targeted temperature, too many startup/shutdown cycles are noticed when the differential pressure exhibits strong variations.

In control strategy S0 (see Tab. 1), the pump is responsible for the pressure differential while the valve is applied to regulate the flow in order to meet the targeted temperature. This method exhibits good performance but the control valve results in higher electricity demand for the pump. In control strategy S1 (see Tab. 1), the pump is responsible for the pressure differential and the 2way valve used as shunt is responsible for the feed-in flow and temperature. The feed-in pump, shall only have enough pressure head to exceed the differential pressure. The cold temperature on the hot side of the heat exchanger is higher than it needs to be resulting in lower solar field efficiency. Finally, in control strategy S2 (see Tab. 1), the hydraulic separator divides the system into two hydraulic loops. The pump located after the extraction is used for temperature control while the other one targets a pressure differential set point. The solution turns out to be a good approach for solving the problems. However, the cost is high as the use of additional components (extra pump and hydraulic separator).

A 3-way valve solution is also possible but was not selected here because of the fast-varying differential pressure, impossible to handle using a 3-way valve (Lennermo et al. (2014).

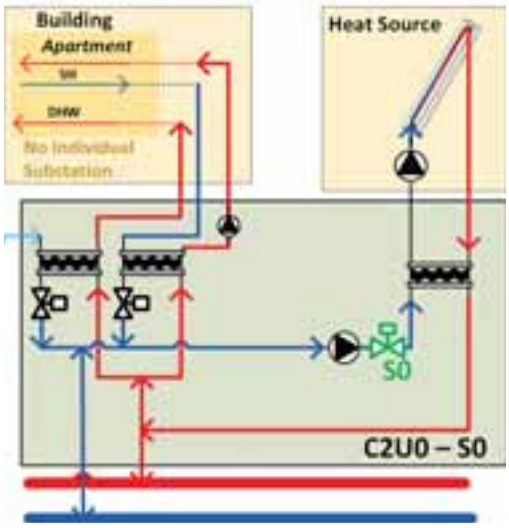

Fig. 6: Bidirectional Substation configuration C2U0 with control strategy S0

As a conclusion of the present section, the performed assessment led to the selection of configuration C2U0 as promising architecture for a bidirectional substation. In this configuration, the hydraulic separation between both the building SH and SHW loops and the DHN is performed in the substation and the solar heat is entirely reinjected in the DHN. Three control strategies have been identified and will be compared in future work. The next section presents the modeling framework developed and the associated preliminary results obtained.

3. Modelling Framework

3.1. Modelling

This section aims at presenting the framework developed for the comparison of the bidirectional substation architectures and control strategies in the frame of the 'THERMOSS' project. It is based on the open source modelling language Modelica used in the commercial simulation environment Dymola. Modelica is an acausal (equation-base) and object-oriented programming language with a large and fast-growing community both for industrial and academic applications (Schweiger et al., 2017). Modelica has native multi-physical modelling capabilities (thermo-hydraulic), is structured in libraries enabling exchange of methods in the scientific community and allows for implementing new components. Moreover, the Annex 60 project from the IEA (Wetter, et al., 2015) promotes the development of computational tools for building and community energy systems based on Modelica and FMI standards, motivating the choice of this modelling framework. As mentioned in the introduction, the Modelica "Standard" Library for its common connectors and fluid ports, the "Buildings" library

(Wetter et al., 2014) for its general building and solar panels models and the "DistrictHeating" library (Giraud et al., 2015) for its heat exchanger and piping models will be used.

As highlighted previously in Fig. 3, the bidirectional substation is surrounded by four boundary conditions blocks, namely the space heating needs, the domestic hot water draw-offs, the solar gains and the network operating conditions. Thus, the present section begins with the core model of the bidirectional substation and then continues with the description of these four boundary conditions blocks.

Bidirectional substation

It is composed of three heat exchangers and associated valves, two pumps (for SH circulation and for the reinjection) and connection piping as shown in Fig. 6. The heat exchangers are discretized in nz elements and the heat exchange in each element 'i' is calculated as $\dot{Q}_i = (UA/nz).\Delta T$ with a constant overall heat transfer capacitance UA and the local temperature difference ΔT between the hot and cold streams. The overall heat transfer capacitance for each heat exchanger is obtained based on nominal operating conditions (see Tab.4). It is worth mentioning that the network side is the hot side for both the DHW and the SH heat exchangers while it is the cold side for the Solar heat exchanger The heat exchangers are modeled with no flow resistance, the pressure drop being entirely considered in the associated valves model. For the latter, a quadratic model is assumed. Finally, regarding the pumps, they are both considered to run at constant speed with the flow rate modulation being performed by the feed-in valve (see S0 in Fig. 6) in the case of the feed-in pump and a thermostatic valve for the SH, as explained in the next paragraph.

Tab. 4: Nominal operating conditions for the Heat Exchangers of the bidirectional substation

Heat Exchanger	$T_{hot,in}$ [°C]	$T_{hot,out}$ [°C]	$T_{cold,in}$ [°C]	$T_{cold,out}$ [°C]	DTLM [°C]	Power [kW]	UA [kW/K]
Solar	90	60	50	85	7.2	56	7.8
DHW	80	50	10	55	31.9	60	1.9
SH	80	50	45	70	7.2	42	5.8

SH needs

The boundary condition dealing with the space heating demand is modeled with i) a heating system and ii) a mono-zone building. For the former, it is connected to the SH pump and is composed of a thermostatic valve and a radiator modelled using the "RadiatorEN442_2" model from the library "Buildings" (Wetter et al., 2014). In this model, the transferred heat is computed using a discretization along the water flow path, and heat is exchanged between each compartment and a uniform room air and radiation temperature. The mono-zone building is modeled using the "mixed air" model (Wetter et al., 2011) from the library "Buildings" (Wetter et al., 2014). The latter considers a perfectly mixed air in the room and takes into account heat exchange through convection, conduction, infrared radiation and solar radiation. Internal heat gains due to occupation (latent heat), lighting (radiation) and home appliances (convection) are included in the model. Constant single-flow ventilation is considered with a flow-rate of about 0.4 room volume per hour. For the present study, the dimension of the building considered were listed in Section 2.1. The total glazed area for the building represents 1/6 of the building living area, shared as follows, 50% on the South wall, 15% on the West wall and 35% on the East wall. The envelope of the building (layers composition and infiltration) can be set to follow various French thermal regulations (RT2000, RT2005, RT2012).

DHW draw offs

For now, the water draw-off system is considered without sanitary loop. As explained initially, the daily or annual (depending on the simulation) profile of draw-offs are obtained from the software DHW calc (Jordan and Vajen, 2005) from Task 26 of IEA which distributes DHW draw-offs throughout the year or the day with statistical means, according to a probability function. The mean daily DHW consumption was obtained from a report of COSTIC (2016) based on the type of apartment and the number of people living in it. Additionally, a correction of the cold water temperature is also included in the simulations using the model of Burch and Christensen (2007).

Network

The network side inputs are the local differential pressure and supply temperature. It was explained beforehand that these two variables are decisive regarding the control scheme of the two-way substation. In the present model, these two variables can either be set to constants to study specific operational conditions or set to follow real DHN variations. For the latter, data were collected in the frame of the THERMOSS project at the DHN of San Sebastian, Spain. Fig. 7 below presents these data for three days with a time step of 15 minutes.

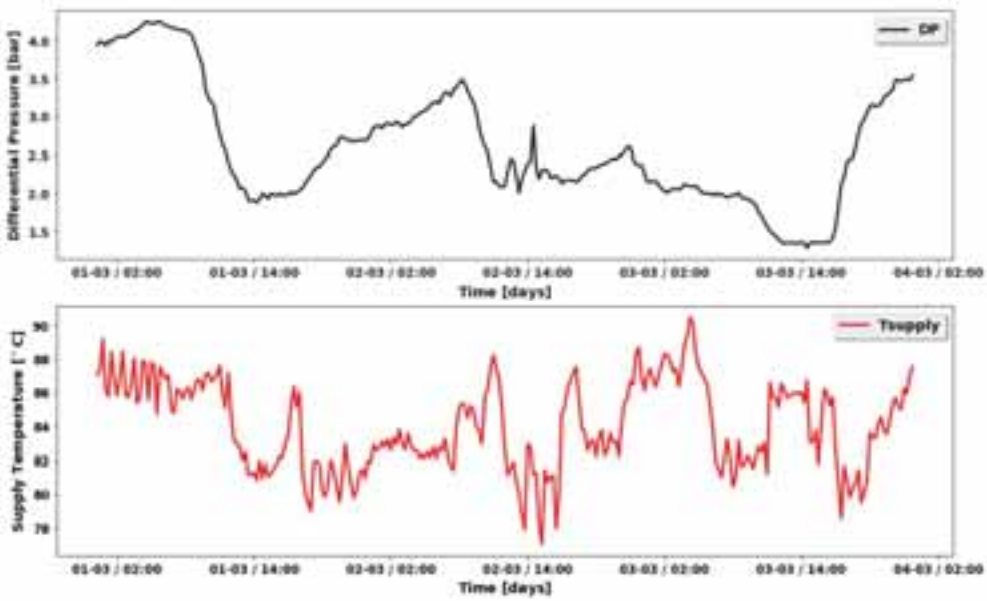

Fig. 7: Differential pressure and Supply Temperature variations in the DHN of Giroa-Veolia in San Sebastian

Solar field

The solar field on the rooftop is modeled using the 'SolarCollectors' package from the Buildings library which models a solar thermal collector according to the ASHRAE93 test standard (ASHRAE93, 2010). The package proposes different pre-defined solar panels set of characteristics. The flat plate panel Guandong Fivestar Solar Energy Co, FS-PTY95-2.0 (area of 2m²) is thus used together with Glycol47 as working fluid. The collector area is discretized and considered to be 80m² for a tilt of 30° as explained in Section 2.1. A solar pump with variable speed is considered. That pump is set to start above a given level of solar irradiance (100W/m²) and is controlled so that the outlet temperature from the solar field remains around 85°C.

Overall model

Fig. 8 presents the final Modelica-based framework built for the bidirectional substation simulations. The core block, i.e. the bidirectional substation, is surrounded by the four boundary conditions blocks described previously, i.e. the network inlets, SH needs, DHW draw-offs and solar gains.

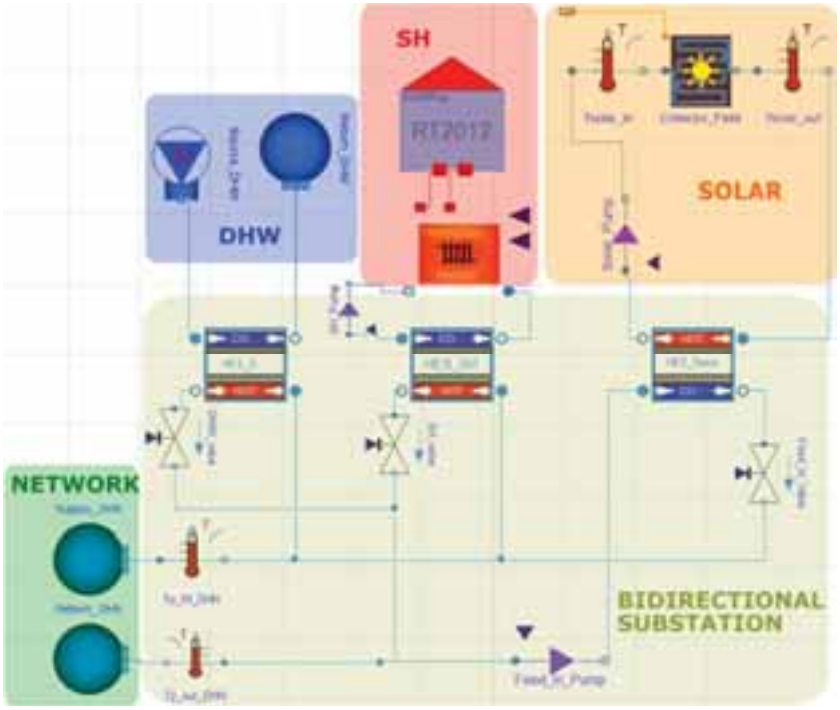

Fig. 8: Overall Modelica-based framework developed

3.2. Preliminary results

In the present study, the modeling framework discussed in the previous section is used to highlight the potential of solar heat reinjection from the multi-family building described in section 2.1. For that preliminary results, only the SH, DHW and Solar boundary conditions blocks were simulated. The location selected for the simulation is San Sebastian, Spain. Monthly energy gains/consumptions results are shown in Fig. 9. From this Figure, it can be calculated that if a configuration allowing for local consumption (U1 or U2) is chosen, up to 19.7MWh/yr could be consumed locally by the building while up to 41.2MWh/yr could be reinjected in the DHN. If a configuration with no local consumption is chosen as C2U0 for example, up to 60.9MWh/yr could be reinjected in the DHN. Future detailed simulations including the bidirectional substation together with the different control strategies discussed in section 2.4 will allow calculating which part of these potential amounts can effectively be used locally and reinjected into the DHN.

At this point, it is worth mentioning that at the level of the DHN, the usage of bidirectional substation is rational energetically speaking in two different situations. The first one is in the case that an inter-seasonal storage is installed on the DHN so that the decentralized contributions from excess heat of different prosumers are collected during summer (see Fig. 9) and reinjected in the DHN during winter. The second one is in the case where the reinjection from few prosumers allow reducing the centralized heat production for the DHW of all the consumers of the DHN, even during summer.

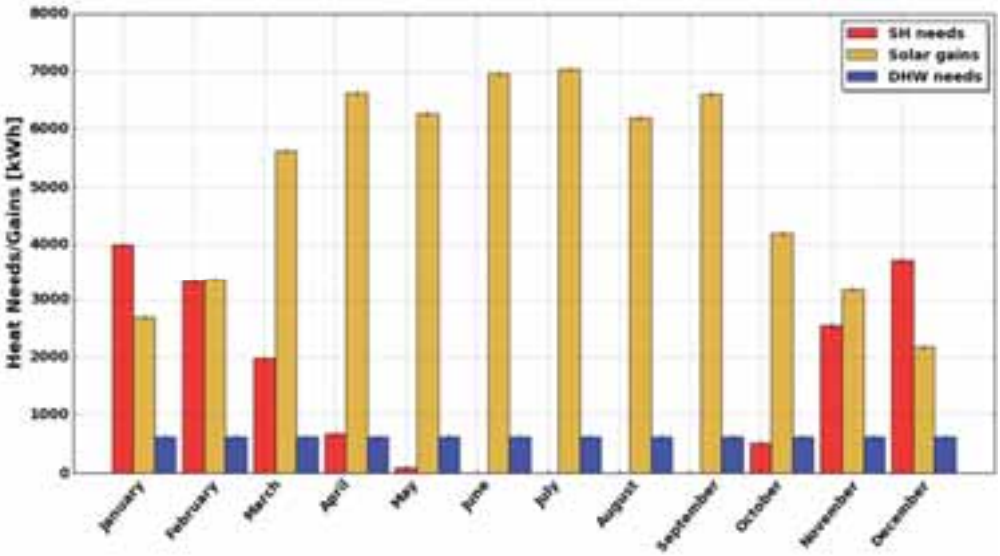

Fig. 9: Simulated solar production and SH and DHW needs for a multi-family building of 6 apartments and a flat plate solar collector area of 80m² located in San Sebastian

4. Conclusion

The present paper has set the basis towards the development of a solar bidirectional substation able to reinject/consume heat on/from a district heating network. Firstly, the main specifications of this bidirectional substation were established, i.e. Return to Supply decentralized feed-in, multi-family building scale, both able to consume and reinject heat. Secondly, features such as the type of connection to the network and the type of local consumption were combined to build an exhaustive list of potential architectures, and the most promising one was selected from a multi-criteria analysis. For this architecture, the hydraulic separation between both the building SH and SHW loops and the DHN is performed in the substation and the solar heat is entirely reinjected in the DHN. Finally, a modeling framework built to study and compare different architectures and control strategies was presented together with preliminary results highlighting the reinjection potential from multi-family building equipped with solar bidirectional substation.

In the frame of the European project 'THERMOSS', variants of the selected architecture with the various control strategies discussed will be compared using the presented modeling framework. Additionally, the impact of multiple reinjection points on the DHN operation will be studied at the network scale in order to have a complete picture of the development of bidirectional substations.

5. Acknowledgements

This project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 723562. The authors also wish to thank Bosch Thermotechnik GmbH and Giroa-Veolia for their valuable inputs.

A Multicriteria Approach for the Integration of Renewable Energy Technologies and Thermal Energy Storage to Support Building Trigeneration Systems

Eduardo A. Pina, Miguel A. Lozano, Luis M. Serra

GITSE-I3A, Department of Mechanical Engineering, University of Zaragoza, Zaragoza (Spain)

Abstract

Trigeneration systems benefit from process integration to achieve primary energy savings, reduction of pollutant emissions, and reduction of unit costs relative to conventional separate production. Achieving such benefits requires an appropriate design procedure. The issue is that finding the best configuration that minimizes total annual cost is not enough anymore, as the environmental concern has become an ever-present theme in the design and synthesis of energy systems. The minimization of costs is often contradictory to the minimization of environmental impact. Multiobjective optimization tackles the issue of conflicting objectives by providing a set of trade-off solutions, or Pareto solutions, that can be examined by the decision maker, so that the best configuration can be selected for a given scenario. This paper proposes a mixed integer linear programming model (MILP) to determine the optimal configuration and hourly operation of trigeneration systems considering the effects of thermal energy storage (TES) and hourly variations of solar radiation, energy supply prices, energy demands, and CO_2 emissions. The objective functions to be minimized are the total annual costs and the total annual CO_2 emissions. Initially, the objective functions were evaluated separately. Then, the Pareto curve was obtained for the minimization of total annual cost subject to CO_2 emissions restrictions. The trade-off solutions were analyzed and the preferred solutions were selected, achieving results close to the optimal solutions with reasonable sacrifices for both objectives.

Keywords: buildings, multicriteria, photovoltaics, solar thermal energy, thermal energy storage, trigeneration.

1. Introduction

Environmental awareness, depletion of fossil fuels resources, and economic aspects are some of the factors that motivate the development of alternative energy systems. Process energy integration is regarded as an effective way to achieve primary energy savings and reduction of pollutant emissions relative to conventional separate production (Mancarella, 2014; Serra et al., 2009). Trigeneration systems benefit from process integration, producing electricity (and/or mechanical energy), heating, and cooling from a common resource. There is a large potential for the incorporation of trigeneration systems in the residential-commercial sector (Liu et al., 2014; Rong and Su, 2017).

In the design of trigeneration plants, two fundamental issues must be addressed (Lozano et al., 2009; Wakui et al., 2016): the synthesis of the plant configuration (installed technologies and capacities, etc.) and the operational planning (strategy concerning the operational state of the equipment, energy flow rates, purchase/selling of electricity, etc.). Finding the optimal configuration of trigeneration systems in building applications is a complex task, given the wide variety of technology options available and great diurnal and annual fluctuations in energy demands and energy prices. Other factors that further increase complexity are: (i) the incorporation of renewable energy technologies, such as photovoltaic panels and solar thermal collectors, which are characterized by intermittent behavior and non-simultaneity between production and consumption; (ii) the incorporation of TES units, which allow to decouple production from consumption; and (iii) conflicting objectives, as the minimization of environmental burdens is often contradictory to the minimization of costs.

Nowadays, sustainability-related issues are ever-present themes in the design of energy systems. Therefore, a purely economic analysis is not sufficient anymore. Multiobjective optimization tackles the issue of conflicting objectives by providing a set of non-dominated solutions (Pareto Frontier), which provides flexibility and allows the decision maker's judgement into the optimization problem (Andiappan, 2017).

doi:10.18086/swc.2017.10.03 Available at http://proceedings.ises.org

One of the most important steps in the optimization problem is data collection, since the quality of the data given as input to the model will directly affect the results obtained. In this regard, it is essential to maintain the same level of detail for all aspects of the model; however, this information is not always easily obtained or identified. In the case of hourly optimization problems, Pina et al. (2017) argued the difficulty of finding hourly CO_2 emissions data associated with the electricity available in the Spanish electric grid, as opposed to the well-established hourly electricity prices. Because the authors could not find appropriate CO_2 emissions data on an hourly basis, a constant annual average was considered; as a result, it was necessary to consider a constant electricity price as well, as it is not consistent to evaluate electricity prices on an hourly basis and electricity CO_2 emissions on a constant annual value.

This work improves the optimization model proposed by Pina et al. (2017) to include hourly electricity prices and the corresponding hourly CO_2 emissions, instead of constant annual values. The MILP model determines the optimal configuration and optimal operation of trigeneration systems, considering the effects of thermal energy storage and hourly variations of solar radiation, energy supply prices, energy demands, and CO_2 emissions associated with the electricity from the electric grid. A multiobjective optimization procedure is presented, taking into consideration the minimization of the total annual cost and total annual CO_2 emissions. The MILP model provides a Pareto frontier, a set of solutions representing the optimal trade-offs between the economic and environmental objectives, in which there can be no increase in one objective without a decrease in the value of the other. The solutions along the Pareto curve were analyzed and the preferred trade-off solutions were selected.

2. Solar assisted trigeneration system

The synthesis of trigeneration systems begins with the definition of a superstructure (Iyer and Grossmann, 1998; Lozano et al., 2010; Yokoyama et al., 2015). The first step in defining the superstructure is to identify design targets, that is, the types and quantities of resources available (e.g. fuels, electricity from the electric grid) and desired products (energy demands of the consumer center that the system must attend), as well as possible restrictions (e.g. permission or not to sell electricity to the grid). Then, the superstructure can be established, considering potential technologies and the feasible connections between them, based on appropriate process integration. Once the superstructure is defined, additional and more specific data are incorporated; this step plays an essential role, since the quality of the data collected will directly affect the results of the optimization model. After the optimization procedure, the superstructure will be reduced to its optimal configuration. These three steps are presented in the following subsections.

2.1. Energy demands

The consumer center considered in this study is a multifamily building located in Zaragoza, Spain. The complex is composed of 100 dwellings, each one with 100 m² surface area. The energy demands of the consumer center are assumed to be known beforehand: the annual electricity, heating, and cooling demands are 254,963 kWh, 573,503 kWh, and 113,989 kWh, respectively. The electricity demand is required all year round. The heating demand is composed of domestic hot water, required all through the year, and space heating, required from November to April. The cooling demand is only required in the summer months (from June to September).

The study covers the period of one year. It was considered that the energy demands and the operation of the system are described by 12 representative days d (NRD = 12) each one composed of 24 consecutive periods h (NP = 24) of 1-hour duration ($NHP(h)$ = 1). Each representative day d is attributed to a month of the year, so the number of representative days d per year is equal to the number of days in the corresponding month ($NRY(1, 2, 3, ..., 12)$ = 31, 28, 31, …, 31). Two additional representative days were included to account for extreme demand situations, as described in Pina et al. (2017); what these extreme representative days do is increase the technologies' installed capacity for safety power margin, with impact on the annual fixed cost, but not on the annual operation cost.

2.2. Superstructure

The superstructure of the trigeneration system considered in this study is depicted in Fig. 1. Natural gas F_p, electricity purchased from the grid E_p, and solar radiation F_{pv} and F_{st} are the resources that can be used by the system to attend the electricity E_d, heating Q_d, and cooling R_d demands of the consumer center. Heat can be

produced at two temperature levels: low-temperature heat is only used to cover the heating demand, while high-temperature heat can also be used for cooling production. The cogeneration module GE (natural gas reciprocating engine coupled to a heat recovery system) consumes natural gas F_c and produces electricity W_c, low-temperature heat Q_{cc}, and high-temperature heat Q_{cr}; also, a portion of the total heat produced can be dissipated to the environment Q_{cl}. The gas boiler GB consumes natural gas F_a and produces low-temperature heat Q_{ac} and high-temperature heat Q_{ar}. The photovoltaic panels PV produce electricity W_{pv} from the incident solar radiation F_{pv}. The single-effect absorption chiller ABS uses high-temperature heat Q_{abs} to produce cooling R_{abs}; this technology also consumes a small quantity of electricity W_{abs}. The reversible heat pump HP and the solar thermal collectors ST are assumed to operate in two operation modes according to the month of the year:

- From January to May and from October to December: The HP operates in heating mode (HPQ), consuming electricity W_{hp} to produce low-temperature heat Q_{hp}. The ST produces low-temperature heat Q_{stc} from the incident solar radiation F_{st};
- From June to September: The HP operates in cooling mode (HPR), consuming electricity W_{hp} to produce cooling R_{hp}. The ST can produce low and/or high-temperature heat Q_{stc} and Q_{str}, respectively.

Both operation modes consider the possibility of dissipating heat from the ST Q_{stl}. Finally, two thermal energy storage tanks are considered, one for low-temperature heat (TSQ) and another for cooling (TSR). Energy can be charged to/discharged from the TSQ Q_{in}/Q_{out} and TSR R_{in}/R_{out}. Energy losses Q_s and R_s are proportional to the stored energy S_q and S_r, respectively, and to an hourly energy loss factor.

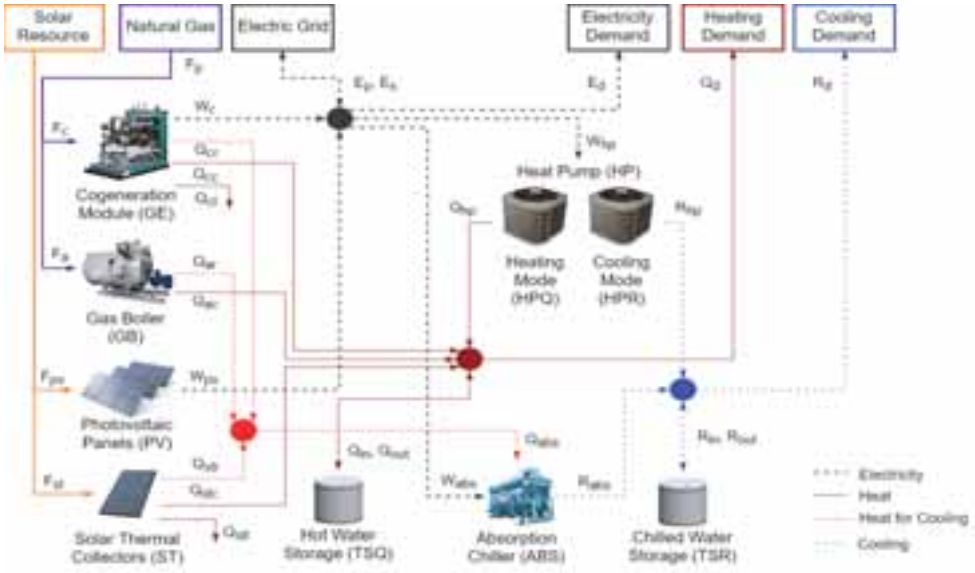

Fig. 1: Superstructure of the trigeneration system

2.3. Data collection and elaboration

Once the superstructure is established, it is necessary to provide more specific information about the system in line with the objective of the analysis. In this regard, in order to contemplate the technical, economic, and environmental aspects of the incorporation of potentially installable technologies, including renewable energy technologies and thermal energy storage units, in the building trigeneration system analyzed herein, the following information is required:

(i) Technical data

All technologies included in the superstructure are commercially available. The equipment can modulate up to nominal load, except for the non-manageable ones (PV and ST). Performance variations with ambient and operation conditions are taken into consideration. Table 1 presents the technologies' main technical parameters obtained from the manufacturers' catalogs. The PV has a maximum power of 0.260 kW, module efficiency of 15.51%, and total surface area of 1.60 m². The ST presents thermal performances of k_0 = 0.789, k_1 = 3.834 W/(m²·K), and k_2 = 0.011 W/(m²·K²), and total surface area of 5.04 m². The hourly unit productions per square

meter of the PV panels and ST collectors were evaluated as explained in Pina et al. (2017).

Table 1: Technologies' technical parameters

Parameter	Value	Parameter	Value
GE Electric power efficiency, α_w	0.26	HP Cooling/heating capacity ratio, *RCAPrq*	0.90
GE Thermal efficiency, α_q	0.61	ABS COP, *COPabs*	0.69
GB Thermal efficiency, η_q	0.95	ABS unit electricity consumption, *kwabs*	0.03
HP COP in heating mode, *COPhpq*	3.24	TSQ hourly energy loss factor, *fpacuQ*	0.01
HP COP in cooling mode, *COPhpr*	3.19	TSR hourly energy loss factor, *fpacuR*	0.01

Based on the geometry of the buildings, a total roof top area of 2000 m² is available for the installation of PV panels and ST collectors. PV and ST are installed with a tilt of 35º and 30º, respectively. Considering their surface areas and tilt, it was possible to determine the roof top area occupied by each square meter of PV and ST: the PV unit surface area usage is equal to 3.1250 m² roof/m² PV and the ST unit surface area usage is equal to 2.2676 m² roof/m² ST.

(ii) Economic data

Table 2 presents the unit investment cost *CI* of each technology *i* included in the superstructure. These values were obtained from manufacturers' catalogs (including taxes) and multiplied by a simple module factor that took into account transportation, installation, connection costs, etc. An operational lifetime *nyr* of 20 years was considered for all equipment. An amortization and maintenance factor *fam* of 0.15 yr^{-1} and an indirect costs factor *fic* of 0.20 were considered (Ramos, 2012).

Table 2: Technologies' economic and environmental data

Technology *i*	Unit Investment cost *CI*	Unit CO_2 emissions *CO2U*	Technology *i*	Unit Investment cost *CI*	Unit CO_2 emissions *CO2U*
GE	2700 €/kW_{el}	65 kg CO_2/kW_{el}	PV	264 €/m²	285 kg CO_2/m²
GB	77 €/kW_{th}	10 kg CO_2/kW_{th}	ST	578 €/m²	95 kg CO_2/m²
HP	481 €/kW_{th}	160 kg CO_2/kW_{th}	STQ	150 €/kWh	150 kg CO_2/kWh
ABS	518 €/kW_{th}	165 kg CO_2/kW_{th}	STR	300 €/kWh	300 kg CO_2/kWh

Gas and electricity rates were taken from a real Spanish distributor (EDP, 2017). The gas price is constant all through the year c_g = 0.057 €/kWh LHV (with taxes). In the case of the electricity purchase price c_{ep}, a time-of-use tariff is applied with three time periods, namely on-peak, mid-peak, and off-peak, whose rates are given in Table 3. The selling price of electricity c_{es} was assumed to be the same as the purchase price c_{ep}.

Table 3: Electricity prices in €/kWh, with taxes (EDP, 2017)

Annual period	On-peak		Mid-peak		Off-peak	
	Hours	c_{ep}	Hours	c_{ep}	Hours	c_{ep}
Winter (Jan-Mar, Nov-Dec)	19-22	0.183	9-18, 23-24	0.156	1-8	0.122
Summer (Apr-Oct)	12-15	0.183	9-11, 16-24	0.156	1-8	0.122

(iii) Environmental data

Table 2 presents the unit CO_2 emissions *CO2U* of each technology *i* of the superstructure. The *CO2U* values were obtained from the literature (Carvalho, 2011; Guadalfajara, 2016; Ito et al., 2009; Ralui et al., 2014).

In terms of CO_2 emissions, the environmental cost associated with the consumption of natural gas is constant throughout the year *kgCO2g* = 0.252 kg CO_2/kWh; this is a Spanish national value obtained from IDAE (2014). *Red Eléctrica de España* (REE, 2017) provides data on the national electric demand, generation, and associated emissions on a 10-minute basis. We have processed this information to obtain the hourly CO_2 emissions associated with the electricity available in the grid for each representative day, as shown in Fig. 2.

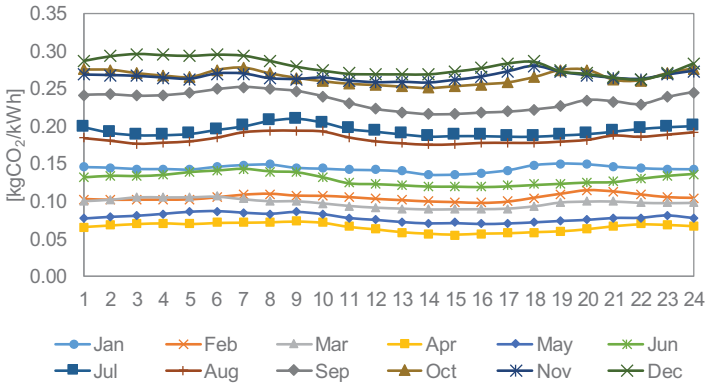

Fig. 2: Hourly CO_2 emissions of the electricity in Spain for each representative day, in kg CO_2/kWh (REE, 2017)

3. Mathematical model

Having defined the superstructure of the trigeneration system, it is necessary to develop a mathematical model, representing the behavior and performances of all elements in the superstructure, to determine the optimal configuration and optimal operation modes of the system. A MILP model was developed using the software LINGO (Schrage, 1999). Two objective functions are included: the first considers the economic aspects of the trigeneration system through the total annual cost, while the second considers the environmental impact in terms of the total annual CO_2 emissions.

The economic objective is to minimize the total annual cost C_{tot}, which consists of the annual fixed cost C_{fix} and the annual operation cost C_{ope}.

$$Min\ C_{tot} = C_{fix} + C_{ope} \tag{1}$$

The annual fixed cost is expressed by Eq. (2)

$$C_{fix} = fam \cdot (1 + fic) \cdot \sum_i CI(i) \cdot CAP(i) \tag{2}$$

in which the *fam*, *fic*, and *CI* were given in Section 2 (*CI* values are given in Table 2).

As explained earlier, it was considered that the year was divided into *NRD* representative days *d*, each one composed of *NP* consecutive hourly periods *h* of *NHP(h)* duration. Throughout the year there are *NRY(d)* days for each representative day type *d*. The annual operation cost includes fuel costs and the purchase/sale of electricity, as expresses Eq. (3):

$$C_{ope} = \sum_{d=1}^{NRD} \sum_{h=1}^{NP} NRY(d) \cdot NHP(h) \cdot \left(F_p(d,h) \cdot c_g + E_p(d,h) \cdot c_{ep}(d,h) - E_s(d,h) \cdot c_{es}(d,h)\right) \tag{3}$$

Regarding the environmental objective, the goal is to minimize the total annual CO_2 emissions $CO2_{tot}$, which is composed of the annual fixed emissions $CO2_{fix}$ and the annual operation emissions $CO2_{ope}$.

$$Min\ CO2_{tot} = CO2_{fix} + CO2_{ope} \tag{4}$$

The annual fixed emissions, annualized for the equipment's operational lifetime *nyr* is expressed by Eq. (5)

$$CO2_{fix} = \sum_i CO2U(i) \cdot CAP(i)/nyr \tag{5}$$

in which the *CO2U* values of each technology *i* are given in Table 2.

The annual CO_2 emissions associated with the operation of the system is expressed by Eq. (6). The first and second terms within the parenthesis correspond to the emissions associated with the purchase of natural gas and electricity, respectively, while the last term corresponds to the avoided emissions due to the selling of electricity.

$$CO2_{ope} = \sum_{d=1}^{NRD}\sum_{h=1}^{NP} NRY(d)\cdot NHP(h) \cdot \left(F_p(d,h)\cdot kgCO2_g + E_p(d,h)\cdot kgCO2_e(d,h) - E_s(d,h)\cdot kgCO2_e(d,h)\right) \quad (6)$$

The objective functions are subject to equipment constraints (capacity limits and production restrictions), balance equations, and electric grid constraints (permission to purchase/sell electricity). The reader is referred to Pina et al. (2017) for a detailed explanation of the restrictions.

4. Single-objective optimization

The two objective functions were initially evaluated separately. Table 4 gathers the main results obtained for the minimization of total annual costs and total annual CO_2 emissions.

For the optimal annual cost solution, all candidate technologies were included except for the PV and ST; further, the TSQ installed capacity is so small (0.4 kWh) that it could be dropped out. Regarding the annual investment cost, 47% is due to the installation of HP, followed by the ABS with 29%, and the GB with 10%. Taking into account the annual CO_2 emissions relative to the manufacturing of each device, the HP also accounts for the highest share, 46%, followed by the ABS with 28%, and the TSR with 21%. This configuration heavily relies on natural gas (363,285 kWh/yr) and electricity from the electric grid (355,040 kWh/yr). Further, all electricity produced by the GE is consumed, so that there is no selling.

Table 4: Main results of the single-objective solutions

Technology	Optimal annual cost (B)			Optimal annual CO_2 emissions (A)		
	Installed capacity	**Investment cost [€/yr]**	**CO_2 emissions [kgCO_2/yr]**	**Installed capacity**	**Investment cost [€/yr]**	**CO_2 emissions [kgCO_2/yr]**
GE	4.2 kW_{el}	2050.8	13.7	0.0 kW_{el}	-	-
GB	204.8 kW_{th}	2838.1	102.4	49.3 kW_{th}	683.1	24.6
HP	162.1 kW_{th}	14,031.7	1296.5	269.6 kW_{th}	23,343.1	2156.9
ABS	94.0 kW_{th}	8761.6	775.2	48.8 kW_{th}	4554.4	403.0
PV	0.0 m²	-	-	461.2 m²	21,873.1	6571.6
ST	0.0 m²	-	-	246.5 m²	25,618.8	1170.7
TSQ	0.4 kWh	10.8	3.0	314.0 kWh	8449.1	2354.8
TSR	39.9 kWh	2148.9	598.9	0.0 kWh	-	-
Annual fixed	C_{fix} / $CO2_{fix}$	29,841.9	2789.8		84,521.6	12,681.6
Energy service	**Consumption [kWh/yr]**	**Energy cost [€/yr]**	**CO_2 emissions [kgCO_2/yr]**	**Consumption [kWh/yr]**	**Energy cost [€/yr]**	**CO_2 emissions [kgCO_2/yr]**
Natural gas	363,285.1	20,557.7	91,547.8	124.2	7.0	31.3
Purchased electricity	355,040.0	54,667.3	60,728.1	355,919.7	54,606.8	63,048.5
Sold electricity	-	-	-	9348.0	1505.1	1521.3
Annual operation C_{ope} / $CO2_{ope}$		75,225.0	152,275.9		53,108.7	61,558.5
Total annual C_{tot} / $CO2_{tot}$		**105,066.9 €/yr**	155,065.7 kgCO_2/yr		137,630.2 €/yr	**74,240.1 kgCO_2/yr**

In the case of the optimal annual CO_2 emissions solution, all technologies were included except for the GE and TSR. Compared with the optimal annual cost configuration, the installed capacity of the HP has increased, while the capacities of GB and ABS have decreased. This configuration heavily relies on electricity from the electric grid (355,920 kWh/yr), while there is virtually no consumption of natural gas (124 kWh/yr); also, a part of the electricity produced (9348 kWh/yr) is sold to the grid. It is interesting to note that all roof top area is used for the installation of PV and ST, which suggests that it could be interesting to increase its availability. Moreover, compared with the optimal annual cost solution, there was a significant shift in the use of thermal energy storage, from 39.9 kWh of TSR to 314.0 kWh/yr of TSQ. Looking at the annual investment cost, 30% is due to

the installation of ST, followed by the HP with 28%, and the PV with 26%. In the case of the annual CO_2 emissions relative to the manufacturing of each device, the three highest contributions are 52% PV, 18% TSQ, and 17% HP.

The optimal CO_2 emissions configuration presents a total annual cost 31% higher than the optimal annual cost solution, while CO_2 emissions are 52% lower. The shift towards a more environmentally sound configuration incurs an increase of 183% in the annual fixed cost and 354% in the annual CO_2 emissions relative to the manufacturing of the equipment. These are offset by a better energy usage during the operation of the system, translated into a decrease of 29% in the annual operation costs and 59% in annual CO_2 emissions relative to the operation of the system.

Analyzing the annual operation of the optimal annual cost solution, the GE, GB, HP, and TSQ operate all year round, the TSR operates all summer, and the ABS operates from July to September. Of the total electricity consumed, 8.4% is produced by the GE and the rest is purchased from the electric grid. Regarding the heat production, the HP and the GB are the major producers, with 48.4% and 38.6%, respectively. The produced cooling comes almost entirely from the HP (91.7%), being the ABS responsible for supplying peak demands in July and August. Considering the total cooling produced by the system, 4.5% is stored.

Focusing on the optimal CO_2 emissions solution, the HP operates all year except for May, the ABS operates all summer except for September, and the TSQ is used all year round. The GB operates marginally in June to attend heat peak demands. It is worth mentioning that there is dissipation of heat from the ST Q_{stl} in May (4977 kWh/yr). The PV panels account for 23.6% of the electricity consumed, while the rest is purchased from the grid. Of the total electricity produced by the PV, 8.7% is sold to the grid, generating economic benefits. The HP is responsible for 76.2% of the heat produced by the system, followed by the ST with 23.8%; the GB has a negligible share. Of the total heat produced, 26.7% is stored in the TSQ. Cooling is produced mostly in the HP (87.9%) and the rest is covered by the ABS with solar heat from the ST.

The optimization model also determines the hourly operation of the system for each representative day. As an example, Fig. 3 presents, for the optimal annual cost solution, the hourly productions of (a) electricity, in the month of January, (b) heating, in the month of January, and (c) cooling, in the month of July.

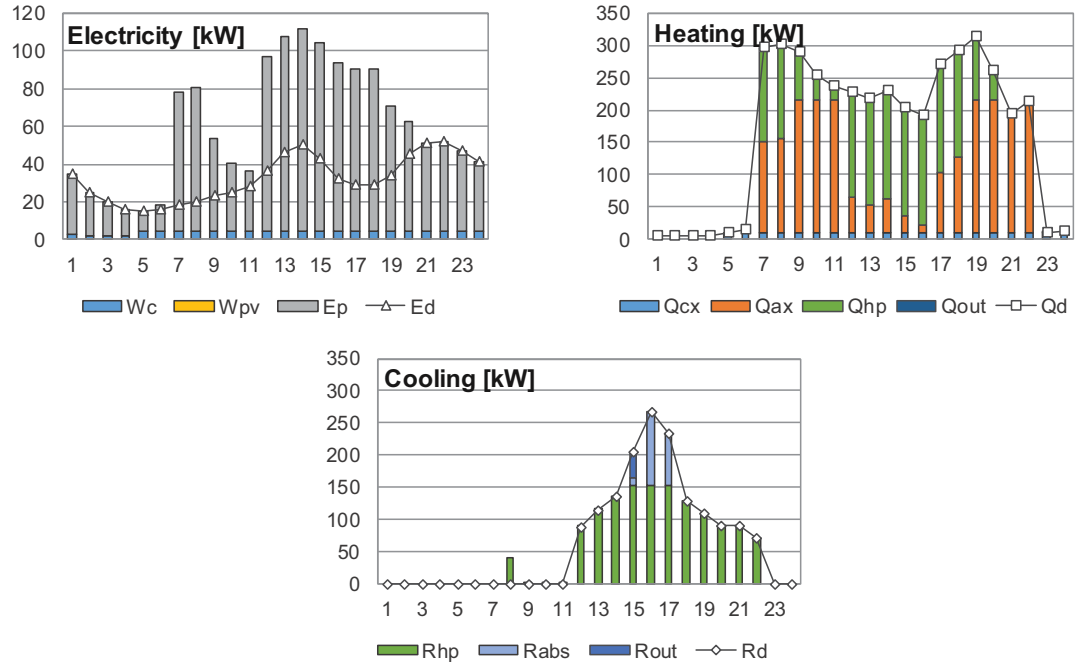

Fig. 3: Hourly production for a representative day of (a) electricity in January, (b) heating in January and (c) cooling in July. Optimal annual cost configuration

In January, only electricity E_d and heating Q_d are required by the consumer center. As can be seen from Fig. 3, the GE operates all through the day producing electricity W_c and heat Q_{cx}; particularly, between hours 6 and 24,

it operates at full load. Also, electricity is purchased from the grid E_p throughout the day. It is interesting to note the increase in the purchase of electricity at hours 7 and 8, which are the last two hours of off-peak rate. Apart from the electricity demand E_d, electricity is consumed by the HP from hour 6 to 20 for heat production Q_{hp}. The HP's load increases in the afternoon, after hour 11; it also complements heat production when the GB is at full load, e.g. hours 9 to 11 and 19 to 20. As already mentioned, the TSQ is used but with negligible shares.

In the month of July, cooling is required from hour 12 to 22. However, as presents Fig. 3, cooling production begins earlier in the day (e.g. hour 8), being stored in the TSR for later use. The ABS operates marginally with heat from the GB at hours 12 and 13, and more significantly from hour 15 to 17, when the HP is at full load. The TSR has one significant charge at hour 8 and one significant discharge at hour 15.

5. Multiobjective optimization

The issue is that economic costs and environmental concern are generally conflicting objectives, which means that the optimal solution for one is not the best for the other, as was demonstrated in Section 4. Multiobjective optimization is used to optimize a problem with two or more conflicting objectives, identifying trade-off solutions among them. These trade-off solutions, also known as non-dominated solutions, constitute the Pareto set, in which no improvement in one objective can be achieved without sacrificing the other (Andiappan, 2017).

Pareto optimization has been extensively applied in the literature concerned with multicriteria problems and many methods are available for solving multiobjective optimization problems. Some methods involve converting the multiobjective problem into a series of single optimization problems. An important question is the role of the decision maker in the procedure. In this regard, *a posteriori* methods for generating Pareto-optimal solutions are preferred. Among them, the ε-constraint has been applied by various authors to the optimization of energy supply systems (Buoro et al., 2013; Carvalho et al., 2012; Fazlollahy et al., 2012; Gebreslassie et al., 2012). In this approach, the problem is optimized with respect to one of the objective functions, while upper/lower bounds are set for the rest of the objective functions. The problem is repeatedly solved for different ε values, obtaining the different trade-off solutions that compose the Pareto set. Based on the Pareto curve obtained, the decision maker has more flexibility to judge the different trade-off solutions and make a more informed decision.

In this paper, the optimization model was solved for the total annual cost objective, subject to CO_2 emissions constraints. The Pareto set obtained is limited by Lim_{sup} = 155,066 ton CO_2/yr (optimal annual cost solution) and Lim_{inf} = 74,240 ton CO_2/yr (optimal annual CO_2 emissions solution). The interval between superior and inferior limits have been subdivided and the model was repeatedly solved. Table 5 presents the ε values considered in the analysis, starting from the optimal annual cost solution (point B), towards the optimal annual CO_2 emissions solution (point A). Along the Pareto curve, different solutions are obtained with different configurations and installed capacities. Fig. 4 shows the Pareto curve obtained, in which equal symbols represent the same configuration (with different installed capacities). As can be seen from Table 5, a total of 33 ε values were evaluated, obtaining 9 different configurations.

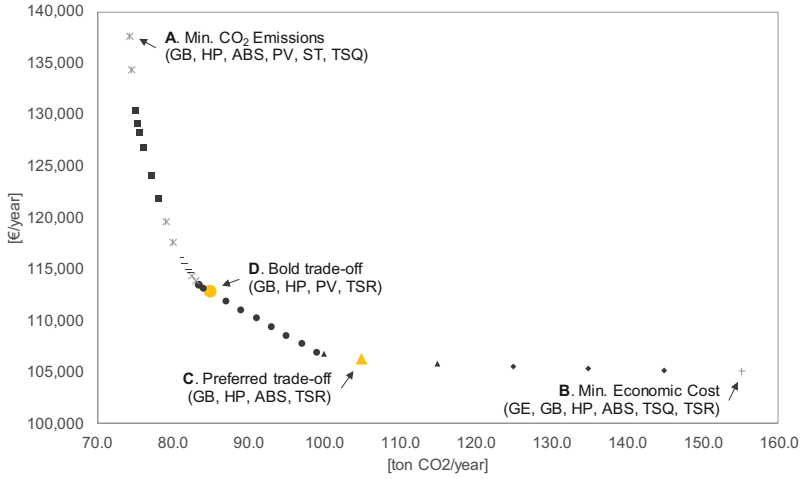

Fig. 4: Pareto curve – Annual economic cost vs. annual CO_2 emissions

Table 5: Trade-off solutions obtained with the ε-constraint method considering economic cost and CO_2 emissions

	ε-CO_2 emissions [tonCO_2/yr]	Economic cost [€/yr]	Installed capacities								Marginal cost [€/tonCO_2]	Average cost [€/tonCO_2]

The graphs in Fig. 5 show the installed capacities of each technology along the Pareto curve, from the optimal annual cost to the optimal annual CO_2 emissions solution. The analysis of the trade-off solutions that constitute the Pareto curve obtained shows that each technology was included in at least one configuration; on the other hand, no configuration included all eight technologies simultaneously. The GB and the HP were included in all solutions obtained and the TSR was included in most solutions. From the optimal annual cost configuration (B), as CO_2 emissions are forced down towards the environmental optimal (A), there is a shift in the installed capacities of GB and HP: the former decreases, while the latter generally increases. GE is only included at CO_2 levels higher than 125 ton CO_2/yr, and even so with relatively small installed capacities. For total annual emissions below 99 ton CO_2/yr, PV panels begin to be incorporated. ST collectors are included at even lower overall emissions levels, 83 ton CO_2/yr, closely followed by the TSQ at 82.25 ton CO_2/yr. There are two different ranges in which the ABS is included: for CO_2 levels higher than 100 ton CO_2/yr and lower than 91 ton CO_2/yr. It is interesting to look into the role the ABS plays in each scenario: at the higher CO_2 emissions range, the ABS is driven with heat produced with natural gas (Q_{cr} and mostly Q_{ar}); on the other hand, at the lower range, the ABS is driven exclusively with heat from the ST (Q_{str}). It is worth noting that GE was not included in any solution simultaneously with PV and/or ST.

From the analysis of the trade-off solutions obtained, point C in Fig. 4 and Table 5 was selected as preferred intermediate solution because of its good trade-off between both criteria: it achieves a 32.3% reduction in CO_2 emissions with an increase of only 1.1% in costs relative to the optimal cost configuration (B). Moreover, solution C includes only GB, HP, ABS, and TSR. Compared with the optimal annual cost solution (A), there is a

reduction in the installed capacities of GB and ABS and an increase in the installed capacity of HP. As a result, the system consumes 75.7% less natural gas and purchases 31.4% more electricity from the electric grid. By supporting a higher sacrifice for the economic objective, point D in Fig. 4 and Table 5 can also be identified as an interesting trade-off solution: it achieves a 45.2% decrease in CO_2 emissions with an increase of 7.3% in costs relative to the optimal cost configuration (B). The configuration includes GB, HP, PV, and TSR.

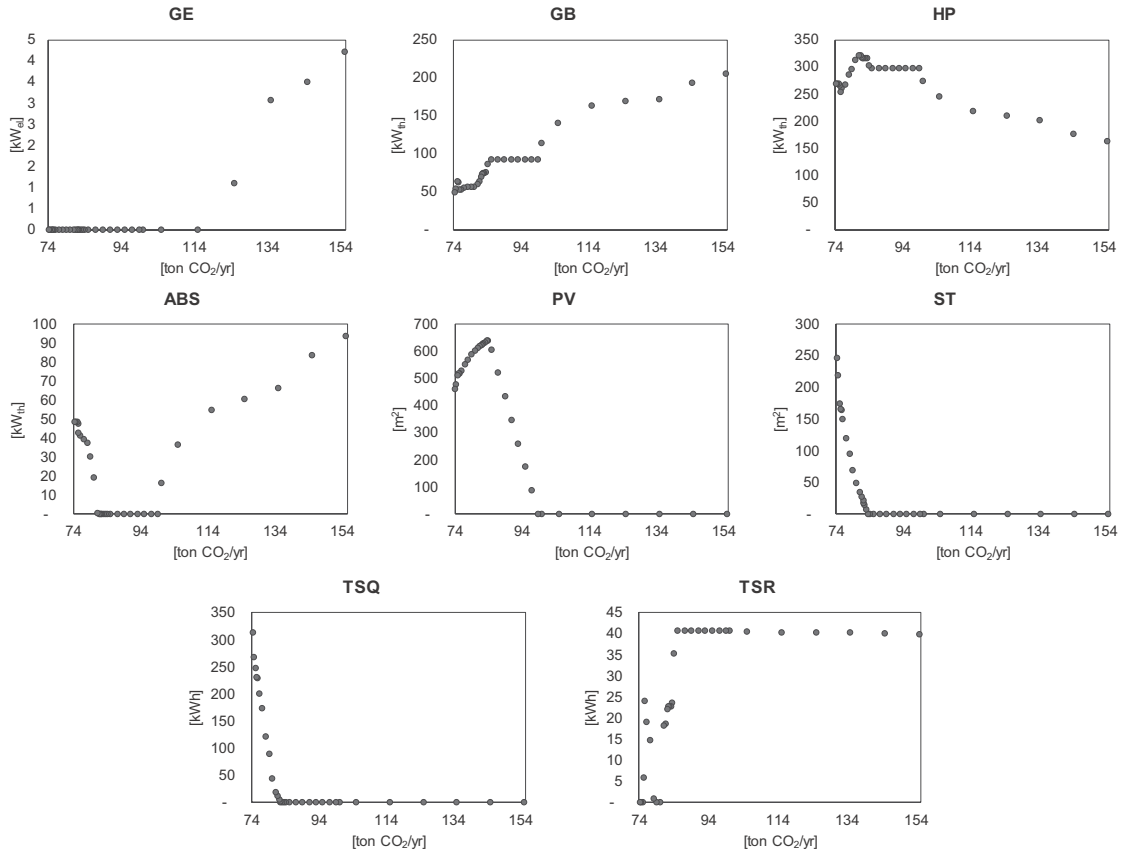

Fig. 5: Installed capacities along the Pareto curve

Table 5 also presents the marginal and average costs of each solution, in €/ton CO_2. The marginal cost represents the cost of moving from one solution to the next in the Pareto curve, while the average cost represents the cost of moving from the optimal annual cost solution (B) to any other. These could be interesting indices to measure the effort the decision maker is willing to make in order to move towards a more environmentally sound configuration. As can be seen from Table 5, it is no surprise that both the marginal and the average costs increase as the system shifts towards more environmentally sound configurations. Moving from one optimum to the other (B → A) involves an average cost of 402.9 €/ton CO_2. However, taking the trade-off solution C into account, the average cost of moving from B to C is only 24.0 €/ton CO_2.

Based on the different circumstances under which the system operates, for instance local subsidies for CO_2 emissions savings and/or stock market prices of CO_2 emissions, the marginal cost could be used to select among the various trade-off solutions obtained. Solution C presents a marginal cost of 49.5 €/ton CO_2. Ensuring a higher economic compensation for CO_2 emissions savings would enable other solutions to be chosen, such as solution D with 414.4 €/ton CO_2.

6. Conclusions

This paper tackled the issue of conflicting objectives in the synthesis of trigeneration systems including renewable energy technologies and thermal energy storage. A MILP model was developed using the optimization software LINGO including two objective functions: minimize the total annual cost and minimize the total annual CO_2 emissions. Both objectives take into account a fixed term, relative to the manufacturing and

installation of the equipment, and a variable term, relative to the hourly operation of the system. The model was applied to a multifamily building located in Zaragoza, Spain.

At first, the objective functions were minimized separately, obtaining the optimal annual cost solution and the optimal annual CO_2 emissions solution. The optimal solutions presented fundamentally different configurations: the optimal cost configuration included cogeneration, whereas the optimal CO_2 emissions configuration included renewable energy technologies. Then, the ε-constraint approach was employed to identify the intermediate trade-off solutions that compose the Pareto curve. As a result, it was possible to identify trade-off solutions that were close to the single-objective solutions with reasonable sacrifices for both objectives; for example, the preferred trade-off solution selected in this study achieved a 46.2% reduction in total annual CO_2 emissions with only an 8% increase in total annual cost relative to the optimal annual cost configuration. This procedure demonstrated the importance of the decision maker in evaluating the trade-off solutions in search for the configuration that best suits the objectives of the analysis.

In the synthesis of energy systems, the quality of the data used plays a central role because it directly affects the results of the optimization model. However, in multiobjective optimization problems, it is essential to maintain all objective functions at the same level of detail. This issue was highlighted in a previous paper by Pina et al. (2017), in which the price of the electricity from the grid and the associated CO_2 emissions were considered constant throughout the year. The present paper improved the optimization model proposed in that work by incorporating hourly electricity prices and CO_2 emissions per kWh, for each representative day. As a result, it was shown that the system takes advantage of the different electricity prices and emissions at different hourly periods to achieve more interesting results in accordance with the objective function.

It is also important to maintain the closest level of detail as possible with regard to the elaboration of the optimization model. For example, it is known that the electricity tariff is generally composed of a power term and an energy term; however, what would be the appropriate counterpart to the power term for CO_2 emissions? Due to the lack of an appropriate value, the authors opted to consider only the energy term in the calculations. Nevertheless, we do recognize having applied an amortization and maintenance factor over the operational lifetime of the system with no equivalent in the CO_2 emissions objective function. These issues should be explored in further studies.

Further work could explore the interconnection with the electric grid, considering local policies on the permission to sell/inject electricity to the grid and its effects on the optimal configuration and operation of the system. Moreover, more technologies could be included in the superstructure, namely prime movers (e.g. microturbines, fuel cell), RES (e.g. wind power, biomass), and energy storage units (e.g. electrical batteries).

Abstract

More and more distributed generations systems have been connected to the power system in Brazil, especially PV systems in the range between a few units (residential) to hundreds (power plants) of kW. On that context, this work is related to operational analysis of a new 34 kWp grid-connected PV system based on local weather conditions measured in the city of Goiania, located in Central Brazil. The PV system had been installed by a research and development project approved by ANEEL (Brazilian Electrical Energy Agency) and it was the first rooftop solar plant installed at UFG (Federal University of Goias) and also among other public universities from Central Brazil. After some basics operational tests, that 34 kWp grid-connected PV system started to work continuously on January 2017 after being registered and authorized by local grid utility. Since then an amount of 4.4 MWh has been generated and fed into the power distribution line up to middle of October 2017. Results registered during February 2017 from an existing and active PV plant were chosen to present a possible operational analysis. At the end, the energy and power performance profiles from grid-connected PV system are discussed in terms of weather measurements and conditions. As a fully one operational year from 34 kWp grid-connected PV system has not been concluded yet, authors still working on its performance analysis.

Keywords: PV systems, Weather measurements, Distributed generation, Grid-connected PV system, Renewable energy, Solar inverter.

1. Introduction

Grid-connected photovoltaic (PV) systems have been regulated in Brazil since 2012 (main document had been reviewed in 2015) by the net metering mechanism related to Distribution Generation (DG) systems (Aneel, 2015). After that almost 25 MWp of new grid-connected PV systems have been installed (Aneel, 2017a).

Although there is a clear growing up of installed PV systems, such amount of power does not represent a huge contribution from solar resources considering the fully power generation capacity in Brazil nowadays. According to Tab. 1, renewables resources represent 78.5% of Brazilian power generation capacity up to now (October 2017). This is already known around the world and that is why Brazil has been always cited in renewable global reports or outlooks.

Tab. 1: Official Brazilian power generation capacity up to October 2017 (Aneel, 2017a).

Energy resource	Solar	Nuclear	Foreign	Wind	Biomass	Oil & Fossils	Hydro	Total
Installed power capacity (GW)	0.31 (0.2%)	1.99 (1.2%)	8.17 (5.0%)	11.50 (7.1%)	14.24 (8.8%)	26.89 (16.5%)	99.40 (61.2%)	162.47 (100%)

doi:10.18086/swc.2017.10.04 Available at http://proceedings.ises.org

However, solar energy (exclusively from PV power plants) represents the lowest contribution (approx. 0.312 GW) of total power capacity in Brazil. It is even lower than the 8.17 GW imported (and paid for) from neighbor countries (Paraguay, Argentina, Uruguay and Venezuela, in descending order). That is obviously an encouraging reason for increasing solar power plants in Brazil over the next years. Considering its geographical localization on Earth, its annual weather conditions and size of its territorial area, Brazil could produce even much more electrical energy from solar resources for sure. Fig. 1 presents an overview of five geopolitical regions of Brazil edited from original file published by (Macedo, 2007) and also its annual global horizontal solar radiation per day estimated by (NREL, 2005). Actually those conclusions are not so new anymore since academics, professionals, foreign and local companies, public agencies, grid utilities and politicians recognize that Brazil still has an unexplored potential for power generation from solar and wind resources.

Fig. 1: Brazilian geopolitical regions (left) and its estimated global horizontal solar radiation (right) (Macedo, 2007; NREL, 2005).

Even under an unofficial (but real) political and economic crisis registered during last years that affects new regulations and investments, step by step solar and wind resources have been more and more explored in Brazil. For example, a new record of power generated by wind plants installed in the Northeast of Brazil was stablished during the beginning of September 2017 (approx. 6.8 GW) but it will not last very long since new wind plants are expected to be added to the Brazilian power grid until 2020 (ONS, 2017). In addition, Brazilian agency ANEEL (National Agency of Electrical Energy) officially predicts that new solar (residential and commercial) power plants will also provide plus 3.2 GW to Brazilian power grid among the 2017-2024 years (Aneel, 2017b).

Under that context, this work is related to operational analysis of a new 34 kWp grid-connected PV system based on local weather conditions measured in the city of Goiania, located in Central Brazil. Central Brazil corresponds to entire Central-West and a part of North geopolitical regions presented in Fig. 1. Also from Fig. 1 it can be concluded that city of Goiania has an estimated annual global horizontal solar radiation around 5.0-6.0 kWh/m2 per day. These estimated values suggest a considerable potential for exploring the annual available solar energy source in terms of electrical energy production.

Some results from that 34 kWp grid-connected PV system operation are presented and discussed in terms to propose a possible operational analysis related to such DG systems. Energy and power performance profiles are also discussed in terms of weather measurements and conditions. At the end, some conclusions are presented.

2. Grid-connected PV system description

Fig. 2 shows the basic topology of the DG system covered by this work. It is based on a 34 kWp grid-connected PV system and composed by 145 PV panels (235 W, 60 cells, poly c-Si) connected (in series and parallel associations) with 8 single-phase power inverters. The PV panels and power inverters have been manufactured by SUN EARTH (model TPB 156×156-60-P) and ELTEK (models Theia 2.9 HE-t and 4.4 HE-t), respectively.

That new 34 kWp grid-connected PV system corresponds to a rooftop structure and its installation was provided by a research and development (R&D) project executed by UFG (Federal University of Goias). The R&D project was financially supported by four local power companies: Espora Energetica; Transenergia Sao Paulo;

Transenergia Renovavel; and Caldas Novas Transmissao (Pimentel, 2017). This R&D project was approved by ANEEL and it proudly became the first rooftop solar grid-connected power plant installed at UFG and also among other public universities from Central Brazil.

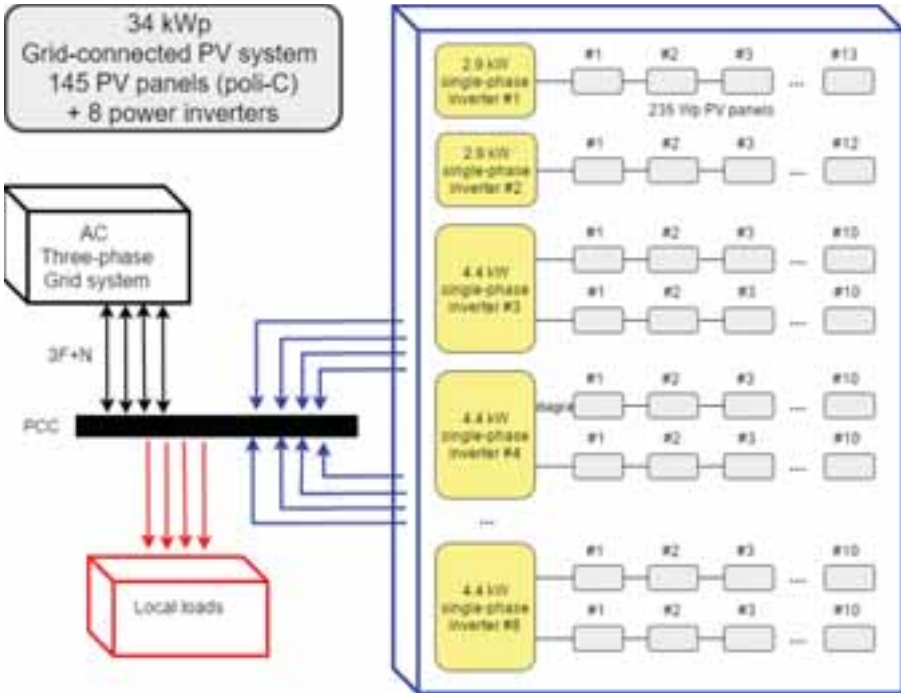

Fig. 2: Basic topology of the 34 kWp PV grid-connected system installed at Goiania (Brazil).

After some basics operational tests during the end of 2016, the 34 kWp grid-connected PV system started to work continuously on January 2017 after being registered and authorized by local grid utility. All the power inverters are connected to the PCC (Point of Common Coupling) which is also connected to the AC three-phase power line based on four wires (more typical situation) and with nominal parameters 220/380 V and 60 Hz. The shunt connection of local loads corresponds to all electrical circuits that feed a three-floor building construction from Electrical, Computer and Mechanical Engineering School (EMC) at UFG.

Fig. 3: A 180° panoramic view from the 34 kWp rooftop PV grid-connected system on April 2017 (autumn).

In addition, Fig. 3 presents a 180° panoramic view from the PV panels related to the 34 kWp rooftop PV grid-connected system during afternoon on April 2017 (autumn). It can be noticed that PV panels had been installed with different orientation and inclination angles. A part of them are faced to North direction (with +15° deviation) with a 10° of inclination (following rooftop's inclination). Others PV panels are faced to South direction with the same deviation and inclination angles. The reason of such different installation procedures is related to R&D objectives and it justifies why nominal power 34 kWp would be never reached all over the year.

3. Power and energy measured performance

It is known that some aspects related to energy production and its performance can be monitored and saved for future numerical analysis. Otherwise other aspects related to local weather conditions can be also involved by that PV system analysis as they could limit overall system performance (Raj, 2016).

This paper discusses the influence of local weather conditions on the operational analysis of an existing 34 kWp PV grid-connected system (presented in Figs. 2 and 3). Its daily operation can be freely accessed by Internet connection through the address (http://200.137.220.91/index.htm) after typing the code 'visitante' into both user name and password fields (from login screen). The web interface (created by power inverters' manufacture)

could be describe as a supervisory system and it provides the amount of power and energy produced by power plant or by each of power inverters during a period of time. Fig. 4 presents a print screen from such supervisory system as it appears on October 15th, 2017. It can be noticed the shapes from total PV power output over the last seven days and also a summary of energy and power over the last twelve months.

Fig. 4: A screen from supervisory system related to 34 kWp grid-connected PV system as it appears on October 15th, 2017.

An amount of registered data from local weather conditions and PV power performance during February 2017 was considered to support the analysis presented in this work. Then Fig. 5 presents the daily electrical energy provided by the 34 kWp PV system to the PCC (as shown in Fig. 2) during February 2017. The biggest and lowest registered values of energy occurred in days 15 (176.3 kWh) and 16 (71.3 kWh), respectively. However, the AC output peak power from a 34 kW (nominal) PV system had a different behavior with lower variations all over the days. Even so, the biggest output peak power value occurred in day 12 (32,7 kWp) and in the same day with a 'poor' energy production (75,4 kWh).

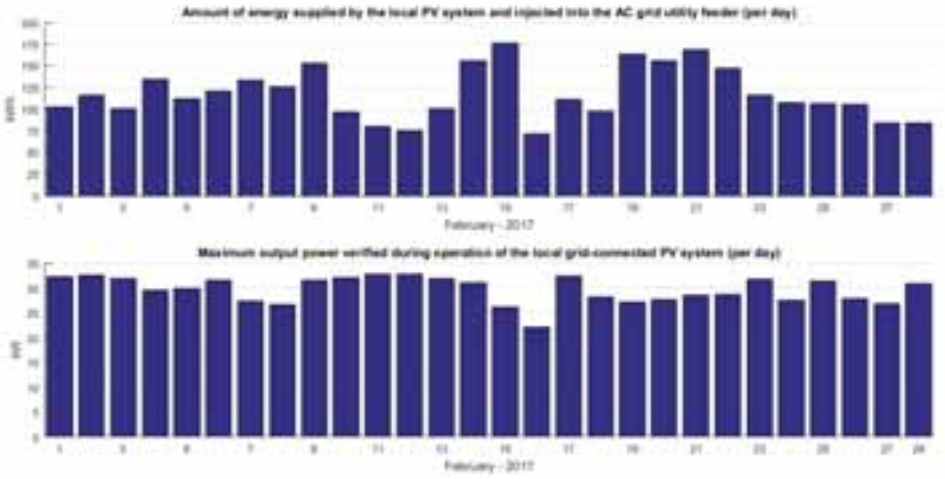

Fig. 5: Daily energy production and output power peak from a 34 kWp PV grid-connected system on February 2017.

Those conclusions suggest that both energy production and maximum power may be used to describe some PV system performance. However, they are not directly dependent just because they are determined by different local weather variables and/or power inverter capability. These issues are described during the next section.

4. Influence of registered local weather conditions

It is well known the direct relationship between power or energy performance from any PV system and the available weather conditions during a period of time. As this particular 34 kWp grid-connected PV system was related to a R&D project, an autonomous local weather station had been also purchased and installed alongside with its PV panels. Fig. 6 presents a general view from local weather station installed closed to the PV panels.

Fig. 6: Local weather station installed alongside the 34 kWp grid-connected PV system at UFG (Goiania, Brazil).

The weather station showed in Fig. 6 automatically collects values from seven different weather sensors during an interval of 10 seconds and registers an average of those captured values over one minute. Each average value from all seven weather variable is then added to a table that could be accessed by user through a serial or IP port. Besides time, the weather measured variables are: wind speed; wind direction; air temperature; relative humidity; precipitation; global solar horizontal irradiance; and atmospheric pressure.

All variable values registered by local weather station since July 2015 are available to visualization (and for free downloading) from an Internet portal through the address: https://sites.google.com/site/sfvemcufg/weather-station. Updates involving data registered by local weather station and its sharing are weekly made by authors of this work. Some of these data had been considered by authors to analyze the operation points from the 34 kWp grid-connected PV system power plant and are presented below.

Fig. 7 presents the horizontal global solar irradiance and air temperature exactly at the 34 kWp grid-connected PV system power plant during February 2017. It can be noticed that from February 12th to February 17th, both local weather variables have distinct behaviors than other days. For that reason, this period of six consecutive days from entire month had been chosen for a more detailed analysis.

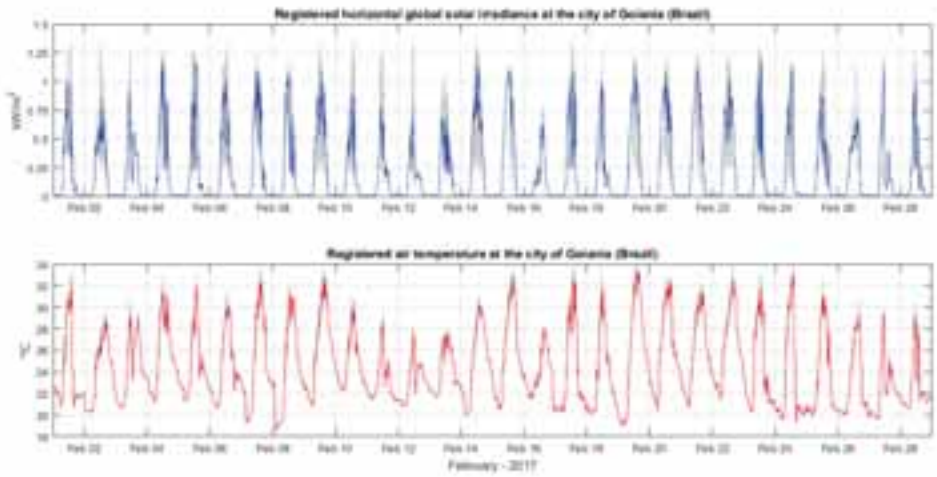

Fig. 7: Local horizontal global solar irradiance (top) and air temperature (bottom) at Goiania (Brazil) during February 2017.

Fig. 8: Amount of local precipitation per minute (blue) and accumulated (red) at Goiania (Brazil) during February 2017.

During the entire month of February 2017, a cyclic oscillation had been verified on air temperature in Fig. 7 (bottom). It suggests that power inverters operation probably had been not limited by temperature. Those peaks verified on horizontal global solar irradiance (not the average blue curve) could explain a possible power saturation on power inverters. It can be noticed that highest values verified in Fig. 5 (bottom) occurred on the same days which global solar horizontal irradiance reached 1.1 kW/m2 (or higher) in Fig. 7 (top).

As February corresponds to a summer season in the city of Goiania and it means a lot of raining days (at least on that of Earth), the oscillations on energy production verified in Fig. 5 (top) can be compared with the local precipitation presented in Fig. 8. And it can be also noticed that significate rains were scattered along the month and have not influenced those energy production oscillations. Even for that period from Feb-12 to Feb-17 that reflects a distinct behavior from the rest of the month, the accumulated precipitation had just a slightly transition over the days 12 and 13.

However, Fig. 8 shows only the precipitation measurements over the month and not how many cloudy were those days (or that distinct period). Fig. 9 exhibits the correspondent part of Fig. 7 related to period from Feb-12 to Feb-17 and Tab. 2 describes this period in terms of energy and weather conditions.

It can be concluded from Fig. 9 that ‘low’ solar irradiance and ‘low’ air temperatures were verified on days 12, 13 and 16. Then, they were probably cloudy days and affected the energy production presented in Fig. 5 (top). In addition, the constant behavior of output power in Fig. 5 (bottom) could be determined by the MPPT capability from power inverters (Hosseini, 2016; Killinger, 2016).

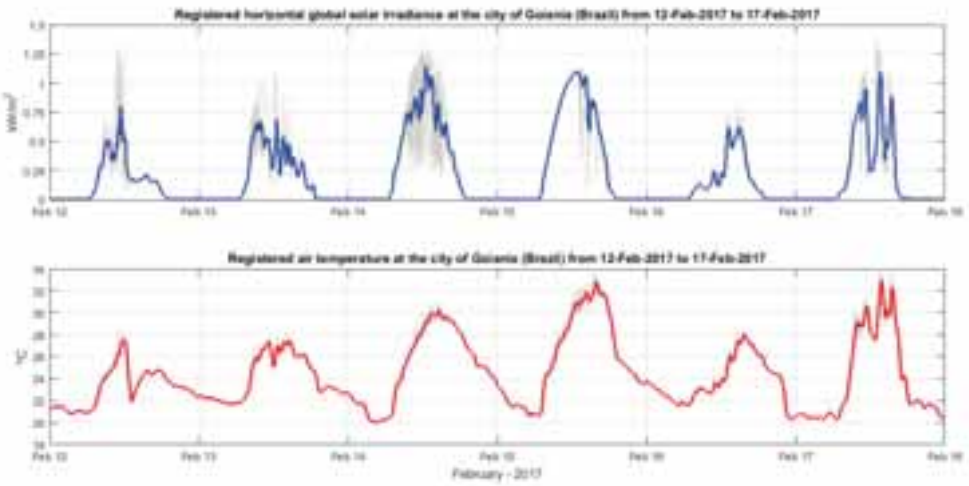

Fig. 9: Particular distinct behaviors verified on local horizontal global solar irradiance (top) and air temperature (bottom) during a period of six consecutive days of February 2017 at the city of Goiania (Brazil).

Tab. 2: Power performance and weather conditions measurements registered during operation of the 34 kWp PV grid-connected system from 12-Feb-2017 to 17-Feb-2017.

Day	Energy from PV system	Output power from PV plant	Daily air temp. range	Effective rain duration	Solar irrad. (average peak)
12-Feb-2017	075.4 kWh	32.7 kW	~ 21-28 ºC	~ 1 h (at 1 pm)	~ 0.8 kW/m²
13-Feb-2017	100.6 kWh	31.8 kW	~ 22-27 ºC	< 1 h (at 7 pm)	~ 0.7 kW/m²
14-Feb-2017	155.9 kWh	31.1 kW	~ 20-30 ºC	~ 1 h (at 3 am)	~ 1.2 kW/m²
15-Feb-2017	176.3 kWh	26.2 kW	~ 21-34 ºC	-	~ 1.1 kW/m²
16-Feb-2017	071.3 kWh	22.1 kW	~ 22-28 ºC	< 1 h (at 10 pm)	~ 0.6 kW/m²
17-Feb-2017	111.6 kWh	32.4 kW	~ 20-34 ºC	~ 1 h (at 6 pm)	~ 1.1 kW/m²

In addition, Tab. 3 presents some values obtained by performance parameters related to PV systems during February 2017. The daily (and monthly) amounts of energy produced by PV power plant, its capacity factor (CF) and the verified performance ratio (or productivity) are presented.

Tab. 3: Daily (specific) and monthly performance parameters registered by 34 kWp grid-connected PV system on February 2017.

Period of time	AC electrical energy produced (kWh)	PV power plant capacity factor (CF)	PV plant performance ratio (kWh/kWp or h)
Feb 12th	75.40	9.24%	2.22
Feb 13th	100.60	12.33%	2.96
Feb 14th	155.90	19.11%	4.59
Feb 15th	176.30	21.61%	5.19
Feb 16th	71.30	8.74%	2.10
Feb 17th	111.60	13.68%	3.28
All month	3302.60	14.45%	97.14

Considering the selected distinct period of six days from Feb-12 to Feb-17, the effects of daily variations on weather conditions can be cleared verified. A capacity factor of 15.0% (average) and a performance ratio around

5 h (average) have been obtained. Such values are typical on good PV systems and they were expected since PV panels and power inverters have been recently manufactured. Among specific days presented in Tab. 3, Feb-15 can be selected as most representative day from a PV system in the city of Goiania during a summer. High solar irradiance and clear sky (no clouds) over a long period of time have been observed during that day. The amounts of CF and performance ratio achieved on Feb-15 are also in accordance with the expected values from Fig. 1 (right) considering the localization of 34 kWp grid-connected PV system.

Considering a higher period of time, Fig. 10 presents some daily CF values observed from April 2017 to October 2017 on the same 34 kWp grid-connected PV system. As it was previously concluded, an average CF value around 15.0% still being observed on 34 kWp grid-connected PV system. Even so, some low FC values have been also noticed from May to August, a period of year related to dry season (no raining) in the city of Goiania. Such reduction can be explained by two typical weather conditions related to that dry season: higher amount of accumulated impurities on the PV panels; and lower solar irradiance over the days (winter). Future measurements from FC values may present the expected efficiency degradation from PV panels over the years.

Fig. 10: Curve of daily capacity factor values observed on 34 kWp grid-connected PV system from April to October 2017.

5. Conclusions

Some operational results from a 34 kWp grid-connected PV system installed in the city of Goiania (Central Brazil) have been presented and discussed.

As the number of installed grid-connected PV systems in Brazil has been increasing over that last five years, this paper described a new 34 kWp grid-connected PV system installed in the city of Goiania (Central Brazil).

After some basics operational tests, that 34 kWp grid-connected PV system started to work continuously on January 2017 after being registered and authorized by local grid utility. Since then an amount of 4.4 MWh has been generated and fed into the power distribution line up to middle of October 2017.

Some operational results observed on this solar power plant during February 2017 have been presented and discussed. For the same 34 kWp grid-connected PV system, a method for validating operational results from PV systems based on weather measurements has been also proposed and discussed.

From presented results, it can be concluded that days with low solar irradiance and low air temperatures cannot be related to raining days only. Some cloudy days may have same aspects and they can also affect seriously the power production from PV panels. Over the next months, the authors concluded that the clearness factor verified during daylight actually has more impact on the efficiency of PV panels than the presence of raining. This conclusion is valid in the city of Goiania since its average temperature does not significantly varies over a year.

Besides, the constant behavior of output power from 34 kWp grid-connected PV system over an intermittent solar month as observed during February 2017 can validate the MPPT capability from power inverters and its efficiency considering the accomplish of DC input voltage range specified by manufacturer.

Some performance parameters related to PV systems have been also calculated. A capacity factor of 15.0% (average) and a performance ratio around 5 h (average) have been obtained. Such values are typical on good PV systems and they were expected since PV panels and power inverters have been recently manufactured.

As a fully one operational year from 34 kWp grid-connected PV system has not been concluded yet, authors still working on its power inverters and weather conditions monitoring, on energy performance parameters analysis and on reliability of solar power plants.

6. Acknowledgments

This work had been developed within the context of all activities related to a R&D project registered with Brazilian agency ANEEL (National Electrical Energy Agency) by code PD-3033-002/2014 and sponsored by the local companies: Espora Energetica S/A; Transenergia Sao Paulo S/A (TSP); Transenergia Renovavel S/A (TER) and Caldas Novas Transmissao (CNT).

Abstract

This work presents the experience gained with the testing of photovoltaic grid-tie inverters to evaluate their compliance with the Brazilian standards. The experience was obtained during the first two years at the Laboratory of Photovoltaic Systems of the Institute of Energy and Environment of the University of São Paulo - LSF/IEE/USP, the first laboratory in Brazil equipped to perform these tests.

Since the LSF is the first laboratory to apply the Brazilian standards procedures, there is still uncertainty if the inverters available international market are able to comply with all the aspects of the standards.

The approach focus on the experiences with inverters that did not comply with the Brazilian standards concerning one or more of its aspects, the difficulties encountered during the tests, and the firmware implementation needed to solve inverter nonconformity with the standards.

By reviewing the data obtained, this work aims to evaluate if the criteria required by the Brazilian standards is obtainable by the inverters that already exist in the market. In case there are non-conformities, the interaction with the inverters technical team will show what are the most critical aspects of the standards, and if they can be implemented in the existing inverters.

To back up the analysis, the laboratory infrastructure is briefly described, mostly to establish the power range and main characteristics of the inverters that can be tested using the LSF infrastructure.

Keywords: Grid tied inverter, equipment evaluation, Brazilian standard.

1. Introduction

Distributed power generation is becoming usual in Brazilian distribution grids, and thus grid-connected systems need compliance with the Brazilian standards, regarding the connection interface and energy quality. The inverters in a photovoltaic system are mainly responsible for establishing the connection and delivering the generated power to the grid. In order to evaluate the string inverters sold in the Brazilian market, the Instituto Nacional de Metrologia, Qualidade e Tecnologia – INMETRO (National Institute of Metrology, Quality and Technology), established a labeling program for inverter evaluation according to the standards NBR 16149, 16150, NBR IEC 62116 of the Associação Brasileira de Normas Técnicas – ABNT (Brazilian Association of Technical Standards) and the INMETRO Normative Regulation Number 357.

To support the inverter labeling program the Laboratory of Photovoltaic Systems of the Institute of Energy and Environment of the University of São Paulo was accredited by INMETRO to test grid-tie inverters and guarantee their compliance to the standards.

This scenario presents a specific challenge for inverters already available in the international market, mostly because for these products to enter the Brazilian market they would need to comply with a new standard specific for that country, where there was still no data available for the inverter performance under the Brazilian criteria.

During the first two years, different inverter brands and models were tested at the laboratory, and although most models showed compliance to the standards, a few cases showed non-compliance with one or more aspects of the standards.

This work presents the data obtained during inverter testing. The main attempt is to inform international inverter manufacturers about the aspects of the Brazilian standards and which aspects will require hardware and software reengineering in order for the inverter to be commercialized in the Brazilian market.

doi:10.18086/swc.2017.10.05 Available at http://proceedings.ises.org

2. Brazilian standards

The Brazilian standards NBR 16149 and NBR 16150 dictate most of the features of photovoltaic systems´ connection to the power grid, except for the anti-islanding aspect, which is fully described in the NBR IEC 62116, and DC polarity inversion and photovoltaic overload, which are described in the INMETRO Normative Regulation Number 357. All the tests for the conformity criteria are listed in Tab. 1, and are briefly described in the following items.

Tab. 1: Inverter tests according to Brazilian regulation.

Number	Test	Reference standard
1	Flicker	ABNT NBR 16149 and 16150
2	DC-Component injection	
3	Harmonics and wave distortion	
4	Power factor	
5	Reactive power injection/demand	
6	Over/undervoltage	
7	Over/underfrequency	
8	Power control under overfrequency conditions	
9	Reconnection	
10	Automatic out-of-phase reconnection	
11	Active power modulation	
12	Reactive power modulation	
13	Photovoltaic system grid disconnection	
14	Fault ride-through – FRT	
15	Polarity inversion protection	INMETRO nº 357 normative
16	PV overload	
17	Anti-islanding	ABNT NBR IEC 62116

2.1. Test 1: Flicker

The flickering caused to the electric system by the inverter is evaluated during the tests. For the criteria used and test procedures the Brazilian standards make reference to the international standards IEC 61000-3-3, IEC 61000-3-11 and IEC 61000-3-5. This is the only test with direct reference to international standards and all inverters tested in the laboratory complied with this aspect.

2.2. Tests 2, 3, and 4: DC-Component injection, harmonics and wave distortion, power factor

Tests 2, 3, and 4 are grouped together because of the similarity in their procedures. These three tests require de measurement of DC component, harmonics, and power factor of the current injected to the grid for different inverter loading conditions. Tab. 2 presents the conformity criteria for the three tests. It is important to mention that the DC component and harmonics are calculated using the inverter current fundamental component.

Tab. 2: Criteria for tests 2, 3 and 4 for inverter evaluation in Brazil.

Test	Criteria	Limit
2	DC component	< 0.5 %
3	Total harmonic distortion	< 5.0 %
	Odd harmonics – 3^{rd} to 9^{th}	< 4.0 %
	Odd harmonics – 11^{th} to 15^{th}	< 2.0 %
	Odd harmonics – 17^{th} to 21^{st}	< 1.5 %
	Odd harmonics – 23^{rd} to 33^{rd}	< 0.6 %
	Even harmonics – 2^{nd} to 8^{th}	< 1.0 %
	Even harmonics – 10^{th} to 32^{nd}	< 0.8 %
4	Power factor	0.98 lead ~ 0.98 lag

2.3. Test 5: Reactive power injection/demand

The fifth test requires the inverter to operate controlling the reactive power flowing between the inverter and the grid. This control is done regarding the actual active power injected into the grid. The Brazilian standards describe two types of reactive power control. The first type of control is referenced as a power factor curve, and in this mode the inverter is required to change its power factor according to a ramp function related to the active power delivered to the grid. The inverter installer should be able to configure the ramp function in the inverter, with the default values for the test as shown in Fig. 1. The second type of control consists of maintaining a fixed proportion between the reactive power flowing and the active power injected into the grid. This is the same as maintaining a fixed power factor during inverter operation, but the standard requires the installer to input a percentage value for the reactive/active power relation and not a fixed power factor value. Fig. 2 shows the expected operation for the inverter in the second type of control.

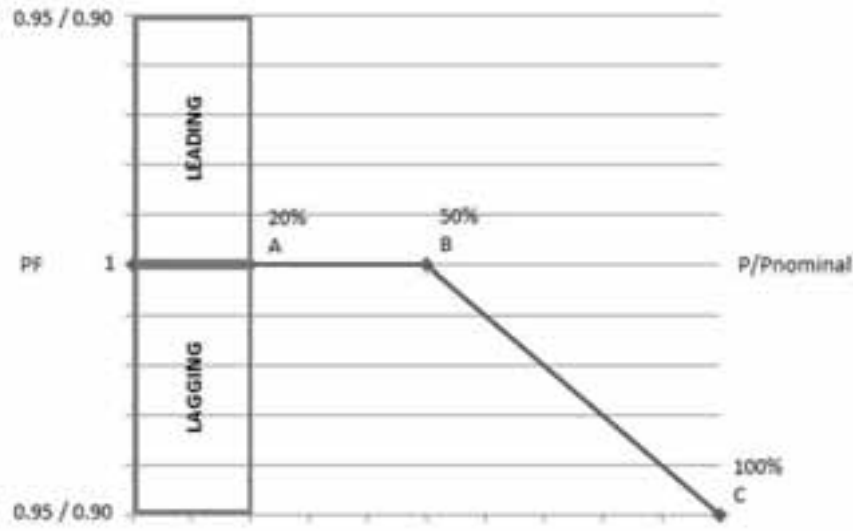

Fig. 1: Reactive power control as a power factor ramp.

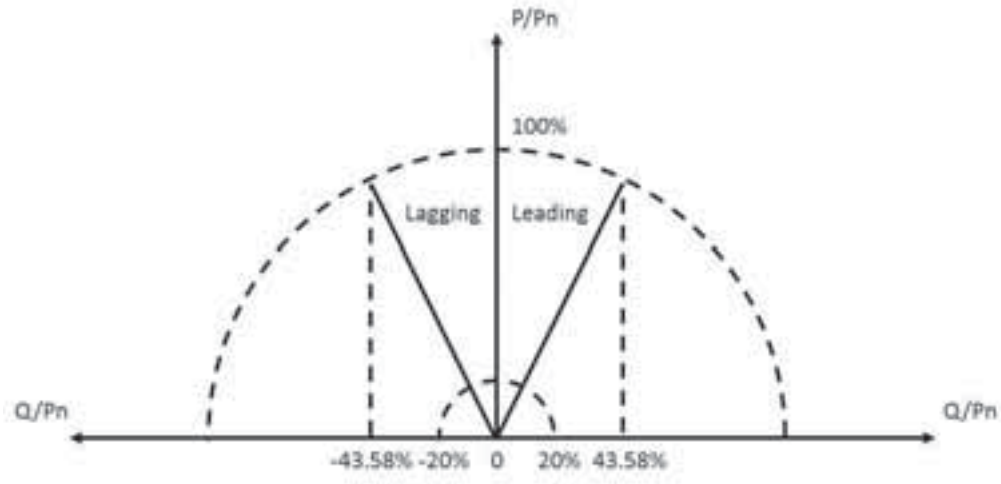

Fig. 2: Reactive power control as a fixed proportion of the active power injected to the grid.

The first type of control is mandatory for inverters with rated power above 3 kW and less or equal to 6 kW; for inverters with rated power equal or above 6 kW, the manufacturer may choose between the two types of control to be implemented in the equipment. Inverters with rated power under 3 kW are not required to have a reactive power control routine.

For the conformity criteria in the first control type, the inverter should be able to attain the power factor values within a ± 0.025 tolerance of the expected values for the injected power above 20 % of the inverter rated power. The second type of control has the same directive but with ± 2.5 % tolerance regarding the expected reactive power.

2.4. Tests 6 and 7: Over/undervoltage, over/underfrequency

The 6º and 7º tests evaluate the inverter regarding the interruption of power injection during abnormal grid conditions. In these tests, the inverter should detect the voltage and frequency values outside the normal operation range and cease to inject power into the grid within the respected time limits. Tab. 3 summarizes the criteria for these tests.

Tab. 3: Grid operation values and power injection interruption time limits for tests 6 and 7.

Voltage range (% V_{rated})	Power injection interruption time limit
$V_{grid} < 80$ %	0.4 s
80 % ≤ V_{grid} ≤ 110 %	Normal operation
110 % < V_{grid}	0.2 s
Frequency range	Power injection interruption time limit
$f_{grid} < 57.5$ Hz	0.2 s
57.5 Hz ≤ V_{grid} ≤ 62.0 Hz	Normal operation
62.0 Hz < V_{grid}	0.2 s

2.5. Test 8: Power control under overfrequency conditions

Test eight requires the inverter to control the active power injected into the grid according to the grid frequency. For frequency values between 60.0 Hz and 60.5 Hz the inverter is required to maintain the power injection unaltered, but for frequency values between 60.5 Hz and 62.0 Hz the inverter must reduce the power injected to the grid according to Eq. 1.

$$\Delta P = [F_{grid} - (F_{rated} + 0.5)] * R \qquad \text{(eq. 1)}$$

where:

ΔP is the active power variation, expressed in percentage, based on the active power injected at the moment the frequency exceeds 60.5 Hz (P_M);

F_{grid} is the actual grid frequency;

F_{rated} is the rated grid frequency;

R is the active power reduction factor, expressed in percentage by Hz, adjusted on - 40 %/Hz.

Also, once an overfrequency event is detected and the injected power is reduced, the inverter is required to reestablish the normal power injection only when the grid frequency returns to a value between 60.0 and 60.1 and maintains this value for at least 5 minutes. When the frequency stabilizes, the inverter is allowed to increase the power injection at a maximum rate of 20 % P_M/minute.

The Brazilian standards divide this test procedure in two parts. The first part corresponds to seven frequency points that evaluate the inverter response to overfrequency events. The second part corresponds to the eighth point that evaluates the power injection gradient. Fig. 3 shows the frequency points and the expected injected power; the power injection gradient is evaluated during the transition between points 8 and 1.

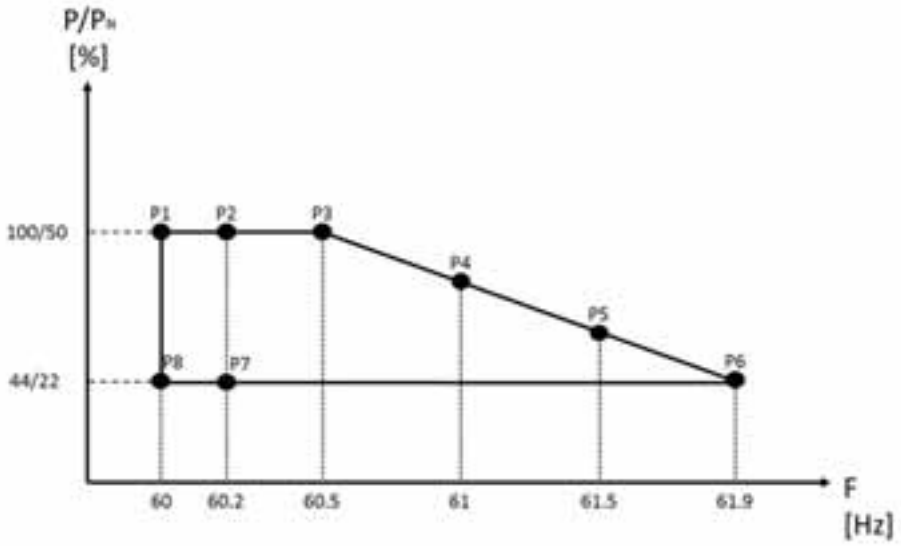

Fig. 3: Frequency points and inverter response for test 8.

The inverter presents conformity with the test requirements if the values measured are as expected in Fig. 3 with a ± 2.5 % tolerance.

2.6. Test 9: Reconnection

This test requires the inverter to reconnect to the grid once the normal operation conditions are detected. The inverter is required to reconnect within 20 to 300 s after the grid returns to normal. After the over and undervoltage tests the reconnection time is measured to verify this test criteria.

2.7. Test 10: Automatic out-of-phase reconnection

This test requires the inverter to withstand two pulses of out-of-phase grid voltage. In the first pulse, the grid voltage waveform skips 90º and, in the second pulse, the waveform skips 180º. The inverter is considered in conformity with this requirement if after each of these events it still injects power into the grid normally.

2.8. Tests 11, 12, and 13: Active power modulation, reactive power modulation, photovoltaic system grid disconnection

Tests 11, 12, and 13 are grouped together because their procedures make use of telecommunication protocols to send commands to the inverter. By using external commands test 11 evaluates if the inverter is capable of limiting the power injected into the grid according to the operator necessity. Test 12 makes use of external commands to evaluate if the inverter is able to operate with reactive power control as described in Fig. 2. These two tests are only required for inverters with rated power above 6 kW. Test 13 is required for all inverters and consists of sending commands for the inverter to start and stop the power injection into the grid.

The Brazilian standards do not establish a communication protocol and require the inverter manufacturer to provide the inverter with a protocol of his choice and all the equipment needed for testing.

2.9. Test 14: Fault ride-through – FRT

Test 14 requires that inverters with rated power equal or over 6 kW withstand voltage sags without disconnecting from the grid. Fig. 4 shows the criteria for the sags duration and inverter expected response regarding the sag event duration.

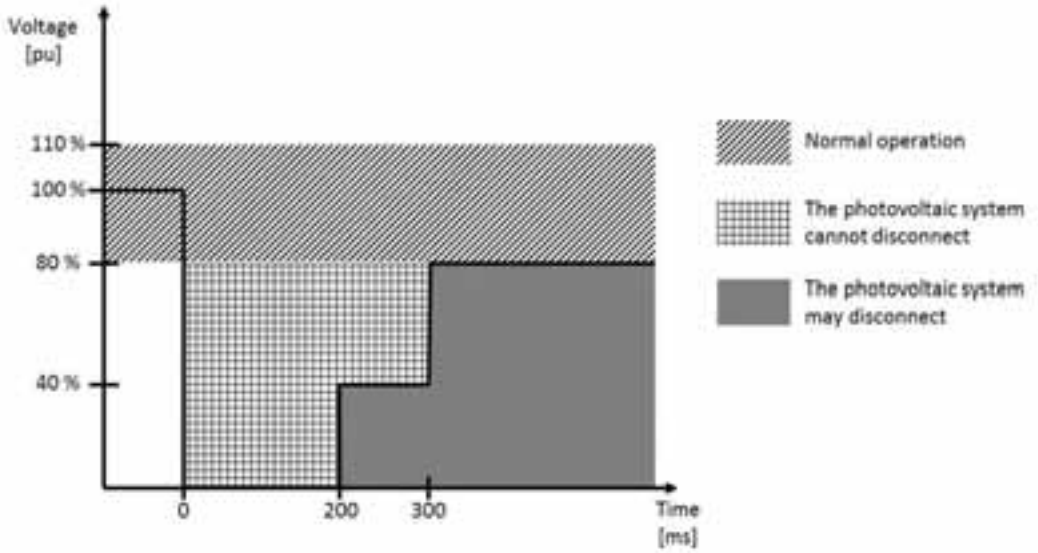

Fig. 4: Inverter response regarding voltage sag duration.

2.10. Tests 15 and 16: Polarity inversion protection, PV overload

Test 15 and 16 are grouped together because their test proceedings are similar and they are both discussed in the INMETRO Normative nº 375. These tests consist of operating the inverter for a period with the DC input polarity inverted, or with an overall DC input capacity 20 % above the inverter rated active power, for each test respectively. After the abnormal operation period, the inverter is operated in normal conditions. The inverter is considered in conformity if after the abnormal conditions it is able to inject power into the grid normally and there is no visible damage to it.

2.11. Test 17: Anti-islanding

The ABNT NBR/IEC 62116, which is a translation of the IEC 62116 standard, describes the anti-islanding test characteristics and procedures. For this test, the inverter is required to detect the absence of grid voltage and stop to provide power to the local load. The procedure takes several test conditions, which vary in power injected by the inverter and the percentage consumed by the local RLC load, but once the grid voltage disconnection occurs the inverter needs to stop the power injection in at least 2 seconds.

3. Laboratory infrastructure

In order to test grid-tie inverters the Laboratory of Photovoltaic Systems of the Institute of Energy and Environment of the University of São Paulo developed a test bench that is composed mainly of: a Solar Array Simulator (SAS) DC power supply, a grid simulator AC power source, a RLC load bank, and a power analyzer. The equipment used in the laboratory and the connection diagram are shown in Fig. 5 and Fig. 6, respectively.

Fig. 5: LSF String Inverter test equipment. From left to right: S.A.S DC power source, grid simulator AC power source, and RLC load bank.

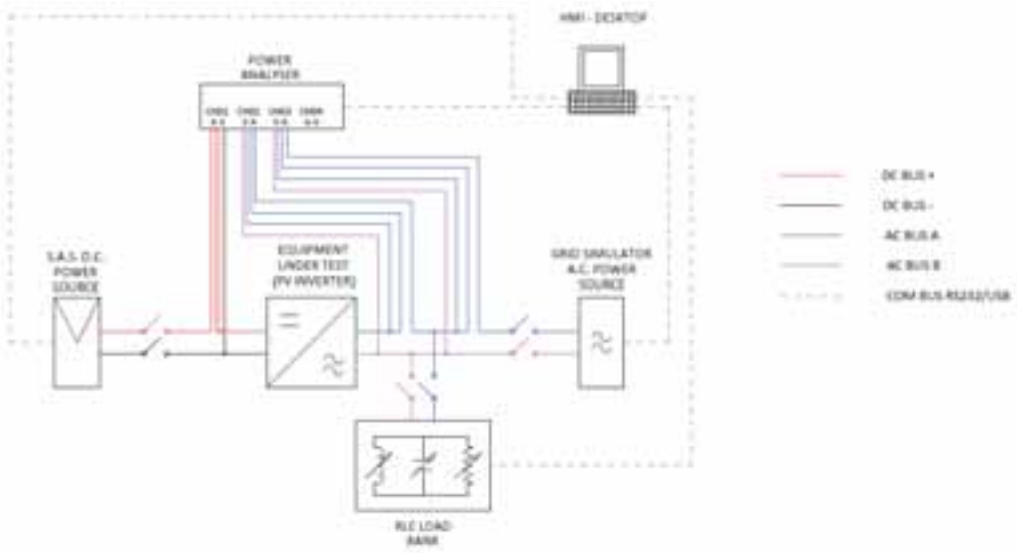

Fig. 6: Laboratory inverter test setup connection diagram.

The test bench equipment allows for testing single-phase inverters with maximum rated power up to 10 kW, as the current INMETRO normative only applies to inverters with rated power equal to or below 10 kW.

4. Inverter test experiences

During the first two years, the laboratory tested 15 inverters with rated power between 250 W and 5,000 W. Among the inverters tested, nine showed conformity with all the tests required by the labeling program, and the others showed nonconformity in one or more tests. Tab. 4 summarizes the inverters tested in the order they were tested, and the conformity criteria.

Tab. 4 shows that the inverters presented nonconformity in tests 2, 3, 4, 5, 6, 7, 8, 13 and 17. Inverters numbers 4, 6, 7 and 8 did not have further development on their firmware, but the manufacturers from inverters 9 and 10 requested to use the laboratory infrastructure to collect data and improve their firmware.

It is important to notice that inverter number 4 is a micro-inverter, designed for use connected directly to a photovoltaic module. This equipment did not have a communication port or telecommunication system that an operator could use to configure its operation or send any type of commands; so it immediately showed nonconformity with test 13.

Tab. 4: Inverters tested and their conformity with the standards.

Inverter	Rated Power (W)	Conformity with the standards?	Nonconformity for tests
1	1,500	Yes	--------
2	3,000	Yes	--------
3	4,600	Yes	--------
4	250	No	6; 7; 13
5	2,000	Yes	--------
6	700	No	3; 4; 8
7	1,500	No	2; 3; 4; 8
8	2,000	No	3; 4; 8
9	4,600	No	3; 5; 8; 17
10	5,000	No	5; 8
11	4,600	Yes	--------
12	1,000	Yes	--------
13	1,500	Yes	--------
14	3,000	Yes	--------
15	5,000	Yes	--------

4.1. Inverter nº 9

Inverter number nine had its firmware updated for harmonic distortion compliance with the Brazilian standards. Fig. 7 shows the results for the 4 evaluations of the harmonic distortion firmware update. The inverter technical team made each update based on the previous results. For the first three evaluations, the inverter presented one or more current harmonics over the limits established by the ABNT NBR 16149. At the fourth evaluation the firmware update lead to an inverter operation in conformity with the Brazilian standard.

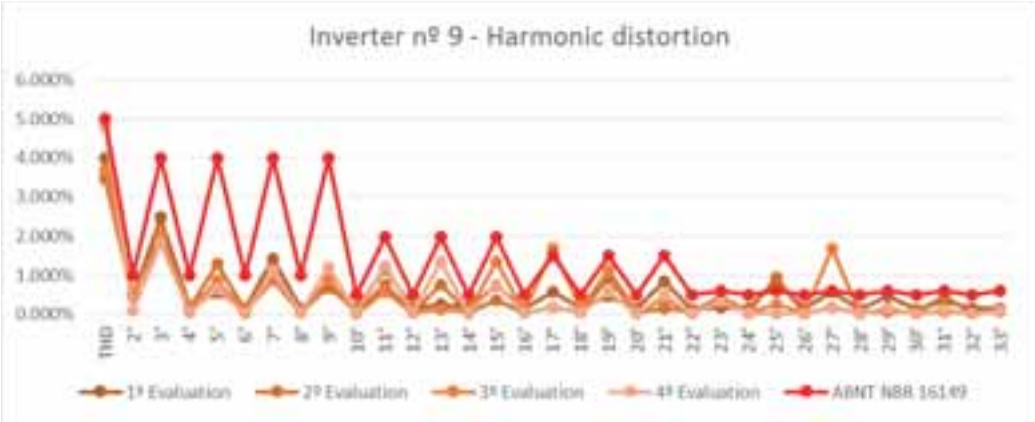

Fig. 7: Harmonic distortion evaluation results for firmware update on inverter nº 9.

After confirming the compliance with the requirements of test 3, the inverter technical team requested to evaluate the power control on overfrequency. At first, the inverter firmware did not present such control. The fourth firmware update implemented the power control required by test 8. One trouble found in this implementation was the misinterpretation of the power injection gradient. During the second evaluation, it was discovered that the value used for the power injection gradient was the inverter rated power and not the P_M value specified by the standard. With this result, the technical team developed a fifth firmware update, which presented conformity for test 8. Fig. 8 and Fig. 9 show the gradient test results for the three evaluations of inverter number nine.

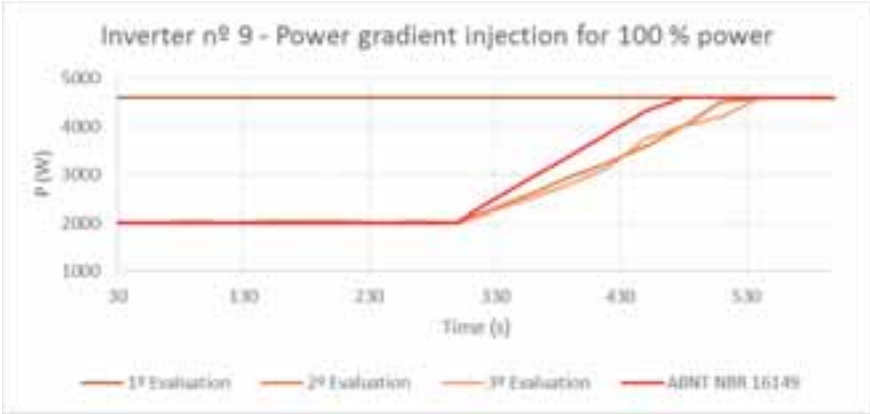

Fig. 8: Power injection gradient evaluation results for inverter nº 9 with 100 % rated power.

Fig. 9: Power injection gradient evaluation results for inverter nº 9 with 50 % rated power.

With inverter nº 9 in conformity with the requirements of tests 3 and 8, the technical team requested the evaluation for the power factor curve. Fig. 10 shows the results for the first and second evaluations of the power curve. At the first evaluation the inverter presented power factor values very close to the standard upper limit, so the technical team implemented a sixth firmware update to bring the values closer to the standard.

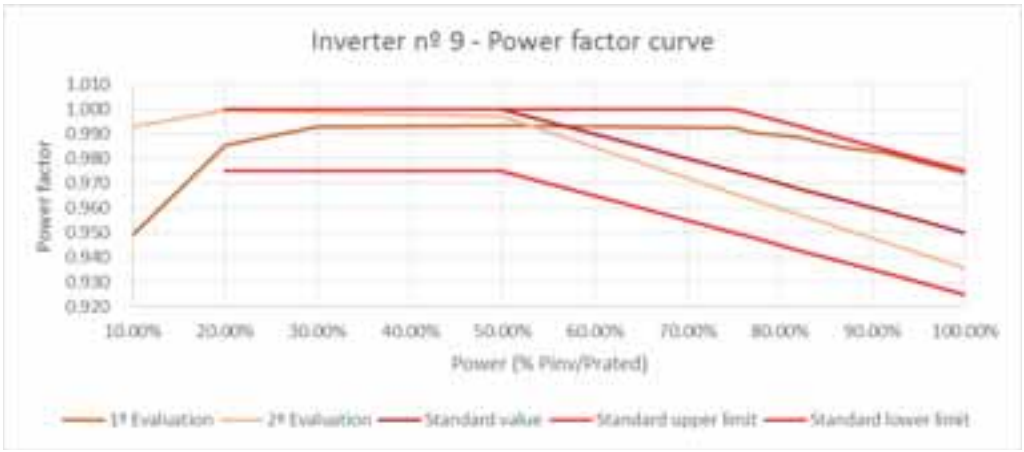

Fig. 10: Power curve evaluation results for inverter nº 9.

Although the inverter did not show conformity with the requirements of test 17, once the inverter showed conformity with tests 3, 5, and 8, the manufacturer did not request additional evaluations and firmware updates.

4.2. Inverter nº 10

Similar to inverter number nine, the inverter number ten also went through firmware updates in order to comply with aspects of the Brazilian standards. The first update was regarding the requirements of test 8. Likewise the values presented by inverter nº 9, inverter nº 10 also used the rated power instead of the P_M value in order to apply the power injection gradient. The inverter technical team then implemented a firmware update in order to comply with test 8. After the first update, the inverter showed compliance with the test requirements but started to present instability problems such as random disconnections from the grid. To correct this problem, the technical team developed a second firmware update to eliminate the inverter operation instability and add the power factor curve operation.

Fig. 13 shows that the firmware update implemented the power factor curve successfully; also, the update solved the disconnection problems. Yet, Fig. 11 shows the power injection gradient did not attain the inverter rated power during the 3rd evaluation, and the equipment was considered in nonconformity with the requirements of test 8. After this firmware implementation, the inverter manufacturer did not request further evaluations for this equipment.

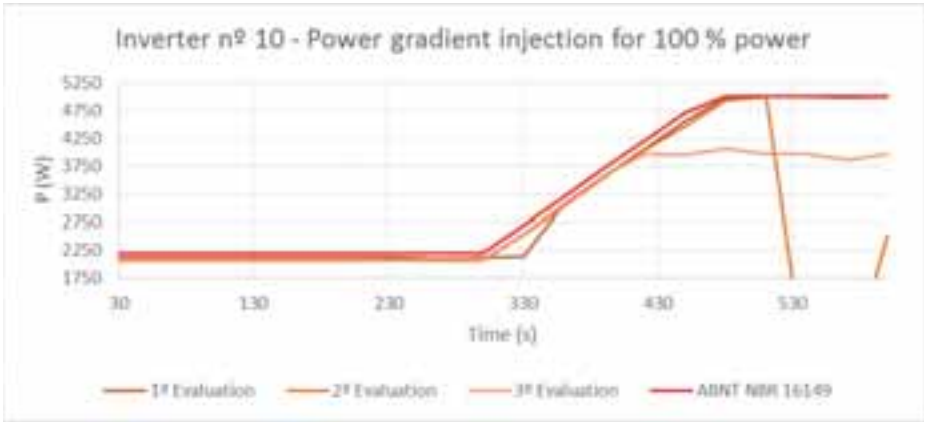

Fig. 11: Power injection gradient evaluation results for inverter nº 10 with 100 % rated power.

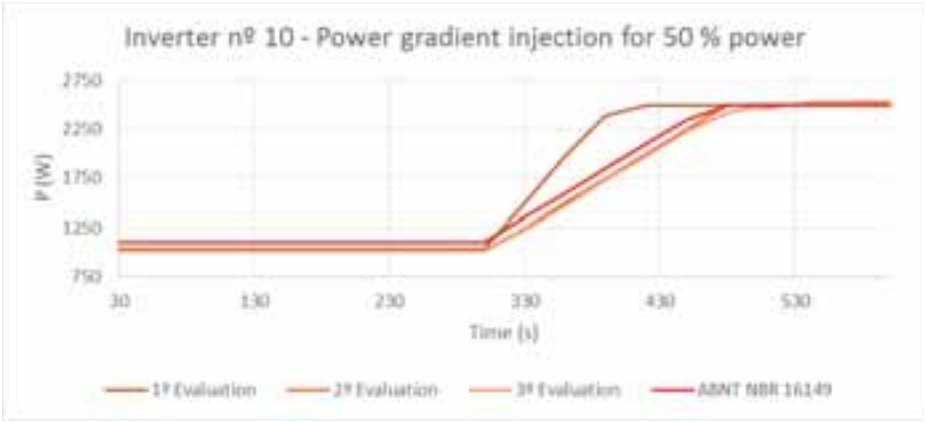

Fig. 12: Power injection gradient evaluation results for inverter nº 10 with 50 % rated power.

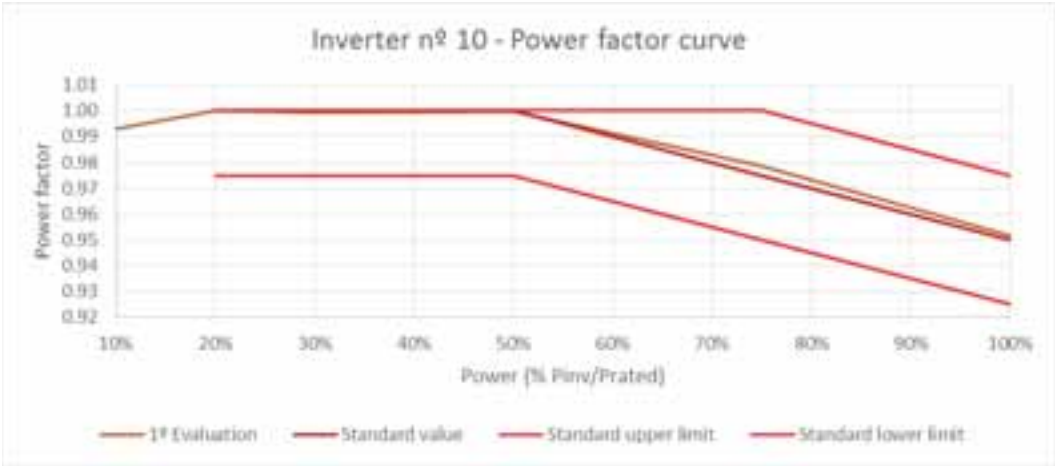

Fig. 13: Power curve evaluation results for inverter nº 10

5. Conclusion

The Brazilian standards evaluate inverters in different aspects: power quality, grid interaction, and safety. Most of the inverters tested in the laboratory were able to present conformity with all the standards requirements. Some of the inverters tested showed nonconformity with different aspects of the standards, but the experience with the manufactures´ technical teams showed that it is possible for equipment already available in the market to attain conformity with the Brazilian standards by firmware update.

The results showed in section 4 back the conclusion where it is possible for equipment already available in the market to receive firmware development in order to comply with the Brazilian criteria. The results also inform manufacturers which aspects should be included in the inverter firmware and how the equipment should perform

under test conditions.

It is important to mention that micro-inverters usually do not have a communication port or telecommunication system able to send commands to change the inverter operation, which leads to a nonconformity with the requirements of test 13 and make firmware update unavailable.

As for the most critical aspects of the Brazilian standards, the power control in overfrequency, the power factor curve, and the harmonic distortion requirements showed to be more difficult to attain for the inverters that did not comply with the aspects of the standards.

The Brazilian standards have a rigorous criteria, some types of inverters, like micro-inverters, won't be able to comply with the all the aspects without hardware and software implementations, this could impact in the equipment cost and performance. So for future challenges there is the question that all types of inverters should comply with one general standard or there should be a specify criteria for each type of inverter. Also there is the question about the limit levels of the standards and the discussion of which ones should be revised, for example, inverter n° 9 at the first firmware implementation showed a power factor curve within the limits required by the standard, but the second implementation showed an improvement on the inverter power curve, so a more restrict limit level could help inverter manufacturers to provide equipment with better performance to the market.

Integrating Desalination with Thermal and Electrical Systems

Dynamic Numerical Simulation of a Mechanical Vapour Compression (MVC) Desalination System That Use Renewable Source Energy

Sergio Morales-Ruiz[1], Joaquim Rigola[1], Jesús Castro[1], Carles Oliet[1] and Assensi Oliva[1]

[1] Heat and Mass Transfer Technological Center (CTTC) - Universitat Politècnica de Catalunya
Terrassa - Barcelona (Spain)

Abstract

This paper presents a numerical model to analyse the thermal and fluid dynamic behaviour of a mechanical vapour compression MVC desalination system, which uses renewable energy to supply the electricity required by the whole system. The reason to use renewable energy is that the MVC desalination system has been though to work in remote places, where an electric grid is not available. The transient and steady-state of the desalination system are evaluated taking into account the variability of the renewable energy sources (solar energy). A scalability study has been carried out to find the relation between the variability of the renewable energy sources and the capacity of the desalination system (distilled water production). Different components which making up the desalination system are considered in the numerical simulation, all of them are solved in a coupled way by mean of an object-oriented tool called NEST. The influence of the feed seawater conditions is also analysed on the system performance.

Key-words: MVC desalination unit; Numerical modelling; Dynamic performance; Renewable source energy.

1. Introduction

The MVC desalination method is an evaporation and condensation process that occurs at low pressure, which requires a compression work to increase the saturation temperature of the vapour. The trend is to use low evaporation temperatures (between 50 to 70^{o}C) to reduce the risk of corrosion and scale deposition (El-Khatib 2004). The compressed vapour is condensed and its latent heat is transferred to the feed seawater. The applicability of MVC desalination systems in remote places where there is not possible a connection to an electric grid depend on the use of renewable energy sources. However, the renewable energy means variability in the power given. This variability should be well defined to avoid damage and establish secure partial working operation of the desalination system. The MVC desalination is used at low and medium scale in comparison with other techniques such as: multistage flash desalination (MSF) or reverse osmosis (RO) (Ettouney, 2006).

The numerical modelling presented in this paper is applied to analyse the thermal and fluid dynamic behaviour of a MVC desalination system, which uses renewable energy source (solar energy) to supply the electric requirements of the system. The electrical energy is used to feed the mechanical compressor, a heater, a group of pumps and the control panel of the system. The well-known variability of renewable sources of energy is considered in the performance system study. Also, the influence of the boundary conditions on the execution of the unit along the time is analysed.

2. Dynamic modelling

The desalination system has been divided in four different subsystems, following the strategy proposed by Bodalal (2010) and Mazini (2014). The first subsystem is the evaporator and condenser, in which the evaporation and distillation processes are performed. The second is the vacuum and deareation subsystem, where the low pressure is achieved and non-condensed gas (Oxygen) is stripped. The third subsystem is the mechanical compressor, which is modelled to know its energetic requirement in function of the desalination performance and the climatic conditions. The last subsystem is the heat exchangers, which preconditioning the feed seawater flow temperature, taking advantage of the heat contained in the distilled water and brine flows at the outlet of the evaporator/condenser.

The evaporator and condenser subsystem is modelled describing it as a brine block, vapour space block, and a tube bundle. A schematic representation of these blocks is depicted in Figure 1, together with the others

doi:10.18086/swc.2017.11.01 Available at http://proceedings.ises.org

subsystems. The vacuum and deareation subsystem is modelled assuming that there are a liquid block, a vapour space block and a package zone, which are depicted in Figure 2. The compressor has been modelled following the mechanical model of a rotatory lobe compressor (blower), which uses the geometric configuration and the relation between velocity (rpm) and the displacement by revolution (cfr) of the compressor.

3. Mathematical formulation

The mathematical formulation of the evaporator/condenser subsystem is based on mass, and energy balance conservation equations.

$$\frac{dm_V}{dt} + \frac{dm_B}{dt} + \dot{m}_B + \dot{m}_{Do} - \dot{m}_{Fi} = 0 \qquad \text{(eq. 1)}$$

$$\frac{dm_V h_v}{dt} + \frac{dm_B h_B}{dt} + \frac{dm_{VT} h_T}{dt} + \dot{m}_B h_B + \dot{m}_{Do} h_{Do} - \dot{m}_{Fi} h_{Fi} = 0 \qquad \text{(eq. 2)}$$

Mass and energy conservation equations of vapour space

$$\frac{dm_V}{dt} + \dot{m}_D + \dot{m}_{v2} + \dot{m}_{nc} - \dot{m}_V - \dot{m}_{nc} = 0 \qquad \text{(eq. 3)}$$

$$\frac{dm_v h_V}{dt} + \dot{m}_D h_V + \dot{m}_{v2} h_V + \dot{m}_{nc} h_V - \dot{m}_V h_V - \dot{m}_{nc} h_V = 0 \qquad \text{(eq. 4)}$$

Mass, energy and salt conservation equation of the brine lump

$$\frac{dm_B}{dt} + \dot{m}_B + \dot{m}_{Fr} - \dot{m}_{Fo} - \dot{m}_C = 0 \qquad \text{(eq. 5)}$$

$$\frac{dm_B h_B}{dt} + \dot{m}_B h_B + \dot{m}_{Fr} h_B - \dot{m} h_{Fo} - \dot{m}_C h_B = 0 \qquad \text{(eq. 6)}$$

$$\frac{dm_B X_B}{dt} + \dot{m}_B X_B + \dot{m}_{Fr} X_B - \dot{m}_{Fo} X_{Fo} - \dot{m}_C X_C = 0 \qquad \text{(eq. 7)}$$

Mass of the bundle tubes and energy conservation equation of the vapour condensed inside tubes, assuming that there is not heat accumulation in solid walls.

$$\frac{dm_T}{dt} = 0 \qquad \text{(eq. 8)}$$

$$\frac{dm_{VT} h_T}{dt} + \dot{m}_{Do} h_{Di} - \dot{m}_{Do} h_{Do} = -\dot{Q}_e \text{ evaluating } \dot{Q}_e = U_T A_T (T_D - T_B) \qquad \text{(eq. 9)}$$

The heat transferred between the vapour condensed inside of the bundle tubes and the fluid outside of tubes is defined in function of the global heat transfer coefficient, transfer area and the difference temperatures. Assuming that the tubes cannot accumulate salt on the external surface, then

$$\dot{m}_C X_C - \dot{m}_{Fr} X_B = 0 \qquad \text{(eq. 10)}$$

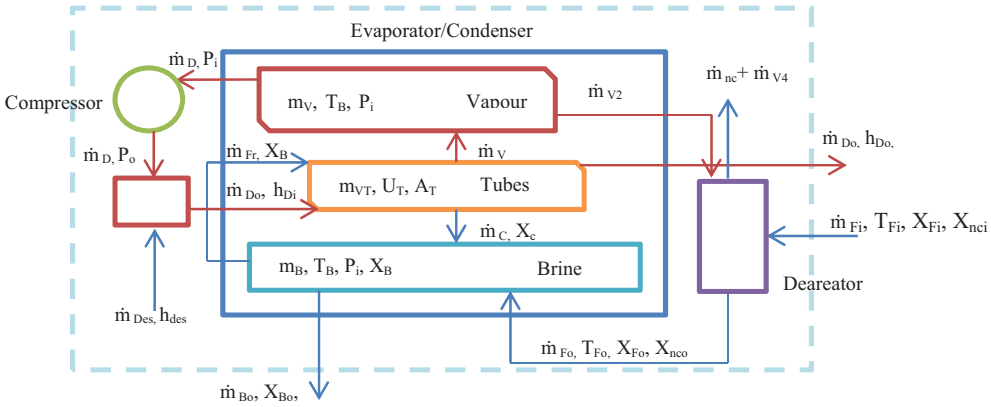

Fig. 1: Schematic representation of the MVC desalination system and evaporator/condenser subsystems

The mathematical formulation of the vacuum and deareation subsystem is based on the same mass, energy and salt balance conservation equations applied on the vapour, liquid and packed zone. The conservation equations are applied on the package zone assuming that there is not accumulation of mass, energy or salt on it. Some extra relations are used to define the value of the non-condensable gas stripped, the flash evaporation, the mass flow condensed into the package and the mass flow at the outlet of the deareator (Suryanarayana, 2011).

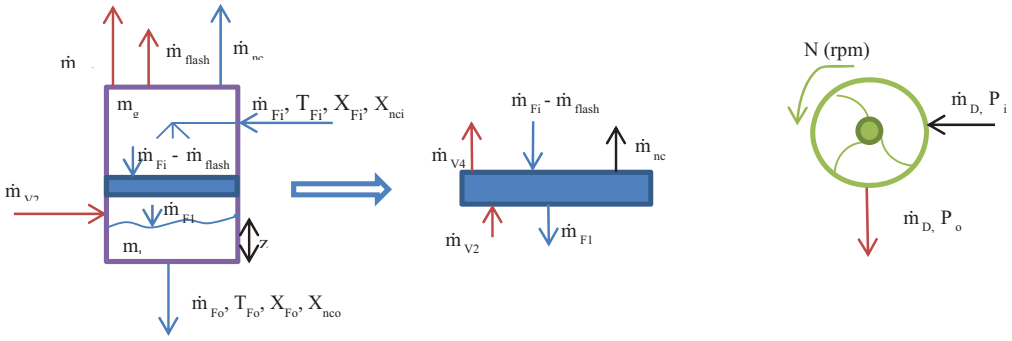

Fig. 2: Schematic representation of the deareator subsystem (including a detail of the package zone) and the compressor

$$\frac{\partial m_g}{\partial t} + \dot{m}_{v4} + \dot{m}_{v3} - \dot{m}_{flash} - \dot{m}_{v2} = 0 \quad \text{(eq. 11)}$$

$$\frac{\partial m_l}{\partial t} + \dot{m}_{Fo} - \dot{m}_{F1} = 0 \quad \text{(eq. 12)}$$

$$X_{nco}\frac{\partial m_l}{\partial t} + m_l\frac{\partial X_{nco}}{\partial t} + \dot{m}_{Fo}X_{nco} - \dot{m}_{F1}X_{nc1} = 0 \quad \text{(eq. 13)}$$

$$\frac{\partial m_g h_g}{\partial t} + \dot{m}_{v4}h_g + \dot{m}_{v3}h_f - \dot{m}_{flash}h_g - \dot{m}_{v2}h_g = 0 \quad \text{(eq. 14)}$$

$$\frac{\partial m_l h_{fo}}{\partial t} + \dot{m}_{Fo}h_{fo} - (\dot{m}_{Fi} - \dot{m}_{flash})h_{fi} - \dot{m}_{v3}h_f = 0 \quad \text{(eq. 15)}$$

Assuming that there is not accumulation on package zone:

$$\dot{m}_{F1} - (\dot{m}_{Fi} - \dot{m}_{flash}) - \dot{m}_{v3} = 0 \quad \text{(eq. 16)}$$
$$\dot{m}_{v4} + \dot{m}_{v3} - \dot{m}_{v2} = 0 \quad \text{(eq. 17)}$$
$$\dot{m}_{F1}X_{nc1} + \dot{m}_{nc} - (\dot{m}_{Fi} - \dot{m}_{flash})X_{nci} = 0 \quad \text{(eq. 18)}$$
$$\dot{m}_{F1}h_{f1} - \dot{m}_{v3}h_f - (\dot{m}_{Fi} - \dot{m}_{flash})h_{fi} = 0 \quad \text{(eq. 19)}$$
$$\dot{m}_{v4}h_g + \dot{m}_{v3}h_f - \dot{m}_{v2}h_g = 0 \quad \text{(eq. 20)}$$

Where:

$$\dot{m}_{v3}h_{fg} = \dot{Q}_{cond} = \alpha_i A_i (T_{sat} - T_{fi}) \quad \text{(eq. 21)}$$

$$\dot{m}_{flash} = \frac{C_p\,(T_{sat} - T_{fi})}{h_{fg}}\,\dot{m}_{Fi} \quad \text{(eq. 22)}$$

$$\dot{m}_{nc} = K_l A_c \Delta X_{Ln} \quad \text{(eq. 23)}$$

Evaluating: $\Delta X_{Ln} = \frac{[(X_{nci} - X^*_{nci}) - (X_{nco} - X^*_{nco})]}{ln[(X_{nci} - X^*_{nci})/(X_{nco} - X^*_{nco})]}$

$$\dot{m}_{Fo} = f(valve) = \sqrt{2gz}\,A_{valv}\,\rho \quad \text{(eq. 24)}$$

The compressor (blower) model is based on the root blower laws, in which the volumetric flow, velocity, power and the displacement by revolution values are related:

$$\dot{V} = cfr * (rpm - Slip_{corrected}) \quad \text{(eq. 25)}$$
$$Power = [0.00436 * cfr * rpm * (P_o - P_i)] + Friccional\ loss \quad \text{(eq. 26)}$$

The ideal gas law is used to evaluate the inlet pressure at the compressor as function of the vapour mass contained into the evaporator, the temperature of the vapour and the volume occupied.

$$P_i = \frac{1}{V_v}\frac{m_v}{M}RT \quad \text{(eq. 27)}$$

The heat exchangers are evaluated in function of heat flux transferred between flows (distilled water, brine and feed seawater) to obtain the temperatures of each one, using the overall heat transfer coefficient (U), the logarithm mean temperature difference (LMTD) and the transfer area (A_{Hex}). Assuming the hypothesis that there is not heat losses in the heat exchangers, the heat transferred should be equal to the heat flux obtained or delivered for the flow.

$$Q_{exchanged} = U\, A_{HEX}\, LMTD = \dot{m}\, C_p(T_{in} - T_{out}) \qquad \text{(eq. 28)}$$

4. Numerical resolution

The group of equations is solved by means of the in-house object-oriented tool called NEST, which is capable to link and solve different elements that making up a system (Damle, et. al., 2011; Farnós, et. al., 2014). The MVC desalination system that is presented in this paper has different components: an evaporator/condenser, a compressor, a deareator, two heat exchangers and a group of pumps. Although in this numerical platform each component is an object, the whole system resolution is carried out iteratively by solving all its components and transferring the appropriated information between them (see Figure 3).

A dynamic model based on mass, energy and salt balances and applied to internal components of the MVC desalination system has been implemented to analyse the transient behaviour of the MVC desalination system, which uses renewable source energy.

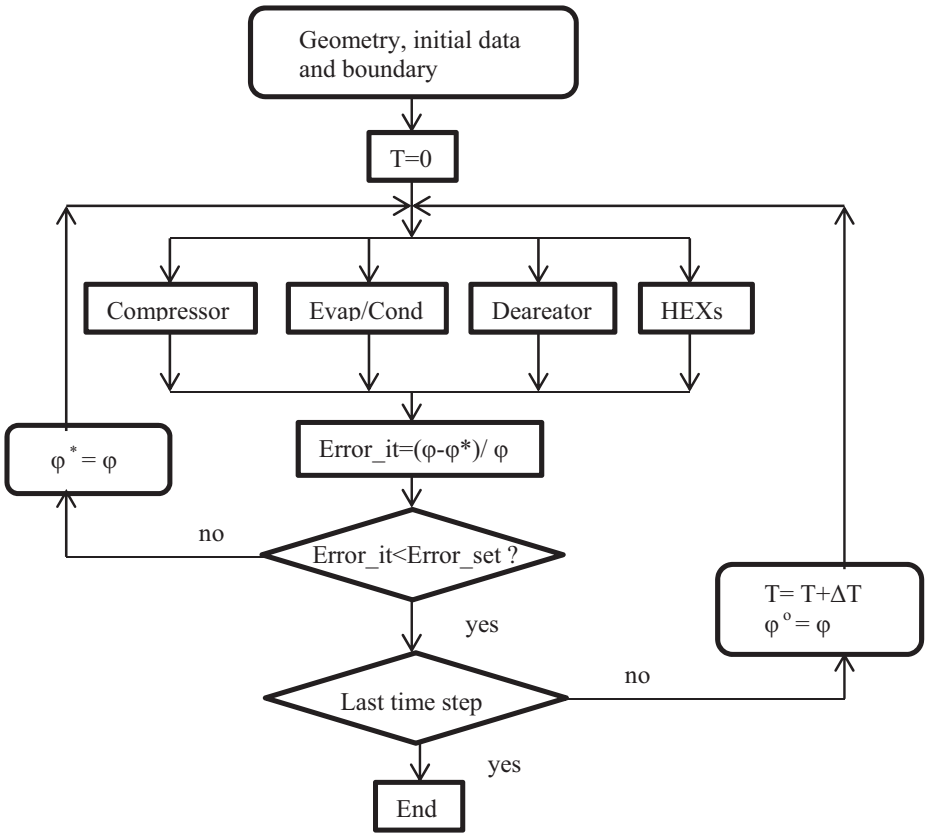

Fig. 3: Global algorithm to solve the MVC desalination unit

5. Results

A numerical analysis has been carried out to define the specific average consumption of the MVC desalination systems analysed. A value of 15.08 kW/m^3 has been defined including the power required by the compressor, pumps and heater of the whole system. A scalability study using three different units, each one with a production capacity of 100, 200 and 400 m^3/day of distilled water, has given 14.98, 15.07 and 15.19 kW/m^3,

respectively. All these values are in agreement with technical literature data (Plantikow, 1999). The numerical results expressed in a percentage relation between the energy used and the distilled water production is depicted in Figure 4. This graphic shows the capacity of supplying distilled water in function of the energy source variability; as an example a reduction of 70% in the energy source represents a decreasing of 58% in the production capacity of distilled water. This value is in agreement with data proposed by Plantikow (1999) for a specific case in which evaporation occurs at 60°C.

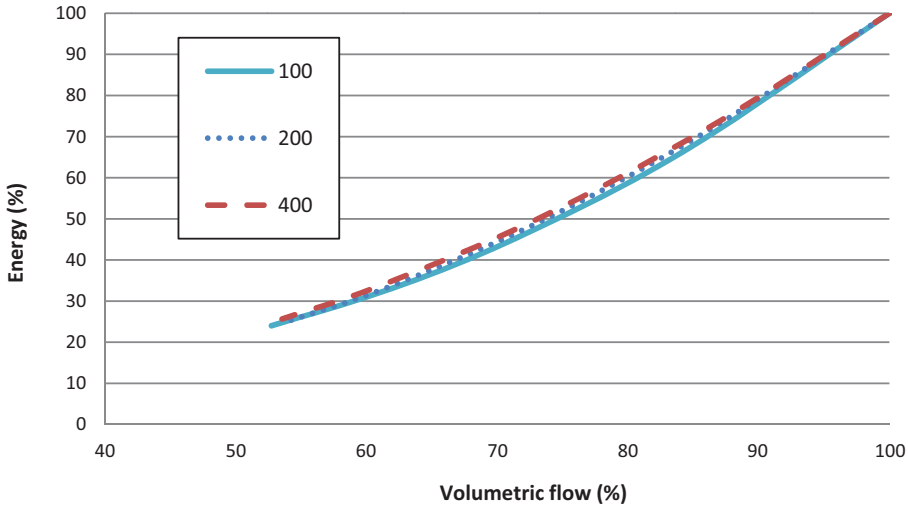

Fig. 4: Percentage relation between energy requirement and volumetric flow demand of the MVC desalination system

A virtual prototype desalination unit capable to produce 1m^3/day of distilled water has been used to evaluate the preliminary results under dynamic conditions. Three different cases have been used to evaluate the thermal behaviour of the MVC desalination unit, in which an evaporation temperature about 60°C has been used.

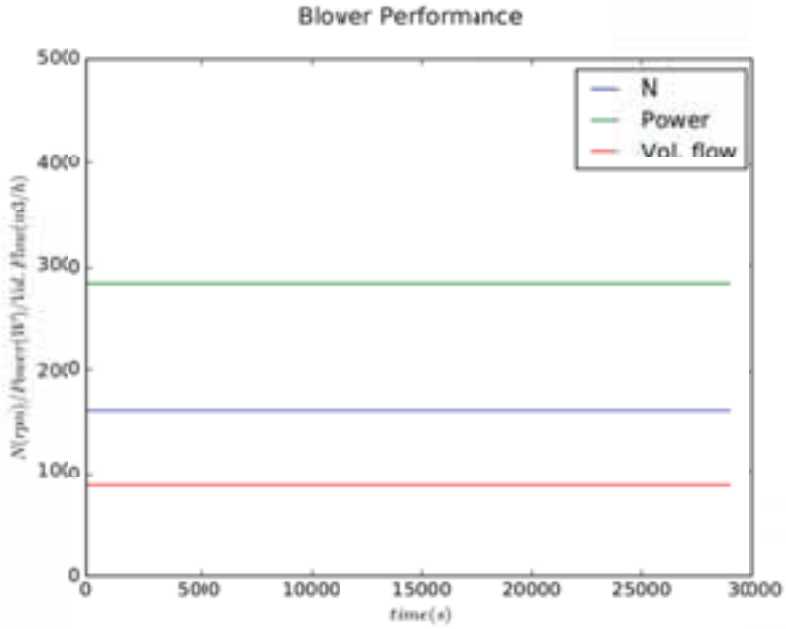

Fig. 5: Compressor (blower) performance: Velocity (N), Power availability (Power) and Volumetric Flow (Vol. Flow)

The first case consist of evaluating the energy required to produce 1m^3/day of distilled water, assuming a complete availability of the energy and constant power (a hypothetical condition: how if the unit will be connected with an electrical grid). The power, the velocity and the volumetric flow of the compressor are shown in Figure 5. A constant power produces not variations in the velocity and the volumetric flow, which produce

that the MVC desalination unit works in stable conditions using a constant mass flow of feed seawater during the working time. The total mass of the seawater required to produce 1m^3 of distilled water is depicted in Figure 6, together with the mass of brine and distilled water produced in the process.

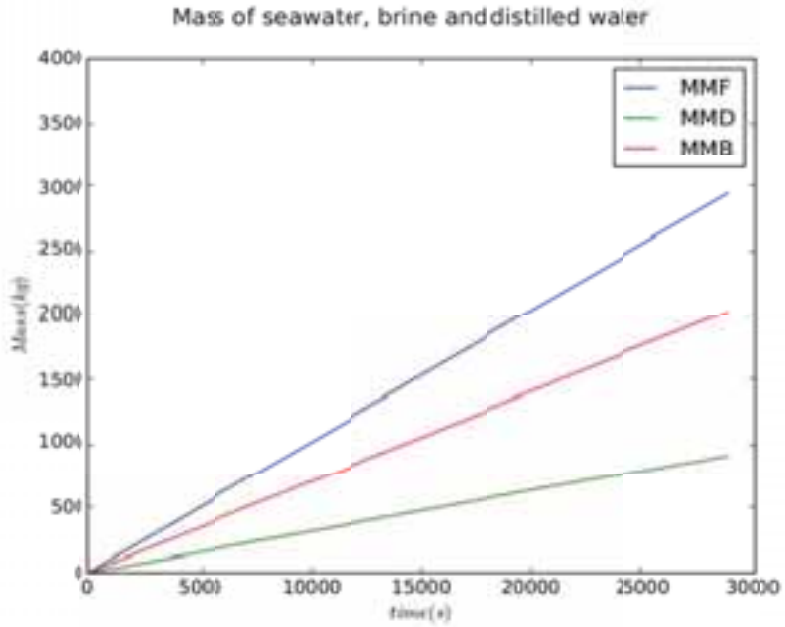

Fig. 6: Masses used by the MVC desalination unit along 8 hours: distilled water (MMD), brine (MMB) and seawater (MMF)

The pressures and the temperatures in the evaporator and condenser of the MVC desalination unit keep their values along the process, achieving a steady state conditions until produce the quantity of distilled product defined. In this case a power of 2850W is required to produce around 1m^3 of distilled water in 8 working hours.

The second case consists of analysing the influence of the energy availability and variability on the compressor performance and their effect on the thermal behaviour of the MVC desalination system. The solar energy is used as source energy of the MVC desalination system in which the energy availability is obtained from meteorological data, assuming that the desalination plant works in Barcelona-Spain (See Table 1).

Tab. 1: Meteorological data for Barcelona on June

Hour	Radiation (W/m^2)	Ambient Temperature (^{o}C)
9:00	515	17.2
10:00	684	18.1
11:00	771	19.8
12:00	860	20.6
13:00	811	21.1
14:00	801	21.9
15:00	734	22.0
16:00	722	20.9

A group of photovoltaic devices should be used to transform the solar radiation in electrical energy, which will be used to feed the compressor and pumps. The radiation data is a parameter needed to evaluate the energy

source, together with the photovoltaic panel efficiency and the effective area used. The electric power evaluated is used to calculate the compressor velocity and the volumetric flow displaced. A sunny day of June has been chosen to evaluate the energy availability and variability along the day. Eight hours have been simulated with the aim of obtaining 1.0m^3/day of distilled product.

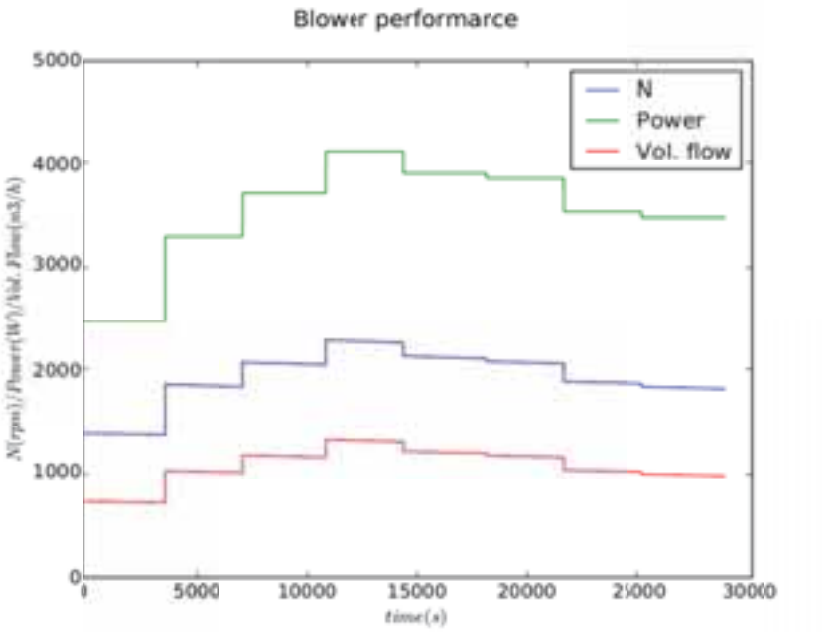

Fig. 7: Compressor (blower) performance: Velocity (N), Power availability (Power) and Volumetric Flow (Vol. Flow)

The compressor performance and the thermal behaviours of the MVC desalination unit are described in next figures. The velocity of the compressor and the volumetric flow are function of the solar energy available, which is defined by a power profile that manages the compressor performance along the 8 working hours.

The volumetric flow moved from the compressor to the evaporator/condenser defines the thermal behaviour of the MVC desalination unit, which requires a specific quantity of the seawater to feed the unit and to produce the distilled water. The mass flows used by the MVC desalination unit are depicted in Figure 8.

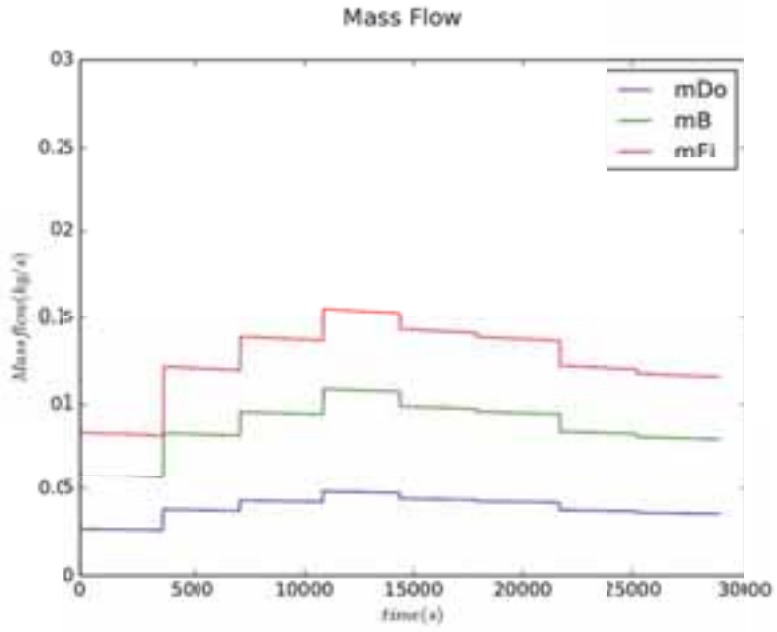

Fig. 8: Mass flows used by the MVC desalination unit: distilled water (mDo), brine (mB) and feed seawater (mFi)

The total mass of seawater needed to produce 1.0 m3 of distilled water (final product) together with the quantity of brine produced in the desalination process can be obtained after integrating the mass flows along the time. The masses of seawater, brine and distilled water are shown in Figure 9, a slight change can be observed if the results are compared with the results of the case with constant power (see Figure 6).

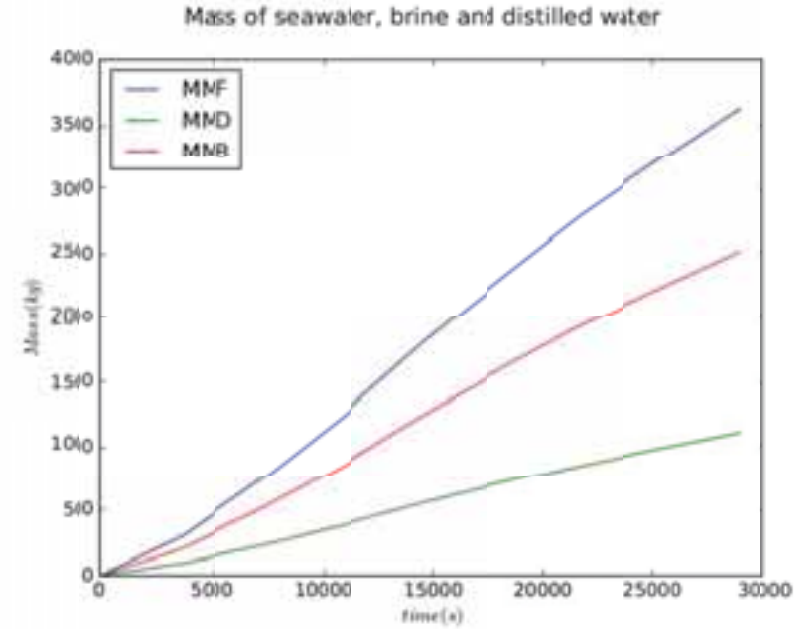

Fig. 9: Masses used by the MVC desalination unit along 8 hours: distilled water (MMD), brine (MMB) and seawater (MMF)

The salt concentration of the recirculation, brine and feed seawater flows are shown in Figure 10. A constant salt concentration value of the feed seawater at the inlet is used, whilst the salt concentration values of recirculation and brine flows present a slight decrease following the same tendency of the pressure in the evaporator.

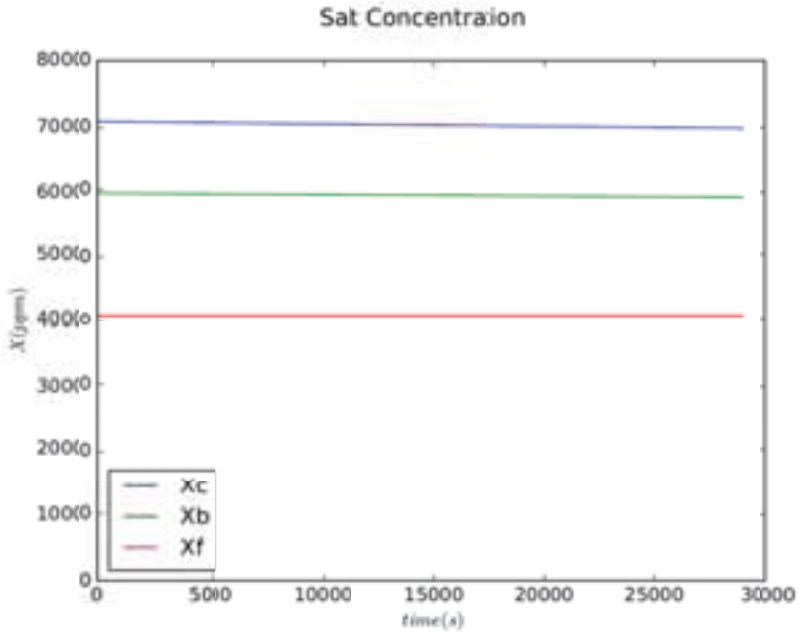

Fig. 10: Salt concentration in the evaporator/condenser: recirculation flow (Xc), brine flow at the outlet (Xb) and feed seawater flow at the inlet (Xb)

The temperatures and pressures into the evaporator/condenser are shown in Figure 11. The vapour, brine and feed seawater temperatures present a stable behaviour as consequence of the evaporation pressure (Pinlet) and condensation pressure (Poutlet) used in the process. A small decrease in the evaporation pressure and temperature are detected, which produces that the differential pressure increase its value, reducing the volumetric flow in the compressor and the mass flows in the MVC desalination unit (see Figures 7 and 8).

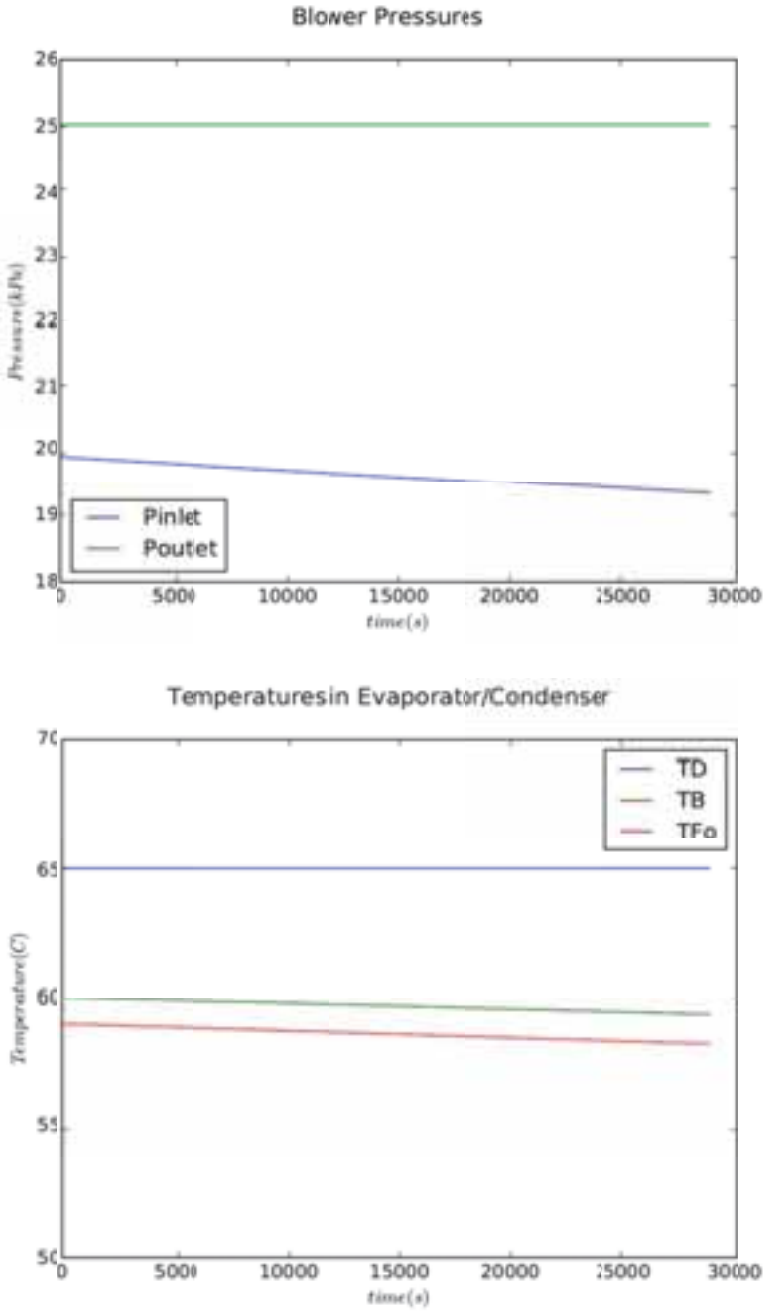

Fig. 11: Temperatures in the evaporator/condenser: vapour (TD), brine (TB) and feed seawater (TFo) and pressures in the blower

The energy transferred between the feed seawater, the distilled water and brine flows in the heat exchangers produce that the seawater increases its temperature from T_{CW} to T_{FI}, whilst the distilled water and brine flows decrease their temperatures from T_D and T_B to T_{DO} and T_{BO}, respectively. The temperature profiles are function of the different mass flows used by the MVC desalination unit, as consequence of the power variability along the working time. These temperatures are shown in Figure 12.

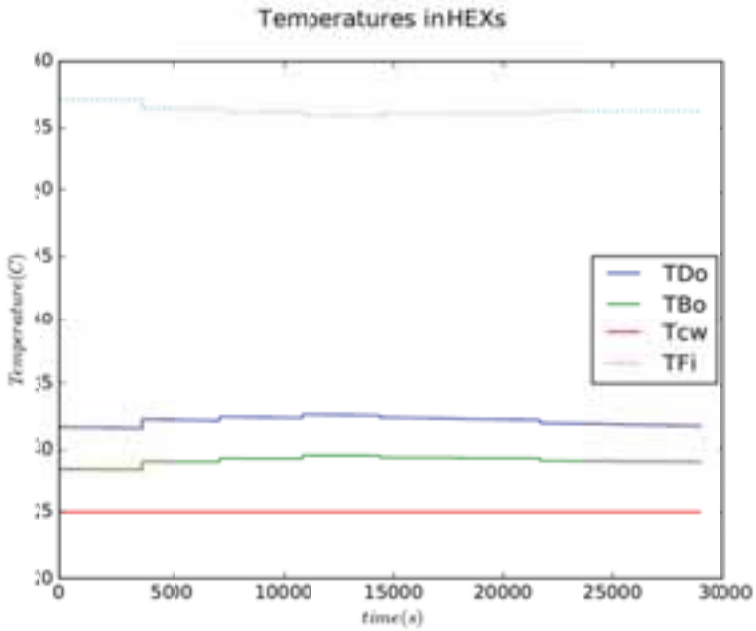

Fig. 12: Temperatures in the heat exchangers of the flows along 8 hours: distilled water at the outlet (TDo), brine at the outlet (TBo), preheating seawater at the outlet (TFi) and feed seawater at the inlet (Tcw)

The third case consists of analysing the influence of the boundary conditions, the feed seawater temperature (T_{CW}) and its salt concentration (X_f) at the inlet of the system, on the distilled water and brine flows at the outlet of the system. Regularly a change in the boundary conditions is applied, details in Table 2.

Tab. 2: Boundary conditions applied in function of time

Hour	Seawater Temperature T_{cw} (^oC)	Salt Concentration X_f (ppm)
1	25.0	41000
2	25.5	42000
3	26.0	42500
4	27.0	43000
5	27.0	43000
6	26.5	42500
7	26.0	42000
8	25.0	41500

The numerical results of the third case are depicted in Figures 13 and 14. The salt concentration of the brine flow (Xb) at the outlet of the unit and the salt concentration of the recirculation flow (Xc) are shown. The salt concentration values tend look for a new steady-state condition along the time, keeping the difference regarding to the salt concentration of the feed seawater at the inlet.

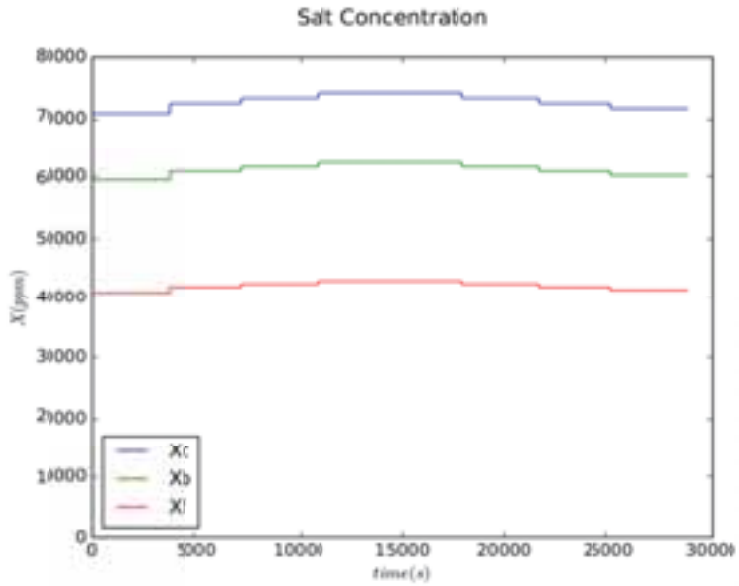

Fig. 13: Dynamic behaviour of the salt concentration in the MVC desalination system

The temperatures of the distilled water, brine and feed seawater flows after pass through the preconditioning heat exchangers are shown in Figure 14. The temperature profiles of the flows depend on the feed seawater conditions (T_{CW}) at the inlet of the MVC desalination unit.

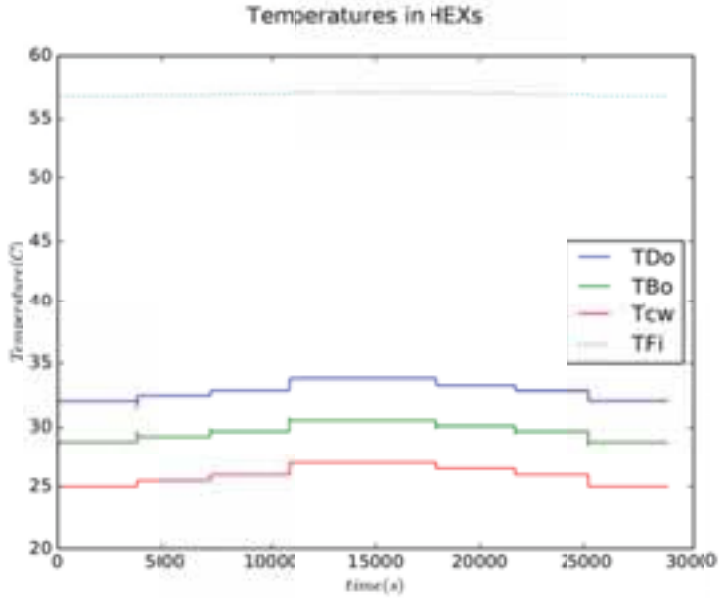

Fig. 14: Dynamic behaviour of the temperatures in the heat exchangers of the MVC desalination system

6. Conclusions

A model to simulate the dynamical behaviour of a MVC desalination unit has been implemented and the numerical results have been presented in this paper. The numerical model proposed is a powerful tool to evaluate the thermal and dynamical performance of the MVC desalination unit working under variable conditions. Three different cases have been simulated with the aim of describing the compressor and MVC desalination unit performance under different conditions of power or boundary conditions.

The mass flows used by the MVC desalination unit depend on the energy used by the compressor during the working period, whilst the temperatures, pressure and salt concentrations into the evaporator/condenser are independent of this value.

The salt concentrations of the flows into the evaporator/condenser depend on the boundary conditions applied at the inlet of the MVC desalination system. The third case shows the variation of the salt concentration of the brine in function of the salt concentration of the feed seawater (X_f).

The temperatures of the distilled water and brine flows at the outlet of the system and the preheated seawater temperature at the inlet of the evaporator/condenser are function of the mass flows used by the MVC desalination unit and depend on the feed seawater temperature (T_{CW}) at the inlet of the precondition heat exchangers.

Abstract

The environmental impact generated by the residential sector on energy consumption is estimated at approximately 40%. Architecture and urban planning practice is on the front line directly applying best-case evidence-based solutions to make the most of conserving and generating energy. The excessive and inevitable growth of cities derived in both high and low rise building in most of urban central areas to accomplish social and regular housing demands. Simultaneously, a sustained development of clean energy production technologies and computer simulation allows for an increasingly more accurate prediction of the potential that the architectural morphology possesses on the production of clean energies. High rise buildings bring together: possibilities of high density housing, daylighting access limitations in low floor apartments and issues related with the exploitation of solar irradiation for renewable energy purposes.

Today's powerful building simulation tools can be leveraged for energy modeling during early design phases and even to shape the morphology of tomorrow's cities. For further reductions in building energy consumption, energy simulations done during conceptual design have potential to impact long term energy use both in architecture and urban planning. This paper reviews early conceptual designs of buildings and their interaction with the immediate built environment looking at the consequences in terms of daylight availability and the potential of irradiation use for clean energy generation.

Keywords: Architectural morphology, Residential housing, Simulation, Daylighting, Renewable energy.

1. Introduction

Planning and Building Codes play a decisive role in regulating the development of urban environments. The regulations of urban planning and environmental management of urban land and other rights should guarantee citizens the right to natural light, as a basic human right. (Bautista, G., 2012).

Building simulation is a powerful tool which can be used at all steps of architectural design complementing and fostering innovations in the field of geometry (Gillchcrist, R., 2010) (Mascaró, J.J.; 2010).

Its predictive capabilities have been reflected in many areas of architectural design and energy assessment of buildings and urban environments. (Ajmat, R. 2008).

This paper seeks to explore the potential energy savings and energy production due to solar radiation under different proposed scenarios: buildings as isolated units and buildings within the urban environment.

That is why, knowing how and to what extent buildings' density of the city affects or diminishes the chances of capturing solar radiation, will allow better planning and generate new appropriate policies for better land use.

2. Methodology

Two study cases of the city of San Miguel de Tucuman, in Northwest Argentina are presented. Particular attention is paid to its central area which does not escape the global trend of massive densification often to the detriment of its environmental quality.

For this study both the global environment and the local level of San Miguel de Tucuman were analyzed in the first stage from the legal and morphological point of view.

The starting point of this methodology is the generation of geometries using appropriate software (Autocad and SktechUp) optimized to work modeling morphological and volumetric scenarios; then processing the incidence of radiation on the surfaces (Ecotect or Revit) and finally the post-processing of results with the aid of spreadsheets and graphic interface (Excel) for the presentation of data.

As mentioned previously two different approaches were taken into consideration:

Case A: Building as a unit complying with social housing requirements

Case B: Buildings as part of the urban grid complying with a particular Code of Urban planning

2.1 Case A:

Building as a unit complying with social housing requirements:

The analysis of case A was based in social housing of two different locations. One located in Tucuman (NW Argentina) -Figure1-the other in Berlin (Germany) -Figure 2-:

Case Study A1.: Tucumán (Argentina)

Figure 1 Left: aerial view of the neighborhood- Right: Picture of one block

The case study selected is the COPIAAT II a neighborhood in the south of the city of San Miguel de Tucumán, Argentina, which was built in 1996 by the Provincial Institute of Housing and Urban Development.

It has 14 blocks of 9 flats each. Each block has 3 levels (lower plan plus 2 storeys) with 3 flats per level.

The average energy demand (ED) for each of the blocks was calculated based on the consumption of each appliance with its approximate power (W) and hours of use (h) per day. The annual ED of each flat is 2991.7 kWh / yr. It is observed that the highest energy consumption corresponds to the air conditioning equipment with a demand of 600 kWh/yr. This implies 49,85 kWh/m2 per year of energy consumption. This is a consideration of a mean value for the same type of units; however, it depends on the level of exposure of its surfaces to the environment and to the different U-values one can consider (or a mean U-value). Notwithstanding, the aim of this study is focused in generating a methodology that cooperates in the first stages of architectural design in the analysis of the link between morphology and clean energy generation potential

Values of annual ED:

Energy demand per flat 2991.7 kWh/yr.

Energy demand in communal spaces 522 kWh/yr

Total energy demand per block 27447 kWh/yr

Case Study A.2: Housing Block Altoner Strasse 4-14 - Berlin, Germany

Architect: Oscar Niemeyer

Location: Hansa Viertel, Berlin, Germany

Figure 2 Left: aerial view of the neighborhood- Right: Picture of the block

"In response to Stalin Allee, a street-neighborhood built in East Berlin with a strong ideological load, Hansa Viertel, a neighborhood designed through an international competition, emerged in West Berlin. It is proposed first of all to give an answer to the question of homelessness in Berlin. The answer must be in the area of housing design, but also in the area of construction and use of new materials.

The organization of the competition invites many German and foreign architects to carry out the projects, with the aim of making an international exhibition of architecture, in the style of the Weissenhof. With this approach and the specific problem of housing, Hansa Viertel is a laboratory in which the proposals experience all types: towers, blocks and detached houses with and without patio. The general arrangement is characterized by the rigid orientation of the buildings, both North-South and East-West, in order to obtain good lighting in all rooms. The proposals of linear blocks are of great interest, highlighting the projects of Frizt Jaenecke and Sten Samuelson, Oscar Niemeyer, Egon Eiermann, Pierre Vago and Walter Gropius. (Moya Gonzalez et al, 2015)

For this case, the energy demand was taken from the one stipulated by the Ministry of Environment of Germany

Values of annual ED: (For social housing dwellings considering water heating with electricity)

Flats for 2 inhabitants with heating 2800 kWh / yr per flat. That means 46,66 kWh/m2 and per year

Flats for 3 inhabitants with heating 3900 kWh / yr per flat. That means 43,33 kWh/m2 and per year

Flats for 4 inhabitants with heating 4400 kWh / yr per flat. That means 40,00 kWh/m2 and per year

Energy Estimations

Flats Type B (2) x 12 = 12 flats x 2800 kWh / yr = 33600 kWh / yr

Flats Type C (3) x 54 = 54 flats x 3900 kWh / yr = 210600 kWh / yr

Flats Type D (4) x 12 = 12 flats x 4400 kWh / yr = 52800 kWh / yr

Total energy demand = 297000 kWh / yr

Methodology for Case A

The study of morphological alternatives linked to energy possibilities is the basis for an environmentally responsible and energy efficient architecture. The shape of a building should not be indifferent to the potential for energy production from renewable sources. Recent computer tools allow new ways of conceiving a building from a morphological perspective. In this study the first step consisted in a geometric analysis in order to build the base case geometry in a friendly interface which can interact with different software (Sketch up). Later the Rhinoceros 3D Software together with the Grasshopper Plug-In make it possible to import the building model and work its morphology parametrically, that is to say, using generative algorithms. The main interface for algorithm design in Grasshopper is the node-based editor. The information goes from component to component by means of cables that connect outputs with inputs.

Starting from the traditional block studied, formal alternatives are proposed, maintaining the number of units and surfaces of each one. A systematization of the simulation process has been studied in order to automate the modeling and the process to obtain output data. This methodology can be applied to various case studies of any city. Once representative geometries of each scenario are generated, the potential of solar radiation on top of the roof of buildings is determined using a graph computer model that works on the basis of hourly weather data. The plug-in Insight was used in this case. This methodology allows us to try different geometries for the block during the very first steps of design, analyzing the potential of solar radiation and, consequently, the potential for the production of clean energy. The whole process is described in Figure 3

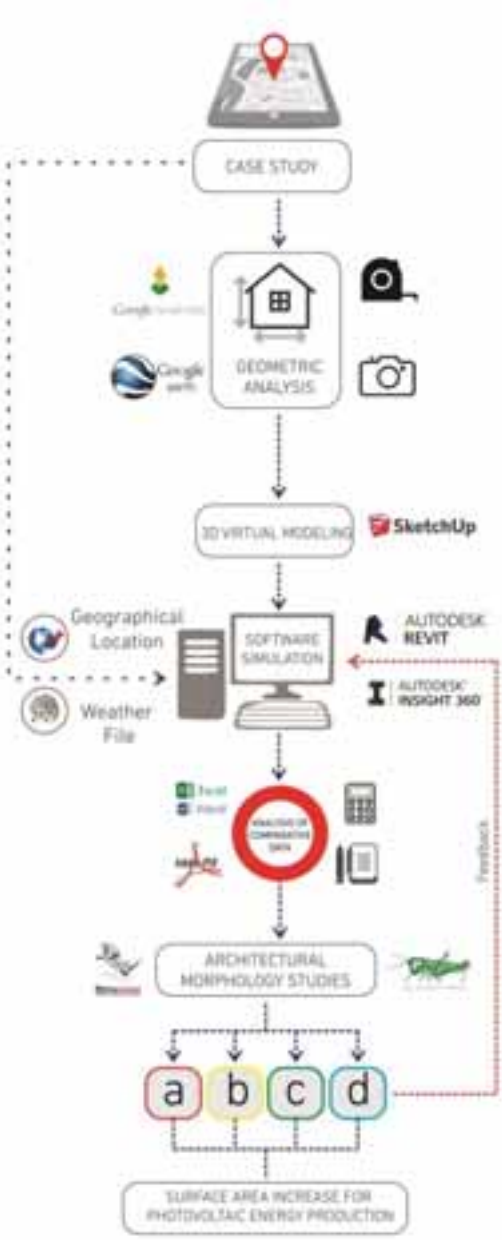

Figure 3 Scheme of the simulation process for case A

Results for Case A

The results of the simulations show the incidence of radiation in different surfaces Figures 4 and 5. However, since the horizontal surfaces are most suitable for the placement of photovoltaic panels, they have been taken as reference in order to make a comparison of the solar-based energy production potential. The alternatives analyzed show the increase of production surfaces that could be obtained from different morphological operations. In that sense, it has been taken as an indicator of the percentage of coverage of the energy demand of the housing complexes under study. Comparatively it can be observed that in the case of Berlin can go over 300% which makes it possible to cover energy demand reaching almost 100%. In the case of Tucumán with smaller scale housing blocks carrying out the same morphological operations only increase up to 65% of the surface. However, due to the potential of irradiation of the climate of Tucumán the possibilities of coverage of the demand are significantly greater reaching 150% coverage of it. In fact the base case has the possibility to cover the excess demand.

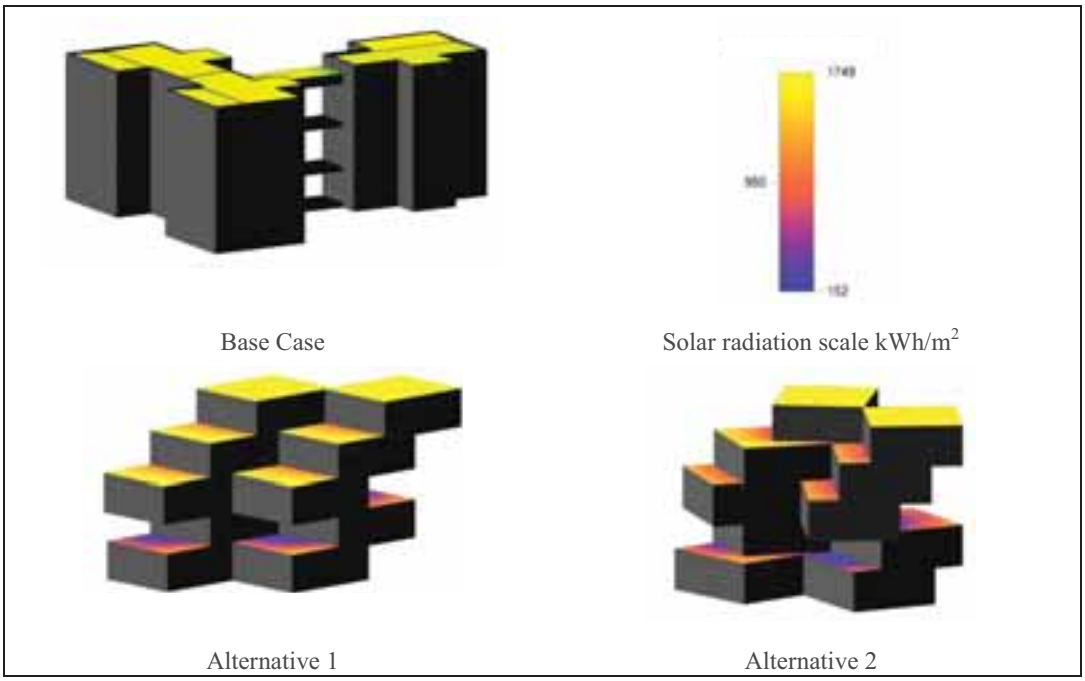

Figure 4: Results of radiation due to morphology exercises for Tucuman-Argentina

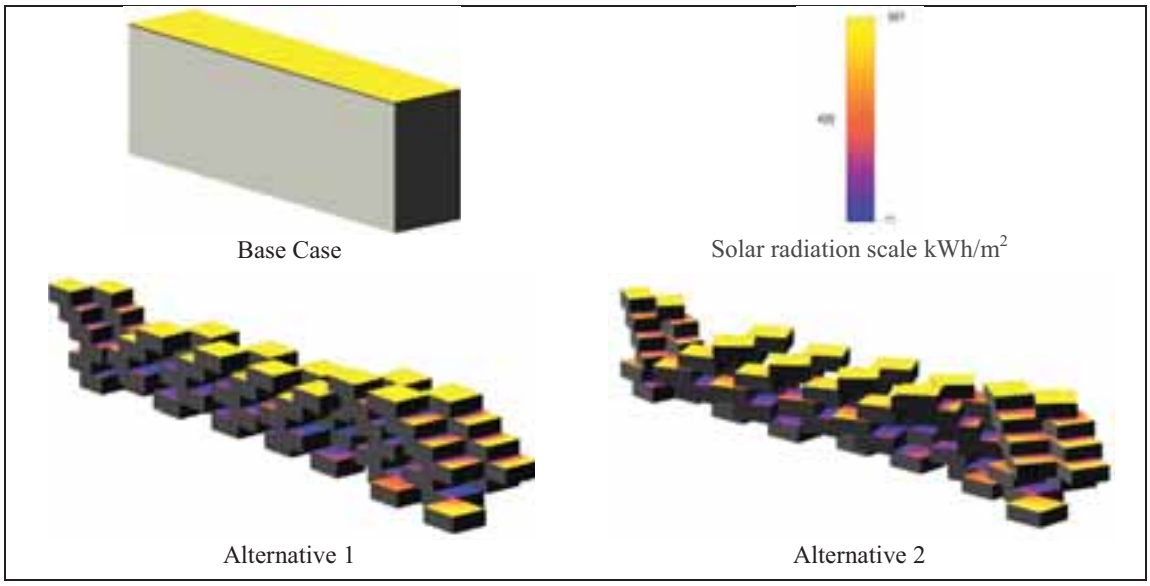

Figure 5: Results of radiation due to morphology exercises for Berlin-Germany

	CASE	SURFACE	CUMULATIVE RADIATION	ENERGY DEMAND	ENERGY PRODUCTION	PERCENTAGE OF ENERGY DEMAND FULFILLED

Figure 6: Summary of annualized radiation due to morphology exercises for both locations.

2.2 Case B:

Buildings as part of the urban grid complying with a particular Code of Urban planning

This exercise aims to explore the potential of energy savings and the production of energy from solar radiation with the application of the current Code of Urban Planning of Tucumán under different scenarios proposed. Solar energy plays an important role in replacing fossil fuels to generate electricity without emitting pollutants and without the need for fuel. (Li, 2014).

For this study the current environmental legislation was analyzed in the first stage in order to know how and to what extent the density of construction of the city affects or diminishes the possibilities of capturing the solar radiation, as well as the generation of new appropriate policies for a better use of the land. For example, we consider the morphology of a solar facade as a building component that is feasible to generate energy and allows the entry of daylight into the interior spaces, a key aspect of the design of such facades is the determination of total energy benefits. (Li & Lam, 2008).

This work has a previous data base generated and processed to be able to obtain the different scenarios proposed (Ajmat et al, 2011). The sector to work is selected, the morphological proposals are generated and the simulation of surface radiation is carried out. The starting point of this methodology is the generation of appropriate software geometries; then processing the incidence of radiation on surfaces and finally post-processing the results with the help of spreadsheets and graphical interface for data presentation. (Hui,2001) (Mesa et al,2010)

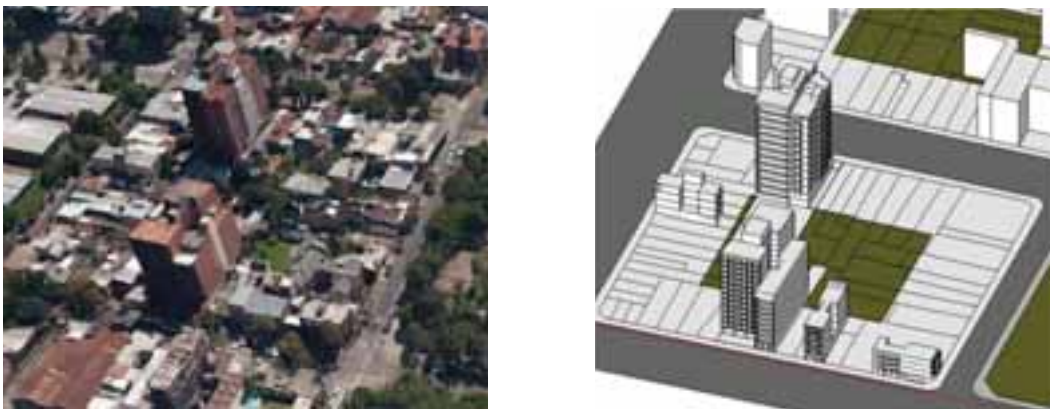

Figure 7: Left: Aerial view of urban sector for simulations - Right: Sketch up model to be exported for calculations.

Methodology for Case B

The proposed Simulation Process (Figure 7) is based on a sequence of data that can be modified at different points, leading to the obtention of data from different scenarios or typologies simultaneously. It analyzes in a first step the basic information of the grid of the city, this information is checked against what the Urban Planning Code proposes for each sector of the city and through a processing of it with different software. It can provide a number of scenarios necessary to carry out studies of the morphology of the city or a selected city sector. Once the necessary information is obtained for each scenario, it is modeled in both 2D and 3D (at this point there is a Loop regarding modifications that can be made on the information data base of the model that result in automatic changes on the 3D morphology of it). Finally the analysis with the calculation of solar radiation and shadows of the 3D model is performed using the appropriate climate file and its geographic location. Once the results are obtained we can review the initial model and make modifications to obtain different morphological alternatives for the same scenario and thus compare different performances.

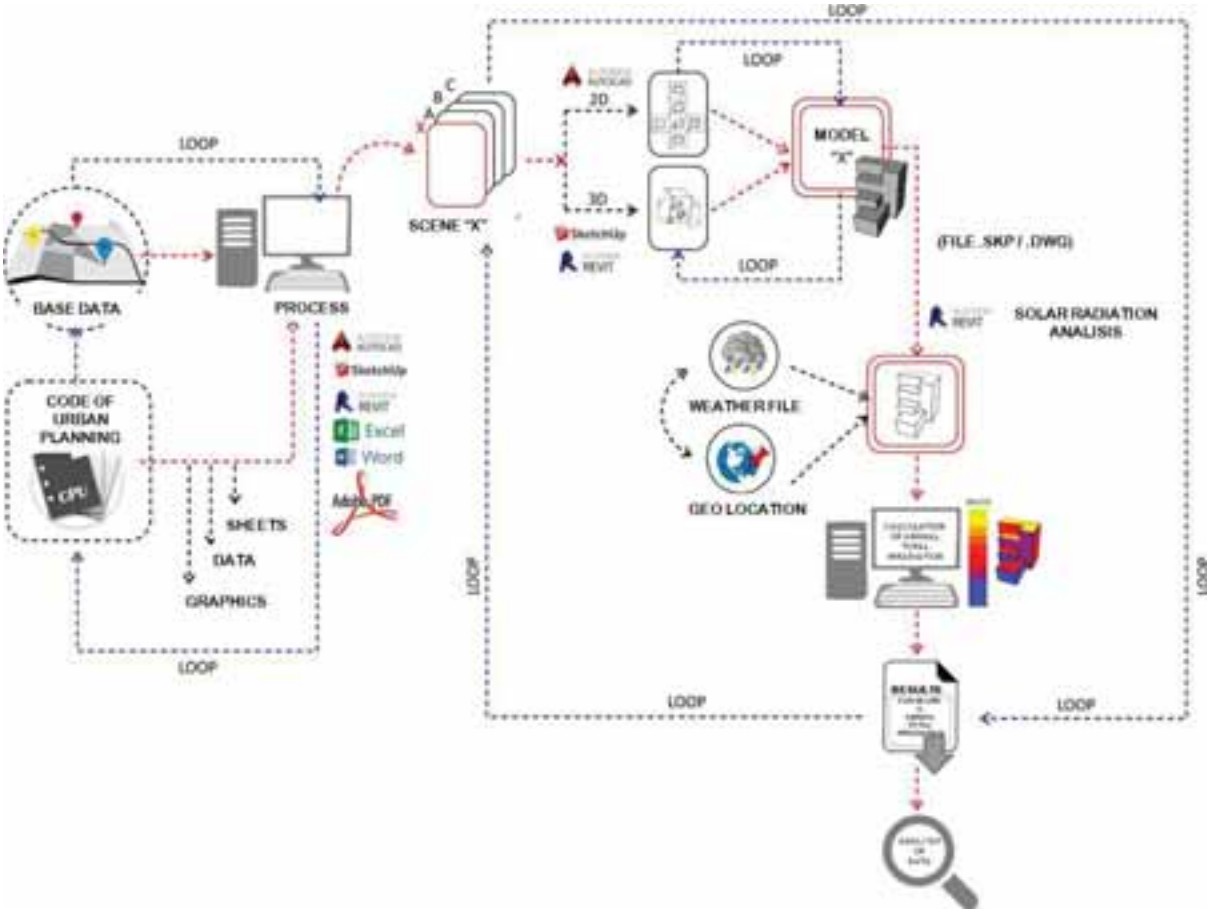

Figure 8 Scheme of the simulation process for case B

Two scenarios were simulated in order to analyze the potential and limitations of the urban densification process: Maximum built surface until the lateral limits and therefore a certain height can be reached. This was identified as: Scene 1. Minimum built surface with maximum height. This was identified as: Scene 2.

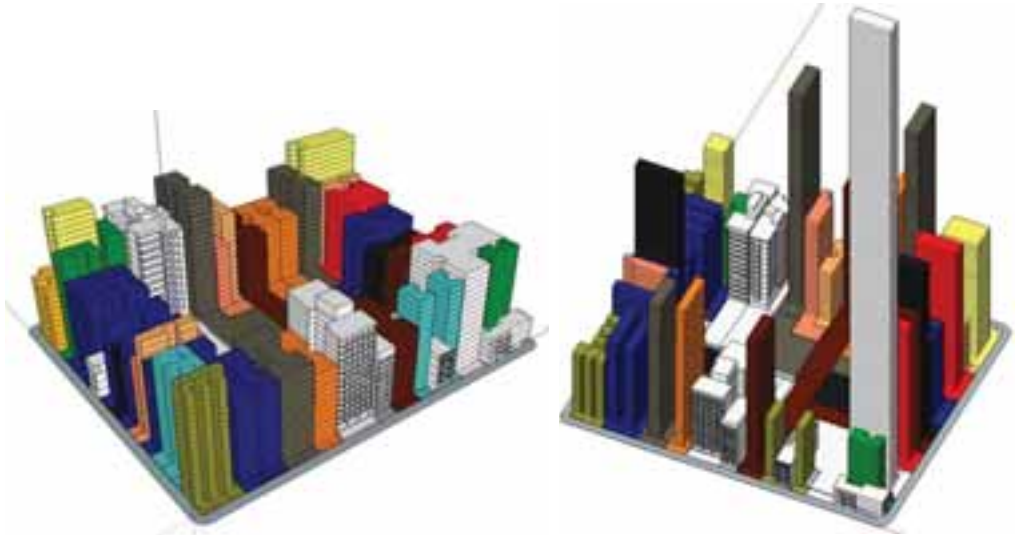

Figure 8 Left: Scene 1 Maximum area constructed minimum height-Right: Minimum area constructed maximum height

Results for Case B

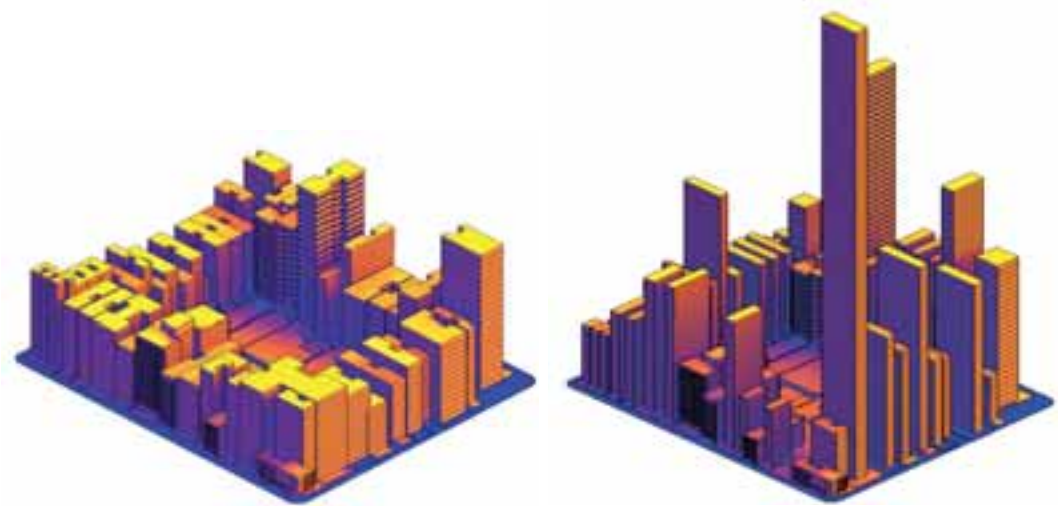

Figure 9 Left: Results of Solar Radiation for Scene 1 Right: Results of Solar Radiation for Scene 2

Based on this modeling, geographic and climate data are loaded. Then it proceed to the calculation of irradiation. As for the area in square meters considered for both cases we observe that Scene 2 is a 14% greater in surface than Scene1. This consideration is made since a greater surface can accumulate a higher radiation amount, however the obstructions due to the morphology of the buildings must be considered too. When analyzing the results Scene 2 exceeds Scene 1 by 6%with respect to amount of accumulated solar radiation per square meters. We can say from these comparisons that for the cases studied Scene 2 exceeds Scene 1 by 19% with respect to its total annual irradiation capacity from the point of view of morphology (Table 1).

Table1: Results comparison between scenarios

	Scene 1: Minimum Height	**Scene 2: Maximum Height**	**Differences %**
Total study surface area [m^2]	506116.57	587776.40	13.89
Study average insolation value [kWh/ m^2]	224.34	238.53	5.95
Total study insolation value [kWh/yr]	113541961.94	140201310.76	19.02

3. Discussion

Case A

The influence of the morphological dispositions can be observed in the first place in the possibilities of extension of the surfaces exposed to the radiation. It is also observed that the type of morphological arrangement, even if it enlarges the surface, can generate shadows thrown between parts of the same building when moving from a compact to a more disaggregated shape. In any case there are direct consequences on the potential of solar energy exploitation. Terrestrial coordinates and the local climate characteristics also influence the availability of the solar resource. It is for this reason that the role of the designer of architectural form must be appropriately combined with local site and local climate considerations. Since we have limited ourselves here to the analysis of the horizontal surface, the behavior of the other surfaces of the architectural form are still to be experimented in order to develop the shape of future buildings..

Case B

It is evident that both the shape and height of each building and the ordering between plots influence the capacity of a city to make the most of solar energy. Urban building codes fulfill a very specific role; the future possiblities of production of clean energy will comply with it and consequently the reduction of carbon dioxide emissions (De Schiller, 2002). In Case B two extreme scenarios of application of the building code of San Miguel de Tucumán were studied. The study of the minimum height scenario is perhaps the most feasible due to the technological possibilities, since the case of maximum height does not seem to be possible execution in all the plots. However, using the minimum and maximum values allowed by the Urban Planning Code of San Miguel de Tucumán, make it possible to question this code, since when generating the scenarios, the morphology of the resulting set of buildings does not seem to come from a basis of criteria, norms and guidelines to be taken into account to improve habitability and solar conditions, but, to restrict densification, raising the problem of land use from the real estate point of view. Thus, the possibilities offered by the technology and the characteristics of the ground where these buildings are located, and not the regulations provided by codes and ordinances, which actually limit urban growth, which give rise to the urban morphology resulting from the city. But the methodology which has been produced would allow simulating an unlimited number of combinations and probabilities with a costless time investment. This would allow us to experiment with new regulations within the code or to test the possibilities of collecting solar energy from a new building to be built in a given context.

4. Conclusions

A methodology of evaluation of the architectural and urban morphology in relation to the potential use of renewable energy has been presented. It is valuable at the scale of building and city in order to assess the influence that the form has on the availability of surface for the capture of solar energy. In both cases - building and city - morphological operations allow designers to increase the possibility of a greater and better use of solar energy whether this is by surface increase or by the study of the shadows that buildings throw each other (Kamal & Smiriti, 2014). From the results obtained we can verify the importance of urban morphology and therefore the influence of city planning codes in terms of the availability of natural light and the potential use of irradiation for energy generation.

This approach arises from the search for strategic solutions, given the need to create conditions of habitability in areas of high density population as well as in the interior and exterior of buildings; which today seems to lack effective solutions. Therefore, a simplified process that facilitates consideration of the morphology and size of future constructions is a valuable goal sought by designers. The possibilities offered by simulation as a prediction tool are significant; energy simulations carried out during the initial stages of design have the potential to impact on long-term energy consumption. On the other hand, we are challenged as architects of the cities of the coming century challenging formal innovation and creativity in relation to the interaction between buildings.

A systematic simulation process to analyze the consequences of densification, an output of the current building trends, applying a methodology to investigate the real effects of the implementation of the urban planning codes enable.

- The analysis of the production potential of clean energy.

- Pre visualization and study of the habitability of particular situations (courtyards within high-rise buildings).

- To propose new legislation that addresses problems of habitability and sustainability.

-To challenge the established morphological paradigms of low and high rise buildings.

Abstract

This paper presents a mobile hardware-in-the-loop (HIL) test bench that has been developed to simulate a solar assisted cooling and heating system for residential buildings in hot climates. The main component of the system is a low cost uncovered solar collector that is used for the production of night radiative cooling or daytime heating energy (hardware component). The collector was designed for low cost housing projects in Egypt, whose cooling and heating demand was modeled using the program TRNSYS (software component). The design and construction of a mobile HIL test bench is presented together with some performance results from the HIL-tests in cooling mode.

Keywords: HIL test bench, space heating and cooling, solar absorber, radiative cooling

1. Introduction

Low cost renewable heating and cooling systems are of prime importance for developing nations with high population densities and limited financial resources. As an example, Egypt is one of the fastest growing countries worldwide, the population increased from 21 million in 1950 to 98 million in 2017 and is currently ranked on place 14 by total population size worldwide. For the year 2050 a total population for Egypt of 153 million it is expected (UN, 2017). Due to this fast population increase, the state of Egypt is facing many social and economic problems. Providing decent and affordable housing for the lower and middle class and the adaptation of the energy system will be two of these challenges for the future.

During the past few years, Egypt has been suffering from recurrent electricity cut-offs, mainly in summer because of the large cooling demand (Elharidy et al., 2013). The national demand has been exceeding the available produced power from generation plants since 2011.

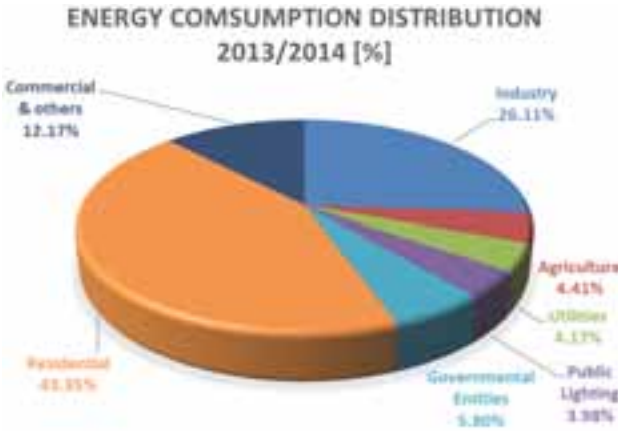

Fig. 1: Electricity-shares sold in Egypt (on all voltage levels) according to the purpose of usage 2013/2014 (Egyptian Electricity Holding, 2014)

Fig. 1 shows the electrical energy consumption distribution among the different sectors in Egypt. The greatest share of the total nationally generated electricity is consumed in residential buildings (43.4%). When considering only the medium and low voltage levels, the residential consumption reaches 51.3% of the total energy sold from the national electricity distribution companies (Egyptian Electricity Holding, 2014).

Urbanized dense cities lead to higher local ambient temperatures. As a result of this, the use of air-conditioning (AC) units for cooling has immensely increased in Egypt. Conventional AC units represent the major energy consumption of the residential energy demand (Xing Lu et al., 2016, Attia et al., 2012). On the other hand, in winter electric water heating accounts for large shares of electricity demand, even in warm-climate countries. Nowadays, cooling in residential buildings in Egypt is provided by not very efficient split units, which number grows very rapidly (Attia et al. 2012). This leads to frequent electricity cut-offs in summer (Elharidy et al., 2013). Integration of renewable energies to the space cooling and heating in residential buildings could be an environment-friendly and sustainable solution.

Within the research project NightCool, funded by the German Federal Ministry of Education and Research (BMBF), a concept for a low-cost system for heating and cooling applications was developed and simulated in detail.

The developed system consists of uncovered solar collectors for the energy production and an activated ceiling for the energy distribution. Fig. 2 shows the principles of the energy supply system for direct cooling (left) and direct heating (right). The space cooling is achieved at night by circulating the heat transfer fluid in the collectors (radiative cooling) while the space heating is provided during the day by converting the solar energy into useful heat. Since these collectors are not expensive, such a heating and cooling system results to be low-cost. The advantages of such a simple system lie in simple installation and low energy costs (Eicker and Dalibard, 2011), which is very important for solar thermal systems in order to achieve a higher market penetration (IEA SHC Task 54).

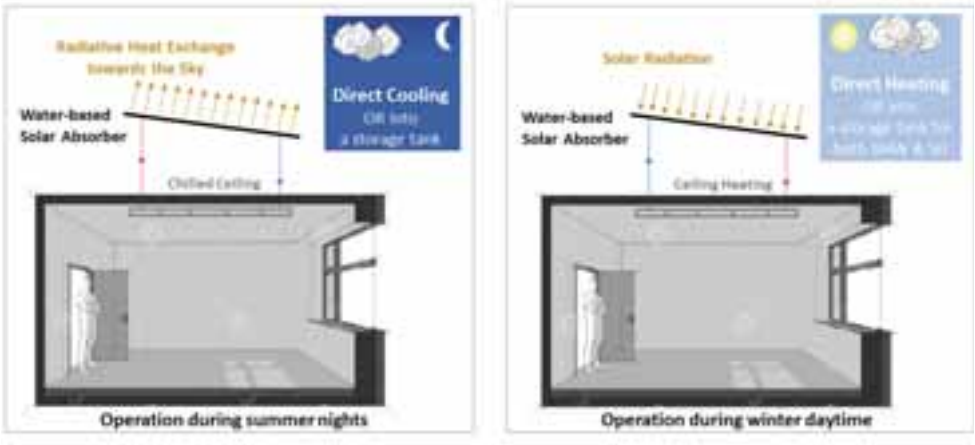

Fig. 2: Energy supply system that provides space cooling in summer (left) and space heating in winter (right)

In order to investigate the potential and limits of such a system, a mobile HIL test bench has been designed and constructed. The present paper aims to show the advantages of using such a HIL environment show its limitations and give some insights for further improvements.

2. Motivation to build a mobile HIL test bench

2.1. Motivation to build a mobile HIL test bench

As before mentioned, the project NightCool aimed to develop a low-cost system for heating and cooling applications for Egyptian climate conditions. The estimation of the achievable return temperatures as well as the cooling power by using solar collectors for radiative cooling applications needs adequate physical collector models.

ISO 9806:2017 specifies test methods for the thermal performance characterization of fluid heating collectors for steady-state and quasi-dynamic conditions (ISO 9806, 2017). Based on this test method parameters for the parameterization of collector models within the simulation environment TRNSYS such as Type 203 (PVT collectors) (Bertram et al., 2011) or Type 1289 (flat plat collectors) can be determined. The deviation between measured collector power output on a test stand and simulated power can vary between night and daytime (Cremers et al., 2015). Especially for night time radiative cooling, the collector parameters determined according to ISO 9806:2017 are not sufficient enough to develop control strategies only by using a simulation model.

The motivation to build the HIL test bench in the NightCool project can be summarized as follows:

- The thermal performance of solar collector at night cannot be modelled accurately with existing available models so that their performance needs to be measured and not simulated.
- Test new market available solar thermal collectors (which thermal performance is not specified by the producer)
- Test the integration of such collector into different systems and for different buildings construction (light or heavy) and achieve a realistic estimation of the dynamics of the system, scalable and adaptable to different kind of loads etc.
- Dimension the system components and optimize the control before it can be installed on a bigger scale

Following table summarizes the main functionalities of the mobile HIL test bench and the benefit by setting up a small scale test environment.

Tab. 1: Main functionalities of the mobile HIL test bench and the need and benefit

Functionality	Need and benefit
Conduct collector performance tests under real conditions and conduct tests of solar collectors at night time	Various solar collectors of different constructions from different producers (basically swimming pool absorbers are recommended) can be tested and a collector with a highest thermal potential and best integration suitability (easily connected hydraulic connections, appropriate mechanical properties, etc.) can be defined For the cooling application, it is essential to know also the cooling potential of different solar collectors. This information is missing in technical data sheets, it can be obtained experimentally.
Analysis of the dynamic behaviour of system components	It is important to understand the behaviour of the solar collector and the building to define optimal control algorithms.
Development and test of control algorithms for heating and cooling systems depending on the defined system	The control algorithm of a system can be easily implemented in a simulation environment such as TRNSYS either for cooling or heating application. An optimal set of parameters such as the set point temperatures to turn on or of the system.
Optimize building construction elements so that they are appropriate for the suggested cooling/heating system	By changing building parameters in the building model on the simulation environment an optimal distribution system can be defined (activated heating and cooling ceiling, floor heating or others)
Estimation of achievable thermal comfort e.g. temperature and relative humidity and analysis of the activation capability of building mass to act as energy storage through different distribution systems e.g. activated ceilings	Direct feedback from the simulation model helps analyse comfort parameters and gives insight into the architectural concept of active and passive measures (active and passive building design).

3. Mobile HiL test bench

3.1. Working principle and construction

The mobile HIL test bench has been designed and constructed within a research project aiming to develop a low-cost space heating and cooling system for Egyptian climate conditions. The working principle of the HIL test bench (Figure 3) is based on hardware-in-the-loop (HIL) simulation, a technique that is used in the development and test of real-time embedded systems. The mobile HIL-Box consists of an uncovered solar collector (hardware component) and a building simulation model (software component). It enables to conduct real-time measurements and simulations to calculate at each time step the dynamic change of the system parameters such as room temperature and ceiling temperature, as well as the cooling or heating power. The solar collector is replaceable, so that different solar collectors can be tested. The building and the distribution system are defined in the simulation environment TRNSYS (www.trnsys.com). Thus, an optimal solar system combination, solar collector (collector-type, -size, etc.) and

building properties (construction, size, materials, etc.) can be chosen. In other words, the HIL test bench enables to optimize the building and the system at the early planning stage.

The main weather data (ambient temperature T_a, relative humidity RH, horizontal global irradiance G_{hor}, net long-wave radiation G_L and wind velocity w) and system parameters (inlet and outlet temperature T_{in} and T_{out}, flow rate $\dot{m}$) are measured and acquired by several ethernet input modules connected with the software LabVIEW. The measured data are given as inputs to the TRNSYS building model which calculates the building behavior and the system response, such as room temperature T_{room} and the outlet temperature of the cooling ceiling T_{cc}. In the hydraulic system the simulated T_{cc} is the same as the inlet collector temperature T_{in}. It is read in LabVIEW and transmitted as set-point temperature via an analog output module to the temperature control unit (TCU). The TCU regulates then the fluid inlet temperature of the solar collector, i.e it sets the inlet temperature equal to the T_{cc} Based on the temperature difference ($T_{in} - T_{out}$) and the fluid flow rate the cooling or heating power of the solar collector can be calculated.

$$Q = \dot{m} c_p (T_{out} - T_{in}) \qquad \text{(eq. 1)}$$

where c_p is the fluid heat capacity.

In the next step, the collector response and the weather data are measured and the procedure is repeated (see Figure 3).

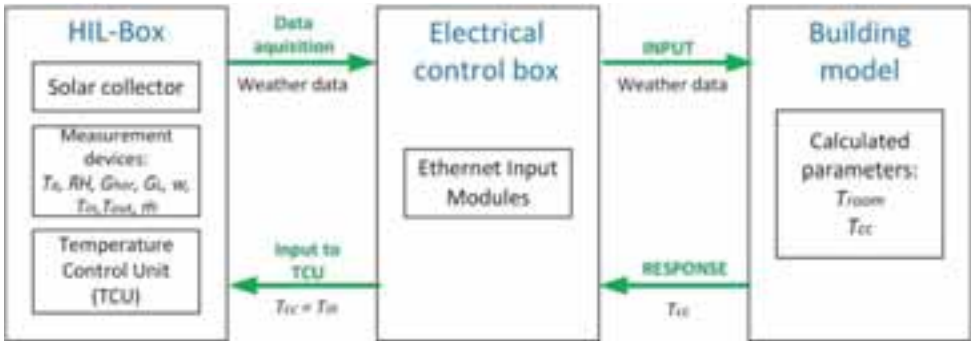

Fig. 3: Working principle of the HIL test bench

The measuring box is shown in Figure 4 and its main components are listed in Table 2.

Tab. 2: List of the main components of the HIL test bench

Number	Component	Manufacturer
1	Solar collector, length 1,8 m	AQSOL
2	Temperature control unit Variocool VC 2000	Lauda
3	Pyrgeometer LP PIRG 01	Delta Ohm
4	Pyranometer LP PYRA 02	Delta Ohm
5	Anemometer "Windgeber – compact" 4.3519.00.161	Thies Clima
6	Temperature and relative humidity sensor HD9008TRR	Delta Ohm
7	Air vent valve	Solar
8	Temperature sensor	Omega
9	Ball valve	-
10	Valve Motor	Oventrop
11	3-way diverter valve Tri-M TR	Oventrop
12	Magnetic inductive flow sensor induQ	SIKA
13	Flexible pipes	-
14	Copper tubes	-
15	Roller Shutter	Turtle24
16	Electric control box	Consists of many components

Fig. 4: HIL test bench: a) general view closed, b) general view open, c) and d) weather station, e) hydraulic system, f) electric control box

The simplified hydraulic scheme of the HIL test bench is shown in Figure 5. The solar absorber is connected to the temperature control unit Lauda and the thermal fluid, forced by the pump, circulates through the absorber. The flow rate is regulated by a valve with motor. The valve can be partly closed to reduce the flow rate. When the valve is closed completely, there is no flow through the absorber.

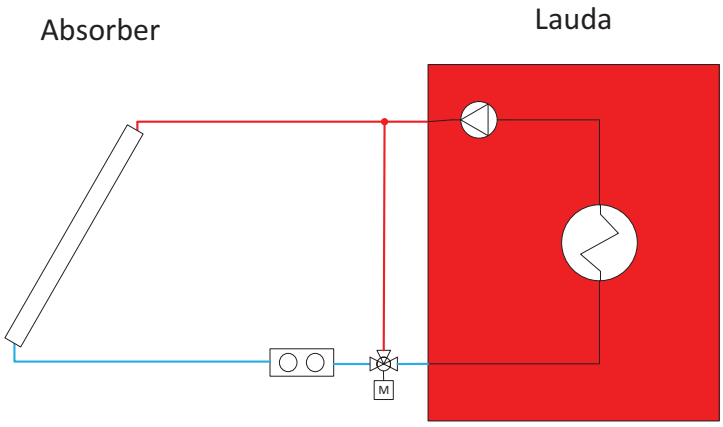

Fig. 5: Simplified hydraulic scheme of the HIL test bench (Lauda is the temperature control unit)

3.2. Data communication

The coupling between LabVIEW and TRNSYS requires a data communication between two softwares, which is achieved by the means of ASCII files (text files read and written by both programmes). The different steps of this communication has been programmed in LabVIEW and are shown in Figure 6.

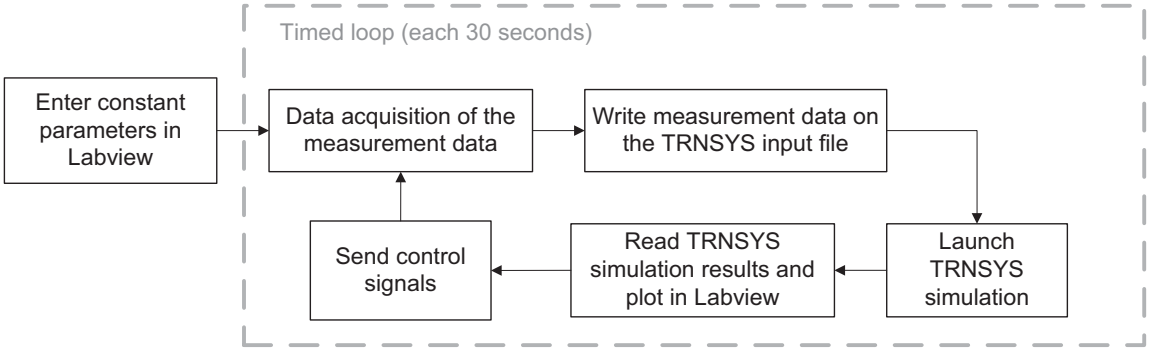

Fig. 6: Data communication steps between Labview and TRNSYS for the HiL configuration

In the first step, the parameters which remain constant during the whole HIL test have to be entered by the user in the LabVIEW graphical interface in order to define the system size as well as the main control parameters. In addition the path locations of the necessary different files have to be defined.

In the second step, the measurement data are acquired in LabVIEW via the I/O modules and written in a ASCII file to be read in TRNSYS. The data required by TRNSYS are listed in Table 3.

Tab. 3: Data transferred from LabVIEW to TRNSYS

Variable	Name	Unit
Ambient air temperature	Tamb	°C
Ambient air relative humidity	RH	%
Horizontal solar irradiance	Gh	W/m²
Effective sky temperature	Tsky	°C
Collector outlet fluid temperature	TcolOut	°C
Collector mass flow rate	mdotCol	kg/h
Collector aperture area	Acol	m²
Specific heat of the collector fluid	cp	kJ/kgK
Density of the collector fluid	rho	kg/m³
Pipe diameter	dpipe	m
Pipe length	Lpipe	m
Building orientation	TURN	°

Then the TRNSYS program is run and the LabVIEW program stops until the simulation is finished. At the end of the simulation, the main results are written by TRNSYS in a text file, read by LabVIEW and shown for visualization (see Figure 7).

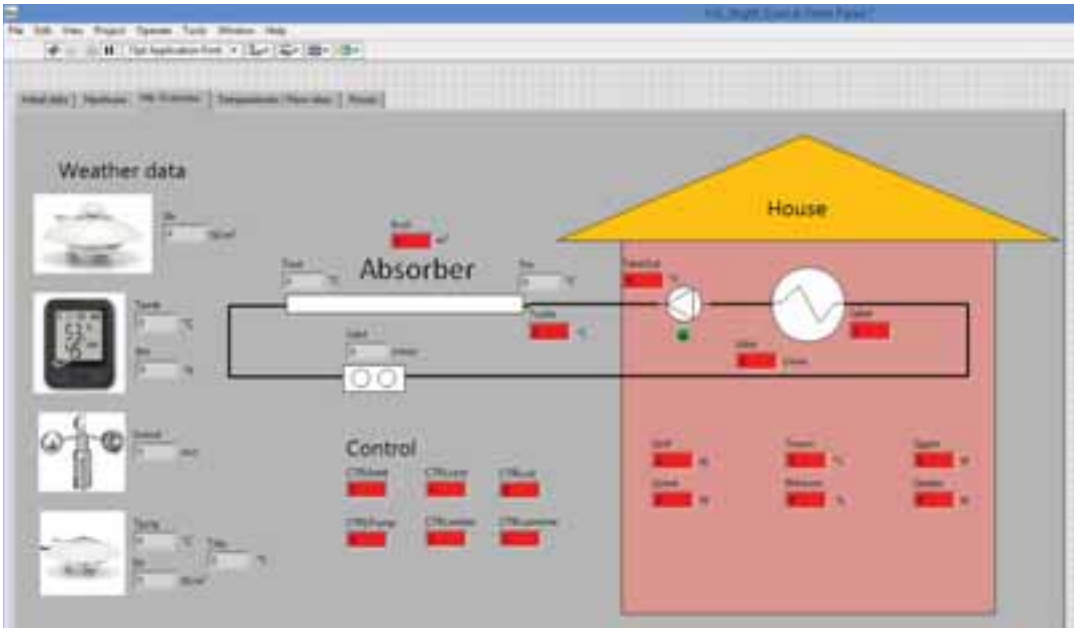

Fig. 7: Screenshot of the HiL visualization in Labview (grey: measurement data, red: simulated data)

The data that are passed from TRNSYS to LabVIEW are listed in Table 4.

Tab. 4: Data communicated from TRNSYS to LabVIEW

Variable	Name	Unit
Outlet fluid temperature of the building heating/cooling distribution system	TdistOut	°C
Collector inlet temperature (after pipe)	TcolIn	°C
Building room temperature	Troom	°C
Control signal of the pump	CTRLpump	[0/1]
Heating/cooling power transferred to the building (+/-)	Qdist	W
Relative humidity of room air	RHroom	%
Infiltration gains	Qinf	W
Ventilation gains	Qvent	W
Radiative internal gains	QgainRad	W
Convective internal gains	QgainConv	W
Total solar radiation absorbed at all inside surfaces of zone	Qtsabs	W
Control signal heating	CTRLheat	[0/1]
Control signal cooling	CTRLcool	[0/1]
Control signal collector	CTRLcol	[0/1]
Control signal season	CTRLseason	[0/1]
Control signal winter	CTRLwinter	[0/1]
Control signal summer	CTRLsummer	[0/1]

Depending on the simulation results, the appropriate control signals of the inlet temperature to the solar collector and the flow rates are sent via the I/O modules.

4. Example of measurement results

In this section, some results obtained in cooling mode with the developed HIL test bench are shown exemplarily. The test bench has been operated for commissioning tests during one week between the 12th and the 19th of June 2017 for a typical Egyptian building and under the climate conditions of Stuttgart.

4.1. Constant parameters

The main constant parameters assumed for the test of the measurement box are summarized in Table 5.

Tab. 5: Main constant parameters

Parameters	Value	Unit
Collector area	70	m²
Fluid density	1043	kg/m³
Fluid specific heat	3.675	kJ/kgK
Cooling set point	22	°C
Activated ceiling area	114	m²
Initial building temperature	23.5	°C

4.2. Weather data

Figure 8 shows the main measured weather data during the considered period: the ambient temperature T_{amb}, the sky temperature T_{sky} which is calculated with the help of the downward longwave radiation measured with the pyrgeometer and the global irradiance on the horizontal plane G_h.

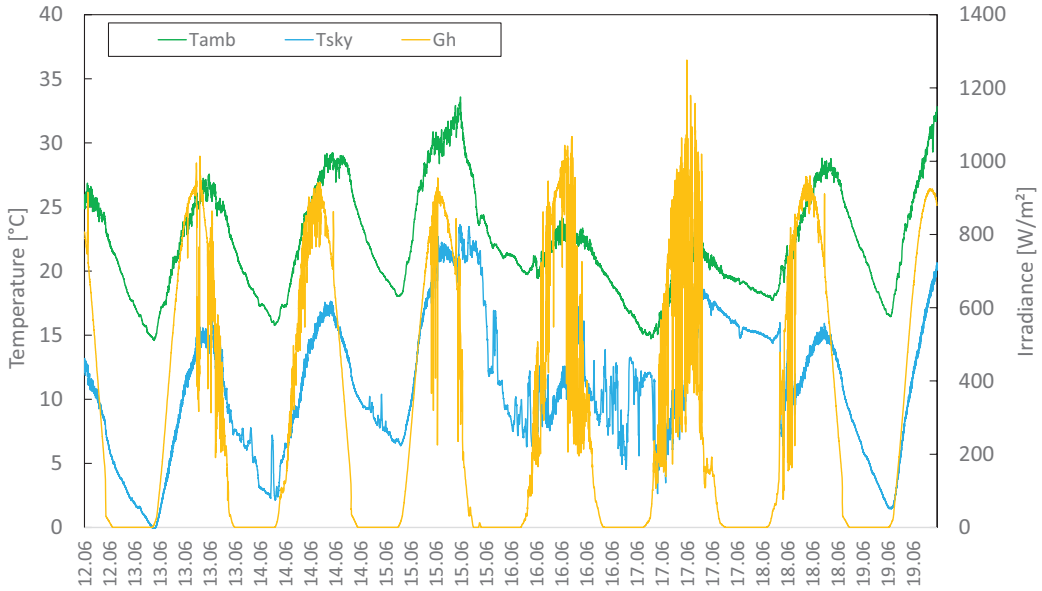

Fig. 8: Main weather data during the measurement period

4.3. Collector operation

Figure 9 shows, in addition to the ambient and sky temperatures, the main collector measured values: the inlet and outlet temperatures T_{in} and T_{out} as well as the volumetric flow rate V_{dot}. The collector is operated in cooling mode, i.e. at night according to a defined control strategy.

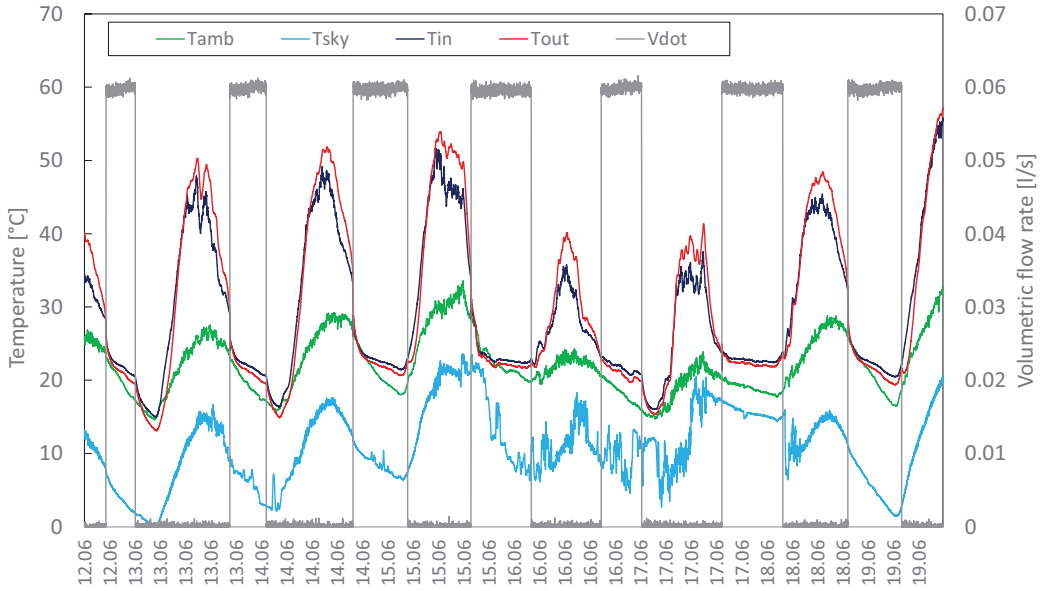

Fig. 9: Collector operation during the measurement period

4.4. Building behavior

Figure 10 shows the simulated building temperature T_{room}, the collector specific power $Q_{dotColSp}$ transferred to the building, as well as the total building specific gains $Q_{dotGains}$. The collector specific power is based on the collector area (70 m²) whereas the building specific gains are based on the apartment floor area (115 m²). $Q_{dotColSp}$ is defined positive when cooling is provided to the building. $Q_{dotGains}$ includes the internal gains, the solar gains, as well as the ventilation and infiltration gains.

It can be seen that the building temperature T_{room} increases suddenly when the collector pump is switched ON at the beginning of the night. This is due to the still hot fluid which is in the pipes and the collector and is pumped to the building causing a temperature increase in the room. This can be easily solved by appropriate changes on the control parameters.

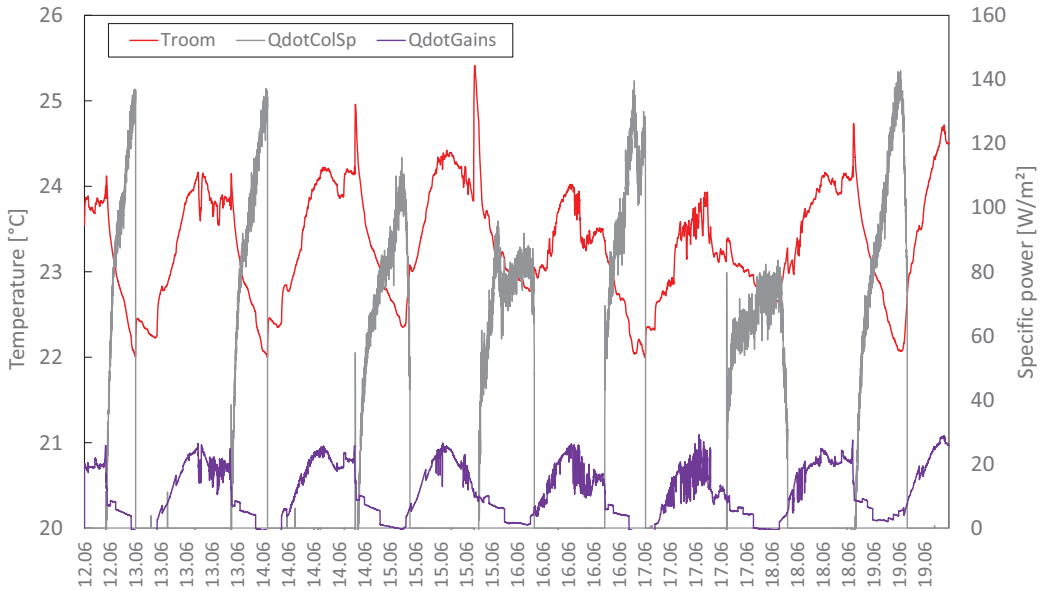

Fig. 10: Main building results during the measurement period

In order to see the influence of the investigated system on the building temperature, a reference system (i.e. without collectors) has been simulated. Figure 11 shows the room temperatures of the reference system and the night cooling system for the three first nights of the considered measurement period. Due to the control problem mentioned earlier,

the room temperature of the radiative cooling system is higher at the beginning of the night (i.e. the building is actually heated up) than the reference system. When the cooling power of the collector is positive (i.e. the building is cooled down), the room temperature is lower than the reference system. The pump is stopped when this temperature reaches 22°C.

Due to the chosen distribution system (thermally activated ceiling), both temperatures merge together as soon as the collectors are not operated. Indeed, the activated ceiling of the TRNSYS building model assumes a unique thermal coupling to the building air node. Therefore, the cooling provided by the collectors cannot be transferred to the building thermal mass, causing a quick drop in the room temperature which has no effect on the room temperature during day time. A better option would be in this case to connect the collector loop to an activated concrete core so that the building thermal mass can be cooled down during the night and therefore providing additional thermal comfort during the day.

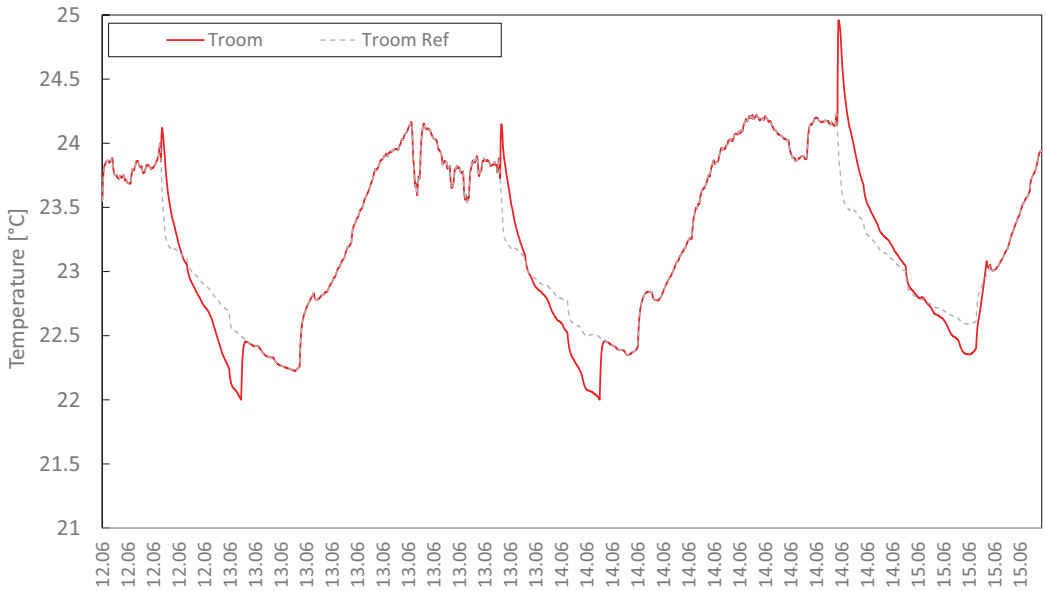

Fig. 11: Comparison of the room temperatures with the night cooling system (red line) and without (grey dashed-line)

4.5. Summarized results

Table 6 shows the main summarized measurement results over the considered measurement period. These values have been averaged or integrated only during the collector operation, i.e. when the collector pump was running (see Figure 9).

Table 6: Summarized main measurement results over the considered period

Parameter	Value	Unit
Collector mean specific cooling power	75.9	W/m²
Mean sky temperature	9.3	°C
Mean ambient temperature	20.3	°C
Mean wind velocity	0.3	m/s
Mean downward longwave radiation	363.2	W/m²
Total cooling energy (one collector)	8,9	kWh

5. Conclusions and outlook

The present paper presents a mobile Hardware in the Loop test bench that allows to test solar assisted heating and cooling systems based on low cost uncovered solar collector for the Egyptian climate. This test bench can be used for collector testing and for system testing in a hardware in the loop configuration. The measurement results show that a 70 m² collector could provide an average of 76 W cooling power per square meter and would be suitable for the cooling of a 120 m² apartment. With the developed test bench, many kind of collector integrations can be tested for different building constructions and system definitions. Also the control algorithm of the system can be tested and optimized before the implementation in real systems.

The developed test bench will be transported to Egypt and further used for both collector and system testing at the German University of Cairo (GUC). In particular the following improvements will be done by modifying the systems in the TRNSYS model:

- Activate the building thermal mass (Type 56) by changing from chilled ceiling to activated ceiling
- Integrate a water store in the system for domestic hot water preparation
- Add a water storage to store the cold at night and use it during the day
- Modify the control so that the collector energy yield is increased

Abstract

Research in the domain of renewable energies has been showing increasing consideration of energetic sustainability due to the escalation of global environmental concern. This paper focuses on implementing an energy storage solution in a hybrid ventilation system. Solar Chimneys constitute an effective technology used in green building architecture that capitalizes on solar energy to provide thermal comfort and air quality. The study centers on the effects of the organic paraffinic Phase Changing Material (PCM) RT-44 panel upon the thermal performance of a laboratory prototype and a stand-alone solar chimney. Furthermore, a numerical model has been established, which solves the thermal exchange of a PCM integrated multi-layered wall. The mass balance of the aerodynamic model of the chimney channel is calculated and input into a coupled model.

Keywords: energy storage, green energy, green house emission, PCM, solar chimney

1. Introduction

For the past years, natural ventilation has increasingly taken into consideration new energy-efficient strategies for thermal comfort as well as air quality improvement. One of the main objectives of the COP21 – Sustainable Innovation Forum meetings (information available at: http://www.cop21paris.org/) has been to decrease energetic consumption and to implement of green energies in order to reduce greenhouse gas emissions.

1.1 Overview

In its simplest design, a Solar Chimney is a channel used to evacuate hot air from a building via a closed conduct at a higher elevation. By means of the greenhouse effect, temperature rises across the canal and induces a thermal updraft. Most recent designs, as the one proposed by Arce, Jiménez, *et al.*, 2009, have made modifications to add elements such as a glazing or an opposite collector wall, both of which maximize the incoming solar energy and improve the chimney's performance. The use of solar chimneys is only profitable during the day, when solar energy heats the chimney and the air within it. Thus far, the induced airflow created in the chimney has been used for ventilation almost exclusively in hot countries.

The chimney acts like a heat engine converting heat generated by a collector into kinetic flow. The main task of the collector is to absorb solar energy for heating air and release it as solar radiation decreases. The initial driver of a solar chimney is the temperature difference between the inside of the building and the inside of the conduit, which causes a density variation. Several previous studies (Bansal, Mathur and Bhandari, 1993; Mathur *et al.*, 2006; Jianliu and Weihua, 2013; Naraghi and Blanchard, 2015) have proven that mass flow rate is directly related to solar radiation. Other investigations focused on the effect of solar radiation intensifiers on the performance of solar chimneys (Shahreza and Imani, 2015), however few have investigated the possibility of after-sundown utilization or the possibility of implementing this ventilation system in cold climate environments.

1.2 Active Solar Chimney

The objective of the study is to analyze the effectiveness of energy storage devices, in particular organic phase changing materials (PCMs), on solar chimneys for after-sundown utilization. The activation (transition from passive to PCM enhanced ventilation) of this technology is achieved through the implementation of these PCM panels.

The interest of phase changing materials lies in their superior energy storage capacity per unit of volume in

doi:10.18086/swc.2017.12.03 Available at http://proceedings.ises.org

comparison to conventional building materials. This type of material stores energy in its latent form. A rise in temperature up to the range of 40 – 44 °C will induce a change of state of the material from solid to liquid. The melting phase is an endothermic process, where heat is absorbed for the phase changing. Furthermore, the stored energy is released during the solidification process once temperature drops. The selected RT44 PCM panel has a heat storage capacity of 250 kJ/kg (or 70 Wh/kg) for a combination of latent and sensible heat in a temperature range of 35°C to 50°C.

Overall, paraffinic phase change materials for implementation in solar chimneys could be an economically viable option for hybrid design solutions to create a healthy indoor environment within residential buildings through renewable solar energy. The aim if this analysis is to evaluate the thermal performance of PCMs for residential purposes particularly after sundown.

Fig.1a represents a simple solar chimney as developed by Arce *et al.*, 2015, which is the basis of our model that integrates the PCM panels as shown in Fig.1b. This study will focus on the macro encapsulated organic PCM panels (bottom) filled with RT44 (top) shown in Fig.1c.

(a) (b) (c)

Figure 1: (a) Solar chimney built by Arce et al. (b) PCM panel integrated solar chimney. (c) Top - Organic paraffinic PCM in solid state. Bottom - macroencapsulated panel.

2. Numerical approach

The system is modeled by a heat transfer model and a pressure code. The first model integrates a multi-layered wall containing PCM and the second by analyzes the air temperature, speed and pressure distribution.

2.1 PCM integrated multi-layered wall

The model was developed using a finite-difference Crank-Nicholson implicit method, which follows a central difference scheme at time $t_{n+1/2}$ and a second order central difference for the space derivative at position x_i by setting the new variable $\bar{T}$:

$$\bar{T}_i = \frac{T_i^{t+\Delta t} + T_i^t}{2} \qquad (eq.1)$$

This method was chosen over other finite-differences approaches due to its faster convergence and its superior stability properties, especially at higher time steps (Δt) however, at the expense of a higher computational cost. Since we test our system over a large time interval, stability must be assured. Unstable approaches are not well suited due to these large time steps. The following expressions allows us to define a mathematical resolution that considers four different types of nodes: nodes in contact with the exterior environment, nodes in contact

with the internal channel, nodes within a solid material and the nodes in the interfaces between materials. The system is defined as follows:

$$\begin{cases} T_1^t = \left(1 + \frac{\lambda_1\gamma_1\Delta t_1}{\Delta x_1^2} + \frac{h_{ext}\gamma_1\Delta t_1}{\Delta x_1}\right)\bar{T}_1 + \frac{\lambda_1\gamma_1\Delta t_1}{\Delta x_1^2}\bar{T}_2 - \frac{h_{ext}\gamma_1\Delta t_1}{\Delta x_1}T_{ext} - \frac{\gamma_1\Delta t_1}{\Delta x_1}\left(\alpha_{clo}\varphi_{clo} + \alpha_{glo}\varphi_{glo}\right) & (eq.2) \\ T_i^t = -\frac{\lambda_i\gamma_i\Delta t_i}{2\Delta x_i^2}\bar{T}_{i-1} + \left(1 + \frac{\lambda_i\gamma_i\Delta t_i}{\Delta x_i^2}\right)\bar{T}_i - \frac{\lambda_i\gamma_i\Delta t_i}{2\Delta x_i^2}\bar{T}_{i+1} & (eq.3) \\ T_j^t = -\frac{\lambda_{j-1}\Delta t_{j-1}}{\vartheta\Delta x_{j-1}^2}\bar{T}_{j-1} + \left(1 + \frac{\lambda_{j-1}\Delta t_{j-1}}{\vartheta\Delta x_{j-1}^2} + \frac{\lambda_{j+1}\Delta t_{j+1}}{\vartheta\Delta x_{j+1}^2}\right)\bar{T}_j - \frac{\lambda_{j+1}\Delta t_{j+1}}{\vartheta\Delta x_{j+1}^2}\bar{T}_{j+1} & (eq.4) \\ T_n^t = -\frac{\lambda_n\gamma_n\Delta t_n}{\Delta x_n^2}\bar{T}_{n-1} + \left(1 + \frac{\lambda_n\gamma_n\Delta t_n}{\Delta x_n^2} + \frac{h_{int}\gamma_n\Delta t_n}{\Delta x_n}\right)\bar{T}_n - \frac{h_{int}\gamma_n\Delta t_n}{\Delta x_n}T_{int} - \frac{\gamma_n\Delta t_n}{\Delta x_n}\left(\alpha_{clo}\varphi_{clo} + \alpha_{glo}\varphi_{glo}\right) & (eq.5) \end{cases}$$

Eqs. 2-5 are solved by the following matricial equation and solving for $T_i^{t+\Delta t}$ in the previous eq.1:

$$T_i^t = A\bar{T} + Bu \qquad (eq.6)$$

2.2 Modelling of PCM Non-linearity in a multi-layered wall

In order to account for the non-linear behavior of phase changing materials, several options were considered. Some studies have explained the behavior of phase changing materials by setting three different working phases: solid, liquid and transitory state (Li and Liu, 2014). Studies such as the one carried out by Mirzaei and Haghighat, 2012 have modelled the behavior in similar ways and adding a discretization along the PCM layer to simulate the progressive phase change of the material. Other articles have opted to work on different approaches such as DTA (Differential thermal analysis) (Zhou, Zhao and Tian, 2012) and DSC (Differential scanning calorimetry) tests (Kheradmand *et al.*, 2016), both techniques in which the difference in the amount of heat required to increase the temperature of a sample and reference is measured as a function of temperature. This last technique was chosen over other options since the data from the test can be simply input into the code instead of calculated at each time interval; thus reducing the calculation time of the numerical model.

(a) **(b)** **(c)**

Figure 2: (a) Preparation of solid state RT44 material. (b) Sample setup for DSC analysis. (c) DSC test machine

The results of the DSC test for the Rubitherm RT44 phase changing material are shown in Fig.3. This test was carried out at a cooling/heating speed of 0.05°C/min, according to the expected charge/discharge speed of the panels in the chimney. The specific heat of the RT44 material is input to each node of the discretization as a function of temperature $C_p(T)$, allowing a more specific evolution along the PCM layer. Specific heat is calculated using the following expression:

$$C_p(T) = \frac{DSC(T)_s}{\varphi} \qquad (eq.7)$$

2.3 Pressure code – Airflow calculation model

The aerodynamic behavior and the heat exchange of the fluid within the conduct are influenced by the boundary wall temperature. This model employs a pressure code for the calculation of airflows throughout the

conduct and is based on the following simplifications:

- Airflow through the channel has been assumed one-dimensional. Only the vertical component parallel to the height of the chimney are considered.
- No losses are considered throughout the air channel. The mass conservation equations only take into account the exchanges between adjacent volumes and boundaries.
- Density is not constant and behaves according to the Boussinesq approximation as a function of temperature to account for the buoyancy driven flow.

The pressure code follows an iterative resolution based on the Newton-Raphson method. The mass balance $\dot{m}$ of a cell i connected to cells j of a domain is expressed by the following equation:

$$\sum_{k=1}^{j} \dot{m}_{ik} = 0 \qquad (eq.8)$$

The mass flow rate depends on the pressures of the neighboring cells. The mass exchange between common interfaces will serve to calculate the new pressure distribution through several iterations until convergence is reached. Density fluctuates due to temperature differences between adjacent zones, which leads to buoyancy driven flow. This phenomenon causes light hot air to rise and flow out while cooler air flows in. The system is solved by using Bernoulli's principle; taking the reference pressure on the lower boundary of the cell P_0 and according to the hydrostatic gradient, the pressure due to stack effect P_i only at height z is:

$$P_i = P_{o,i} - \rho_i g z \qquad (eq.9)$$

$$\rho_i = \rho_0 \frac{T_0}{T_0 + T_i} \qquad (eq.10)$$

where T_0 corresponds to a reference temperature and T_i the air temperature of the cell. Boundaries between volumes are written in terms of ΔP to account for the interaction between adjacent volumes. This substitution is then input into the mass conservation equation in order to satisfy the expression in equation 7 and rewritten in terms of Bernoulli:

$$\sum_{k=1}^{j} \dot{m}_{ik} = \sum_{k=1}^{j} \rho_{ik} \left[C_d W \sqrt{\frac{2\Delta P_i}{\rho_{mean}}} \right] \qquad (eq.11)$$

where C_d is a discharge coefficient inherent to the system and W the perpendicular surface to the flow. Calculation of unknown pressures is derived by application of mass balance equations in each node. The solution of the system, as stated before, is based on a Newton-Raphson iterative method. Each cell pressure is adjusted to satisfy mass balance. The new cell pressures are computed from the previous estimated pressures and a correction vector P_{corr} as follows:

$$P_{iter+1} = P_{iter} - P_{corr} \qquad (eq.12)$$

P_{corr} is calculated using:

$$P_{corr} = J^{-1}\, x\, Mb \qquad (eq.13)$$

where Mb is a mass balance vector when considering no source terms, computed by the following expression:

$$Mb_j = \sum_{k=1}^{j} Q_{ik} \rho_{ik} \qquad (eq.14)$$

and J is the Jacobian matrix calculated by:

$$J_{ij} = \frac{\partial Mb_j}{\partial P_j} \qquad (eq.15)$$

The convergence of the aerodynamic model is given by a convergence factor, which is defined by a correction vector in order to end iterations. This correction factor was set to $\varepsilon = 0.001$.

2.4 Model coupling

The data obtained in the previous sections and equation systems share information through a Matlab Simulink interface called HYBCELL (El Mankibi *et al.*, 2006, 2015) which displays the temperature evolution, pressure distribution and air flow across the chimney.

From an initial temperature distribution, aerodynamic model computes pressures and flow distributions. These results will allow new temperature calculations by changing convective heat fluxes. The model was developed to run with meteorological data from Lyon.

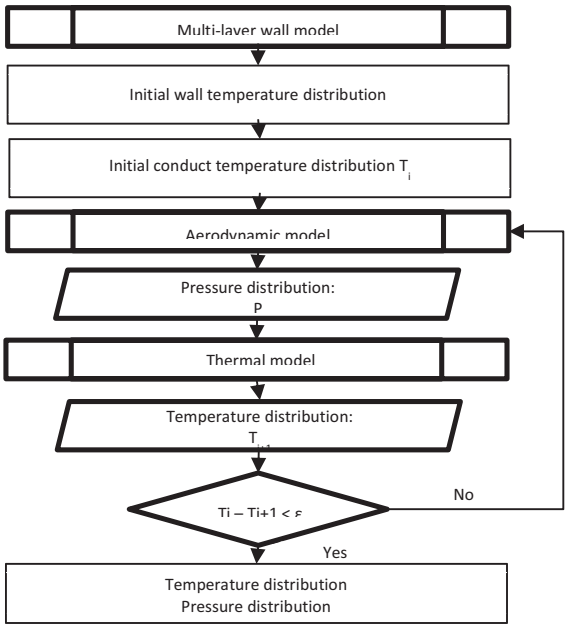

Figure 3: Flowchart of the coupled model.

3. Experimental procedure

3.1 Laboratory set-up

In order to analyze and validate the numerical models, a laboratory prototype was developed. The prototype is based on the chimney built by Acre et al. (Arce, Jiménez, *et al.*, 2009; Arce, Xaman, *et al.*, 2009) at the Almeria Solar Platform (PSA). The laboratory prototype is made from 5cm-wide polystyrene plates, supported by an aluminum beam structure (3cm cross section). The prototype is connected to one of the sections of the Guarded Hot Box (shown in Fig.3) in order to simulate the temperature in a controlled volume.

(a)

(b)

Figure 4: Laboratory prototype showing (a) the prototype and the both sides of the Hot Guarded Box and (b) ongoing experiment with PCM panels.

3.1.1 Experimental protocol

Fig. 5 below shows the protocol used for the experimentation. The experimental protocol is composed of seven consecutive phases of 6 hours each (0.25 days), completing a full cycle in roughly 1.75 days. Phases depend on the state of the opening (open/closed) for natural ventilation, and heating provided by the halogen lamps, which simulate solar radiation. The lamps are evenly distributed over the 3m glass face of the chimney and provide a net heat flux of 700 W/m².

Phase 1 corresponds to the initialization of the system. In this stage, the outlet is closed and there is no present heat source. Phase 2 was designed to charge the panels in order to ensure the melting process of PCMs. Phase 3 allows air circulation by opening the outlet and maintaining the heat source. Phase 4 removes the heat source while allowing air circulation. Phase 5 reinitializes the system. Phases 6 and 7 work in the same way as phases 2 and 4.

Phase 1 : Initialization

Phase 2 : Heating Only

Phase 3 : Chimney Activation

Phase 4 : Ventilation only

Phase 5 : Initialization

Phase 6 : Heating only

Phase 7 : Ventilation only

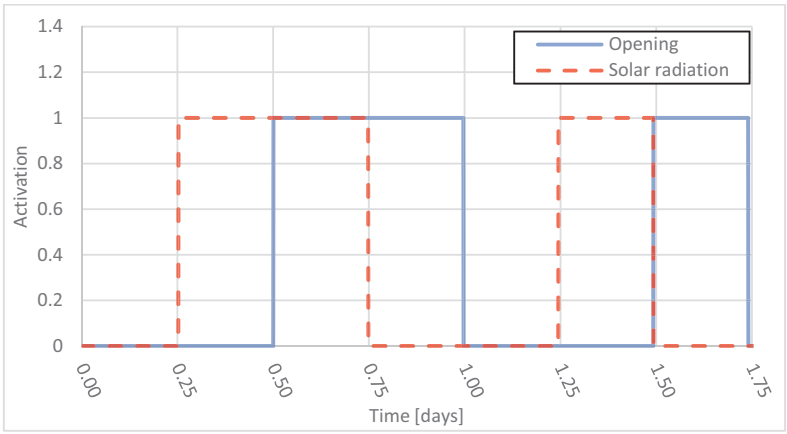

Figure 5: Experimental protocol showing the Boolean behavior between the outlet (open/closed) and the solar gain (on/off)

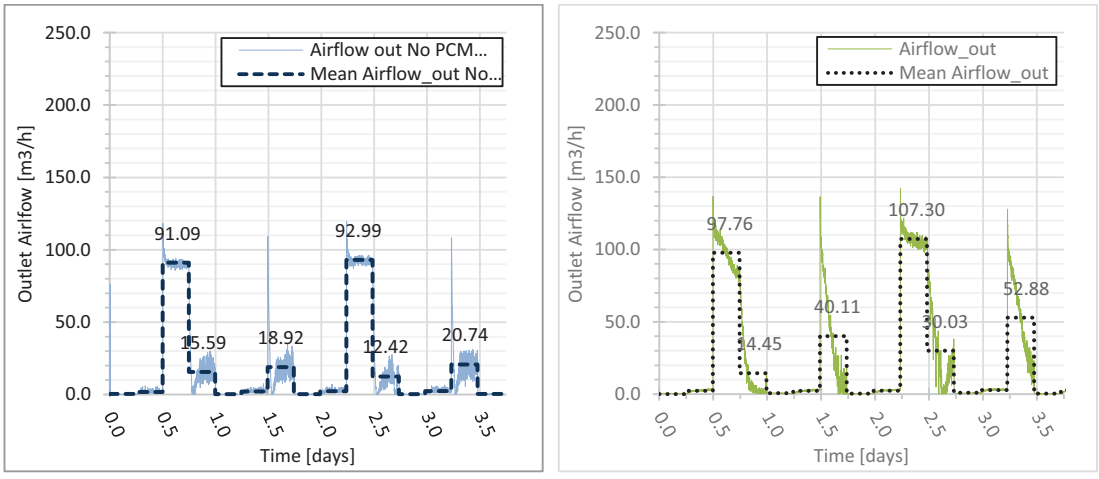
3.1.2 Laboratory test results

Outlet mass flow rate, air gap temperature and temperature difference between inlet and outlet, are some of the most important quantities for the design of a solar chimney. Outlet airflow for no PCM and PCM integrated solar chimney (ASC) are shown in Fig. 6-8. The results represent two continuous cycles from the experimental protocol. The results shown below were carried out under two different conditions: input temperature set by the Hot Guarded Box and no input temperature, thus following the exterior temperature.



(a) **(b)**

Figure 6: Outlet airflow results for (a) 09/05/2017 No PCM Solar chimney for a set temperature of 17°C (Cycle 5 No MCP) and (b) 16/08/2017 RT44 PCM integrated Solar Chimney for a set temperature of 17°C (Cycle 4 MCP)

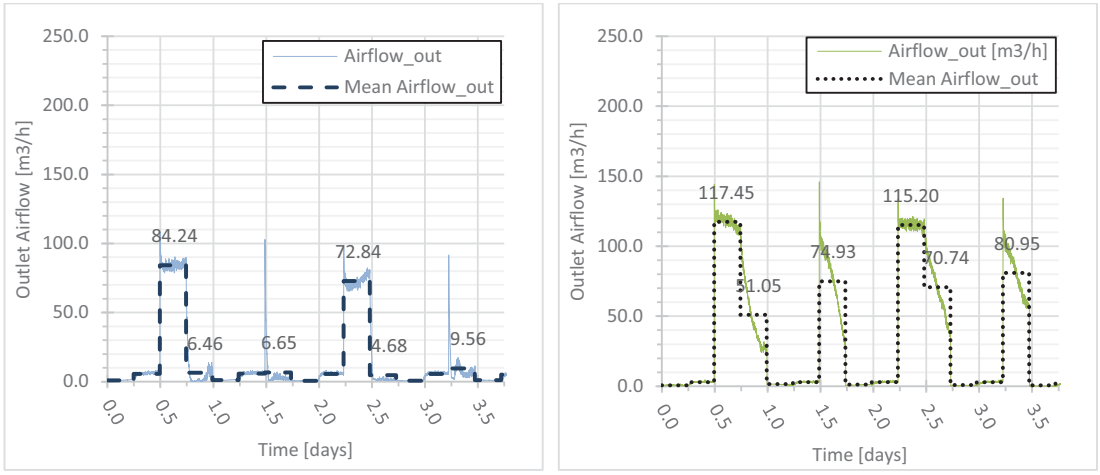


Figure 7: Outlet airflow results for (a) 25/07/2017 No PCM Solar chimney following exterior temperature (Cycle 7 No MCP) and (b) 23/08/2017 RT44 PCM integrated Solar Chimney following exterior temperature (Cycle 5 MCP) – Max outside temperature of 42°C

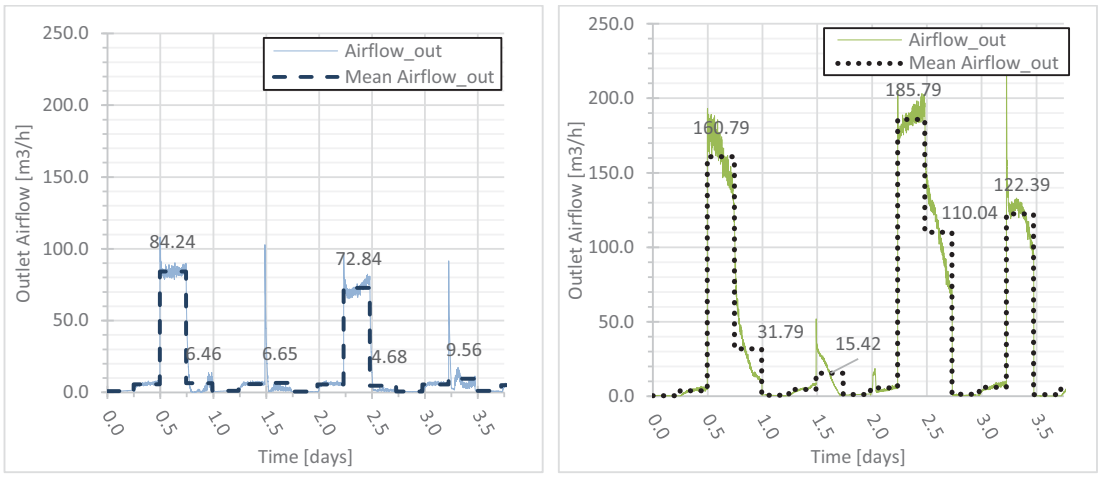

Figure 8: Outlet airflow results for (a) 25/07/2017 No PCM Solar chimney following exterior temperature (Cycle 7 No MCP) and (b) 15/06/2017 RT44 PCM integrated Solar Chimney following exterior temperature (Cycle 3 MCP) – Max outside temperature of 45°C

The results demonstrate the influence of the different stages of the experimental protocol on the outlet mass flow rate. The impact of the PCMs is particularly noticeable during ventilation only phases (4 and 7). Solar chimney mass flow rate values drop dramatically during the aforementioned phases, as shown in Fig. 6a – 8a. The polystyrene structure provides no thermal inertia to the system, which causes a drop in outlet mass flow rate as soon as there is no longer a heat source. In turn, ASC results (as shown in Fig. 6b – 8b) display a slow decrease of mass flow rates between phases. The PCM panels work as expected, absorbing available energy during each charging phase and releasing once the source is withdrawn.

Additionally, ASC results display as well, an overall higher mean mass flow rate across all phases of the experiment. In some cases, up to a twofold increase of mass flow rate can be noted for the active solar chimney.

3.2 In-situ experimentation

The stand-alone chimney was developed in Almeria in 2009. The latest iteration of the system is 5.60 m tall, 1.20 m width and 0.52 m deep. The chimney is composed of a 0.15m thick concrete absorbing plate, thermal insulation behind the concrete plate, a 5mm thick glass cover to reduce convective and radiative losses to the environment, a wood casing, and a driving air protection; which generates a fall of pressure near the exit and,

at the same time aids the extraction of air. The prototype is shown in Fig 9. (Arce *et al.*, 2015).

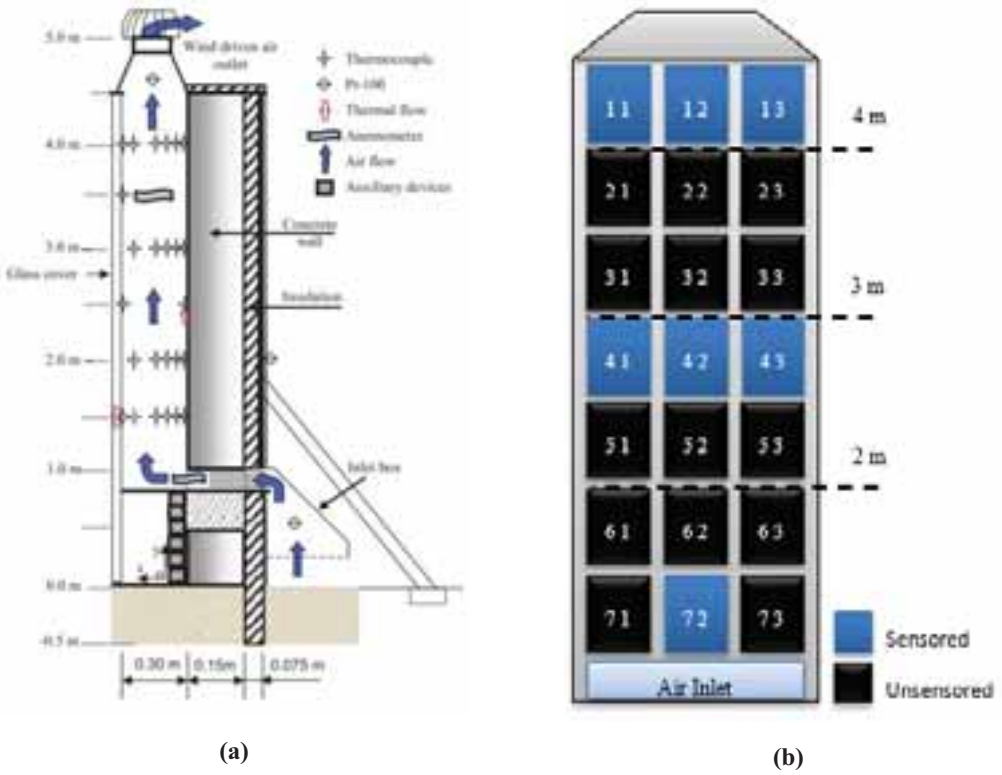

Figure 9: (a) Lateral view of the PSA solar chimney and the instrumentation set up by Arce et al. and (b) Panel distribution on the PSA solar chimney

3.2.1 PCM implementation

The dimensions of the Almeria solar chimney, as well as the cable distribution do not allow the placement of PCM panels on the perpendicular sides to the glazing. The panels are distributed over the concrete collector wall as shown in Fig. 4b in a matrix manner. The sensors are placed in the center of the panel, over and behind at three different levels: inlet panel (72) at 1,25m, center of the solar chimney (41, 42 and 43) at 2,75m and the outlet panels (11, 12 and 13) at 4,25m. The panels' southern surfaces were painted matte black in order to maximize the absorption of solar radiation and to ensure the phase change.

3.2.2 Instrumentation

The experimental instrumentation used for the different measurements of the solar chimney is detailed in the technical note published by Arce et al. (Arce, Jiménez, *et al.*, 2009). Platinum thermoresistance (PT100, 1/10 DIN) sensors are used to record surface temperature of the panels via a four-wire connection. These sensors consist of a very small sensing element embedded in a slim rubber substrate. The sensors were glued to the center of the panels as marked in Fig.9b and painted black matte to integrate them as much as possible with the corresponding surface.

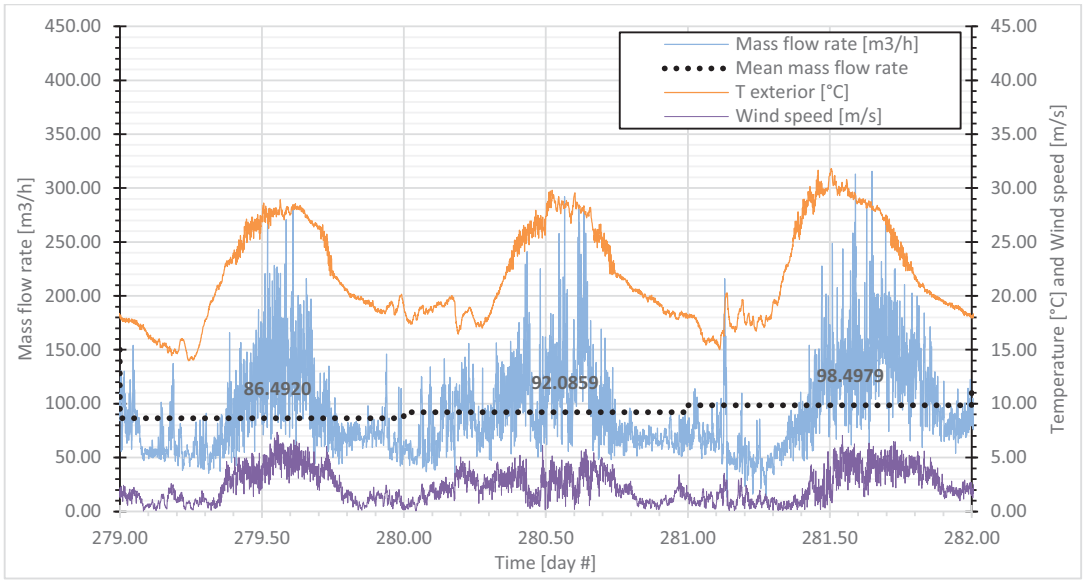
A data acquisition system with the following characteristics is being used: 16-bit A/D resolution, range of measurements fitting sensor output, modules distributed to minimize wiring, based in Compact Field Point modules manufactured by NATIONAL INSTRUMENTS.

The Solar Platform of Almeria counts with its own meteorological station, which measures data ever second. Data is averaged and recorded every minute. Further details concerning the meteorological station can be found in the aforementioned article.

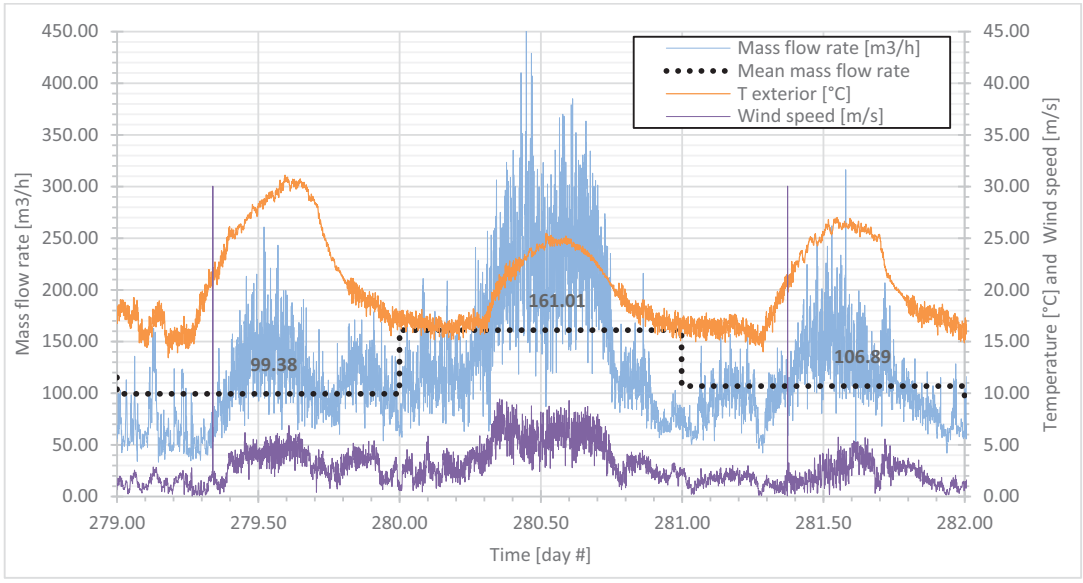
3.2.3 Mass flow rate

The results presented below show the exterior temperature and wind speed for the period from October 6 to

October 9 in 2016 and 2017 respectively.



(a)



(b)

Figure 10: Influence of exterior temperature and wind speed on the mass flow rate for (a) Arce et al. solar chimney and (b) PCM integrated solar chimney

Fig. 10 (a) and (b) show an increase in mass flow rate for the PCM integrated solar chimney for the same period between both year samples. For this specific period, the overall mass flow rate is higher across the three days. The maximum and minimum differences are 62.98 m^3/h and 8.39 m^3/h respectively. The maximum temperature from the three days in 2016 is approximately 30°C, thus there is a +5°C difference in relation to the results of 2017. The highest mass flow rate values for the PCM integrated solar chimney are obtained at 25°C where wind speed has a mean wind speed of 6.5 m/s.

3.2.4 Panel surface temperature distributions

Fig. 11 (a) – (c) show the panels' surface temperature evolution for the period from October 6 to October 9 2017. In Fig. 11 (a) and (b) the phase change can be appreciated through temperature evolution of curves 12, 42 and 72 back. This phenomenon starts as soon as the temperature approaches 40°C. Once the material is fully melted temperature continues to rise until it reaches the maximum level. When solar radiation decreases

and outside temperature starts to drop, the surface temperature of the panel falls as well until it drops to 44°C. At this point, the stored energy is being released from the PCM and thus, the temperature decrease occurs at a slower rate. Moreover, Fig. 11 (c) represents the temperature evolution of the outlet level of the solar chimney. At this level, surface temperatures do not reach the phase change range. This is explained by the lack of direct sunlight due to the shadow of the top level of the solar chimney.

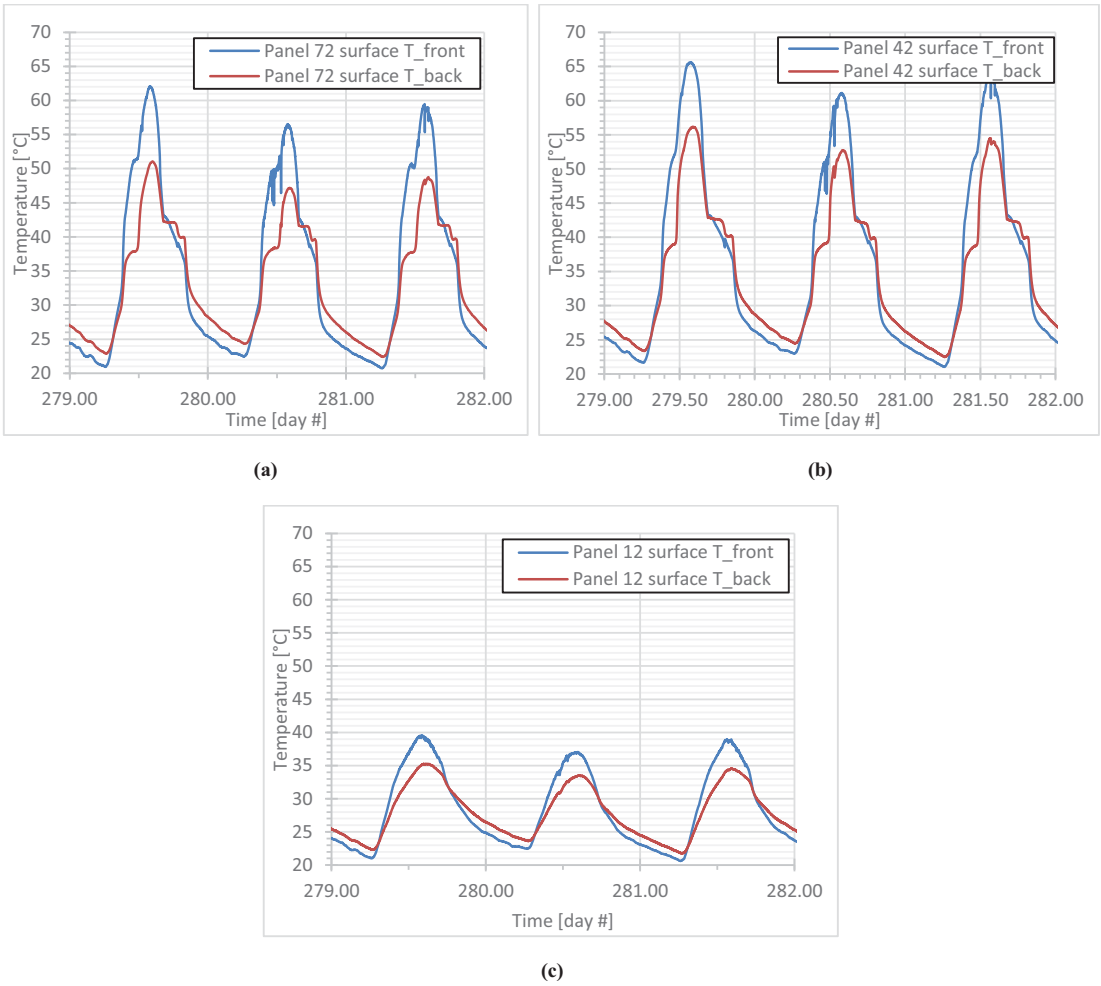


Figure 11: Frontal and back surface temperatures of the PCM panel integrated in the solar chimney at three different levels (a) inlet, (b) mid-level and (c) outlet.

4. Conclusions

An experimental study of the implementation of RT44 phase changing material panels was carried out for a solar chimney prototype under laboratory and in situ conditions. Laboratory results show a clear influence of solar radiation on the outlet mass flow rate when integrating PCMs to the solar chimney. Moreover, the interest of phase changing materials can be appreciated in these results since the mass flow rate slowly decreases once there is no longer a heat source. Outlet mass flow rate shows a steady reduction rather than the abrupt drop observed without PCM. Although the decrease is cut by the duration of each stage of the experimental protocol, its effect on mass flow rate is noteworthy. After the PCM has completed the melting process and the heat source is taken away, surface temperatures and air temperatures follow as well a slow discharge.

The increase in mass flow rate is proportional to the energy stored by the PCMs. Lower mean mass flow rates are the result of unattained melting temperatures at one or several levels of the active solar chimney. Further studies will act on the optimization of the laboratory parameters such as the heat source and the time lapses.

In situ results are yet inconclusive and require additional tests in order to validate the wind speed and melting assumptions made in order to explain the differences between the results obtained by Arce et al. and the Active

Solar Chimney. Results, even though promising, are yet to be optimized to obtain a better performance. Thus far, it can be concluded that the undercharge of the system can have an impact on the performance of the chimney. The chimney is oriented to the south; this will be particularly impactful during winter when the chimney receives an almost absolute impact of the sun. A better exposure to the sun and lower ambient temperatures will show the performance of the active solar chimneys under disadvantageous conditions.

Finally, the numerical analysis aims to describe the behavior of the phase changing materials through the combination a multi-layered wall. Further studies will emphasize in the validation of the numerical model via the experimental data obtained by both experimental procedures.

Abstract

Semi-Transparent Photovoltaic panels (STPV) have become an important element in the building integration of photovoltaic panels (BIPV). STPV panels can be integrated on double skin facades (DSF) and insulating glazing units (IGU) acting as their exterior layer, generating electricity, controlling the solar heat gains and utilizing daylight. In addition, a mechanically ventilated DSF integrating STPV panels (DSF-PV), can cool down the PV panels, increase their efficiency but also use the preheated air to enhance the thermal efficiency of the mechanical system connected to the DSF-PV. Two virtually identical STPV are integrated on a DSF-PV and a IGU-PV respectively and their electrical performance is evaluated experimentally. Under the same exterior and interior conditions, it is found that the DSF-PV has a 3% greater electrical performance than the IGU-PV and if the cavity of the DSF-PV is selectively ventilated, the DSF-PV can generate more than 9% of electric power than the IGU-PV.

1. Introduction

It is very common for both commercial and residential modern buildings to use curtain wall systems as part of their envelope design. A well-designed curtain wall system is able to seal the building, protect it from weather phenomena and provide to the building the modern architectural aesthetics. The large transparent facades are preferred due to the reduced cost and the great appreciation of daylighting, as the sun light can penetrate deeper into the building. This architectural tendency is likely to remain, due to the low cost of the curtainwall application and the fact that more studies link daylight and view to the outdoors with increased worker productivity, well-being (Veitch and Galasiu 2011) and reduced lighting loads (Tzempelikos and Athienitis 2007). Highly glazed facades may maximize the daylight potentials of the building but they may require an oversized mechanical system, as excessive solar gains may lead to increased cooling loads during the day and low insulation may lead to increased heating loads during the night, adding to the thermal and visual discomfort of the occupants.

The disadvantages of highly glazed facades may be minimized or overcome by either integrating photovoltaics (PV) on windows or by adding an additional exterior layer forming in this way a double skin façade (Miyazaki, Akisawa, and Kashiwagi 2005). Solar cells may be used instead of reflective coating or ceramic frits to reduce the solar gains, forming in this way semi-transparent photovoltaics (STPV) that could be integrated on parts of the façade of the building (James, Jentsch, and Bahaj 2009; Qiu et al. 2009). As a result, solar heat gains may be reduced, maintaining at the same time adequate levels of daylight, provide view to the outdoors (Vartiainen 2001) and generate electricity.

When PV cell overheating is of concern, instead of a window with a sealed cavity (IGU), a ventilated one can be utilized, turning the façade into a Double Skin Façade integrating photovoltaics (DSF-PV). The possibility of recovering the heat from within the DSF-PV, along with the electricity generation and the daylight transmission, gives the opportunity to the creation of an active façade (Gaillard, Giroux-Julien, et al. 2014). As the air circulates behind the PV cells, it cools down the cells through convection, reducing the temperature of the cells and increasing their

doi:10.18086/swc.2017.12.04 Available at http://proceedings.ises.org

electrical efficiency.

STPV façades could have a substantial effect on the daylighting/lighting performance as well as energy and peak power demand reduction on highly-glazed office buildings. The objective of this study is to experimentally investigate the energy performance of two prevailing STPV façade configurations: i) curtain wall systems incorporating STPV insulated glazing units (IGU-PV), ii) Double Skin Façade incorporating STPV technologies on the outer skin (DSF-PV). The study focuses on offices in a continental climate region (Northeastern United States and Southeastern Canada) and it is part of a bigger effort to provide input to the design guidelines for the utilization of advance fenestration technologies that will help to achieve net-zero energy building performance targets and beyond, through energy conservation and renewable energy generation.

2. Literature review on experimental investigation

A series of experiments have been held to characterize the performance of windows and double skin facades integrating photovoltaic panels. Single, double and ventilated windows have been investigated, while the majority of the studies used amorphous silicon (a-Si) photovoltaic panels. The experiments were mainly focused on the electrical performance of the integrated photovoltaics, but many studies focus as well on the thermal and daylight performance of such systems.

2.1 Windows integrating Photovoltaic

To assess the electrical performance of amorphous silicon STPV modules, the Sandia model was first validated experimentally by Peng et al, with indoors and outdoors experiments (Peng et al. 2015b). It is reported that Sandia model is able to predict the electrical output of the STPV modules on a sunny day but in order to predict the electricity production on an overcast day a spectral correction should be applied to correctly simulate the performance of the STPV windows. It is reported that a comprehensive spectral correction function is needed to be developed in the future.

An experiment was set-up by Robinson and Athienitis (2009), integrating STPV on a double glazing window in Montreal (Robinson and Athienitis 2009) focusing on its electrical and daylight performance. A design methodology for optimizing the electricity generation and the daylight utilization was validated showing the potentials of south facing STPV facades.

In addition to the electrical performance, the thermal performance of a double glazing STPV module was studied under standard test conditions and outdoor conditions (Park et al. 2010). For an increase of 1ºC of the PV module, it is observed that the temperature coefficient (β) is 4.8% and 5.2% under STC and outdoor conditions respectively (irradiance of 500W/m^2). It is also reported that the type of glass used at the STPV window does not affect the electrical performance of the module but affects the thermal performance of the system.

A comparison is held between an a-Si STPV double glazing unit and common single and double glazing units in terms of their electrical and thermal performance (Liao and Xu 2015). Liao and Xu focused mainly on the room and façade dimensions to develop a model and later validate it with field experiments in order to simulate it with the use of Energy Plus. Amorphous silicon STPV windows are found to be better suited for small rooms with high WWR or tall rooms. It is also found that they perform better than single and double-glazing units, mainly because they reduce the cooling loads of the interior zone.

The SHGC of STPV modules and STPV windows was measured using a calorimetric box in a solar simulator (Chen et al. 2012). Three laminated and two double glazing units with amorphous and micromorph are tested in the Solar Simulator and it is reported that it is sensitive to the spectrum of the solar simulator and the reflection properties of the absorber plate. It is also reported that the SHGC reduces significantly for incident angles greater than 45º.

In addition, a hot-box is used by He et al. (He et al. 2011) to compare an amorphous single-glazing PV window to a ventilated double-glazing PV window. With an electrical efficiency of less than 5% and with a packing factor of 0.8 the SHGC of the IGU integrating STPV is 46.5% in comparison to the single glazing STPV. A CFD analysis is held using ANSYS FLUENT and RNG k-epsilon turbulence model. The difference between the experiments and the model created, for the total heat gains, is 11.7% and 2.7% for the ventilated double-glazing PV window and the single-glazing respectively and the estimated temperature difference is less than a degree C for both cases.

A ventilated thin-film PV window is experimentally assessed and verified using a developed ESP-r simulation model that is then used to compare the STPV window with a simple absorptive glazing (Chow, Qiu, and Li 2009). For an electrical efficiency of less than 5%, the STPV window is compared to an a-Si STPV product available in the market and an to absorptive glazing. It is shown that the see-through PV installation can reduce the consumption of the HVAC by 28%.

An exterior experimental facility was set up by Olivieri et al (2013), to assess the electrical, thermal and daylighting and behavior of an STPV window (Olivieri et al. 2014). It is reported that the transparency of the PV window is not the most important factor concerning the electrical performance. Four a-Si STPV modules with visible transmittances between 0.1 and 0.4 have been experimentally compared to a reference glass. All four modules present higher SHGC, approximately 40% larger heat losses and the U-values are almost double in comparison to the reference glass.

The optimal packing factor of STPV windows for office buildings in central China was investigated, for different room lengths, WWRs and orientations (Xu et al. 2014), analyzing its electrical, thermal and daylighting performance. A parametric analysis is performed, using Energy Plus, to identify the impact of different cell coverages into the energy consumption of the zone, stating that the selection of the optimal configuration can reduce the energy consumption up to 13% in comparison to the least favorable configuration.

2.2 Double Skin Facades integrating Photovoltaic

The integration of PV on DSF is an idea that has recently received the attention of the academic community. The majority of the research is focused on naturally ventilated DSF integrating STPV made out of amorphous silicon.

Peng et al, set-up an experimental facility in Hong Kong, consisting of a DSF integrating see-through a-Si PV (Peng et al. 2015a; Peng, Lu, and Yang 2013). The DSF has a cavity width of 400mm that is created between a double glazed see-through PV and the interior window and inlets at the top and the bottom, both at the exterior side. Four different operation modes of the dampers and the interior window were experimentally investigated showing that the temperature of the air at the outlet can be more than 2ºC higher than the one at the inlet. It is also reported that the SHGC for the different operation modes are between 0.1 and 0.13.

The same experimental facility was later used to validate a developed simulation model, based Energy Plus (Peng et al. 2016). For a cool-summer Mediterranean climate zone, a thickness between 0.4m and 0.6m could be recommended as the optimal cavity width while the DSF-PV, used 50% less net-electricity than other glazing systems. In addition, it is highlighted that the future of the DSF-PV is promising because of the decrease of the prices and the increase of the efficiencies of the PVs.

Three prototype DSFs integrating semi-transparent photovoltaics are tested and a comparison between the thermal response of the semi-transparent photovoltaics and the air inside the cavity is presented (Gaillard, Ménézo, et al. 2014). The two-storey West North-West DSF of the building is designed to increase the electrical performance of the semi-transparent photovoltaics installed by utilizing the stack effect (Gaillard, Giroux-Julien, et al. 2014). As reported by the experimental data collected under real conditions, in a span of a year, the behavior of the system can be predicted by using simple relationships.

An experimental facility was built in Hong Kong to compare the energy performance of a Double Skin Façade (DSF) and an insulation glass unit (IGU) integrating semi-transparent photovoltaics (Wang et al. 2017). The thermal

performance of the IGU integrating STPV was found to be better by 2% than the naturally ventilated DSF integrating photovoltaics (DSF-PV), although the authors mentioned that an appropriate ventilating mode for the DSF-PV would potentially result into better thermal performance.

In Table 1, the available state of the art is shown, presenting the experimental research performed on windows and double skin facades integrating semi-transparent photovoltaics. The available literature is also analysed presenting the different type of PV utilized, the types of windows used and whether the DSF is mechanically or naturally ventilated. In addition, the focus of the study is presented along with whether any simulation models are used. The last row states the location of the experimental facility, if it is an exterior one, or if the experiments are performed on a solar simulator.

Based on the Mataro Library in Barcelona, Mei et al, developed a dynamic thermal model on TRNSYS for a DSF integrating STPV (Mei et al. 2003). For a 15% transparency and an assumed as constant transmittance-absorptance of 0.8 STPV panel a thermal model was developed. It is reported that the air at the outlet of the DSF-STPV can reach

50°C in summer and 40°C in winter and this preheated air can be introduced into the HVAC system to reduce the heating load by 12%. Based on the same building the potential to use a desiccant cooling machine in combination with the DSF-PV is investigated (Mei et al. 2006). The 70°C heated air within the DSF can be fed into the desiccant cooling machine and regenerate the sorption wheel, resulting into an average COP of 0.518 during the summer season. The approach of four different terms describing the ventilation gains, the transmission losses and the temperature components are used in a steady state analysis to simulate the Mataro Library DSF-PV (Infield, Mei, and Eicker 2004) (Infield et al. 2006). In this way, monthly U and g values have been derived and the energy thermal gains have been calculated.

An integral (electrical, thermal and daylight) simulation model is used to carry out an annual performance study for an architype office building located at Toronto, Canada (Kapsis and Athienitis 2015). The model is experimentally-verified. The analysis demonstrates that the use of STPV façades have the ability to generate enough electricity to cover the annual electricity demand of the building on electric lighting and plug loads. In case of STPV/T or double skin façade, a significant amount of heat (in the form of preheated outdoor air) could be also generated. The heated air could be used to a solar assisted air-source heat pump that could be used to partially cover the heating and cooling demands of the building. Moreover, the use of STPV/T or double skin façade reduces the heat losses through the building skin during the heating season.

3. Experimental set-up

Two virtually identical semi-transparent photovoltaics (STPV) are used for this experimental set-up, located in Montreal, Canada (45° 30' N / 73° 35' W). The first STPV is used as the exterior layer of a DSF forming in this way a DSF-PV and the second one is used as the exterior layer of an Insulating Glazing Unit (IGU-PV). For each STPV, 48 cells of 17.80% nominal efficiency are used and are distributed in 8 rows with 6 cells in each row. In Figure 1, the experimental test cell is presented, showing the IGU-PV on the left side and the DSF-PV on the right. An automated damper with a Belimo actuator (0-5V) is integrated underneath the DSF-PV and is controlled to ventilate the DSF-PV. The test cell faces towards the south, while the south view of the façade is shown on the panoramic picture of Figure 1. It can be seen that most of the days of the year, the sky-scraper at the east, south-east shades the test cell, in the early morning and for a couple hours after the solar noon the test cell is shaded by the building that is located at the south, south-west.

The characteristics of the STPV modules are presented in Table 2 and the layers of the first and the second STPV are show in Figure 2. Both the STPV have the same layers: glass, Ethylene-vinyl Acetate (EVA), PV cells, EVA and glass. The dimensions of both the STPV panels is 1.968m by 0.992m and the PV cells used are square and have sides of 15.6cm, while the seven transparent strips have a width of approximately 10.3cm. In this way, 63.4% of the area is covered by the cells and the remaining 36.6% is transparent. The insulating glazing unit is assembled with a hard low emissivity coating at the back of the STPV. The space between the STPV and the double glazing is vacuum and 13mm wide.

The cavity of the DSF-PV is 17cm wide and the back layer of the DSF-PV extends from the bottom of the test-cell to a height of 1.90m. The top of the DSF-PV is sealed and a plenum is used to collect the air and drive it through a manifold (Figure 3). A rectangle FLST 25.4cm by 25.4cm (10in by 10in) flow meter by Dwyer is flashed at the middle of this manifold and its location is selected to be at distance from previous and later elbows that could affect the flow.

Both the systems are integrated on the test-cell using mullions and pressure plates that are mainly used in curtainwall applications. On the interior side of the DSF-PV, the double glazing that is used as the interior layer of the DSF-PV, is mounted following the same principal. In this way, the mullion in its width acts as the spacer between the internal and external layer of the DSF-PV and makes it easy for the integration on buildings.

Thermocouples (T-type) are place on the interior side of the STPV and on both sides of the clear IGU of the DSF-PV. In addition, thermocouples are placed in the middle of the cavity, approximately 8.75cm from each side and in the vertical direction. The thermocouples are placed at the same heights in all layers and are evenly distributed along the

height of the DSF-PV (Figure 3). Because the dampers are located underneath the exterior layer of the DSF-PV, the thermocouples on the DSF-PV start at the second height level. Similarly, because of the manifold, the thermocouples on the interior layer stop before the last height level. In Figure 3, all sixteen of the height levels of the thermocouples are shown with each color indicating a different layer.

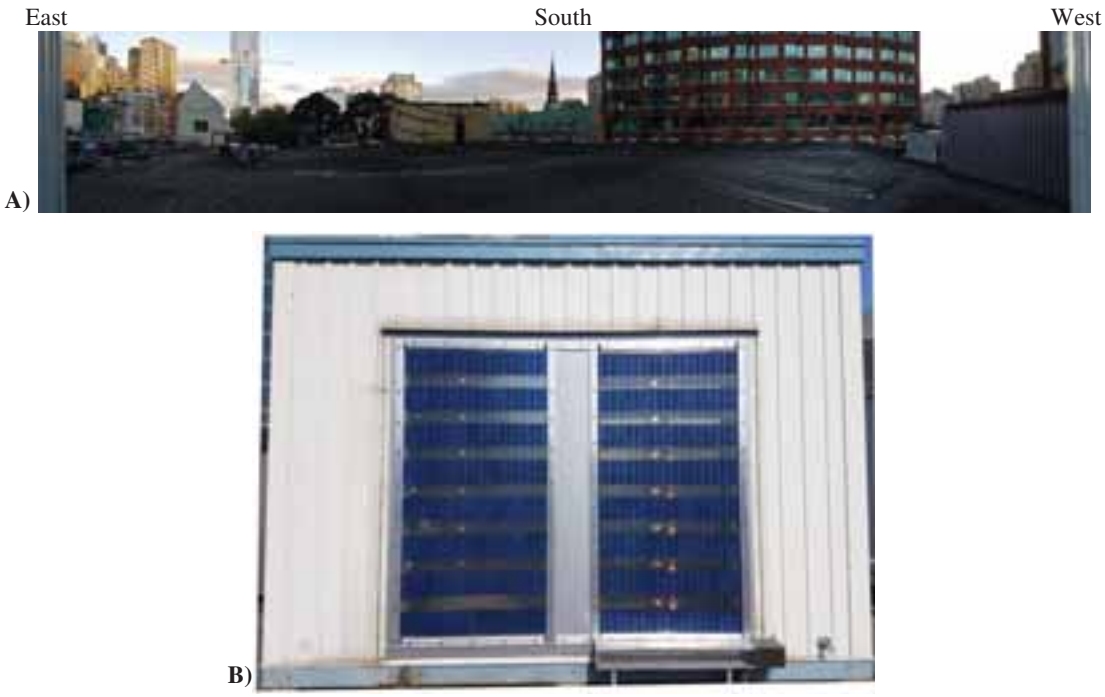

Figure 1 A) View from the south façade of the test-cell, where the STPV are integrated. B) The IGU-PV is installed on the left and the DSF-PV is on the right. The mechanical dampers are shown under the DSF-PV installation.

		*under Standard Test Conditions

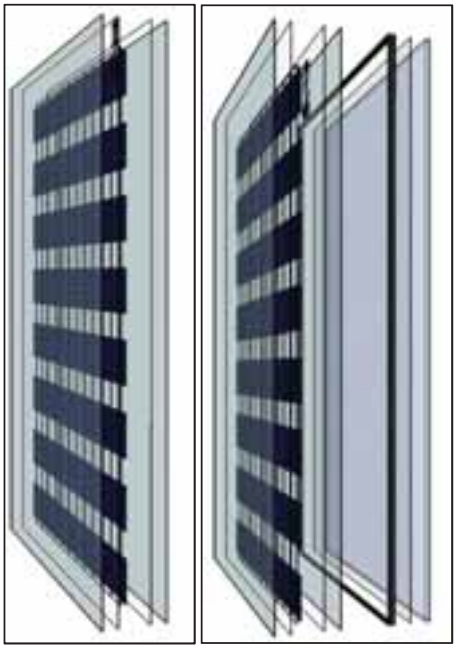

Figure 3 Layers of the STPV used at the DSF-PV (Left) and of the IGU-PV (Right).

Figure 3 Thermocouples are placed on four layers on the DSF-PV (Left) and on the IGU-PV (Right).

For the IGU-PV, thermocouples were installed on the side of the IGU that faces the room, distributed in the same way as they are on the DSF-PV. The data acquisition system used is the LabView using national instruments (NI). For the thermocouples the NI 9213 module is used (National-Instruments 2016). For the accurate measurement of the power output of the DSF-PV and the IGU-PV, an identical electric assembly was set up for each PV module. This assembly consist of a charge controller with maximum power point tracker (MPPT) a battery of 12 V and 110 Ah and a dump load (TE Connectivity 2005). The multi-stage MPPT solar charge controllers used are the Solar Boost SB3024i (Blue Sky Energy Inc. 2009) and the battery is the 8A31DT AGM sealed (MK Battery 2015). The voltage of each PV module is measured with a NI 9223 module (National Instruments 2016) and a shunt resistor (Riedon Inc. 2018) is used to measure the current flowing from the PV. The electrical configuration and connections are shown in Figure 4. The selection of shut resistor was based on the range and precision of the voltmeter. In our case a NI 9213 was used to measure the voltage difference (range of $\pm$78 mV) and using a safety factor of two (2) over the short circuit current from the PV (~16 A), the value of the shunt resistor was calculated to be 5 mΩ. For the selection of the battery, an empirical rule was used to calculate the battery capacity (Ah), which is equal to the watt peak of the STPV multiplied by the daily solar exposure and the days of battery autonomy of the system, divided by the battery loss factor, the depth of discharge and the battery voltage. In order the MPPT to supply the battery with the maximum current possible, the battery should not be full and this is why a single day of battery autonomy was preferred. Assuming that the PV average daily solar exposure is three hours, the battery loss is 0.85 and the depth of discharge is 0.5 the battery capacity is calculated to be approximately 110 Ah. A resistor is used as dump load to release, in the form of heat, the total electricity generated by the STPV and stored at the battery, during the night, when the heating loads from the resistors will not interact with the STPV experiments. For a 1 Ω resistor and a 12 V battery supply, a 144 W resistor should be used, instead a 300 W resistor was selected to avoid the overheating of the resistor.

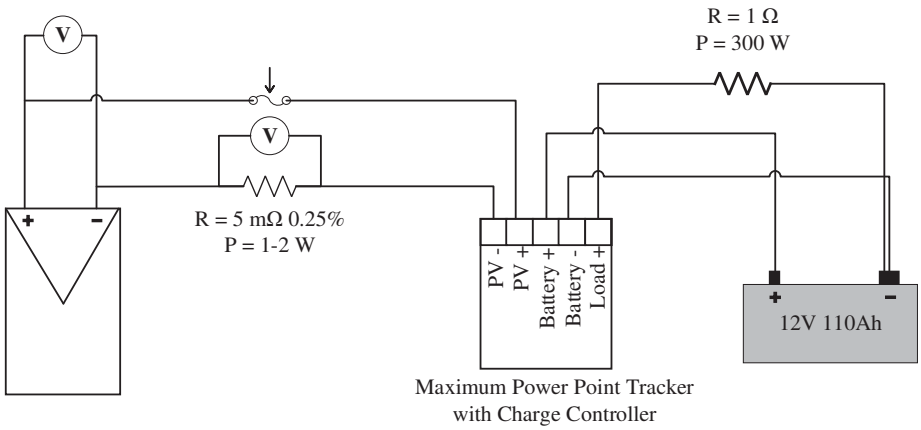

Figure 4 Schematic showing the electrical connection between the STPV, the MPPT and the batteries. The location of the shunt resistors used for the current measurement and the resistors used as a dump load is shown.

4. Experiments and result discussion

The test-cell and the experimental set-up described earlier, is used to characterize the electrical performance of the DSF-PV and the IGU-PV. In addition, a comparison is held between their performance under the same exterior and interior condition.

Experiments that are presented in this paper are for a series of eight (8) consecutive days, under different weather conditions and under different ventilation strategies for the cavity of the DSF-PV. The average velocity within the cavity and the incident solar radiation for these days are presented in Table 3. From Table 3, it can be extracted that for all the monitored days, the DSF-PV out-performs the IGU-PV by a 3% to 10% difference, depending on the strategy selected for the ventilation of the cavity of the DSF-PV.

From the same table, it can be seen that clear sky days are Day 1,4,6,7 and 8 and the overcast days are Day 2, 3, 5. If the cavity is ventilated, the electricity production of the STPV integrated on the DSF is greater than this of the IGU-PV by 7.27% to 9.20%. The days that the cavity is ventilated but the sky is overcast (Day 2 and 3), the electrical performance of the DSF-PV is approximately 4.5% greater than the IGU-PV. Lastly, when the cavity is closed, the difference between the electricity generated by both the STPV, is the smallest encountered but is still between 3.6% and 4.1%. On the last column of Table 3, the percentage of the time that the power of the DSF-PV is greater than the Power of the IGU-PV is presented showing that more than 87% of the time, the DSF-PV performs better than IGU-PV

In Figure 5, a comparison of the power produced and the current generated by the DSF-PV and the IGU-PV is depicted for Day 1 between 7:00 AM and 2:40 PM. The shaded with different colors zones, represent time-periods where different average velocities within the cavity were measured, due to different fan operation.
As it can be seen, the power generation between 7:30AM and 8:00AM drops and this is because of the shading that is provided to the test-cell by the sky-scraper presented in Figure 1. For the same reason, the power drops after 2:15PM, where the building located at the south-west shades the test-cell. The power of the IGU-PV drops first, as it is located on the west side of the test-cell.
When the cavity of the DSF-PV starts to be ventilated, the power generated by the DSF-PV starts to be greater that this of the IGU-PV. The current generated by both the STPVs is almost identical, and this is because the STPV are similar and under the same incident solar radiation. On the other hand, the difference of the power generated by the integrated STPVs should be correlated to the voltage difference created by each system and thus the temperature their cells, as the operating voltage of the STPV panels is dependent on the temperature of the cells.

For the same day (Day 1), the power generated by the DSF-PV and IGU-PV and the voltage at which this power is generated is shown in Figure 6. It can be seen that the DSF-PV operated at a higher voltage of about 2 V than the

IGU-PV. Consequently, the power generated by the DSF-PV is approximately 10 W higher than this of the IGU-PV, for the majority of the time, resulting in the average 9.20% difference presented in Table 3.

Table 3 Experimental data for eight (8) consecutive days in Montreal.

	Average Velocity within the Cavity	Average Incident Solar Radiation (W/m^2/day)	Average diffuse Solar Radiation (W/m^2/day)	Electricity generated by the DSF-PV (Wh/day)	Electricity generated by the IGU-PV (Wh/day)	Daily Difference	Percentage of time $P_{DSF}>P_{IGU}$
Day 1	1.25 m/s	194	44	704.01	644.67	9.20%	96.49
Day 2	0.65 m/s	156	70	561.06	537.31	4.42%	93.81
Day 3	1.10 m/s	156	77	462.91	442.40	4.64%	89.27
Day 4	closed	201	46	637.04	611.58	4.16%	91.24
Day 5	1.20 m/s	170	61	637.62	594.39	7.27%	95.72

5. Conclusions

This study is focused on assessing the electrical performance of two similar STPV panels under the same exterior and interior conditions, integrated on different systems. An exterior experimental facility is set up to monitor the electrical performance of the STPV panel integrated on the exterior layer of a DSF and on an IGU, forming in this way a DSF-PV and an IGU-PV.

It should be noted, that the study presents some limitations. One of these is the short duration of the experiment. In the contrary, these days are around the September equinox and thus makes it easier for the results to be used for future studies and simulations. Also, the eight (8) monitored days that are presented in this manuscript are part of a longer experiment that is set-up to run for a whole year, in Montreal (Canada). Annual results can be later used, with more confidence to simulate IGU-PV and DSF-PV under different climatic conditions.

During the monitored days, the STPV integrated on the DSF out-performs the one integrated on the IGU. For all the eight (8) monitored days that the experiment lasted, the electrical performance of the DSF-PV presented increased values between 3% and 9% depending on the ventilation strategy of the cavity of the DSF-PV and the incident solar radiation. Even when the DSF-PV is not ventilated and acts as a buffer zone, the electrical performance of the STPV panels is 3% to 4.5% greater than this of the IGU-PV.

Abstract

Understanding of the knowledge of classroom temperature distribution is critical to design of solar system terminal. The temperature non-uniformity caused by solar radiation is not negligible, especially in high-latitude and strong radiation areas. This paper presents a detailed and comprehensive experiment in a primary and secondary school in northwestern China that was used to determine the thermal distribution and validate a simulation model. The temperature variations in both the vertical and horizontal directions were analyzed in detail. The indoor air temperature distribution was investigated with a systematic simulation of different conditions, including five solar radiation intensity levels, four southern external walls thicknesses and five window-to-wall area ratios. The results showed that the average air temperature difference in the vertical direction was nearly 3.0°C, whereas it was approximately 1.0°C in the horizontal direction. The optimal results of the non-uniform temperature distribution can provide the basis for determining the parameters of thermal design and heating system settings in primary and secondary school classrooms.

Keywords: Temperature distribution, simulation, classroom, non-uniform, in-situ measurement,

1. Introduction

Healthy and comfortable microclimate conditions are essential in any type of environment, but schools in particular are buildings, in which a high level of environmental quality can considerably improve attention, concentration, learning, listening and performance (Corgnati et al. 2007; Corrado and Astolfi, 2002).The need to provide good environments in commercial and educational buildings relies on the fact that people spend more than 90% of their time indoors. Students spend approximately 30% of their life in schools (Valeria et al. 2012), so researching the thermal environment in schools is essential. Existing research on indoor thermal environments has primarily focused on thermal comfort in the whole environment; information on indoor temperature distribution is limited, as current studies on indoor temperature distribution have concentrated on urban office and residential buildings (Srebric et al. 2008; Catalina et al. 2009). However, primary and secondary schools are different because students have a higher metabolic rate, classrooms have a higher density of personnel, and classroom time is relatively fixed. Thus, current distribution laws may not apply to primary and secondary school classrooms in northwestern China due to the unique indoor thermal environment requirements for students; it is essential that it need to study these temperature distributions.

Indoor temperature distribution is not only affected by interior personnel and equipment but also by factors such as wall thickness, materials and window-to-wall ratios etc. The latter factor is significantly influenced by solar radiation and other outdoor parameters. Because of economic underdevelopment, improving the indoor thermal environment of primary and secondary schools has primarily relied on renewable solar energy resources. This provides the basis and foundation for the study of classroom temperature distribution under different conditions for the construction of solar buildings.

Computational fluid dynamics (CFD) is a proven and effective simulation tool for predicting and analyzing buildings with reliable results. Building temperature and other parameters are strongly affected by the outdoor environment and the building envelope properties, which can be simulated and predicted using CFD (Desta and Janssens, 2004). Currently, CFD consistently provides a convenient method for indoor thermal environment evaluation and design for offices (Stamou and Katsiris, 2006), lecture halls(Cheng et al. 2003), and industrial

doi:10.18086/swc.2017.12.05 Available at http://proceedings.ises.org

premises (Rohdin and Moshfegh, 2007). Catalina (Catalina et al. 2009) showed test results for wall surface temperatures to be consistent with thermal boundary conditions. Rundle (Rundle et al. 2011) simulated indoor air temperature distribution given the temperature boundary condition of the outside wall surface and the heat flux boundary condition of the indoor heat source. In addition, because of the complex nature of windows, research has rarely considered the natural convection and radiation coupling of windows and the indoors. Behnia (Behnia et al. 1990) considered the effect of solar radiation and change of temperature inside the glass when modeling windows. Ismail (Ismail and Henriquez, 2003) simulated a corridor with a window inside of an air flow and temperature distribution and then analyzed the building energy consumption and use of solar energy. CFD is essential when studying the heat transfer properties of glass and room air flow and temperature effects.

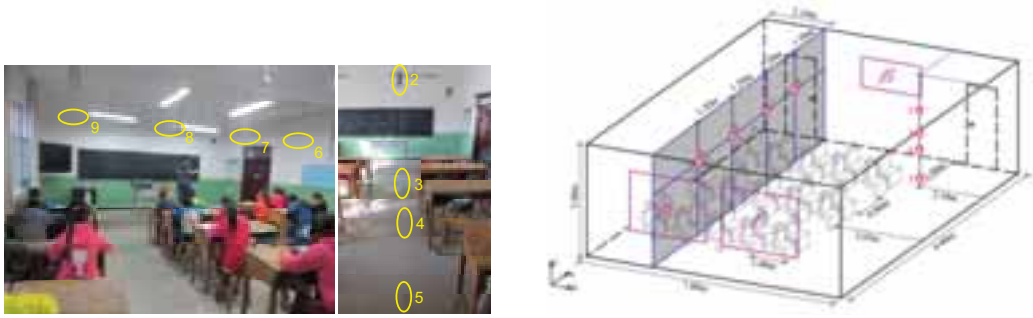
A comprehensive test was conducted to determine the temperature distribution features of primary and secondary school classrooms with enriched solar energy resources in an actual passive solar classroom. On the basis of the actual test, temperature distribution is simulated through Fluent. There was a high degree of concurrence between the measured and the simulated results. The indoor air temperature distribution was investigated with a systematic simulation of different conditions, including different solar radiation intensity levels, southern external walls thicknesses levels and five window-to-wall area ratios. Therefore, the non-uniform characteristics of temperature change provided the foundation for the construction designs of solar buildings and system heating settings.

2. Methods

2.1. Experimental classroom

The experimental classroom was located in Huangzhong County (latitude:36°34′N, longitude:101°49′E, altitude: 2645m), Qinghai, China, where the average annual air temperature and precipitation were 5.1°C and 509.8mm, respectively, as provided by a meteorological station.

The experimental classroom is shown in Fig. 1. The east, west and north walls were constructed of 20 mm of plaster, 300 mm of aerated bricks, 20mm of polystyrene board and 20 mm of plaster. The roof and ground structures were constructed with 200 mm of steel-reinforced concrete and 50 mm of aerated concrete and 100 mm of poured concrete and 80mm of polystyrene board, respectively. The heat transfer coefficient of the windows was 1.1 (W m-2 K-1). The size of the south window was 2.3m×1.8m×2; the north window was 1.8m×0.9m×1.The north door was 2.1m high×0.9m wide in the front and back of the classroom.



(a) Layout of experimental classroom (b) A real-scale 3-D model of the experimental classroom

Fig. 1: Measurement locations and dimensions of the experimental classroom

2.2. Measuring parameters, instruments and experimental procedure

The outdoor temperature and relative humidity were simultaneously measured according to the indoor classroom measurements by means of a portable automatic meteorological station located on the roof of the school building. The indoor environment measurements were automatically recorded every 10 minutes over 24h every day for a total of seven days (from 5 to 11 December 2015). Tab. 1 summarizes the characteristics of the equipment. The measurement equipment was fitted to the classroom to collect indoor environmental variables, such as air temperature, relative humidity, air velocity. The equipment was placed at eight locations inside the classroom and at one outdoor location without disturbing class activities and far from any heat sources, such as projectors or computers. The detailed measurement points are shown in Tab. 2 and correspond to Fig. 1.

Tab. 1: Measuring equipment specifications

Parameters	Instrument	Model	Accuracy	Operating method
Solar radiation intensity	Solar pyranometer	TBD-1	±8.789 W m^{-2}	Automatic recording every 10 min
Outdoor air temperature and relative humidity	Portable automatic meteorological station	Vantage Pro2	±0.5°C/±5%	
Indoor air temperature and relative humidity	Recording thermometer	TR-72U	±0.2°C/±5%	
Wall surface temperature	Thermocouple thermometer	CENTER309	±(0.3%rdg)+1°C	

Tab. 2: Measurement details of monitored positions at the cross-section shown in Fig. 1

Monitored position(P)	Measured items	Notes
1(Not shown)	Outdoor air temperature, Wind velocity, Solar radiation, etc.	Portable automatic meteorological station placed on roof (open space)
2	Indoor air temperature	Height:2.30m
3		Height:1.60m
4		Height:1.10m
5		Height:0.25m
6/7/8/9	Indoor air temperature	Height:2.30m

2.3. Computer simulation

Physical model. A real-scale 3-D model (shown in Fig. 1) of the experimental classroom was created with two modules: for fluid computational domains such as inside and outside air, and solid computational domains such as walls, roof and floor. Energy and Standard *k*-*ε* Turbulence Models were selected.

Model simplifications. 1) Humidity was not taken into consideration; 2) Air exchange between the inside and outside of the classroom was neglected because natural ventilation was negligible for the closed experimental classroom; and 3) The heat processes of the east wall, west wall and roof were considered to be adiabatic.

Governing equations. CFD is a numerical methodology that solves the governing equations of fluid flow by using a finite volume method to convert partial differential equations into a set of algebraic equations (Molina-Aiz et al. 2010; Zhang et al. 2016). It is based on the resolution of the governing equations of three conservation laws that include mass, energy, and momentum transport equations as follows (Versteeg and Malalasekera, 1995):

$$\frac{\partial(\rho\delta)}{\partial t} + div(\rho\mu\delta) = div(\Gamma_\delta \cdot grad\delta) + S_\delta \qquad \text{(eq. 1)}$$

where δ is the universal variable; ρ, μ, Γ_δ and S_δ are the density (kg m^{-1}), velocity vector (m s^{-1}), generalized diffusion coefficient (m^2 s^{-1}), and source term (W m^{-1}), respectively. This presents as a continuity equation when δ is 1, an energy equation when δ is T and a momentum equation when δ is u, v, w (m s^{-1}) with velocities in the directions of x, y, and z, respectively.

Initial and boundary conditions. Five types of boundary conditions were defined: the outside air temperature (T_{out}), the air temperature of the north corridor (T_c), the radiant sky temperature (T_{sky}), the surface convective heat transfer coefficient (h_o) and the soil surface temperature (T_f). The initial temperature of the inside air was set as an average value at 8:00 during the experimental period.

The air temperature (including T_{out} , T_c)changed over time; the conduction equation was solved inside the walls and can be fitted based on the experimental data during the entire day as follows:

$$T_{out} = 268.7 - 6.9 \times \cos(0.000073\tau + 5.2) \qquad R^2 = 0.9173 \qquad \text{(eq. 2)}$$

from 8:00(t=0 s $\tau = t + 3600 \times 8$) to 18:00(t=36000s)

$$T_c = 276.8 - 0.5 \times \cos\left(0.000073\tau - 26.3\right) \qquad R^2 = 0.7222 \qquad \text{(eq. 3)}$$

where τ is the time(s) and $28800 \le \tau \le 36000$; R^2 is the degree of fitting.

The heat transfer of the exterior wall can be determined by the convective heat transfer coefficient that can be calculated by eq. (4).

$$K_0 = \frac{1}{\frac{1}{h_i} + \sum \frac{d}{\lambda} + \frac{1}{h_o}} \qquad \text{(eq. 4)}$$

where K_0 is the heat transfer coefficient, W m^{-2} K^{-1}; h_i and h_o are the heat transfer coefficients of the inner and outer wall surfaces, respectively, W m^{-2} K^{-1}; d is the thickness of the wall, m; and λ is the thermal conductivity coefficient, W m^{-1} K^{-1}.

The thermal radiant exchange with the sky influences the heat balances of the exterior wall. It is therefore necessary to determine the radiant sky temperature T_{sky} (Tang et al. 2003). The following proposed empirical formula (Berdahl and Fromberg, 1982) was used:

$$T_{sky} = \varepsilon_{sky}^{0.25}\left(T_a + 273\right) \qquad \text{(eq. 5)}$$

$$\varepsilon_{sky} = 0.74 + 0.006T_{dp} \qquad \text{(eq. 6)}$$

where T_a is ambient air temperature, K.

The dew point temperature T_{dp} has the following empirical correction expressed in degrees Celsius(Cook,1985):

$$T_{dp} = 26.14 + 16.99C + 1.8893C^2 \qquad \text{(eq. 7)}$$

$$C = \ln\left(Rh \cdot Pa\right) = \ln\left(Rh\right) - 8.0929 + 0.97608\left(T_a + 42.607\right)^{0.5} \qquad \text{(eq. 8)}$$

where Rh is the relative humidity, %; and Pa is the saturation vapor pressure of the air at any air temperature.

The final fitting equation of T_{sky} is below:

$$T_{sky} = 276.8 - 6.8 \times \cos\left(0.000073\tau + 5.2\right) \qquad R^2 = 0.8498 \qquad \text{(eq. 9)}$$

To conveniently validate and utilize the established simulation model, the floor was regarded as playing a constant wall temperature role.

The evaluation of the metabolic rate in the school building was obtained from Havenith (Havenith, 2007), who studied the metabolic rate and clothing insulation of children and adolescents. The metabolic rate was set at 52 W m^{-2} in accordance with a simple writing task or sedentary activity. The total heat release of a human body was set at 76 W per person (Srebric et al. 2008). The temperature around the body was simulated by a given body surface heat flux.

2.4. Model applications

Once the computer simulation was validated, it was used to predict the thermal environment with different conditions in terms of varying solar radiation intensities, south external wall thicknesses and window-to-wall area ratios, as listed in Tab. 3. The same model parameters, initial and boundary conditions and solving methodology were used in all models.

Tab. 3: Different cases of different conditions for simulation

(a) Five cases of solar radiation intensity for simulation

Case	Solar radiation intensity level(W m^{-2})
1	800
2	600(Case validation)
3	400
4	200

5	100

(b) Four cases of thickness of the south wall for simulation

Case	Thickness of the south wall(mm)
1	240+20
2	370+20(Case validation)
3	520+20
4	630+20

(c) Four cases of window-to-wall area ratio for simulation

Case	Area ratio of window to wall	Length(m) × Width(m) × Number
1	0.3(Case validation)	2.3×1.8×2
2	0.4	2.4×2.4×2
5	0.5	2.8×2.5×2
3	0.6	3.0×2.8×2
4	0.7	3.2×3.2×2

3. Results and discussion

3.1. Measuring results and analysis

Ambient air conditions. Fig. 2 shows the indoor and outdoor air temperatures along with the solar radiation intensity for one measured day. During the day, the maximum global and direct radiation levels were 557 W m^{-2} and 470 W m^{-2}, respectively. The mean outdoor air temperature and relative humidity were -1.3°C and 54.6%, respectively. The air temperature ranged between 6.1°C and 13.4°C, with an average of 8.7°C during the day. The relative humidity ranged between 16% and 74% and the air velocity ranged from 0 to 0.49 m s^{-1}. However, the variations in global solar radiation, outdoor air temperature and indoor air temperature ranged from 0 to 557 W m^{-2}, from -6.2°C to 8.1°C, and from 6.1°C to 13.4°C, respectively, with averages of 284 W m^{-2}, 1.8°C and 10.8°C during the school day.

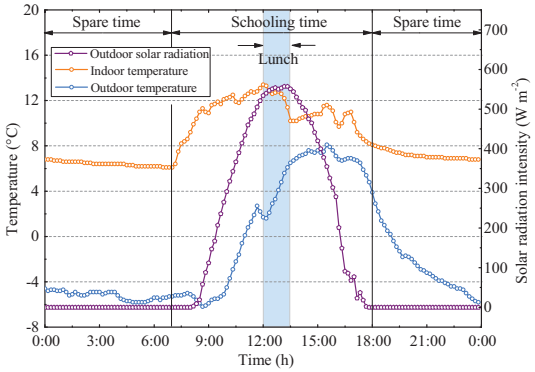


Fig. 2: Indoor and outdoor air temperatures and solar radiation intensity

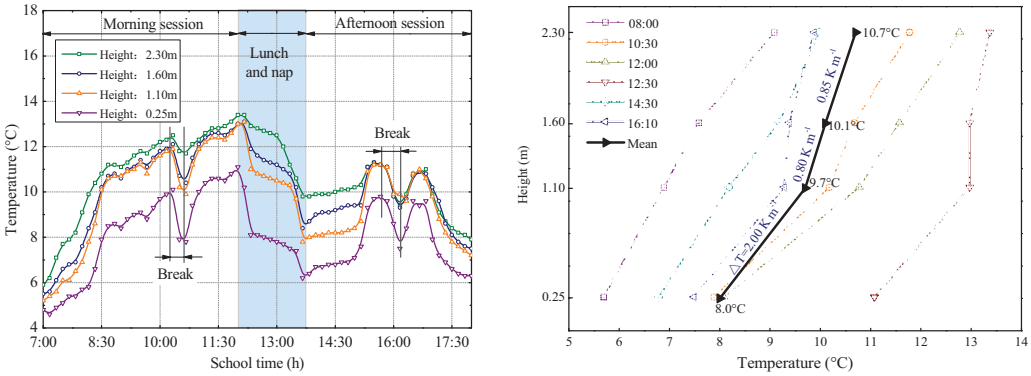
Vertical temperature distribution. There are considerable differences in ambient building temperatures that also influence the distribution of temperature fields inside buildings. According to the measured temperature data, there was significant non-uniformity in the temperature field distribution inside the measured building. The uneven distribution of the temperature field was analyzed in the vertical and horizontal directions.

The temperature variation in the vertical direction is shown in Fig. 3(a). The building temperature field, as

observed in the temperature distribution, shows significant non-uniformity in the vertical direction. The measured temperature at 2.3 m was consistently higher than the other locations. The temperature at 1.6m was slightly higher than at 1.1m but substantially less than at 2.3 m. Obviously, the temperature is the lowest at ground level. It can be seen from the diagram that the change tendency of the four lines is roughly the same. The temperature decline was primarily due to students leaving the room for recess, lunch and nap. Heated air moves upward in the classroom, the heat loss of human body at 1.1~1.6m makes the temperature higher than at ground level (0.25m).

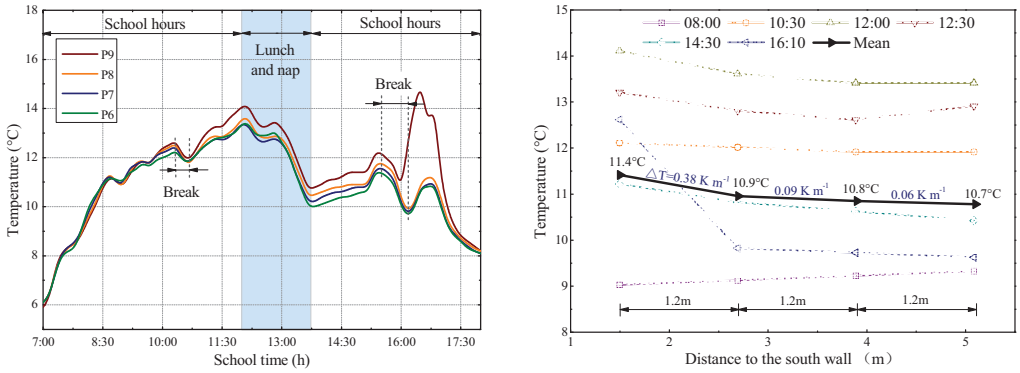
To facilitate analysis, the measured temperature data at representative timings (8:00, 10:30, 12:00, 12:30, 14:30, and 16:10) were selected for assessing non-uniformity. The temperature values at different points are shown in Fig. 3(b). It can be seen that the tendency of the temperature distribution was generally similar. The mean temperature during the school day (from 7:00 to 18:00) was calculated. In the range of 0.25 to 1.1m, the rate of temperature increase was greater due to the heat dissipation from the human bodies to the indoor environment at 2.0 °C m^{-1}. Because of the lower personnel density, the rate of temperature increase reached 0.8 °C m^{-1} at 1.1 to 1.6m.



(a) Temperature variation (b) Temperature distribution at different times

Fig. 3: Temperature distribution in vertical direction

Horizontal temperature distribution. The temperature at the south measuring point was generally higher than the north. The average value was 11.4°C, 10.9°C, 10.8°C and 10.7°C from south to north in turns. It can be seen from Fig.4 (a). that the tendency of the temperature distribution was generally similar except for the curve at P9. Because the P9 point was located in the south, the influence of solar radiation was the strongest. From 16:00 to 17:00, the temperature at P9 rose sharply.



(a) Temperature variation (b) Temperature distribution at different times

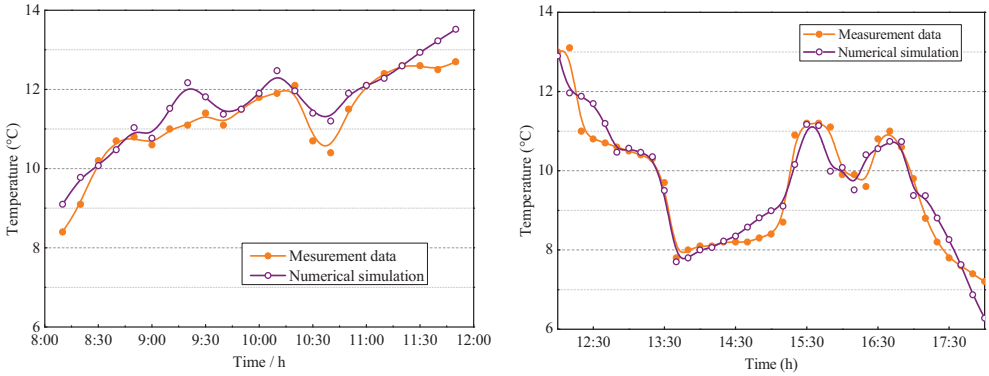
Fig. 4: Temperature distribution in horizontal direction

The temperature values at different points are shown in Fig. 4(b). It can be seen that the tendency of the temperature distribution was generally similar except at 8:00 and 16:10. At 8:00, the temperature elevated from south to north due to less solar radiation. With the increase of solar radiation, the temperature increased rapidly at the south end of the room. At 16:10, the temperature at south rises sharply. The differences between the northern and southern temperatures are caused by the increased heat loss on the north side due to differences on both sides of the outdoor environment temperature in the winter and the increased solar radiation heat gain in

the south. Based on the above, solar radiation intensity plays a decisive role in the south - north temperature distribution differences.

3.2. Model validation

To verify the differences between the measured and simulated results and verify the reliability of the simulation and the measurements, a comparative analysis of the measured and simulated temperature values between 1.1 m and 1.6 m are shown in Fig. 5. It can be seen that the simulated temperatures at each measurement position concurred with the experimental temperatures, with the same trend over the measurement period. For example, the temperature tendencies of the measurement and the simulation at P3 in the morning and at P4 in the afternoon are shown in Fig. 5(a) and Fig. 5(b), respectively. It can be seen that the mean simulated results were higher than the measured results by 0.3°C to 0.4°C; the mean simulated and measured temperatures at P3 in the morning were 11.7°C and 11.3°C, and the mean simulated and measured temperatures at P4 in the afternoon were 9.9°C and 9.6°C, respectively. This small difference was caused by objective factors. Although the simulation closely adheres to the actual situation, there are certain simplifications that cannot be fully considered such as various indoor objects and accidental disturbances. In addition, the specific locations of the actual measuring points are not precisely the same as the simulation locations.



(a) Verification of P3 at 1.6m in the morning (b) Verification of P4 at 1.1m in the afternoon

Fig. 5: Comparison of the temperature distribution obtained by simulation and in-situ measurements

3.3. Simulated temperature distribution

Different solar radiation intensity levels. Fig. 6(a) shows the temperature changes of different positions at a height of 1.1m. The temperature at the same location essentially shows a linearly increasing trend with increasing solar radiation intensity. The temperature amplification differs with the increase of solar radiation at different locations from the south wall; the closer to the south wall, the greater the slope of increased temperature. The temperature increased by 2.3°C, 2.1°C and 1.9°C from distances of 0.8m, 3.3m and 5.8m to the south wall, respectively, when the solar radiation increased in100 W m^{-2} increments. At 3.3 m from the south wall, the temperature increased by 14.7°C when the solar radiation increased from 100 W m^{-2} to 800 W m^{-2}. The temperature increased by 0.7°C and 1.0°C at different locations from distances of 0.8m to 3.3m and from distances of 3.3m to 5.8m at a solar radiation of 600 W m^{-2}. The temperature gradient is lower when closer to the south wall and greater when further away.

Different thicknesses of south external wall. The simulation was carried out under the following conditions: a solar radiation of 600 W m^{-2}, a window-to-wall area ratio of 0.3, and a time of 12 noon. Fig. 6(b) shows the temperature changes of different positions at height of 1.1m.The temperature at the same location shows a trend of initial decrease and subsequent increase with the increase of south wall thickness. When the wall thickness is increased from 260mm to 390mm, the temperature significantly decreases by 5°C at 3.3 m distance to the south wall. When the wall thickness is increased from 390mm to 540mm, temperature slightly decreases by less by 1°C. When it increased from 540mm to 650mm, the temperature only decreases by 0.2°C. In short, the impact on indoor temperature is significant with increasing south wall thickness, but the indoor temperature will eventually rise when the wall thickness increases to a certain extent.

Different window-to-wall area ratios. The simulation was carried out under the following conditions: a solar radiation of 600 W m^{-2}, a 540-mm south wall thickness, and a time of and 12 noon. Fig. 6(c) shows the temperature changes of different positions at height of 1.1m. The temperature at the same location essentially

showed an increasing trend with the increased window-to-wall area ratios. The temperature growth trends differed with the increase of the window-to-wall area ratio at different positions to the south wall. At 0.8m from the south wall, the temperature increase was greater with an area ratio of 0.3 to 0.4 and more gradual with an area ratio of 0.4 to 0.7; the further from the south wall, the more gradual the temperature variation. This may be due to an increase in the area of the window. The window increases the quantity of heat but simultaneously contributes to heat loss because it is poorly constructed for heat gain and loss reduction.

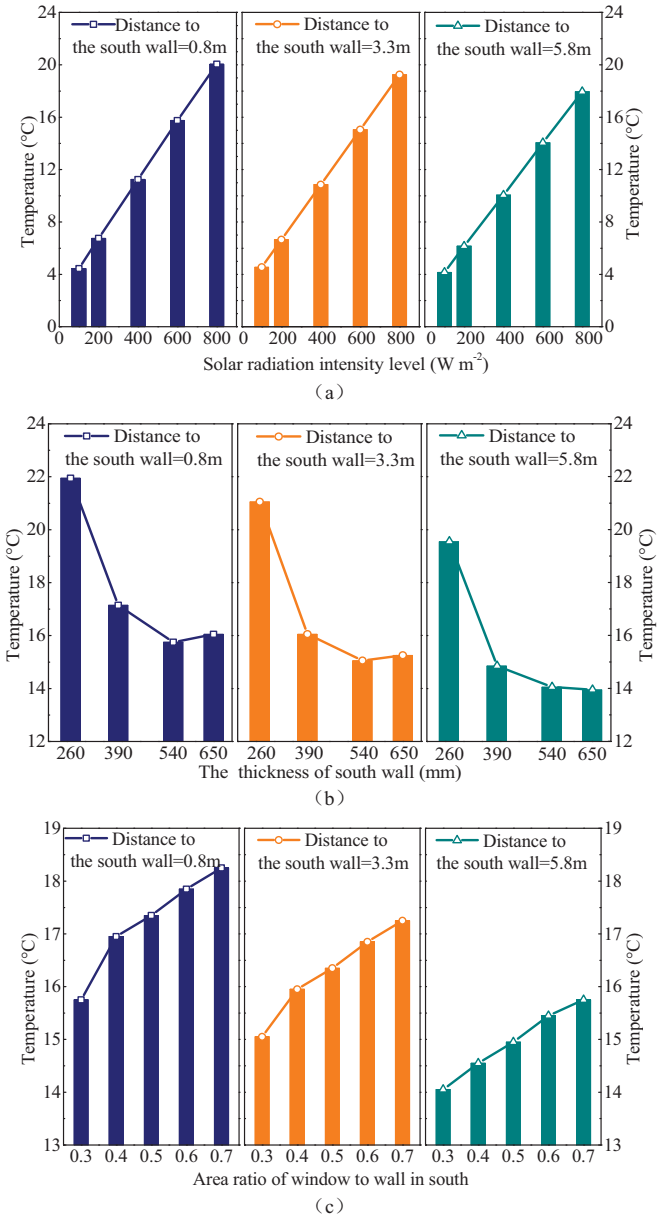


Fig. 6: The evolution of temperature distribution under different simulation cases

4. Conclusions

A computer simulation model using the finite-volume-based commercial software Fluent was used to evaluate classroom temperature distributions. Experiments were conducted in an experimental primary school classroom in northwestern China to validate the simulation model. The simulated results concurred with the measured temperatures. The validated computer simulation model was applied to predict classroom temperature distributions with various conditions. The following conclusions were obtained:

(1) Based on the measured temperature data, there is significant non-uniformity in the temperature field

distribution inside the measured building. The vertical direction of the average air temperature in the classroom was nearly 3.0°C; the horizontal direction of the average temperature was approximately 1.0°C.

(2) Within the range of 0.25m to 1.10m in vertical direction, the temperature gradient was approximately 2.0 °C m^{-1}, whereas the temperature gradient was reduced to 0.8 °C m^{-1} at 1.10 to 2.30m. The closer to the south wall, the more obvious the temperature difference in horizontal direction. From 1.5m to 2.7m, 2.7m to 3.9m, and 3.9m to 5.1m, the temperature gradients were 0.38, 0.09 and 0.06 °C m^{-1}, respectively.

(3)The simulated results showed that the indoor temperature changed when the solar radiation intensity was varied; the temperature trends were linear. The temperature gradient is lower when closer to the south wall and greater when further away.

(4)The indoor temperature changed when the thickness of the south wall was varied and the temperature trends were non-linear. The temperature at the same location shows a trend of initial decrease and subsequent increase with the increase of south wall thickness. So a thinner south wall was preferable.

(5)The indoor temperature changed when the window-to-wall area ratio was varied, and the temperature at the same location essentially showed an increasing trend. At different positions, however, the temperature growth trends differed with an increase of window-to-wall area ratio; the further the distance from the south wall, the more gently the temperature varied.

Development of Automation Models for the Intelligent Use of PV Energy and Energy Storage in Regarding to Air Quality and Comfort in Buildings

Alexander-Nicolai Köhler[1], Markus Fischer[1], Andreas Böttcher[1] and Bolli Björnsson[1]

[1] University of Applied Sciences Fulda, Fulda (Germany)

Abstract

The so-called "Plus-Energy-House" can make an important contribution to the future through a more efficient use of energy. In cooperation with numerous partners from the industry as well as the Fulda University of Applied Sciences (Fulda UAS), a multifunctional school building which meets the requirements of a Plus-Energy-House was built. Intelligent energy management achieves a high level of self-consumption and an energy excess. This paper explains the energy concept of the building, which consists of numerous components. These include for example, prediction algorithms for generating as well as using PV energy and a computer vision (CV) system, which integrates the human as a thermo-technical component in the energy concept of the building.

Keywords: Plus Energy House, Control, Prediction Algorithm

1. Introduction

The recent years have shown that the current method of energy production and energy consumption is not sustainable. As a result, energy transition in the Federal Republic of Germany is currently a very relevant issue of today's world. Energy transition defines the transition from unsustainable fossil fuels and nuclear energy to a sustainable and environmental friendly energy supply through renewable energies (Verbruggen, 2014). An important goal is to reduce the social, health and ecological problems caused by the conventional energy industry. A decarburization of the energy industry plays a significant role in stopping global warming. (Lüdeke-Freund, 2014) (Poizot and Dolhem, 2011) (Armaroli and Balzani, 2007) Therefore, a basic change in thinking of energy production and the use of energy has to follow in the future. (Mertens, 2011) The construction and housing sector provides a great energy saving potential. Currently, about 40 percent of the total primary energy consumption is spent on it (Ministry of Environment, Energy and Climate Protection, 2013). As shown by Köhler, Fischer and Lambeck (2014) the technology of the so-called "Plus-Energy-House" can make a major contribution to that. A plus energy house produces more energy than it needs for heating and the entire household electricity by using modern energy technologies in conjunction with energy storage (Lüdeke-Freud and Opel, 2014). Combining the technology of plus energy houses with additional energy optimization systems, further improvements are possible regarding energy consumption.

2. Application

A new multifunctional school building (see Figure 1) was built on the campus of the Johannes-Keppler-School in Neuhof (Germany) in cooperation with the manufacturer "Bien Zenker" as well as numerous other partners from industry and the handicrafts (Figure 1). It is in conformity with the requirements of a plus-energy-house. Fulda UAS is using the building for research purposes.

doi:10.18086/swc.2017.12.06 Available at http://proceedings.ises.org

Fig. 1: Front view of the school building

The modern, energy-saving and efficient house contains numerous systems that produce, store and distribute the required energy for the operation of the building in an intelligent way. For example, there is a photovoltaic system on the roof of the building. The generated energy can be used for operation, stored in a battery or fed into the grid. To ensure the lowest possible energy consumption, only highly efficient and energy-saving systems are used inside the building. A ventilation system with heat recovery ensures ideal air quality. An infrared heating system is used to heat the building. The control of actuators such as lighting, blinds as well as some sensors e.g. temperature, CO2, brightness or presence is done by a radio bus system.

The use of special prediction algorithms enables the prediction of energy generation and energy consumption in the building and helps to optimize the energy usage. In addition, the use of special camera systems to predict the CO2 concentration and room temperature help to improve the energy balance. The camera system makes it possible to determine the number of persons in the building. With the help of a Computer Vision (CV) system (see 4.1) the influence of the room temperature and the CO2 concentration can be calculated by the persons inside the building and their change can be predicted.

3. Efficient energy management

3.1. Three pillars concept

The energy of the building is used sensibly. As a result, only a little energy is taken from the public grid and the own consumption is increased. To achieve this, the energy concept is based on *three* fundamental pillars.

First, efforts are necessary to save as much energy as possible. The built-in highly efficient technologies contribute significantly to energy saving. It is important to reduce the energy consumption of the building as much as possible. Energy should only be used when necessary. For example, make contacts and presence detectors are installed inside the building, which allow some consumers to be switched off if there is no one inside.

Secondly, the storing of the energy has to be made possible. The photovoltaic system generates energy only during the day. As there is no solar energy available at night, it must be saved during the day time. This increases the self-consumption of the generated energy and thus has a decisive influence on the autonomy of the building. A battery system can be used for this purpose. In addition, the building has a special cement flooring, which has a high heat capacity.

The *third* priority is the preventive use of excessive energy. The excessive energy is used where it is required in the near future, e.g. for heating or ventilating the building. The battery has only a limited capacity. In spring, summer and autumn the capacity is enough to supply the building at night without any power from the grid. In the winter, the infrared heating requires a lot of energy that the battery cannot cover. That is when the usage - optimization is put to use. There is a sufficient number of sunny days in the winter time, when the photovoltaic

system produces enough energy. On these days surplus energy which is normally fed into the grid, is to be effectively used in the building in order to prevent energy consumption at a later time.

3.2. Use of prediction algorithms

Renewable energy has many advantages like low environmental impact and endless resources. However, there are also some disadvantages. For example, the energies are highly weather-bound and therefore not always available. This makes it necessary to store and use such time-dependent energy. It would be ideal to adjust the power consumption to the power generation. Thus, the produced energy could be consumed concurrently, peak loads would be reduced and stored energy would be available longer. To realize this, it is advantageous to forecast the produced energy by suitable methods to plan their use in advance. Thus, the energy consumption of the produced energy can be tracked by PV forecasts and suitable activation of electric loads. On the one hand this prevents unwanted load peaks and on the other hand economic losses of the system. The basis for a forecast-based operating method are suitable methods to predict the PV production in order to plan the usage of the generated energy better.

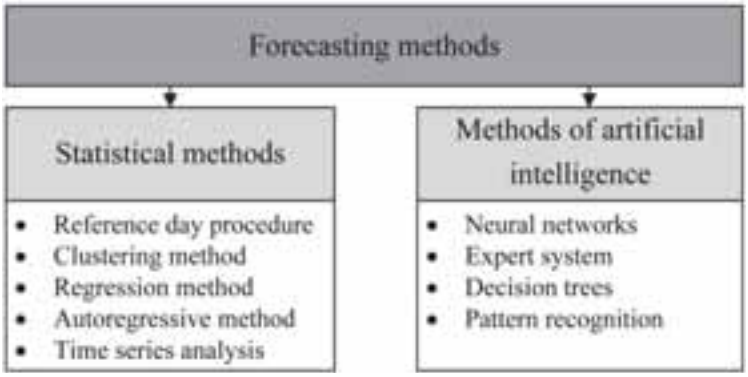

Fig. 2: Overview of typical forecasting methods (Köhler, Fischer and Lambeck, 2014)

There are two typical types of forecasting methods, as Figure 2 shows. Statistical methods use mathematical combinations of historical data combined with information on the influencing variables to predict the future behavior of consumers. However, if no expedient prediction can be made because of unavailable influence factors, it could be helpful to use methods of artificial intelligence. Methods of artificial intelligence learn patterns of behavior with the help of historical data and project these as a function of the expected operating conditions into the future. To select the optimal forecasting method for a particular application, it is also important determine the required time horizon of the forecast. Short-term forecasts (forecast horizon for one day) can be created on the basis of measurements and current data. In contrast to long-term forecasts (forecast horizon for several months) where mostly methods of artificial intelligence are used. These learn the different patterns of behavior based on historical data and project them into the future. Sometime various forecasting methods can work differently for certain sectors of the influencing factors. Because of this, combined or cascaded models are increasingly used. These include a number of methods. Each of them operates only for certain input variables and complement each other. A combination of different methods for a forecast can improve the forecasting accuracy. (Prokhorova and Heimel, 2013) (Theil, 1966) (Schlittgen, 2001)

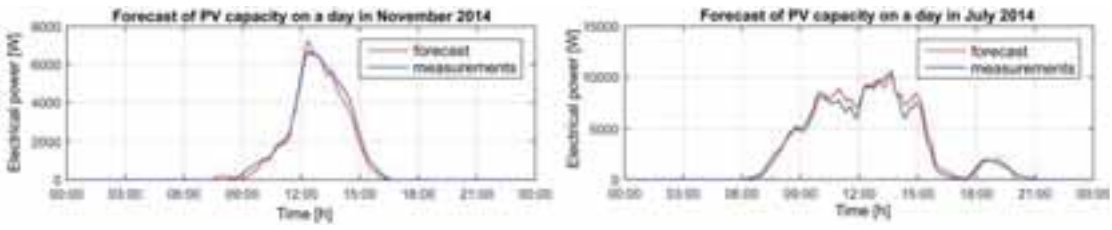

Fig. 3: Comparison between simulation and measurements on two days (Köhler, Fischer and Lambeck, 2016)

4. Comfort and air quality for people

A major problem in well-insulated buildings is the air quality. The high insulation makes the air exchange with the environment more difficult. This has advantages and disadvantages. One advantage is that the energy, like heat from humans, remains inside the room. A disadvantage is that old depleted air remains inside the building. For these reasons, various systems have been integrated into the building, which also significantly increase the energy efficiency.

4.1. Use of prediction algorithms

Figure 4 shows that an average person with a light activity produces a heat current of 120 W. This results in a daily heat output of about 2.9 kWh per day 8 (24 hours). This factor is multiplied many times due to the many students inside the public building. Accordingly, this would be a heat flux of 3000 W at an average of 25 students. (Specht, 2005) Thus, the human is a part of heating system which is an important factor in the control of heating and ventilation.

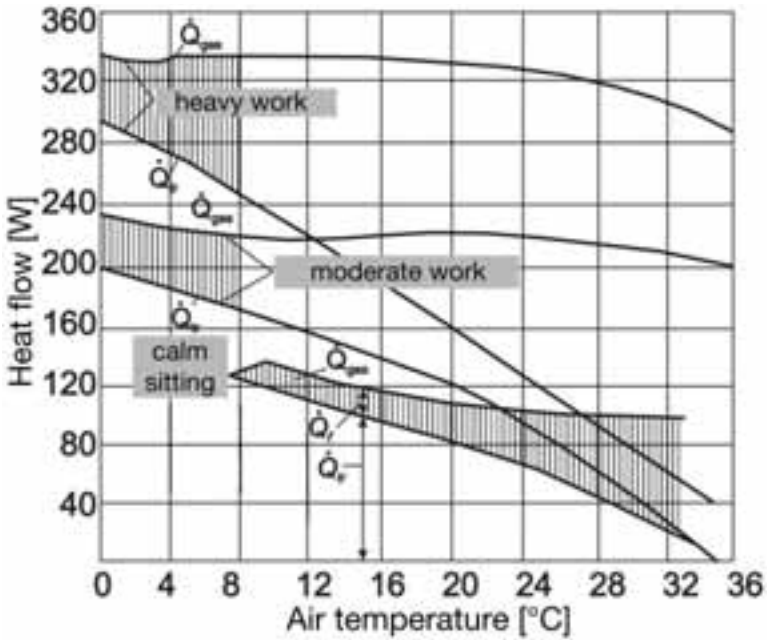

Fig. 4: Heat emission of humans (Specht, 2005)

A Computer Vision (CV) system (ADBF-Vision) was developed to recognize the number of people in the room. Depending on the number of detected persons in the room, the heating is throttled and unnecessary energy is saved. The Viola-Jones algorithm, which was originally presented in 2001 by Paul Viola and Michael Jones as a possible solution for the problem of facial recognition, is used to realize the recognition of persons. (Behera and Mohapatra, 2015) information on this development, refer to (Böttcher and Köhler, 2017). This can also be applied to detect other objects.

The algorithm gains high acceptance because of the comparatively high computational efficiency that allows real-time image processing. In one iteration, a migrating window moves over the input image pixel by pixel. After completion of a run, the image can be scaled into a smaller format or the mask can be enlarged. The image area inside the movable window is analysed step by step. The Haar wavelets developed by Alfred Haar are processed (see figure 5). These are folding masks. The black and white areas represent the sign for the summation of the brightness values of the covered pixels.

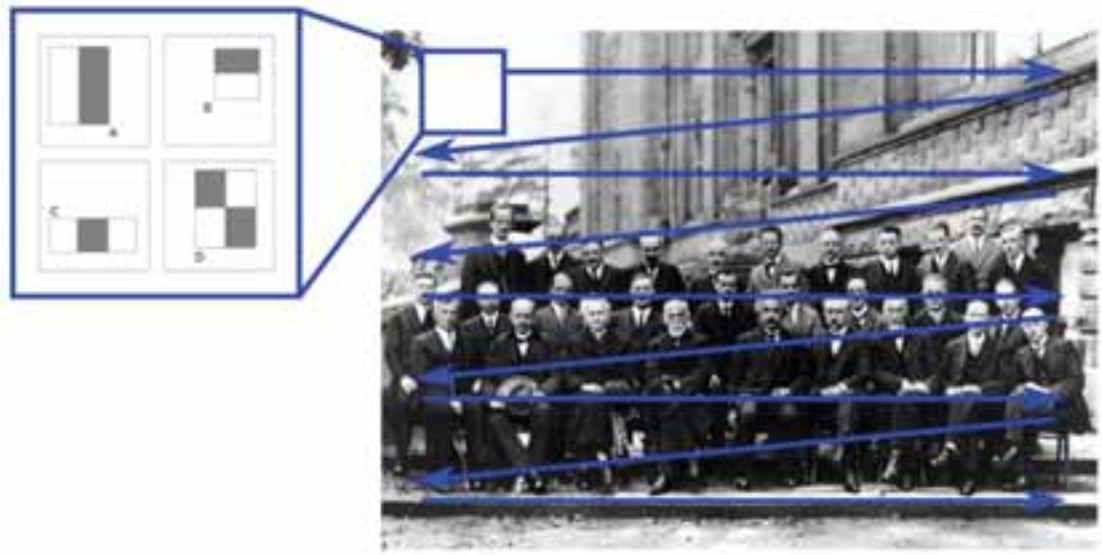

Fig. 5: Bewegliches Fenster und Haar Kaskadenmuster (Zhenyu, 2012)

The object detection is based on the cascade filter. Within a position of the moving window, different Haar-cascade elements are applied according to the state of the filter on this area. The individual results of the masks are summed. If a specific threshold is exceeded, the area is passed on to the following level. If the threshold for matching with the masks falls to a certain level, the content of the window is not checked anymore for correspondence and the window moves. If the content of the windows can exceed the required threshold in all levels of the filter, it is included in the result set of the detected objects. Therefore, it is possible for the algorithm to search for possible facial shapes inside the movable window (figure 6). For further information on this development, please refer to (Böttcher and Köhler, 2017).

Fig. 6: Person detection inside the classroom

4.2. Carbon dioxide (CO2) and temperature

Various studies have shown that the air quality in classrooms is poor and that CO2 concentration is too high, especially during the winter months. This can lead to tiredness or lack of concentration for teachers and pupils. The amount of CO2 depends on the activity of the people inside the room. Breathing air contains about 4 percent by volume CO2. This corresponds to 18 to 20 l/h CO2 per person (Benedix, 2006). In contrast to water vapor, the exhaled CO2 is not absorbed by surfaces. It accumulates completely in the air. During a lesson, it leads to an increase of the CO2 concentration from 400 ppm up to 2000-2500 ppm. The maximum permitted

CO2 limit in public areas is 1500 ppm according to DIN 1946-2. The CO2 and temperature sensors as well as the computer vision (CV) system allow a predictive control of the ventilation. Thus, it is possible to maintain the air quality inside the room under efficient conditions.

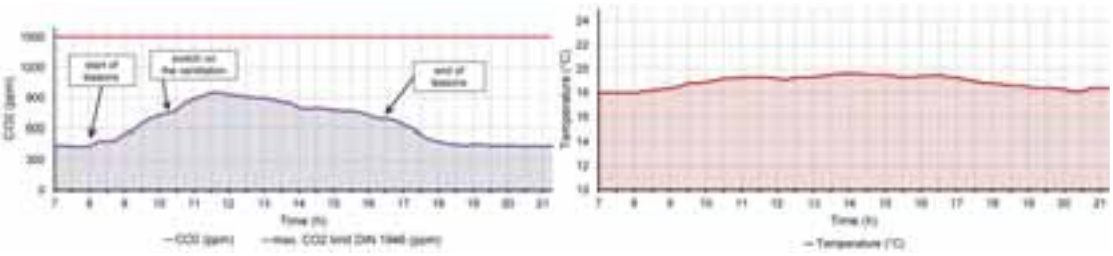

Fig. 7: measurements of carbon dioxide (CO2) and temperature for one day in school

5. Conclusion and prospects

The energy management of the multifunctional school building has already proved over the past few years that intelligent, predictive control strategies allow an environmental friendly operation of the building and an efficient use of renewable energies. In particular, the low energy consumption of the building as well as a high part of renewable energy in the total energy consumption should be highlighted. The strategies used to regulate temperature and CO2 concentration leads to an ideal air quality and comfort.

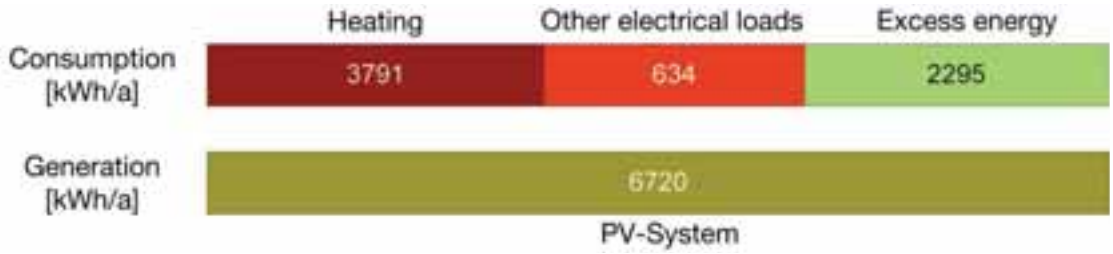

Fig. 6: energy balance

Through integrating the Computer Vision system into the existing automation unit, further energy saving potentials will be realized in the near future. A statement about the level of energy saving or an improvement in air quality can only be made when the system is operating in the building over a longer period of time. In the future, it is also important to coordinate the integrated systems and optimize their functions in order to increase the efficiency of the building.

Abstract

One way to improve the efficiency of renewable energy system is by integrating two or more devices or so called the hybrid system. In this study, the change of the Ground Source Heat Pump (GSHP) seasonal performance factor will be observed when it is integrated with Photovoltaic-Thermal (PVT) to meet the multiple loads of house and office. Basically, the strategy to get this efficiency improvement is by combining the water outlet of GSHP which firstly heated by desuperheater and the output of PVT in one (preheat) tank. In the solar preheat tank, the heat from PVT will be added through heat exchanger as the supplementary to the hot water which is previously from city water passing desuperheater of GSHP. The final output of GSHP with the heat addition from PVT and the efficiency of stand-alone GSHP will be compared. GSHP-PVT hybrid system has the lowest energy consumption followed by GSHP stand-alone and reference case (simple sum of house and office) with 31.8 kWh/m^2-yr, 78.7 kWh/m^2-yr and 107 kWh/m^2-yr

Keywords: *Ground Source Heat Pump (GSHP), Photovoltaic-Themal (PVT), Multi-Load, Energy, Net Zero Energy Building(nZEB)*

1. INTRODUCTION

The requirement for alternative low-cost and efficient energy sources has triggered people to the development of Ground Source Heat Pump (GSHP) system for residential and commercial heating and cooling applications. Earth temperature always stable throughout the year and this is also the reason why GSHP is very attractive. The heat pump on GSHP system operates using the same cycle as a vapor compression refrigeration cycle. Both systems absorb heat at a low temperature level and reject it to a higher temperature level. The difference between these two systems is that a refrigeration application is only concerned with the lower temperature effect produced at the evaporator, while a heat pump may be concerned with both cooling effect produced at the evaporator as well as the heating effect produced at the condenser in GSHP system. A reversing valve system is used to switch between heating and cooling modes by changing the refrigerant flow direction. GSHP system can be seen in Fig.1

A photovoltaic-thermal or PVT module is a combination of photovoltaic cells with a solar thermal collector, forming one device that converts solar radiation into electricity and heat simultaneously. The excess heat that is generated in the PV cells is removed and converted into useful thermal energy. The PVT system can produced efficiency up to 75% as the efficiency of PVT increases and the cell temperature is decreased. PVT can be distinguished into two types based on the manufacturing process: PVT collectors and PVT panels. PVT collectors are very similar in appearance to a regular solar thermal collector, consisting of a PV-covered absorber in an insulated collector box with a glass cover. PVT panes on the other hands are similar in appearance to regular PV panels. Due to lack of extra insulation and a glass cover, PVT panes have a lower thermal efficiency but higher electrical yield. Fig.2 shows the PVT panels. In this study, two cases will be compared which are GSHP system and GSHP coupled by PVT system in order to perform the annual performance analysis.

Fig.2. PVT Module

2. MICRO-GENERATION SYSTEM MODELING FOR EACH CASE STUDIES

In this study, three systems will be introduced for applications in residential and commercial buildings. Case one is simple sum of residential and commercial buildings (house and office) heating/cooling demand. Both thermal loads of residential and commercial buildings are provided by boiler and chiller system also fan coil unit as presented in Fig.3. The fan coil unit is located inside the building and a duct system is used to distribute the cooling/heating air inside the building. Domestic hot water (DHW) tank in installed inside the house and connected with the boiler via pipelines. This case will be the reference case for this simulation study.

Case two is a load sharing system with Ground Source Heat Pump (GSHP) to meet the combined load of houses and offices. Case two is load sharing hybrid system of GSHP integrated with PVT module. Load sharing in this case means houses and offices will use one system to provide heating and cooling demand instead of using separate system for each house and office. In case one, as presented in Fig.4, uses GSHP system to provide the heating/cooling demand instead of boiler/chiller system (conventional system). The desuperheater of GSHP is used to preheat the city water for DHW usage. A hot water storage tank is equipped to provide space heating and DHW heating. A gas burner is located at the bottom of the tank to provide supplementary heat in cases where GSHP alone cannot provide sufficient heat in very cold days or to heat the DHW water in summer. Water from the hot water tank is supplied to the two buildings through pipelines for DHW demand loads. In this case, the city water has enough pressure to flow the water in the system without using a pump. A cold water storage tank is used in the cooling season to provide chilled water for the cooling coils. Three way valves are used to switch between GSHP heating and cooling loops in winter and summer cooling seasons.

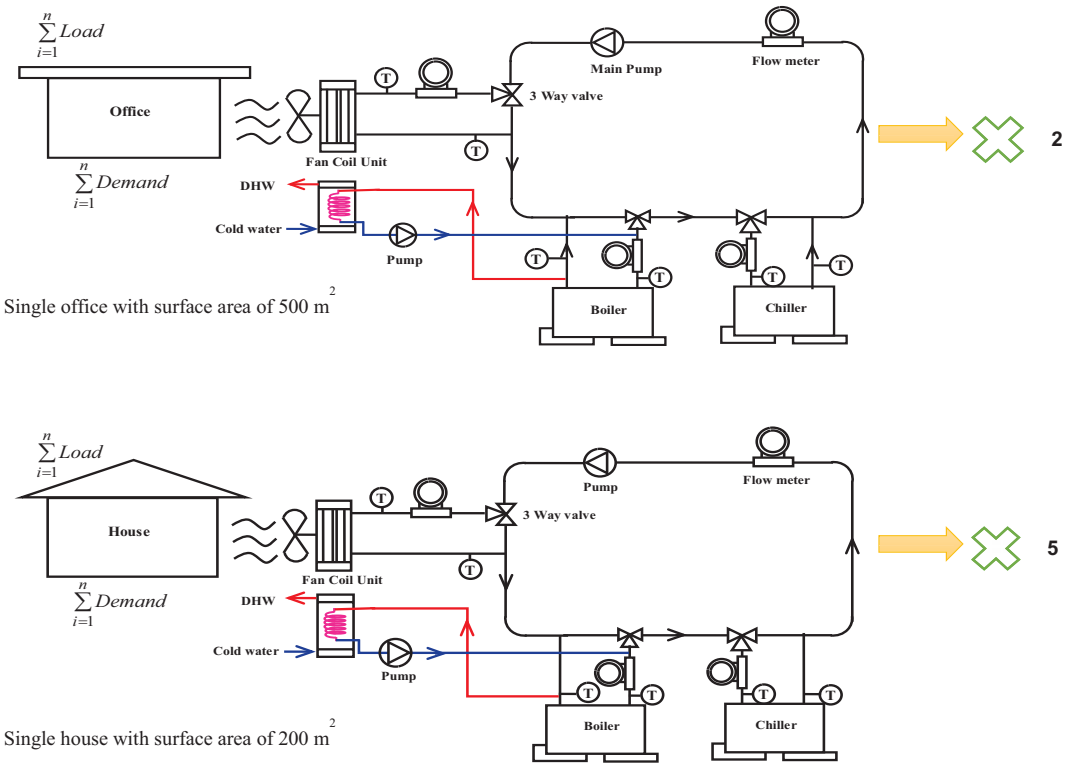

Fig.3. Simple Sum of Residential and Commercial Buildings System

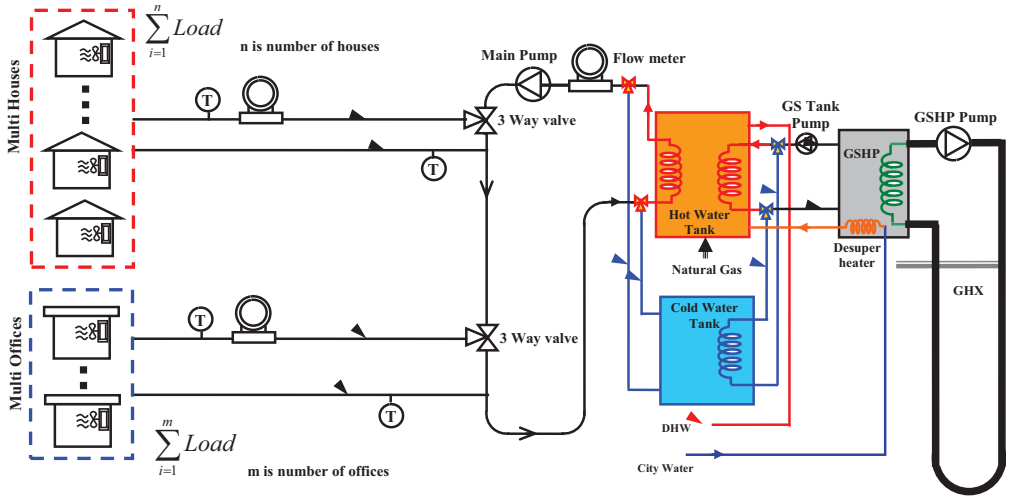

Fig.4. Load Sharing (Houses & Offices) Using GSHP System

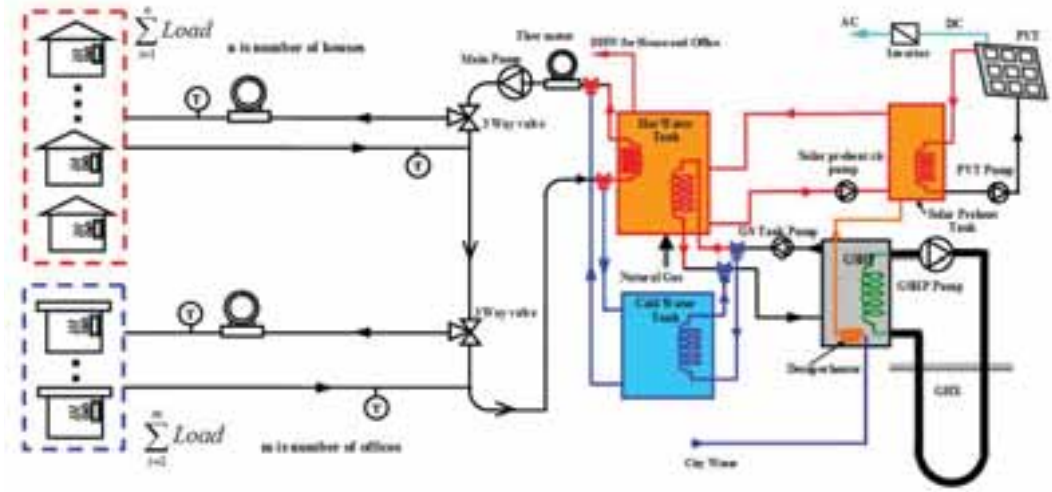

Fig.5. Load Sharing (Houses & Offices) Using Hybrid Micro-Generation System (GSHP-PV/T)

Tab. 1. Summary of Modelling Cases

Cases	Heating/Cooling Systems			Remarks
	Cooling	Heating	DHW	
Case 1	Chiller + Fan-Coil	Boiler + Fan-Coil	Boiler + DHW Storage Tanks	Simple Sum Loads (House + Office)
Case 2	GSHP - Fan-Coil	GSHP - Fan-Coil	GSHP (DSH) + Storage Tanks	Load Sharing
Case 3	GSHP - Fan-Coil	PV/T- GSHP- Fan-Coil	PV/T-GSHP (DSH) + Storage Tanks	Load Sharing

Case three is a hybrid micro-generation system integrating a photovoltaic thermal system to a GSHP system. PVT panels can generate both electric and thermal energy. The generated energy can be used to reduce the electrical power import from the grid to houses and offices and also used for space and water heating. There are many possible ways to integrate the PVT's thermal system to the GSHP system. In this study, system configuration with solar preheat-tank as shown in Fig.5 was chosen for the present study. The collected solar thermal energy is stored in a preheat-tank for two purposes: preheat the DHW and transfer the heat to the hot water storage tank in condition where the preheat-tank bottom temperature is few degree Celsius higher than the top of hot water storage tank. The remaining part of the system is same as that in case one.

Tab. 1 presents a summary of different modeling case studies and the corresponding technologies used for space heating, space cooling and DHW heating

3. SIMULATION AND ANALYSIS METHODOLOGIES

In the present study, all hybrid system models analysis from previous chapter are done by TRaNsient SYStems (TRNSYS-17) which is a popular software platform for advanced dynamic building energy simulation. TRNSYS library includes a large database of component models related to buildings, thermal and electrical energy system, input and output data management and other dependent functions. All components models in this study were selected from TRNSYS libraries and enhanced with latest manufactures' system performance data. Additional models were developed for some components that are not present in the TRNSYS libraries such as PV module, GSHP desuperheater and etc. A PVT module has 2.56m2 dimension, 295W electrical output and 1535W thermal output.

Based on that approach, detailed simulation models were developed and applied for all three cases. In order to evaluate the load sharing system performance, multi-building block consists of five identical houses (with floor area 200m^2 each) and two identical houses (with floor area of 500m^2 each) were introduced. The building specifications meet the building envelope requirements for climate zone 4 recommended by ASHRAE Standard 90.1-2007.

For systems serving multiple buildings, it will typically have a lower thermal peak than the sum of thermal peaks of each homogeneous house and office. This is mainly due to the fact that individual buildings reach their respective thermal peaks at different times during the day. A load diversification factor is commonly used to take this phenomenon into consideration in load estimation and equipment sizing for systems that serve a number of mixed buildings. This factor is commonly in the range of 0.90 and tends to be lower when the central system serves a mix of office and residential buildings with peak demand occurring at different times.

The simulation models were run with Incheon, South Korea weather data over a year to simulate and analyze the energy systems' performance. The energy consumption results from the TRNSYS simulations were then used for energy and cost analyses to evaluate and compare the performance of various systems (cases)

4. ENERGY ANALYSIS RESULTS AND DISCUSSION

In this section, simulation results of the case one, case two and case three systems that serving multiple buildings (five houses and two offices) will be presented and discussed. While the houses are identical to the house studied in the previous section with a floor area of 200 m2 per house, the office is enlarged and each has a floor area of 500m2. The total combined floor area with five houses and two offices is 2000 m2.

Both thermal and non-HVAC electric loads of the simulated houses and offices were analysed through appropriate time series methodology prior to the system simulation models development. The houses and offices were assumed to be separated from each other with no thermal interaction between them. Both type of buildings are square shaped and are assumed with a single interior zone in the simulations. The domestic hot water volume assumption was according to ASHRAE-124 recommendations for residential and small office buildings. Following "Office of Energy Efficiency Statistics and Analysis", NRCan, Non-HVAC electric loads

were developed based on "average" consumption of a detached house and a small office in Canada which is 43.9 kWh/m^2-yr. Those are presented in Tab. 2:

Tab. 2. Annual Thermal Load and Non-Electric Load Intensities

Load Intensity (kWh/m^2-yr)	Building Blocks Five Houses + Two Offices(5x200 m^2 + 2x500 m^2=2000 m^2)	
Weather data	Incheon, South Korea (TMY2 weather data)	
DHW	8.6	6.6%
Space Heating	47.2	36.1%
Space Cooling	31.2	23.8%
Non-HVAC Electricity	43.9	33.5%
Total	*130.9*	*100%*

Initial simulation study found out that if a GSHP system integrates with PVT panels only, the PVTs thermal and electrical energy generations are restricted by the volume and temperature of the solar pre-heat tank directly and building thermal demand indirectly. Therefore, it may be more efficient to design a GSHP-PV/T system with combination of both PVT and PV panels rather than installing PVTs only. In this way, the electricity generation will not be restricted or reduced by the thermal demand compare to systems with all PVT panels. In addition, it is anticipated that the initial capital cost could be reduced as PV panels are usually cost less than PVTs. For this reason, 5 GSHP-PVT systems (Case 3) with various combinations of PVT and PV panels were simulated, as shown in Tab. 3:

Tab. 1. GSHP-PVT Systems for Simulation Study

Number of PV Panels	Number of PVT panels	
	0	60
0	GSHP	GSHP-PVT60-PV0
120	GSHP-PVT0-PV120	GSHP-PVT60-PV120

	Electricity	-	13.5	11.8	13.5	11.8	13.5	11.8
Space cooling	Electricity	16.2	8.6	7.9	8.6	7.9	8.6	7.9
Fans		4.2	5.3	6.0	5.3	6.0	5.3	6.0
Pumps		0.8	3.8	3.1	3.8	3.1	3.8	3.1
Non HVAC (lighting, equip.)		43.9	43.9	43.9	43.9	43.9	43.9	43.9
Electricity Production		0	0.0	-3.8	-19.0	-22.8	-38.0	-41.8
Total (Net) Energy Use		*107.6*	*78.7*	*69.8*	*59.7*	*50.8*	*40.7*	*31.8*
Energy Savings		-	*28.9*	*37.8*	*47.9*	*56.8*	*66.9*	*75.8*

Energy Savings (%)	-	*26.9%*	*35.1%*	*44.5%*	*52.8%*	*62.1%*	*70.4%*

The result shows that the reference case (Case 1) has the highest total energy consumption at 107.6 kWh/m2-yr followed by GSHP system at 78.7 kWh/m2-yr and GSHP-PVT systems are showing better energy consumption compared to others ranged from 31.8 kWh/m2-yr until 69.8 kWh/m2-yr. The main reason why GSHP-PVT has better energy consumption is because this system only use small amount of natural gas for auxiliary burner inside the hot water burner and also GSHP-PVT system produced electricity so that reduced the net amount of energy consumption. Those results are shown in Tab. 4 and Fig. 6

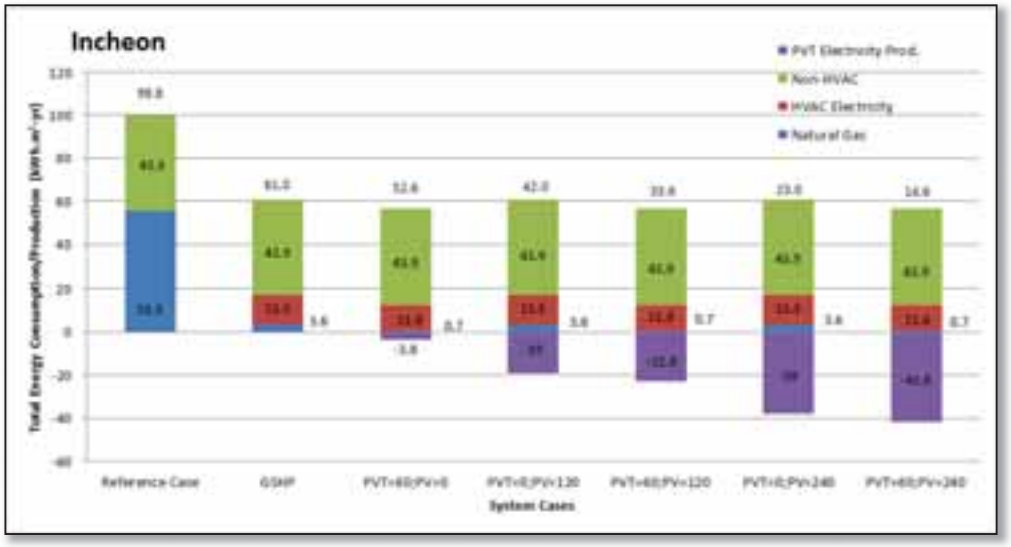

Fig. 6. Energy Analysis Results for Each Study Case

Based on those Tab. and graph, the system performance is evaluated and presented in COP values for the three studied cases. The COP is the ratio of the total energy delivered to the buildings (which includes space heating, space cooling, and DHW energy as well as electricity production if any) to the total consumed energy (natural gas and electricity) in the respective period as shown in Tab. 6

Tab. 3. System Performance (COP) For Multi-Building Cases In Incheon

Incheon	COP		
	Heating Period	Cooling Period	Overall/Annual
Reference System	0.92	1.47	1.08
GSHP	2.87	2.09	2.50
GSHP-PVT60-PV0	3.09	2.56	2.85
GSHP-PVT0-PV120	3.42	2.64	3.05
GSHP-PVT60-PV120	3.70	3.24	3.49
GSHP-PVT0-PV240	3.97	3.19	3.59
GSHP-PVT60-PV240	4.30	3.92	4.13

The result in Tab. 5 shows that Case 3 which is GSHP-PVT system has the highest COP ranged from 2.56 to 4.30 followed by GSHP system (Case 2) and simple sum of residential and commercial buildings (case 1). This result indicates that hybrid system has a better performance compared to conventional system and GSHP-PVT is the best combination. One of the reasons is the additional contribution from solar energy to produce electricity so that electricity that consumed from the grid can be reduced as shown in Tab. 6

Tab. 4 Annual Electricity Generation and Supply of Various GSHP-PVT system

Incheon	PV/T Electricity Generation		System Electricity Supply	
	Used by System	Exported to Grid	Supplied by PV/T	Supplied by Grid
Reference System	-	-	-	100%
GSHP	-	-	-	100%
GSHP-PVT60-PV0	100.0%	0.0%	5.2%	94.8%
GSHP-PVT0-PV120	83.4%	16.6%	21.1%	78.9%
GSHP-PVT60-PV120	80.5%	19.5%	25.2%	74.8%
GSHP-PVT0-PV240	62.3%	37.7%	31.5%	68.5%
GSHP-PVT60-PV240	60.0%	40.0%	34.4%	65.6%

The results in Tab. 6 indicate that the PV/T panels, depending on its capacity, meets 5.2% to 34.4% of the total electrical loads in Incheon. The remaining 65.6% to 94.8% required electricity is imported from the grid. Increase of the PV/T capacity certainly reduces the hybrid MG system's dependency on the electric grid, on the other hand this will result high initial capital costs

5. CONCLUSION AND FURTHER WORK

In this study, three different renewable and hybrid micro-generation cases were analyzed for application in combination of residential and commercial buildings. Five houses and Two Offices were selected in this study to perform the annual energy performance for each technology. Based on the result in previous chapter, we can conclude that:

• The total energy consumption of all the studied GSHP-PV/T systems (Case 3) is lower than that of the GSHP system (Case 2), and also the reference case (case 1) due to the use of geothermal and solar renewable energies. The overall system performance (COP) increases with the increase of the PV/T panels.

•The simulation results show that it is more efficient to design a GSHP-PVT system with combination of both PVT and PV panels. The PVT panels (operated with thermal-load control strategy) are primary used for covering part of the building heating loads and the PV panels (operated when there is solar radiation available) are mainly used for generating electricity for building usage. In this way, the electricity generation will not be restricted or reduced by the thermal demand compared to systems with all PVT panels. Any excessive electricity could be sold to the grid for additional income or stored in batteries for later use.

• Due to the PV/T electricity production is intermittent and not synchronized with the building demand, the GSHP-PV/T systems not only require electricity from the grid, but also have excessive electricity to be exported to the grid. The amount of electricity imported and exported to the grid is dependent on the number of the PV/T panels integrated to the systems.

• The GSHP-PV/T systems are able to meet 5.2%-34.4% of the building total electric load in Incheon. The remaining electric load is met by the grid. Increase the number of PV/T panels certainly reduces the system dependency on the electric grid.

• For the simulated GSHP-PV/T systems, between 60% and 100% of the PV/T generated electricity is used by the buildings themselves and the remaining 0% to 40% excessive electricity is exported to the grid. The

percentage of exported electricity increases with the increase of the PV/T panel numbers.

For Further work, an artificial intelligence (AI) control strategy to be embedded in a gateway wireless platform for optimal control of the hybrid system will be developed to further apply the new concept of energy cloud. The strategy will be simulated and investigated for variety of system sizes and applications. The hybrid systems will be optimized and the optimal component and system configurations will be simulated and assessed for maximum utilization. Variety of simulations will be conducted using system integration optimization technique to approach real life situations where a group of multi-type buildings will be served by the hybrid energy system in load sharing applications. Further, and more in depth, economic analyses will be performed to investigate the viability of the hybrid energy systems in selected scenarios and their impact on the overall installation and operation costs.

Switchable Windows - Spectral Transmission and Switching Times

Philippe Lemarchand[1], Eoin McLean[1] and Brian Norton[1]

[1] Dublin Institute of Technology, Dublin (Ireland)

Abstract

The switching time and spectral transmission in fully clear and fully opaque states of polymer dispersed liquid crystals (PDLC), suspended particle device (SPD) and electrochromic (EC) switchable windows were evaluated to assess their suitability to control solar heat transmission though glazed façade and comfort to building occupants. The transmission measurement on a SPD film showed a very effective absorption modulation in the visible range but fast decrease in the near infrared region. The switching speed was demonstrated to be related strongly to wavelengths. A SPD film with a larger absorption and faster switching speed in the infrared region was shown to be preferable to control solar heat transfer through glazings and thermal comfort. The PDLC window did not modulate transmission but rather modulated scattering. In the opaque state, the PDLC window was highly scattering resulting in spectral transmission varying at short distances from the window while being constant in the far field. The switching speed measurement demonstrated that liquid-based switchable windows can respond as fast as the eye to have the potential to control spontaneous glare. The EC window demonstrated a lower absorbance efficiency than the SPD in the visible range but appeared to have a much higher efficiency in the infrared region measured. EC windows are characterized by their slow switching speed when compared to SPD and PDLC. This makes them unsuitable for spontaneous glare control and are more suited to predictive solar heat gain control over a defined time horizon. With the increasing integration of adaptive technologies into building facades and to predict the energetical and ambient performance of such buildings and the impact on the occupants' comfort, this paper emphasises on the importance to provide spectral performance information of switchable windows.

Keywords: switchable window, spectral transmission, switching speed, adaptive façade, solar control.

1. Introduction

Switchable windows switch between a clear and an opaque transparent state by controlling light absorption, reflection and/or scattering. EC, liquid crystal (LC) based and electrophoretic or SPD technologies are the most promising for manufacturing large area electrically activated switchable windows for control of solar energy through building and vehicle glazings.

The coefficient of solar energy transmittance (g-value) or solar heat gain coefficient (SHGC) and shading coefficient are determined knowing the incident solar insolation and the spectral transmittance of glazing over the entire solar spectrum (Geymard, 2007; Gueymard and duPont, 2009; Waide and Norton, 2003). These coefficients vary significantly with the incident solar insolation. With adaptive windows dynamically adapting their optical transmission these coefficients will vary furthermore. As visible light transmission and scattering is modulated, indoor lighting conditions vary with illuminance, colour rendering index and daylight glare probability (Wienold, 2010) the affected quantities. It is therefore important to disaggregate the impact of the visible component of the spectrum affecting indoor lighting and glare, and the infrared component of the spectrum contributing to the indoor thermal performance via solar gain and the greenhouse effect further affecting the cooling and heating loads of the building and occupants' comfort.

Switchable windows do not prescribe requirements on switching times. For building application, the short time change of glare (visible wavelength) and solar heat (infrared wavelengths) incident on a surface typically vary with the passage of watery clouds. Considering an instant change of the solar irradiance by the passing of a cloud, the required switching time for switchable windows would correspond to the human response to light. Presumably, switchable windows would need to switch as fast as the eye response, i.e. 13ms to 80ms (Lewis, 2014), to have a spontaneous control of the glare.

The human sensation of heat given by the heat index varies by 8°C when moving from shade to sunlight (NWSWFO,

doi:10.18086/swc.2017.12.08 Available at http://proceedings.ises.org

2004). Moreover, the human skin response time to cold is 0.1°C/s (Jones, 2009) and discomfort is perceived with only 1°C difference to body temperature which is felt in the order of 10 seconds (Kenny, 1998). Consequently, the 8°C difference felt from shadow to sunlight brings a sensation of discomfort in the order of 1.25 seconds which would then be the desired response time to solar heat transfer (infrared wavelength) through the switchable glazing.

Knowing the spectral transmission and switching time performances of switchable windows as further studied below can potentially enable to appropriately and more accurately control such adaptive technologies with the desired building energy performance and occupant comfort.

2. Methodology: sample characteristics and optical setups

2.1. Sample characteristics

The EC EControl™, SPD SmartGlass™, PDLC SmartGlass™ glazings as well as SPD and PDLC films (without glass panes) presented in Tab. 1 and Fig. 1 were characterized. The EC glazing was electrically switched by its controller applying between -1Vdc and +2Vdc measured at the window's electrodes. The window transmissions provided by the manufacturer are measured according to DIN EN 410 within the 380-780nm region. The EC window were specified to be 50% and 10% in the transparent and opaque state respectively with a tolerance of +/-2%. Both the SPD and PDLC films and glazing were electrically switched between 0Vac and 110Vac. Consequently, the EC and SPD films worked either in a transparent mode when turned ON or into an opaque mode when turned OFF, the window appearing tinted with a dark blue colour. The LC films were in their transparent state when turned ON, and exhibited a milky-white tint when turned ON and were consequently in their opaque mode. A Lambda900 spectrophotometer was used to measure the full and scattered transmission through the SPD and PDLC films, the glazings and each individual component forming the SPD and PDLC glazings. Due to the size of the EC glazing that could not fit in the Lambda900, a second dedicated optical setup was used. This setup was used to measure the optical transmission of the EC glazings and the switching time of the SPD, PDLC and EC glazings.

Tab. 1: SPD, PDLC and EC tested samples.

Sample name	Shape	Size	Thickness Configuration
SPD glazing	Flat	L=28cm, H=18cm	4mm glass/~1mm space/4mm glass
PDLC glazing	Flat	L=28cm, H=18cm	4mm glass/~2mm space/4mm glass+silver coating
EC glazing	Flat	L=32cm, H=32cm	4mm glass/~1mm space/4mm glass/cavity/4mm low-E coated glass
SPD film	Flat	L=5cm, H=5cm	ITO/SPD film/ITO
PDLC film	Flat	L=5cm, H=5cm	ITO/PDLC film/ITO

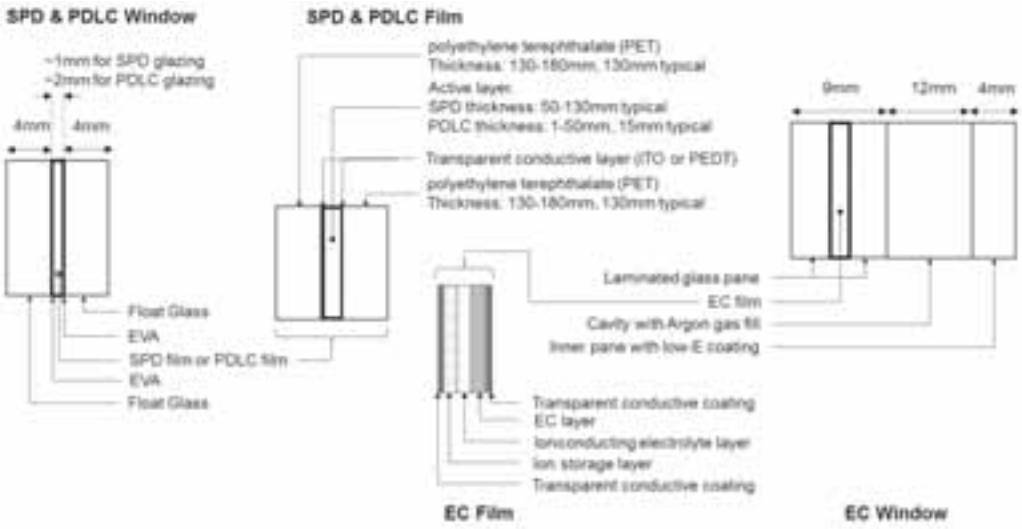

Fig. 1: Schematic of the tested SPD and PDLC films and SPD, PDLC and EC windows

2.2. Lambda900 spectrophotometer for film transmission analysis

Fig. 2 and Fig. 3 represent the reference beam (1) and the sample beam (2) within the Lambda900, with same optical path length (D≈36cm) from their respective cuvette holder to the integrating sphere (IS) aperture of diameter Φ=5mm. Wavelengths from 250nm to 2500nm were scanned in 1nm steps to look at the film ultraviolet (UV), visible (VIS), near-infrared (NIR) and short-wave infrared (SW-IR) transmission and compare them with the optical bench

setup results. Absorbance calibration was done in air. For measurement of all transmitted light, a maximum of scattered light was collected for the switchable film (SPD or LC film with ITO layers on both sides and no glass) located flat at the integrating sphere aperture entrance. All forward scattered light sketched in Fig. 4 was collected by the integrating sphere. Transmission in the far-field (~36cm from the IS) was achieved by setting the film flat at the cuvette or further named "sample port" (SP). The cone angle θt of collected transmission is reduced to θt ≈0.15º as illustrated in Fig. 5. The cone angle in that configuration being close to 0º, transmission measurements are considered to correspond to the specular and direct (0º) transmissions.

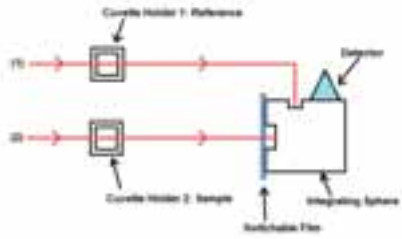

Fig. 2: Film scattered transmission measurement at the Lambda900 integrating sphere.

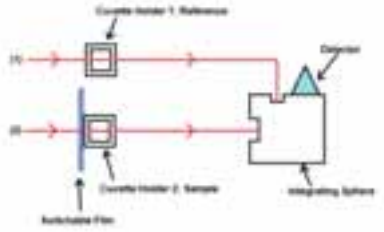

Fig. 3: Far field film transmission at the cuvette in Lambda900.

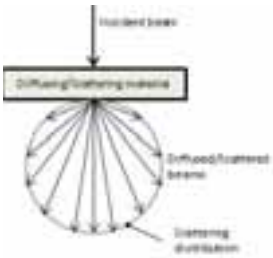

Fig. 4: Scattered transmission sketch. The doted circle represents the irradiance distribution of the scattered light.

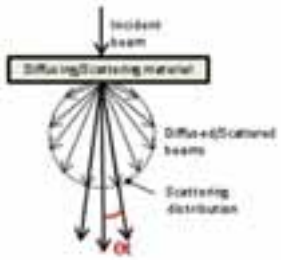

Fig. 5: Far field transmission sketch.

$$\eta_{abs} = \frac{T_{clear} - T_{opaque}}{T_{clear}} = 1 - \frac{T_{opaque}}{T_{clear}} \quad \text{(eq. 1)}$$

$$T_{scatt}(\%) = T_{IS}(\%) - T_{SP}(\%) \quad \text{(eq. 2)}$$

$$\alpha = \frac{\pi * D_p}{\lambda} \quad \text{(eq. 3)}$$

The dynamic light attenuation when switching ON and OFF the samples could be obtained from the transmission curves. The relative attenuation of the signal can be seen as the relative absorption efficiency η_{abs} of the film expressed by (eq. 1. As calculated by (eq. 2, the difference between transmission measurements at the IS port (T_{IS}) and sample port (T_{SP}) provided information on the percentage transmission affected by scattering. (eq. 3 describes the scattering dimension less parameter α with D_p the diameter of a spherical particle and λ the wavelength. The parameter α enables to distinguish three types of scattering: 1) Rayleigh scattering for $\alpha << 1$; 2) Mie scattering for $\alpha \approx 1$ and 3) geometric scattering for $\alpha >> 1$. With the incident light wavelength of the same order as the particles' sizes. The condition where α≈ Mie scattering (α≈1) enables to have a view of the particles size distribution across the studied film. Once the switchable film is in position, transmission measurements in clear and opaque states are separated by several minutes (~5minutes) to ensure the films in their opaque state reach their thermodynamic equilibrium and are optically stable.

2.3 Optical bench setup and its validation with float glass and EVA transmission

A solar simulator and integrating sphere fibre connected to a handheld spectrometer was used to i) determine the absorption contribution of glass and EVA layers in the final glazing, ii) to ensure the optical bench setup results coincide with the Lambda900 spectrophotometer and iii) to measure the switching time of the EC, SPD and PDLC glazing. A first sample, named 'FGEVAFG' hereafter, comprised of an ethylene-vinyl acetate (EVA) layered in between two float glass (FG) panes 6mm thick was measured in transmission using both setups. The absorption measurement of a single 6mm FG pane further enabled the determination of the transmission of the EVA layer only.

Both transmission measurements at the IS and SP of the Lambda900 were perfectly matching between 250nm and 2500nm, demonstrating no scattering occurred. Transmission measurements compared using the optical bench setup validated the setup results between 385nm and 1020nm (see Fig. 6).

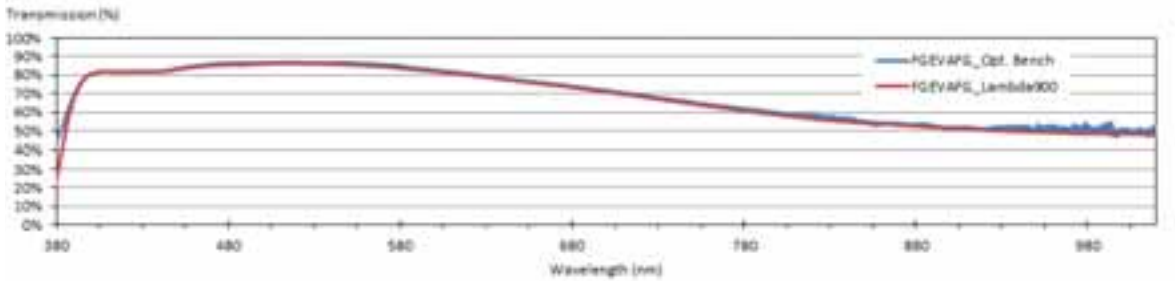

Fig. 6: FG-EVA-FG transmission and optical bench setup validation.

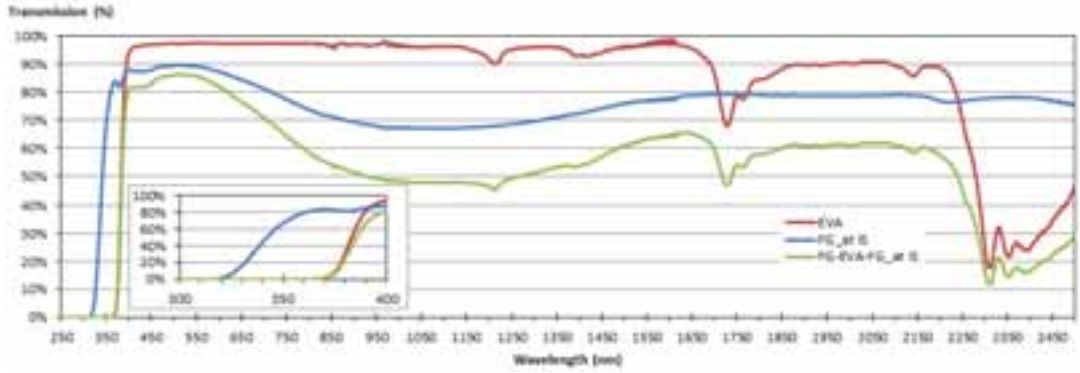

Fig. 7: Transmission of 4mm float glass (FG), FG-EVA-FG sample and EVA layer.

The absorbance (Ab) of the float glass and the FGEVAFG sample measured, the transmission of the EVA layer was calculated using (eq. 4.

$Ab_{FGEVAFG} \approx A_{FGEVAFG} + R_{FG} \approx R_{FG} + A_{EVA} + 2 * A_{FG}$ discarding multiple internal reflections $Ab_{FG} = A_{FG} + R_{FG}$ and $Ab_{FGEVAFG} - 2 * Ab_{FG} \approx A_{EVA} - R_{FG}$ leading to:

$$T_{EVA}(\%) = \frac{100}{10^{Ab_{FGEVAFG} - 2*Ab_{FG}}} * 10^{-R_{FG}} \qquad \text{(eq. 4)}$$

(eq. 4 requires the spectral reflection at the air-FG interface R_{FG} approximated using the Fresnel reflection in (eq. 5 for unpolarized light (Albregtsen, 2008) and considering the known refractive index of BK7 available between 300nm and 2500nm (Polyanskiy, 2016).

$$R_s = \left|\frac{n_1 * \cos\theta_i - n_2 * \cos\theta_t}{n_1 * \cos\theta_i + n_2 * \cos\theta_t}\right|^2 = \left|\frac{n_1 * \cos\theta_i - n_2 * \sqrt{1 - \left(\frac{n_1}{n_2} * \sin\theta_i\right)^2}}{n_1 * \cos\theta_i + n_2 * \sqrt{1 - \left(\frac{n_1}{n_2} * \sin\theta_i\right)^2}}\right|^2$$

$$R_p = \left|\frac{n_1 * \cos\theta_t - n_2 * \cos\theta_i}{n_1 * \cos\theta_t + n_2 * \cos\theta_i}\right|^2 = \left|\frac{n_1 * \sqrt{1 - \left(\frac{n_1}{n_2} * \sin\theta_i\right)^2} - n_2 * \cos\theta_i}{n_1 * \sqrt{1 - \left(\frac{n_1}{n_2} * \sin\theta_i\right)^2} + n_2 * \cos\theta_i}\right|^2$$

$$R = \frac{R_s + R_p}{2} \qquad \text{(eq. 5)}$$

In the equations above, the subscripts 's' and 'p' respectively denote the perpendicular and parallel electric field direction of the light electromagnetic wave. The subscripts 'i' and 't' refer to the incident and transmitted angles θ at the air-FG interface of respective refractive index n_1 and n_2.

The resulting EVA transmission curve in Fig. 7 showed relatively flat transmissions of above 95% from 430nm to 1650nm and ≈ 90% from 1850-2200nm. Strong absorption bands occurred in the 1655-1750nm and 2325-2400nm ranges. The glazing thickness is mostly comprised of glass. The FGEVAFG sample transmission showed that the

choice of glass highly affects the overall glazing performance– most importantly the NIR, SW-IR ranges and the consequent solar transmission. The UV cut-off wavelengths of float glass and EVA were respectively noted around 320nm and 370nm. The EVA, absorbing UV, acts as a protective filter for particles embedded into switchable windows but UV sensitive particles would still deteriorate under long-term UV exposure (Czanderna, 1996).

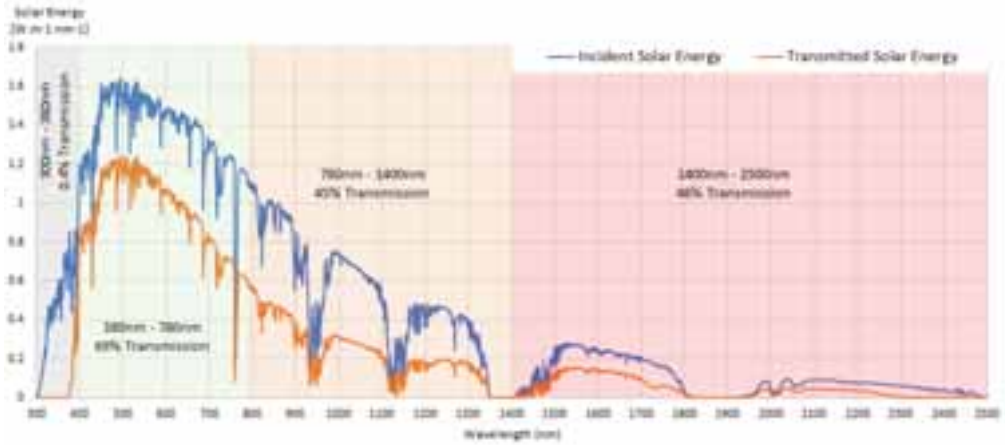

Fig. 8: Solar energy spectrum incident and transmitted through 12mm of the measured clear float glass and 0.4mm EVA layer.

Knowing the absorbance of the float glass and the EVA layers enabled the calculation of the Napieran attenuation coefficient of the materials and simulation of the transmission through three glass panes 4mm thick and two EVA layers 0.2mm thick (see Fig. 8). This configuration, similar to the EC window without the active EC film and the low-E coating, enabled an understanding of the amount of solar energy available for transmission modulation by a switchable film. The measured clear float glass showed ~69% transmission in the visible and strong absorption in the NIR and SW-IR regions with transmission to ~45% and ~46% respectively. The transmitted solar energy was about 371W.m^{-2}, 145W.m^{-2}and 47W.m^{-2} in the respective wavelength ranges. The EVA layer absorbing UV, ~0.4% transmission is calculated between 300nm and 380nm, representing ~120mW.m^{-2}. Simulation on clearer glass such as the Planiclear^{TM} from Saint-Gobain demonstrated transmission of about 1.2%, 83%, 63% and 63% in the UV, VIS, NIR and SW-IR respectively and therefore enabling a larger fraction of the solar energy to be modulated by an active film integrated between the two EVA layers.

3. Spectral transmission analysis

3.1. SPD and PDLC films

The SPD film tested, about 0.35mm thick, is mainly made of a polymer (most likely PMMA) for which absorption bands occurred around 1657nm, 2143nm and 2328-2450nm in Fig. 9 and again for the PDLC film in Fig. 10. The transmission curves at both the IS and SP positions for the ON state were matching, meaning reflections from all internal interfaces and absorption are the only occurring phenomena. In the OFF state, particles in random orientations strongly absorb light in the visible and NIR range. The transmission curves at the IS and SP showed differences in the transmitted blue and NIR wavelength ranges. Plotting the scattered transmission (difference between the two curves), a Poisson distribution was obtained between 760nm and 2250nm with a maximum of the particles having a size about 1µm corresponding to the particles length (Saxe et al. 2003) and confirming this difference is attributable to a Mie scattering process ($\alpha \approx 1$ in eq. 2).

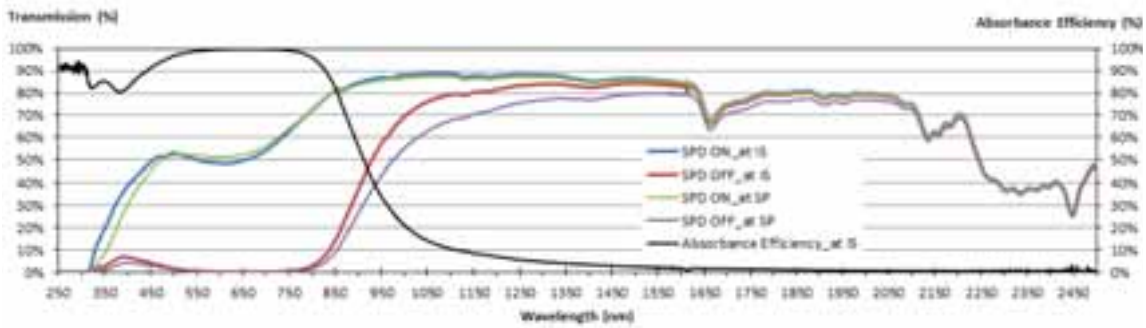

Fig. 9: SPD film transmission and absorbance efficiency

Multiplying the transmission curve by the global solar irradiance at an air-mass of 1.5 (ASTM, 2012), the spectral solar irradiance and solar energy transmitted through the SPD film (i.e. without glazing and interfacing EVA) in the transparent and opaque states was obtained and summarised in Tab. 2.

Tab. 2: Global solar energy modulated by the SPD film.

		Transmitted solar energy (W/m^2)			
Spectral range (nm)	Global solar energy (W/m^2)	Transparent	Opaque	Solar energy modulated (W/m^2)	Fraction of solar energy modulated (%)
280 - 379.5	32.1	6.5	1.1	5.4	16.9%
380 - 780	535.5	274.0	8.4	256.6	49.6%
781 - 1400	323.8	272.8	166.7	106.1	32.8%
1401 - 2500	101.9	76.0	74.9	1.2	1.1%
280 - 2500	993.3	629.4	251.1	378.3	38.1%

Fig. 9 shows the SPD window highly modulated transmission in the wavelength range from 390nm to 820nm with transmission varying from 50% to 70% above 450nm and averaging at 51.2% transmission over the visible range (380nm-780nm). The SPD showed a strong absorption from 1000nm to 2100nm with a modulation efficiency continuously decreasing below 30% from above 1000nm and below 10% above 1350nm. In Tab. 2, the SPD film appeared to modulate 16.9% of the UV light (280nm-380nm) with $6.5W.m^{-2}$ of solar UV transmitted in the transparent state. Considering the ~$120mW.m^{-2}$ transmitted through the simulated glazing, between $4mW.m^{-2}$ and $24mW.m^{-2}$ is transmitted in the opaque and transparent modes. To mitigate degradation of the SPD film, exposed to ~$850mW.m^{-2}$ after 4mm glass and 0.2mm EVA layer, or other materials within the occupant environment, UV protection is initially achieved with float glass and EVA layers forming the window and would benefit from the potential addition of a UV filter. In the transparent state, about half of the solar energy in the visible range is absorbed which significantly limits the fraction of natural light entering the occupant environment on cloudy days. With 49.6% of visible solar energy controllable, this is the spectral band most effectively controlled by the SPD film. In the near-infrared (781-1400nm) the SPD still modulated 32.8% of the input solar energy but a high $166.7W.m^{-2}$ solar energy was transmitted in the opaque state and represented more than 51.4% of the solar energy in that range. This implies that there is significant infra-red solar heat transfer in the switched-mode that is ostensibly intended to reduce solar gain. SPD materials with an absorption efficiency in the NIR similar to current performances within the visible range could lead to an additional 16.8% to the current modulation capability. The latter represents an additional 51.2% of energy modulable through a glazing integrated the active film. For the simulated glazing with 12mm glass thickness and 0.4mm EVA layer, it represents an additional 4.3% solar (280-2500nm) energy modulation compared to 4.9% for a clearer glass such as the Planiclear^{TM}. Considering the film thickness and the low dynamic absorption of SPD material above 1400nm, only 1.1% of the solar energy in the short-wave infrared (1400-2500nm) could be modulated with more than 73% of the solar energy transmitted through the SPD independently of the SPD optical state. The 780nm-2500nm solar range containing 42.6% of the $1kW.m^{-2}$ global solar energy and ~34% of the solar energy transmitted through the simulated window, innovative SPD materials with an efficient dynamic control of the infrared range would significantly contribute to the infrared solar heat transfer modulation offered by switchable windows. Overall, in the 280-2500nm range, the SPD film could modulate 38.1% of the solar energy passing through a glazing

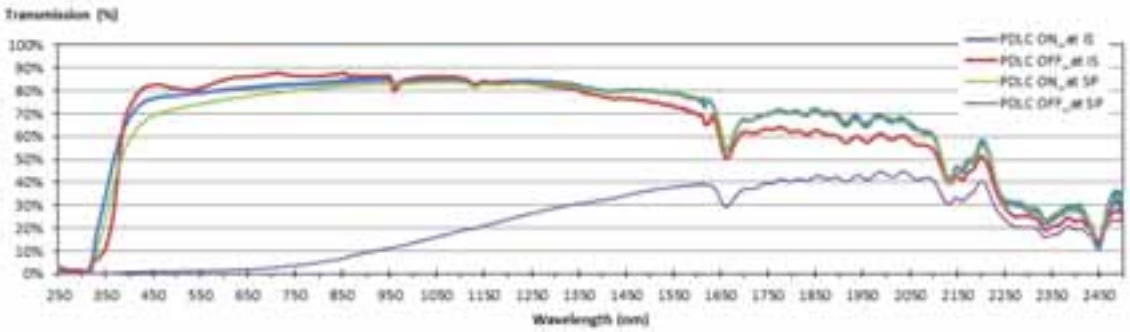

Fig. 10: PDLC film transmission.

Transmission results on the PDLC film shown in Fig. 10 demonstrated very similar transmission in the clear and opaque state over the entire scanned range when measured at the integrating sphere. This result led to conclude that light passing through the film is not further absorbed nor significantly more reflected when switching ON or OFF the film. However, when setting the film at the sample port, transmission is highly reduced in the OFF state meaning

that 1) almost all visible light passing through the film in the OFF state is scattered (giving the milky-white appearance) and 2) that the transmission loss mechanism in the OFF state is uniquely related to the distance between the detector and the film until the cone angle becomes small enough (close to 0 radian) that the transmission will not change anymore.

3.2. EC window transmission

The EC window transmission curves for both the opaque and transparent states are shown in Fig. 11 together with the absorbance efficiency. In the transparent state, the EC window tested, demonstrated transmission in the visible (380-780nm), near-infrared (780-1020nm) and solar (380-1020nm) ranges of 50.1%, 50.8% and 29.2% respectively. In the opaque state, the EC window transmission went down to 15.3%, 14.9% and 0.8% at the respective range. The transmission tolerance in those ranges were ±1.0%, ±1.1% and ±4.9% due to the intensity of the source, the fluctuation of the lamp, the sensitivity of the spectrometer and the signal noise in the various wavelength ranges. While the 50.1% visible transmission in the transparent state of the window was matching the manufacturer information, the 15.3±1.0% transmission in the opaque state was not matching the 10±2% transmission. A possible cause of this, suggested by the manufacturer, was the lack of sunlight exposure of the glazing and switching in the time leading up to the test. The EC glazing requires UV sunlight exposure to allow it to fully darken. This encourages further understanding of the influence of outdoor solar conditions and temperature on the glazing transmission and switching speed capabilities. In the visible range the window has an absorbance efficiency varying from about 70% at 380nm down to 50% at 480nm before rising to nearly 95% at 780nm. The signal noise in the opaque mode did not allow a clear transmission measurement above 880nm but it appeared the window absorbance efficiency tends to 100% up to 1020nm likely due to the low-E reflective coating in the fifth glass surface of the window. A measurement of the EC film only using the Lambda900 is desirable to have a higher accuracy of results over the entire solar range.

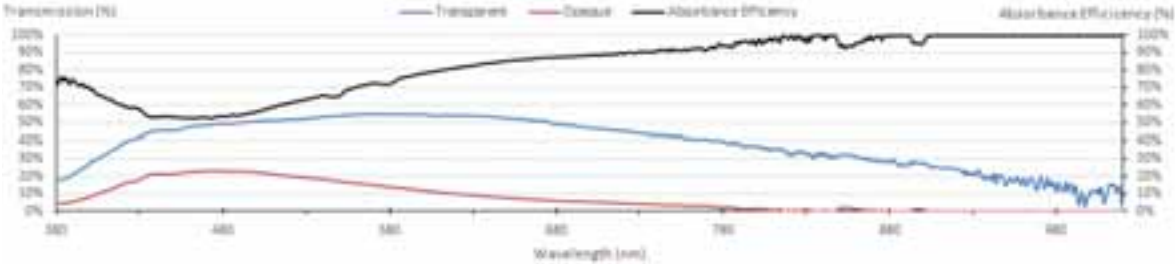

Fig. 11 EControl EC Window – Transmission in the transparent and opaque states and absorbance efficiency

Similar to the SPD film, the global solar irradiance transmitted through the EC window in the transparent and opaque states was obtained in Fig. 12 and the solar energy summarised in Tab. 3.

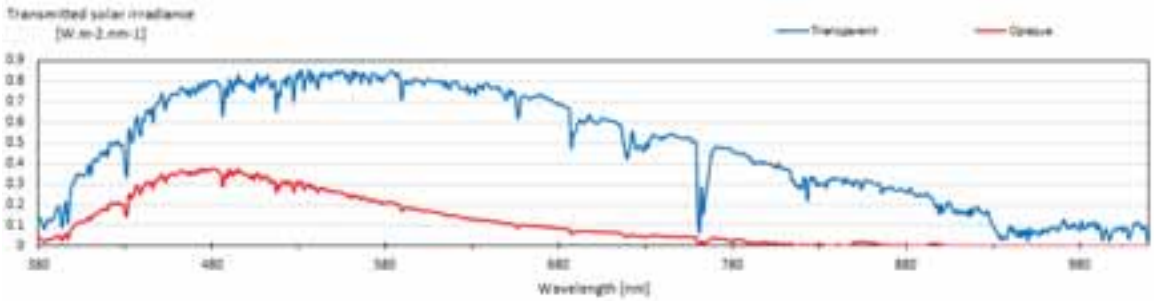

Fig. 12: Calculated solar irradiance transmitted through the EC window in the transparent and opaque states

Tab. 3: Global solar energy modulated by the EC window.

		Transmitted solar energy (W/m^2)			
Spectral range (nm)	Global solar energy (W/m^2)	Transparent	Opaque	Solar energy modulated (W/m^2)	Fraction of solar energy modulated (%)
380-780	535	258±6	70±6	188	35.1%
780-1020	188	50±9	1±9	49	26.1%
380-1020	723	308±8	71±8	237	32.8%

Similar to the SPD film in the transparent state, Tab. 3 shows that the EC window transmission in the visible range

significantly limits the fraction of natural light entering the occupant environment on cloudy days. With 35.1% of visible solar energy controllable, this is the spectral band most effectively controlled. In the near-infrared (780-1020nm) the fraction of solar energy modulated goes down to 26.1% with about 50W.m^{-2} solar energy transmitted in the transparent state and 0-10 W.m^{-2} in the opaque state. Such low transmission in the infrared in both states is the result of the film light absorption and the light reflection from the low-E coating on the fifth glass surface. Such configuration would allow the window to significantly reject infra-red solar heat transfer but still be able to modulate a small portion of the solar energy in that region. Thus, it is convenient for climates with a high solar irradiance. In low to moderate solar irradiance conditions, the window would benefit from modulating a larger fraction of the solar range as more visible light and infrared solar heat passing through the window might be required. Overall, the EC window could control 32.8% of the solar energy contained within the 380nm-1020nm range.

4. Switching time of SPD, PDLC and EC windows

In principle, the complete switching time between fully clear to fully opaque is identical at all wavelengths due to the time it takes for the SPD particles and LC molecules to rotate or the ions to be fully absorbed by the EC layer according to the voltage applied. However, the relative spectral switching time further on called "switching time" varies according to the intensity of the source and the spectral transmission in the transparent and opaque states at the wavelength considered. Using the optical bench setup, the switching time of the SPD, PDLC and EC windows could be measured. When switching the windows, the light transmission change with time, was observed rising and decreasing similar to the charging and discharging curves of an electronic Resistor-Capacitor (RC) circuit. As illustrated in Fig. 13, the time τ was defined as the time required for the window to reach 63% of its final state (transparent or opaque). The defined switching time 3τ is the time required to reach 95% of the transition and 5τ for 99% of the transition.

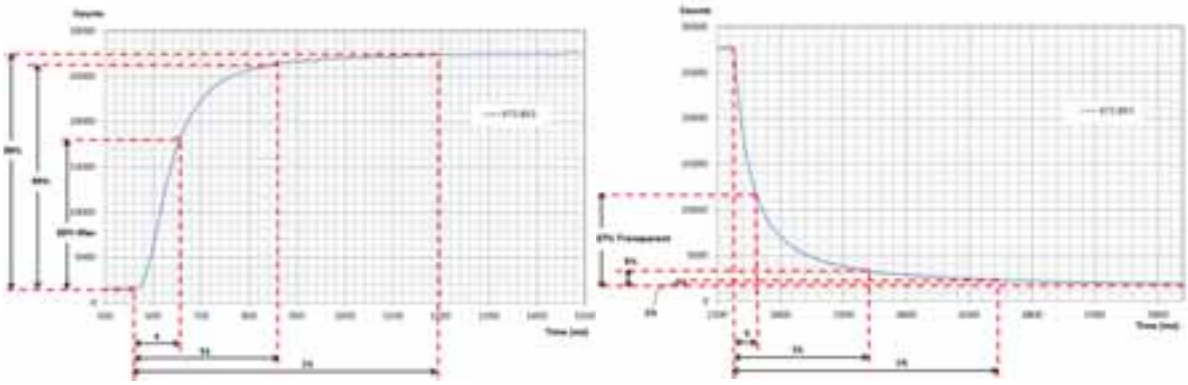

Fig. 13: (left) Switching ON time (τ_{up}) and (right) switching OFF time (τ_{down}) definition. Examples with the SPD glazing at 473nm.

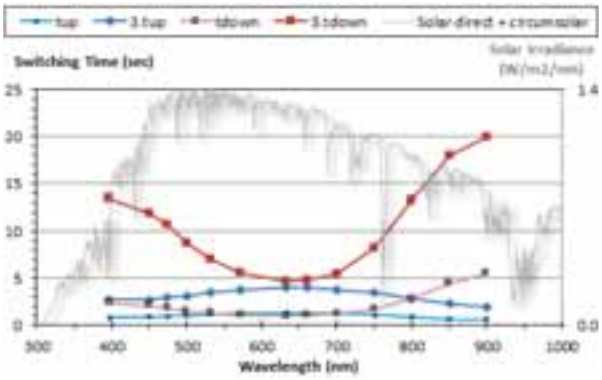

Fig. 14: SPD window switching ON and OFF times.

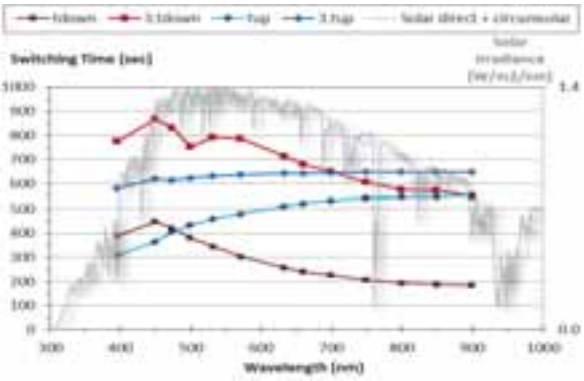

Fig. 15: EC window switching ON and OFF times.

$$f = \frac{3\tau_{down}}{3\tau_{up}} \qquad \text{(eq. 6)}$$

Fig. 14 compares the up (to transparent state) and down (to opaque state) switching times of the SPD glazing with the solar spectrum. The curves show opposite behaviours affected by a factor f defined in (eq. 6). In the 400-700nm region the transmission switches from 48.54% to 1.27% (Lemarchand, 2014). Simultaneously the "f" factor

decreased from x4.9 at 400nm to a minimum x1.17 at 633nm, before it started strongly picking up in the infrared region. At 900nm, the switching "down" time was x10.7 longer than the switching "up" time. Particles are forced to align with the electrical fields between the conductive layers when the window is switched ON. Reversely, when turned OFF, the voltage across the SPD film drops to 0Vac, the electrical field disappears and the particles are free to naturally disperse in random orientations within the Brownian fluid forming the SPD film. It was then expected, as the experiment confirmed, that the switching ON time would be much shorter than the switching OFF time. The switching ON time could not be calculated theoretically due to a lack of information on the particle composition but this one was expected to be in the hundreds of milliseconds – this was also confirmed by the results obtained in Fig. 14. Using Hsu et al. (2005) equations, the theoretical switching OFF time was calculated to be about 1100ms or 2000ms respectively for ethanol and propanol as the organic fluid considered. In the OFF state the window appeared with a dark blue tint as a direct consequence of the particle rotating and reaching a chaotic order. The time it took for the particles to rotate could then be best visualised in transmission when looking at the blue wavelengths, meaning at wavelengths the particles are efficiently absorptive but with the least absorption. The τ_{down} time measured at 450nm and 473nm were 2100ms and 1800ms respectively and match with the particle rotation time order of magnitude expected. Strongly absorbed wavelengths have their transmitted intensities reach a minimum even before the particles finish their rotation, consequently reducing the switching OFF time. This appeared in Fig. 14 from 572nm to 700nm with a factor below x1.5. The particles being increasingly transparent as the incident infrared wavelength is increased, the intensity variation tends to zero and the switching OFF time tends to infinite.

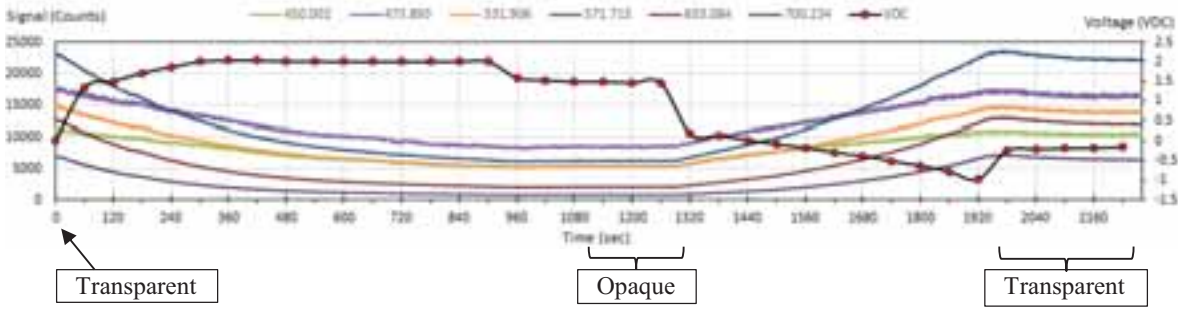

Fig. 16: EC window voltage and transmission variation in time at selected wavelengths.

Fig. 16 illustrates the intensity variation of the transmitted light at specific wavelengths when switched from transparent to opaque and from opaque to transparent. The voltage measured at the window electrodes is plotted on the secondary axis. In the initial transparent state the window was not operated for 7 days prior the experiment and voltage was 0Vdc. When switching off the window, the voltages rises up to +2Vdc after ~ 5 minutes and remained constant until the windows reached its opaque state with the voltage reduced down to +1.5Vdc. At this stage, it is believed the window acting as a capacitor was fully "charged" and retained the +1.5Vdc. Small crystallite systems such as those used in EC windows have been shown to behave more like capacitor than faradaic systems and this may offer an explanation for this apparent discharging behaviour (Ho et al. 1997). A plot of charge versus applied voltage could aid in better understanding this behaviour. Switching the window to the transparent state reduced the voltage to just above +0Vdc. The voltage continued decreasing to -1Vdc when the window reached a maximum transmission. Once the transparent state was reached, the voltage flattened just below 0Vdc. The final transmission state was slightly lower than the initial state but it is believed that, should the transmission and voltage measurements be monitored over a longer period, the transmission would have equalised and the voltage reached 0Vdc.

Fig. 15 shows a $3\tau_{down}$ switching times of the EC window from transparent to opaque varying from 867 seconds at 450nm down to 549 seconds at 900nm. Switching from opaque to transparent resulted in curves in the opposite trend. The τ_{up} increased from 308 seconds at 400nm to 552 seconds at 900nm. The $3\tau_{up}$ switching time to the transparent state varied from 582 seconds to 648 seconds at the respective wavelength. The $3\tau_{up}$ values appeared relatively constant across the visible range. A switching speed of this order makes EC windows unsuitable for instantaneous glare control and reactive rule based control (RBC). The ambient temperature at the time of testing was 21°C and EC switching time is known to decrease with an increase in temperature (LBNL, 2006) such as in the warm condition of sunny climates. Whilst this slow switching speed may be seen as a disadvantage, it is worth noting that this slow switching speed would be imperceptible to building occupants. The rapid switching of SPD and PDLC would however be noticeable and may have an impact on occupant comfort as they experience rapid changes of their environment. To mitigate such issues, controllers can adjust the switching speed to control the desired indoor lighting condition. A slow switching EC window, if properly controlled offers the possibility to modulate visible light and

heat transmittance without any obvious change in the window appearance. A model predictive control (MPC) strategy, with an appropriate time horizon, could offer the possibility of using the slow response time of the EC window combined with expected building conditions over the prediction time horizon to maintain a comfortable occupant environment, primarily by reducing heat gain in the IR range. This type of system is likely to perform better in cooling dominated climates where a constant glare reduction is required rather than a strategic glare control.

Switchable windows need to switch in the visible range as fast as the eye response, i.e. 13ms to 80ms, for the user to have spontaneous control of the glare. Measurements on the SPD glazing showed that 95% of the full transmission change occurred with switching times of ~0.5s and ~1 second when respectively switching ON and OFF the window. These switching times were consequently 6 to 77 times too long to instantly control glare to the eyes visible response. Moreover, considering a perception of discomfort can be perceived in the order of 1.25 seconds, it would be preferred to have a similar response time in the infrared to instantaneously control solar heat transfer through the switchable glazing. A faster switching speed, achievable with increased absorption from the particles, would then be preferable for wavelengths above 800nm.

Tab. 4: PDLC switching time.

Wavelength (nm)	378	396	473	532	572	633	660	850	900
Average Switching OFF time (ms)	25	25	30	35	50	45	55	40	45
Average Switching ON time (ms)	15	15	15	15	15	15	15	15	15

As shown in Tab. 4, the switching time for PDLC under applied voltage was as low as 15ms but is likely to be even faster and wavelength dependent as the recorded values were limited by the spectrometer integration time. For the same window size the SPD required 300-400ms which was at least 20 to 25 times longer. The relaxation time of the LC molecules was at least 2-3 times longer than the switching ON time. Due to their light scattering properties, PDLC windows are primarily applied as indoor privacy walls. The control of glare and thermal response from outdoor conditions is not relevant in that particular case but LC based windows with an embedded dye absorbing the desired wavelength range such as the Licrivision^{TM} product from Merck (2017) enable control of glare, solar heat transfer and the desired window colour. The fast switching speed of the PDLC windows is noted to be as fast as the human eye response (13ms to 80ms) and LC based technologies are consequently ideal for glare control.

5. Conclusion

The SPD window highly modulated the transmission from 390nm to 820nm with 51.2% transmission over the visible range in the transparent state. It also showed a strong absorption and low modulation efficiency in the infrared range reaching below 30% efficiency from above 1000nm and below 10% above 1350nm. These results led to 49.6%, 32.8% and only 1.1% of the solar power dynamically controllable respectively in the visible, near-infrared and the short-wave infrared wavelength range. Using the simulation results of a glazing formed of three 4mm thick glass panes and two EVA layers 0.2mm thick, improving on the SPD film dynamic absorption efficiency by 16.8% within the near-infrared range could lead to additional modulation of up to 51.2% of the transmitted solar energy within the 780nm-1400nm range. This is equivalent to an additional modulation of the solar energy transmitted from 4% to >5% according to the clearness of the glass used. The switching time was shown to be strongly dependent on the wavelength. Switching to the transparent state, the 3τ switching time varies from 200ms to 400ms but, most importantly varies from 450ms to 2000ms when switching the window to the opaque state. The measured 1800ms switching time to the opaque state at 473nm is in concordance with the theory. In the visible range, the 3τ switching time of the SPD window is in average 4 to 66 times slower than the human eye response. Increasing the switching speed in the visible range would further help instantaneous glare control. To match the estimated 1.25 seconds required for a human to feel some discomfort from instantaneous solar heat transfer variation due to the passing of clouds, engineering windows with a faster and stronger modulation over a wider wavelength range starting at 800nm is preferable. Scattering effects were low for SPD windows but were the major physical effect of PDLC windows and indicated the need to specify the distance between the detector and the window when referencing optical transmission. The switching time to the transparent state of the PDLC was below 15ms but also varies from 25ms to 55ms according to the wavelength when turning back the window to its opaque mode. In both case this switching time is sufficiently fast to control glare but, due to its milky-white appearance, is most appropriate for privacy rather than façade glazings. However, a UV filter with a wavelength cut-off at 380nm would provide additional protection where both EVA and PMMA are highly transparent and consequently extend the service lifetime of building integrated switchable windows and protect from the degradation (colour fading) of indoor materials. The switching

time of the EC window appeared particularly dependant to the wavelength when switching the window to the opaque state while it appeared relatively uniform when switching to the transparent state. It should be noted that these times may be expected to decrease with an increase in temperatures above the 21ºC measured during testing and with an increased exposure to sunlight. These switching times are slow compared to SPD and PDLC windows and for this reason they should not be subject to the same control methodologies. Switching times of this order make them unsuitable for instantaneous glare control and better suited to predictive control where heating/cooling or lighting demand can be predicted in advance of the required switching operation. The EC window was able to modulate only 32.8% of the solar energy within the 380nm-1020nm range making it more suited to climates with high solar irradiance. An increase in the transmission levels, particularly in the infra-red range, would make it more suitable in climates that may require greater levels of visible light and solar heat gain.

Abstract

This work describes a novel HVAC system consisting in a solar-assisted ground-coupled absorption heat pump. The aim of this work is to analyze, using a TRNSYS simulation program, the influence of different design parameters, such as the area of the solar collectors; the building occupancy and the using schedule, as well as an assessment of the influence of the weather conditions in the energy performance of the installation during winter and summer season. Finally, an annual analysis of the energy transferred by the main elements of the installation (solar collectors, boiler, geothermal heat exchange, generator, condenser, evaporator, radiant floor) under the actual operating conditions was carried out.

Keywords: Solar energy, solar cooling, sustainable HVAC, geothermal heat exchange, absorption heat pump, radiant floor, TRNSYS

1. Introduction

The building sector consumes almost 120 EJ per year worldwide, representing 30% of total final energy consumption in all sectors of the economy and half of the world's electricity demand. Despite the great efforts of politicians to improve the energy efficiency of buildings, energy use in this sector has increased by almost 20% since 2000. Fossil fuels (coal, oil and natural gas) used directly inside buildings and in the generation of electricity represent a significant part of the energy used. The building sector represent almost 30% of global CO_2 emissions and 36% of the final energy consumed in buildings is used for heating (IEA 2015).

The European Union has identified the building sector as a key sector to achieve the 20/20/20 objective (Reduce greenhouse gas emissions by 20%, achieve that renewable energies cover 20% of final energy consumption and achieve 20% savings in energy demand by 2020), as well as to achieve a reduction of greenhouse gas emissions from 80% to 95% by 2050. To achieve these goals, heating and cooling technologies that use renewable energy as an energy source will play a vital role within a sustainable energy system. This has been identified by the European Commission as a "no-return" point in its energy roadmap towards 2050, as it can provide a "local production" of energy. Renewable energies, in addition to being a decentralized system and a highly available energy sources, has also a significant economic impact: about half of the investment will go to the bottom of the value chain, job creation and economic growth at the local level (Ivanic et al. 2014).

As explained above, there is an interest in integrating different renewable technologies to cover the heating and cooling needs in the building sector, and thus help to reduce the demand of fossil source in this sector. Thus, this work is focused on the energy assessment of an installation, which integrates solar energy and geothermal energy with an absorption heat pump, as a way to cover the heating and cooling demand in an office building. In this paper has done several simulation and the idea is to identify the influences of different parameters such as area solar collector, occupancy of the building and weather conditions (different localization) in the performance of the installation.

2. Installation description

doi:10.18086/swc.2017.12.09 Available at http://proceedings.ises.org

The facility under study is located in one of the buildings of the CARTIF technology center in Boecillo Technology Park, Valladolid (41º north latitude and 720 m altitude), Spain. It is a building of tertiary use with an approximate area of 1200 m^2.

The main elements of the experimental installation are: The single-effect, lithium bromide - water (BrLi / H_20) absorption heat pump, THERMAX LT 1; a solar field composed by 42 vacuum tube solar collectors, Vitosol 300; a geothermal energy exchanger consisting in 12 vertical boreholes; and an energy storage system based on water tanks. The system was described in detail by (Macia et al. 2013). The characteristics of the main elements of the system are listed in Table 1.

Tab. 1: Main characteristics of experimental installation

Element	Characteristics
Absorption chiller (Thermax LT1)	35 kW
COP nominal	0.7
Vacuum tube solar collectors (Vitosol 300)	84 m^2
Borehole heat exchanger	12 boreholes
Depth of borehole	100 m
Energy storage system (water)	8 m^3
Radiant floor	1200 m^2

The main novelty of the installation is that the absorption heat pump is connected simultaneously to a geothermal field and to a solar collector field, which allows its use throughout the year with two modes of operation (summer and winter):

Summer: The heat pump condenses with the geothermal exchange; evaporator is connected to the cooling radiant floor system that is distributed throughout the building and the generator is connected to both the solar storage tanks and the gas boiler.

Winter: The evaporator of heat pump is connected to the geothermal exchange, condenser is connected to heating radiant floor which supports the conventional systems installed in the building and the generator is connected to the solar tanks or to the boiler, when there is not enough temperature in the tanks. Figure 1 shows the scheme of the installation.

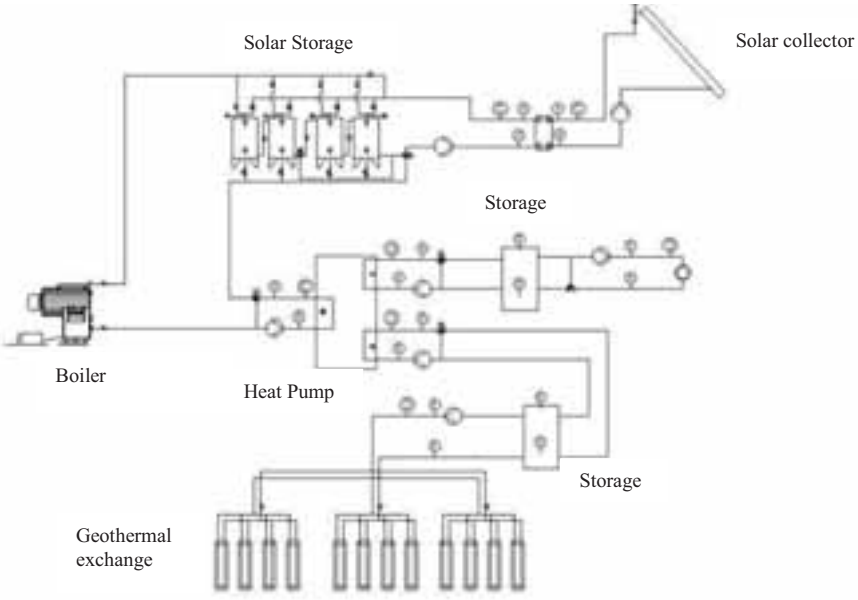

Fig. 1: Schema of experimental installation

3. Simulation approach

In this paper an analysis of the operation of the installation is done under different scenarios, both in summer and winter season. The scenarios that will be analyzed are: influence of solar collector's area; building occupancy, schedule and influence of the weather conditions in the performance of the installation. Finally, an annual analysis of the energy transferred by the main elements of the installation under the actual operating conditions is carried out.

In Figure 2 is possible to observe a schematic of the model developed in TRNSYS for the simulation of the installation, and how the components of the installation are interrelated, from the weather conditions to the building. The simulation model was validated with experimental data collected in actual working conditions of the experimental installation in summer and winter operation modes.

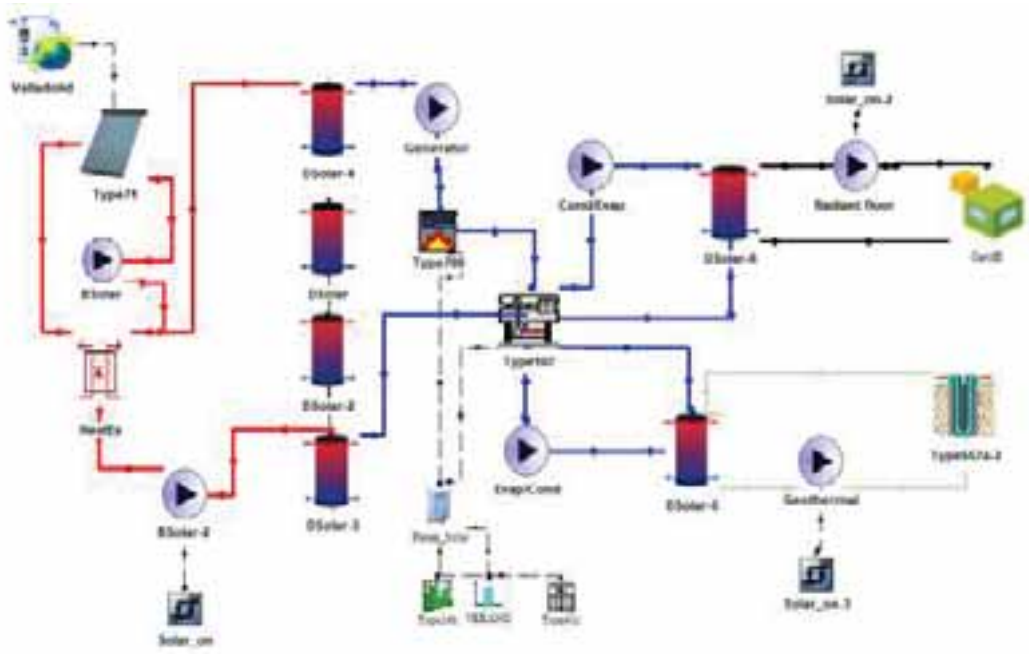

Fig. 2: Diagram of TRNSYS model of experimental installation

The TRNSYS Model is a transient system simulation program with a modular structure that was designed to solve complex energy systems problems by breaking the problem down into a series of smaller components known as Types (Klein 2004). Figure 2 depicts the TRNSYS model scheme developed to simulate the experimental plant. The main modules are described below.

To simulate the performance of the Thermax LT1 absorption chiller, type 107 was used. Since this type uses a catalogue data look up approach to predict the output of the absorption chillers, and the default data file of the type differs from real operation of the installation, several data files of absorption chillers were created, according to the manufacturer technical data.

Type 71 was used to simulate the solar collectors of the solar field. Since standard efficiency curves are calculated for a single solar collector in clear days, at normal sun incidence and nominal flow rate of the water, a few correction factors are introduced in the model, in order to account for series connection, clouds, etc.; details regarding the correction algorithms are given in the TRNSYS documentation. In addition, since evacuated-tube collectors are optically asymmetric, the model takes into account some biaxial Incidence Angle Modifiers (IAM) coefficients for both beam and diffuse radiation. These adjusting parameters are available for any collector tested (ASHRAE 2003) or European Standards (EN12975 – 2:2006)

The natural gas fired boiler used as auxiliary heater is represented by Type 700 in TRNSYS library. The boiler is activated only when its upstream water temperature is lower than a fixed set-point. A vertical ground heat exchanger model must analyze the thermal interaction between the duct system and the ground, including the

local thermal process around a pipe and the global thermal process through the storage and the surrounding ground. Ground heat exchanger has been modeled using the known as 'duct ground heat storage model' (Claesson et al. 1981). This model assumes that the boreholes are placed uniformly within a cylindrical storage volume of ground. There is convective heat transfer within the pipes, and conductive heat transfer to the storage volume. Also U-tube pipe parameters correspond to the properties of polyethylene pipes DN 32 mm PE100.

Type 4 is used to simulate the thermal energy storage water tanks. Simulation is based on the assumption that the tanks can be divided into N fully-mixed equal sub-volumes. The storage tanks are also equipped with a pressure relief valve, in order to account for boiling effects. The model takes into account the energy released by the fluid flowing through the valve, whereas the corresponding loss of mass is neglected. The temperatures of the N nodes are calculated on the basis of unsteady energy and mass balances. For the radiant floor system in the building, TRNSYS type 56 component was used. Building was simulated using TRNBUILD taking into account internal gains by occupancy, working schedule and the radiant floor was simulated as active slab. Weather conditions are represented by the Typical Meteorological Year (TMY) for Valladolid (Spain). Temperatures, wind speeds and solar radiations at regular time intervals are read by a data processor to generate direct and diffuse radiation outputs for a number of surfaces with arbitrary orientation and inclination.

The control strategy that has been developed for the summer and winter operation simulation may be separated in four principal components, each one with its own conditions.

The solar field consists of several elements: solar collectors, primary pump, secondary pump, heat exchanger and storage tanks. The primary pump switches on between 9:00 and 20:00 h every day. The secondary pump has two conditions that it has to carry out before switch on: the first condition is that primary pump is switched on, and the second condition is that the outlet temperature of the solar collectors is higher than the solar storage tanks temperature.

The control for the switch on of the absorption heat pump has to achieve three simultaneous conditions: *Schedule*: The building is occupied between Monday and Friday from 7:00 to 15:00, so the heat pump only operates on these days. *Solar conditions*: In this simulation the installation only operates with solar energy, without the boiler back up. The solar condition is that temperature of storage tank is above the set point generator temperature. *Demand condition*: Summer, heat pump is only in operation when evaporator storage tank temperature is between 8ºC and 15◦C. Winter, heat pump is switch on when condenser storage tank is between 28º and 30ºC.

The control for the switch on of the pump of the geothermal heat exchanger has to fulfill two conditions: that absorption heat pump is in operation and that the temperature of the condenser storage tank is above the condenser set point temperature (summer season) or the temperature of evaporator storage tank is under evaporator set point temperature (winter season).

The control for the switch on of the pump of the radiant floor circuit has to fulfill two conditions: the building occupancy schedule, and the temperature of the evaporator storage tank being between10ºC and 15ºC in summer or condenser storage tank being between 28ºC and 30ºC.

4. Results

On this section, the assessment of three scenarios during winter and summer are analyzed, solar collector area, building occupancy and weather conditions. For the simulation, the summer season is from 1st June to 30th September, and winter season is from 1st October to 31th of May.

Performance of the installation will be evaluated in terms of some indicators described by (Macia, 2016) such us solar fraction defined by equation 1, solar efficiency defined by equation 2, and COP of the heat pump, defined by Equation. (3).

$$Solar\ fraction = \frac{Q_{solaruseful}}{Q_{gen}} \quad \text{(eq. 1)}$$

$$Solar\ efficieny = \frac{Q_{solaruseful}}{Q_{solaresource}} \quad \text{(eq. 2)}$$

$$COP_{summer} = \frac{Q_{evap}}{Q_{gen}}, COP_{winter} = \frac{Q_{cond}}{Q_{gen}} \quad \text{(eq. 3)}$$

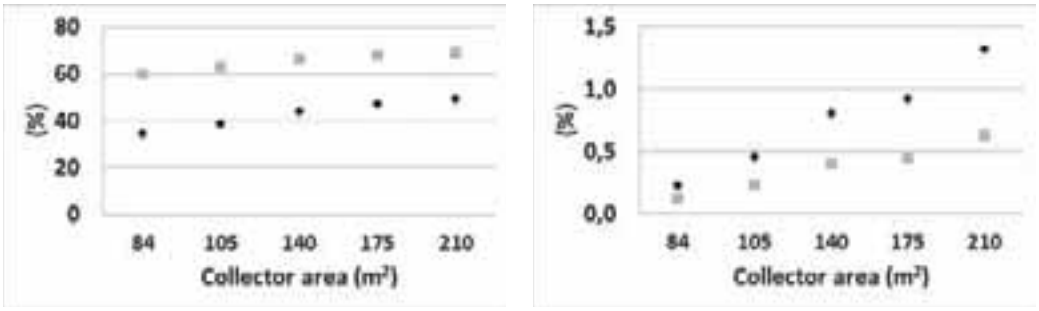
Where Q_{evap}, Q_{gen} and Q_{con} are the energy transferred to the evaporator, generator and condenser of the heat pump, calculated by integrating numerically the respective heat flows. $Q_{solaresource}$ is the total amount of solar energy captured by the solar field during the considered period of time. $Q_{solaruseful}$ is the useful energy used for the installation. Qevap evaluated through equation (4).

$$Qevap = \sum \dot{m}_p \, C_p \left(T_{eva,i} - T_{eva,o}\right) \Delta t \quad \text{(eq. 4)}$$

Where $\dot{m}_p$ is the flow through the evaporator. C_p is the fluid specific heat capacity. $T_{eva,i}$ is the inlet temperature to evaporator. $T_{eva,o}$ is the outlet temperature to evaporator and Δt is the time interval.

4.1 Performance of the installation for different solar collector area

One of the difficulties when designing these types of installations is to know the best relation between the area of solar collectors and the power of the heat pump. For this reason, it has been decided to make seasonal simulations (summer and winter) of the installation for several areas of solar collector. Figure 3 shows the relation between the solar fraction (%), solar efficiency and solar collector area for summer (a) and winter (b).



a. Summer, solar fraction (●) solar efficiency (■) b. Winter, solar fraction (●) solar efficiency (■)

Fig. 3: Relation between solar fraction and solar collector area for summer and winter

In summer, when the solar collector area increases from 84 m^2 to 210 m^2, the solar fraction increases from 34% to 50%, which means that 50% of the energy demand of the heat pump is covered by solar energy. In figure 3a, it can be seen, that by increasing the area from 175 m^2 to 210 m^2, the solar fraction does not change, and it is in accordance with (Eicker et al. 2014), who say that the solar fraction increases until achieve the saturation. This demonstrates that in order to avoid overcosts in this kind of installations, the design must be done with caution, and always trying to undersize in order to achieve higher hours of operation with a lower investment. In figure 3b is clear that, although the solar collector area increase from 84 m^2 to 210 m^2, the solar fraction just rises from 0.2% to 1.4% and with solar efficiency less than 1%.

These results show that it is possible to use this installation in both summer and winter seasons. The using of absorption heat pump in winter with other auxiliary energy source is feasible, because it will have higher performance than using the energy of the boiler in a direct way for the heating of the building by the radiant floor. In addition, the primary energy consumption is reduced when it is compared to conventional installations.

4.2 Performance of the installation as function of building occupancy

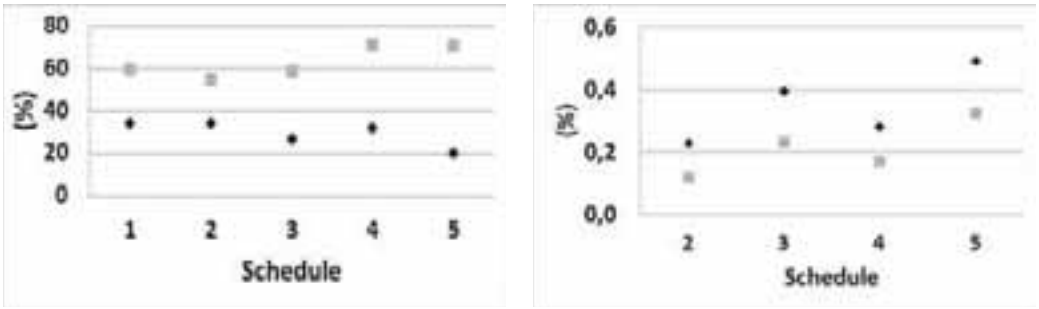
A simulation has been carried out to know if there is any influence of the building occupation schedule on the solar efficiency and solar fraction of the installation. . The schedules were chosen to cover the most common work schedules in Spain, which according to (Nogareda et al. 2014) are: morning and afternoon 40.2%, morning 28.7%, 24 hours 7.2% , morning or afternoon 14.5%, just nights 1.7%, just afternoon 4.6% and 3.1%

corresponding to other work schedules. The five schedules of occupation defined for the simulations are listed in table 2.

Tab. 2: Schedule of building occupancy, absorption heat pump and radiant/cooling floor whole year

Schedule	Days of working	Schedule of building	Schedule of heat pump	Schedule of radiant/cooling floor
1	Monday to Friday	07:00 – 15:00	07:00 – 15:00	09:00 – 15:00
2	Monday to Friday	07:00 – 15:00	04:30 – 11:30	04:30 – 12:00
3	Monday to Friday	07:00 – 15:00	20:00 – 6:00	20:00 – 06:00
4	Monday to Friday	06:00 – 20:00	06:00 – 20:00	06:00 – 20:00
5	Monday to Friday	24 hours	24 hours	24 hours

The figure 4 shows the result of the simulation for both season summer and winter. The assessment was done with two indicators: solar fraction, solar efficiency.



a. Summer simulation **b. Winter simulation**

Fig. 4: Solar fraction (●) and solar efficiency (■) of installation as function of schedules.

In summer, when comparing the 24 hour operating hours (schedule 5) and the CARTIF schedule (schedule 1), the efficiency of the installation is higher in the 24 hour schedule with 70% compared to CARTIF with 60%. This result shows that is better from the solar energy use point of view keep the building open 24 hours. On the other hand, the solar fraction changes from 35% in the CARTIF schedule to only 20% solar fraction in the 24 hour schedule. This decrease in the solar fraction is due to the increase in the energy demand of the generator to cover the 24 hours of operation, causing that the solar installation does not have the sufficient capacity and it is necessary a greater support of the auxiliary energy, CARTIF schedule to 24 hours schedule the generator demand increases 2.6 times.

In winter, with 84 m^2 of solar installation, the solar fraction for any of the simulated schedules is less than 0.5%, demonstrating the need for an auxiliary energy source to cover demand.

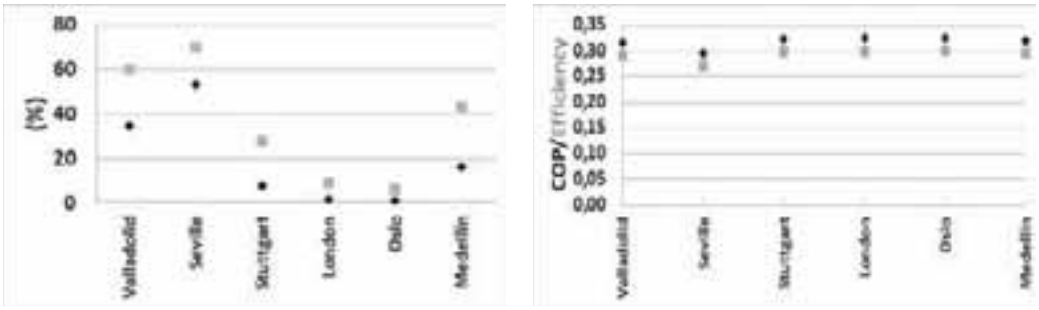
4.3 Performance under different weather conditions.

To make an analysis of the influence of climatic conditions on the performance of the installation, simulations for different weather conditions were carried out. For the selection of cities to be simulated, the climatic severity index has been taken into account, according to the Technical Building Code (CTE, 2006) the climatic severity of a locality is the quotient between the energy demand of any building in that locality and the energy demand of same building in a reference locality. The advantage of making the geographic classification based on the index of climatic severity, (Rodríguez, 2015) is that in contrast to the degrees day total year; this index takes into account other variables as the radiation.

According to (Rodríguez, 2015) with the use of the climatic severity index it is possible to discriminate between cold areas of Europe with high solar radiation in winter and other areas with low solar radiation in summer, that having classification by degrees days would not be possible differentiate.

According to the classification explained before, it has been decided to do the simulation for six different cities, each one belonging to a different zone. They are: Valladolid, Seville, Stuttgart, London and Oslo and Medellin.

For the simulations in different climatic conditions, the same characteristics of the heat pump, the building and the same characteristics of the soil have been considered for all the locations. Only the slop of the solar field has been modified according to the latitude of each of the cities. The analysis only has been focused on the influence of both solar radiation and climatic conditions, on the performance of the installation and the heat pump, as well as the solar fraction. The results of simulations are depicted in figure 5.



a. Solar fraction (■) solar efficiency(■)

b. COP(■), installation efficiency (■)

Fig. 5: Solar fraction, solar efficiency, COP of installation as function of weather conditions

Solar efficiency in Valladolid and Seville is greater than 60%, which means that more than 60% of the energy of solar field becomes useful energy for the installation. In Oslo and London the efficiency is less than 9% showing that useful solar energy is negligible and it would be necessary to increase the collector area to increase the solar fraction. The results of simulation during winter season for the main elements of installation are presented in table 3.

Tab. 3: Energy of main elements of installation during winter season

City	Q_{boiler} (kWh)	$Q_{solaresource}$ (kWh)	Q_{useful} (kWh)	Q_{gen} (kWh)	Q_{con} (kWh)	Q_{eva} (kWh)	Q_{floor} (kWh)	Q_{geo} (kWh)
Valladolid	8666	16974	20	8686	11486	1800	10425	1968
Seville	6701	21751	372,9	7122	9389	1509	6673	1203
Stuttgart	9545	11047	0	9768	12965	2010	9456	2463
London	9217	9545	0	9278	12270	1913	9456	2184
Oslo	11196	8198	0	11118	14808	2272	11892	3197

The amount of solar energy used by the heat pump during winter (solar useful energy) for three cities Stuttgart, London and Oslo is zero and all energy demand must be covered by the boiler. On the other hand, for Valladolid the contribution did not reach even 1% of total energy demand. A greater contribution was achieved in Seville, with 5% of the total demand of the generator. These results indicated that for the demand conditions of the heat pump with 84 m^2 of solar collector, the solar fraction is zero or very low.

When comparing the solar energy (Qsolar) in Table 3 among the different cities, it is seen that in Seville is where there is a greater uptake with 21750 kWh, but of this energy the contribution to the installation is only 372 kWh, which represents a total of 21378 kWh of solar energy were not used. Oslo on the other hand, it was the city with a lower solar energy with 8198 kWh, this is due to the few hours of solar radiation in winter. This result suggests that in winter the solar energy should be given another use, such as the preheating of the supply water to the boiler.

In table 3, it can also be seen that the demand for radiant floor is higher in Oslo (11892 kWh) being almost double the demand of Seville (6673 kWh), it is expected since the weather conditions in Oslo are more severe than in Seville. The coefficient of operation of the heat pump (COP) in all cities was 1.32 and there is no influence of external conditions on the performance of the pump, one of the reasons is that its three exchanges (generator, condenser and evaporator) are not affected by the external conditions, since the conditions of the

ground, the conditions of the radiant floor and the conditions of the boiler have been considered equal in all the locations.

4.4 Annual energy balance

Finally, after all the simulations carried out in previous section such as: the influence of the building's schedule, the area of solar collector and the study of the influence of the weather conditions on the performance of the installation. On this section, an analysis of the energy flows by each one of main element of the installation during one year of operation under CARTIF conditions (schedule, location) was done.

Figure 6 display the energies exchanged in each one of the main elements of the installation both in summer and winter season.

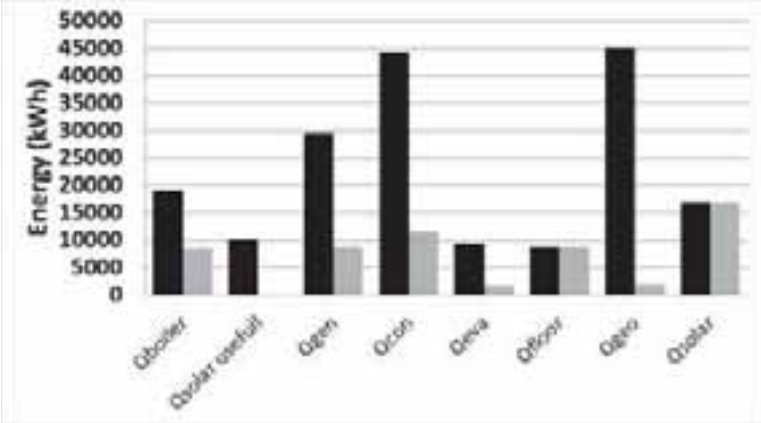


Figure 6. Energy season by each element of installation, summer (■) winter (■)

A holistic analysis of Figure 6 shows that there is a greater exploitation of the facility in summer than in winter, since the energies transferred in all elements are greater in summer. The solar useful energy during the winter is almost null even though the solar energy (Qsolar) is even greater than the energy transferred by the boiler, this result suggests to search another use to the solar energy captured, although it is not possible to use it directly in the installation for the temperature conditions necessary for its use, if it is possible to use all "free" energy as preheater of the supply water entering the boiler or for the floor heating in a direct way.

Another result of Figure 6 that should be paid attention, is the energy exchanged with the geothermal field (Qgeo). In the summer, the facility exchange 23 times more energy to the terrain than it absorbs in winter (45008 kWh versus 1968 kWh). This result suggests a more detailed analysis of the geothermal field and its performance over the years in order to avoid saturation of the soil, due to the decoupling between the energy transferred in summer and winter, coefficient of heat transfer is reduced.

5. Conclusions.

In winter, increasing the solar collecting area in Valladolid does not have a significant effect on the solar fraction, the energy captured goes from 17 MWh to 18 MWh, which can be an energy to be used for preheating the supply water to the boiler or to domestic hot water (DHW) of the building. On the contrary, in summer, if the solar collector area increases from 84m^2 to 210 m^2, the solar fraction increases from 34% to 50%, but above 175 m^2 the solar fraction is practically constant. This demonstrates that to avoid over costs of this type of installations, the design must be done with great care and always trying to undersize to achieve higher hours of operation with a lower investment.

The simulations allow concluding that the occupation schedule of the building has an influence on the solar fraction and yield, showing that with more hours of occupation, a higher efficiency is obtained, but the solar fraction decreases.

The analysis of the weather conditions shows that the use of solar energy in winter for this type of facilities,

with demand of high temperatures is negligible in all simulated cities, this result suggest that in winter it should be look for other uses for the solar energy in order to increase the useful energy during this season. In summer, on the other hand, in cities such as Seville, solar fractions are achieved in excess of 50% and solar efficiency in excess of 60%. In northern cities, both summer and winter, solar yields remain low; giving to think that perhaps this type of facilities have a better exploitation in countries of the Mediterranean.

96% of the total annual energy transferred to the geothermal field corresponds to its operation during the summer, when the heat pump capacitor exchanges with it. This result suggests a more detailed analysis of the geothermal field and its performance over the years to avoid a saturation of the terrain, generating a degradation of the terrain due to the lag between summer and winter

Experimental Investigation of Thermal Enhancements for a Building Integrated Photovoltaic/Thermal Curtain Wall

Eftsratios Dimitrios Rounis, Zisis Ioannidis, Olesia Kruglov, Andreas Athienitis and Konstantinos Kapsis

Dept. of Building, Civil and Environmental Engineering, Concordia University, Montreal (Canada)

Abstract

Building integrated Photovoltaic/Thermal (BIPV/T) systems provide a cost-effective way of incorporating solar technologies on buildings for the generation of electricity and useful heat, by replacing common building materials. Air-based systems are generally better suited for large façade or roof installations, they are however, less efficient in extracting heat from the PV due to the thermo-physical properties of air and therefore need enhancements for their thermal performance. This study investigates ways of enhancing air-based Building Integrated Photovoltaic/Thermal (BIPV/T) systems, focusing on the use of multiple-inlets and presents the development and initial testing of a BIPV/T curtain wall prototype. The testing of the prototype showed superior performance for the double-inlet versus the single-inlet configuration, thermally (up to 18% higher thermal output), lower peak PV temperatures (reduced by up to 3.6ºC) and a marginal increase in electrical output due to enhanced cooling.

Keywords: Building Integrated PV/Thermal, thermal enhancements, experimental performance

1. Introduction

The building sector is responsible for approximately 40% of the global energy consumption (Agathokleous & Kalogirou, 2016). Incorporation of solar technologies for electricity and useful heat production on buildings is essential for the design of net-zero energy buildings and for reducing the energy footprint of retrofits.

Photovoltac/Thermal (PV/T) hybrid systems combine the generation of electricity and useful heat. The photovoltaic layer of such a system also acts as the absorber and a circulating fluid removes part of the excess heat from it, which may be then utilized by various means, depending on the fluid's outlet temperature and delivery rate. PV/T systems have been found more efficient than independent PV or thermal collectors covering the same surface area (Kumar & Rosen, 2011a).

Building-Integrated Photovoltaic/Thermal systems come from the integration of PV/T with the building envelope. This integration may have several advantages over using PV/T systems as stand-alone (Yang & Athienitis, 2016). Apart from the architectural integration and the superior aesthetic result, the PV panels replace the outer shell materials (roof shingles, siding, concrete or masonry panels for façade etc.), increasing the cost effectiveness of the installation and the whole system functions as a building envelope element. A BIPV/T system must fulfill the requirements of the building envelope in terms of heat, air, water and moisture control (Jelle & Breivik, 2012). Integration with the façade or the roof may offer a larger installation area, which would otherwise not be available for use, although BIPV/T systems cannot be optimally oriented and tilted as opposed to stand-alone PV/T systems.

Ventilation and cooling of building integrated PV is essential since they do not have the same wind-driven cooling potential as racked PV (Bloem, 2008; Fossa et al, 2008). An air channel formed between the PV layer and the rest of the wall section for the ventilation of the system may serve two purposes: the cooling of the PV to prevent a decrease in electrical efficiency, and the collection of the preheated air for various purposes. Fan-assisted convection has been found to be more efficient in cooling the PV and extracting heat, in comparison to natural convection, especially in larger systems (Kaiser et al, 2014).

Depending on the coolant, BIPV/T systems are divided into water and air-based systems. Water based systems have greater heat exchange effectiveness. They require special casing and piping and are generally limited to smaller scale roof applications to avoid leakage and freezing issues within the wall section. Air-based systems on the other hand are easier to install and maintain, they do not pose leakage or freezing issues and can be adapted to different kinds

doi:10.18086/swc.2017.12.10 Available at http://proceedings.ises.org

of facades and roofs. However, due to the thermo-physical properties of air they are less efficient in the extraction of excess heat from the PV. There have been several studies on ways to enhance the thermal performance of PV/T and BIPV/T systems, which are discussed in the next section.

BIPV/T systems currently hold a small share of the PV installations. Usually, a harmonic architectural integration with an existing façade or roof is enough to characterise the system as integrated. However, there are few examples of systems that entirely replace the typical wall or roof structure of a building (Athienitis et al, 2011; Chen et al, 2010). The lack of more examples like those is mainly due to the fact that there is no current BIPV/T standard related to its integrated performance and function as a building envelope element.

This study presents the development and initial testing of a BIPV/T prototype, which was designed based on existing curtain wall practices and intended for full building integration. The main purpose was to be able to test and compare different thermal enhancements on the same experimental prototype, and provide design insight on fully integrated air-based BIPV/T systems. The initial experimental test set-up focuses on the effect of different PV module transparencies, the introduction of an additional air intake and the use of a flow director on the electrical and thermal performance of the prototype. The use of fins and varying channel depth will also be incorporated and studied in the future.

2. BIPV/T Thermal Enhancements

2.1 Air based systems thermal enhancements

Air-based systems are generally more suitable for envelope integration and large-scale applications, but less efficient in heat extraction than water-based systems. Several researchers have looked into ways of enhancing the thermal performance of air-based systems. These enhancements may only involve geometric and/or flow optimization, or the addition of material elements such as double glazing, fins or other porous media. Most of the proposed enhancements were applied to a reference PV/T system (Fig.1), while others refer to specific prototypes.

Fig. 1: Typical PV/T configuration

The criteria for enhancement vary among studies. For naturally ventilated systems with no heat collection the goal is to enhance the electrical output and PV durability by reducing the PV temperatures. This is generally achieved by optimizing the collector's aspect ratio (length over depth) for which the velocity of the buoyancy driven flow is maximized, but it may also involve the optimum tilt angle (Brinkworth, 2000; Brinkworth et al, 2000; Brinkworth & Sandberg, 2006; Brinkworth, 2006; Gan, 2009). In general, studies on naturally ventilated systems agree on a 10-15 cm optimum channel gap and a 45^{o}-55^{o} tilt angle.

The enhancement of mechanically ventilated systems varies considerably, depending on whether the priority is given to either the electrical output, or the thermal output, or a balance between the two and whether the consumption of the cooling system is also considered. Several researchers have investigated the optimal aspect ratio of the collector length to the collector depth and the optimal flow for air-based PV/T systems (Kaiser et al, 2014; Bambrook & Sproul, 2012; Zogou & Stapountzis, 2011). In addition, some studies include the effect of pressure drop within the collector (Bambrook & Sproul, 2012) and within the ducting that connects the PV/T to the HVAC system (Farshchimonfared et al, 2015). The suggested optimal flows vary between 0.026-0.050 kg/m2s, and the optimal channel depth between 0.025-0.090 m.

The practice of adding one or more glazing layers over the PV layer has been studied as a means to increase the thermal output of the system by reducing the wind induced heat losses (Hegazy, 2000; Tiwari et al, 2006; Sopian et al, 2000). The boosted thermal performance comes at the cost of the electrical, due to the higher PV temperature and the reduced solar radiation transmitted through the extra glazing (occasionally due to the formation of condensation on the outer glazing). The PV temperatures can be decreased with a double-pass configuration, by placing the PV

layer between two air channels, independent or connected. Tripanagnostopoulos (2007) suggested that, unless the system is optimized for thermal output, glazed PV/T systems are not recommended, due to PV overheating and poor electrical performance.

Heat extraction from the PV layer can be further enhanced with the use of material elements inside the air channel. These elements could either be fins in contact with the absorber that act as heat sinks (Othman et al, 2007), or fins set on the back surface which induce turbulence and boost the convective heat transfer (Kumar & Rosen, 2011b; Tonui & Tripanagnostopoulos, 2006). Other elements can be porous media, such as a metallic mesh (Pantic et al, 2010; Yang & Athienitis, 2014), honeycomb heat exchanger (Hussain et al, 2015), and suspended thin metal sheet [24] which further increase the radiative and convective area. These techniques have been proven very effective in removing heat from the PV, as opposed to the reference design (Fig. 1). However, a major limitation is that they cannot be used for systems with long channels due to the added flow resistance in the air channel and consequent increase of fan consumption.

Most of the aforementioned studies has been based on small scale experimental models (collector length generally 1-1.5 m), the behaviour of which could be different in larger scale applications. This is primarily due to the formation of a thermal boundary layer and a consequent temperature rise of the PV layer along the collector, leading to non-uniform PV temperature distribution and lower performance of the collector.

One major issue that is raised is the lack of common criteria for the enhancement and optimization of the systems. Usually the enhancement refers to the PV/T system without considering the integration with the mechanical system (heat pump, direct heat supply, heat exchanger, desiccant cooling etc.) and the corresponding requirements in terms of flow and fluid temperature, along with limitations for allowed PV temperatures. Furthermore, it is difficult to have a clear comparison between the various proposed systems due to the difference in dimensions and testing conditions, while the proposed numerical models are usually case specific and the convective correlations are not generally applicable.

2.2 Multiple-inlet BIPV/T

A more recent method of thermal enhancement is the introduction of more than one air intakes along the collector's channel. This technique is based upon the breaking of the thermal boundary layer and taking advantage of the introduced entrance effects. The convective heat exchange from the PV layer to the air stream is enhanced and more uniform PV temperatures can be achieved by regulation of the inlet flow distribution. The concept of a multiple-inlet BIPV/T evolved from the hybrid unglazed transpired collector (UTC) - PV/T system introduced by Athienitis et al (2011), which is installed at the mechanical penthouse of the John Molson School of Business (JMSB) building of Concordia University in Montreal. This system consists of custom PV modules attached onto a layer of UTC.

A double-inlet system was numerically investigated by Yang & Athienitis (2014). Convective heat transfer correlations were developed based on the testing of an experimental single-inlet prototype in an indoors solar simulator facility, which were used for the simulations of the performance of a two-inlet system. The addition of a second inlet increased the thermal efficiency of the system by 5%, reduced the maximum PV temperatures and marginally increased the electrical efficiency. Rounis et al (2016) proposed a method of modelling multiple-inlet BIPV/T systems and simulated the performance of a single and a multiple-inlet BIPV/T system for a large-scale office building application. Results showed that the multiple-inlet system had the lowest and most uniform PV temperatures, as well as higher electrical and thermal efficiency. Mirzaei et al. (2014) investigated experimentally the role of cavity flow on the performance of naturally ventilated BIPVs placed on inclined roofs. The experimental configurations included a flat and a stepped arrangement, which was essentially a multiple-inlet formation. It was found that the PV temperatures were significantly lower for the stepped configuration (multiple-inlet) cases, as opposed to the flat roof.

3. BIPV/T Prototype Development

A BIPV/T prototype was designed at Concordia University and developed in collaboration with Unicel Architectural and Canadian Solar, based on the curtain wall façade system. The prototype (Fig. 2) represents part of a full BIPV/T curtain wall façade. The purpose of the prototype was to address issues of architectural and structural integration, but also to investigate and compare experimentally different configurations and performance enhancement methods. The objective of this effort would be to provide insight on the development of a BIPV/T design and performance standard.

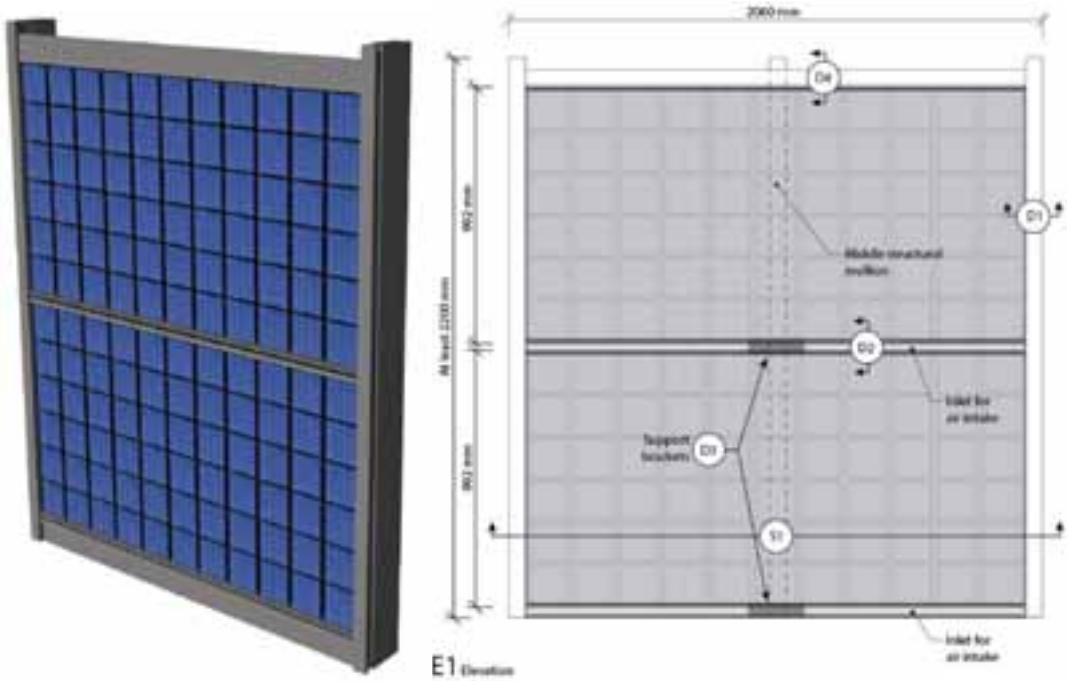

Fig. 2: BIPV/T curtain wall concept

The BIPV/T curtain wall prototype consists of a metal frame, two frameless PV modules and a 2-inch rigid insulation sandwiched between aluminum sheets. The metal frame was fabricated by Unicel Architectural using commercial mullion extrusions. The frameless, semi-transparent PV modules were provided by Canadian Solar. Two sets of semi-transparent PV modules were used, one with 66 cells and one with 72 cells, in order to investigate the effect of different transparencies on the prototype's performance.

A second inlet was introduced between the two PV modules, while the PV panels were placed horizontally to take advantage of the entrance effects of the second inlet flow. The panels were fixed with pressure plates at the side and top mullions and a shorter middle mullion was used to reduce counter deflection and provide extra support for the dead load of the panels.

Figure 3 demonstrates the cross side section of the prototype and the building envelope functions of its layers.

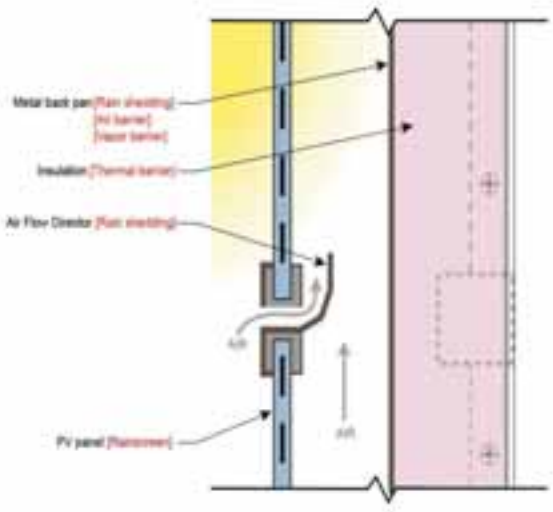

Fig. 3: BIPV/T curtain wall cross section

The prototype was designed with a reduced height to fit the test platform, but is considered as part of a story-high, or taller, system. Regarding the flow of the air channel, several aspects were considered. The primary factor that dictated the overall flow design was the introduction of a second inlet between the PV panels. The opening of the inlet was roughly estimated by previous analysis (Rounis et al, 2016) to approximately provide one third of the total

flow when fully open. Furthermore, air flow directors were used (Fig. 3) to direct the air stream of the second inlet closer to the surface of the top PV module. This also acted as a measure against rain penetration. Finally, a custom manifold was built and connected to holes opened on the top mullion, at the top side of the collector. This consisted of four take-offs from the collector connected to the main duct of the air collection unit. The number of take-offs was a compromise between flow uniformity and reduction of the structural integrity of the top mullion.

4. Experimental Process and Preliminary Results

The experimental prototype was tested in the Concordia University indoor Solar Simulator (Fig. 4). The Solar Simulator consists of a lamp field which emulates the sun light and a test bench upon which the test specimens are placed. The 8 metal halide lamps that comprise the lamp field can be moved individually in the horizontal and vertical axis and can produce irradiance intensities from 500 to 1200 W/m2 with a uniformity of up to 97% (Kapsis et al, 2016). The spectral quality of the lamps fulfills the specifications of ISO 9806. Both the lamp field and the test platform can rotate between a horizontal and vertical orientation to accommodate testing cases varying between flat roofs, tilted roofs and vertical facades. The experiments carried out for the experimental process presented here was in the vertical position, corresponding to a façade integrated BIPV/T.

This paper includes the results from testing conditions similar to the Nominal Operating Cell Temperature (NOCT) conditions, namely:

- Average solar radiation, G=842 W/m2
- External wind velocity, Vwind=1 m/s
- Ambient temperature, Tamb=20ºC

Two sets of PV modules were used (66 and 72 cell) and for each set, three configurations were tested: single inlet (with the middle inlet covered), double-inlet without the flow director and double inlet with the flow director installed. For each configuration, three total mass flow rates were investigated, namely, 400 kg/hr, 500 kg/hr and 600 kg/hr, with corresponding average channel velocities of 0.5 m/s, 0.62 m/s and 0.74 m/s. The most important results from this first set of experiments are presented in the following sections.

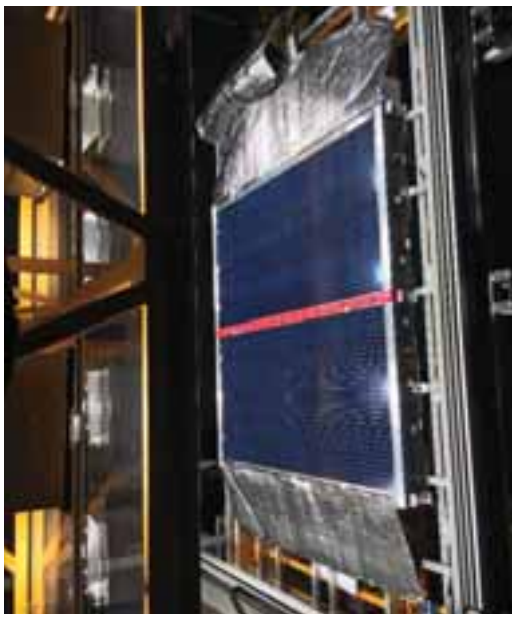

Figure 4: The BIPV/T prototype during testing in a vertical position at the Concordia University Solar Simulator

4.1 Effect of transparency

As expected the set of more transparent modules (66-cell) had lower electrical output of about 10-11% versus the 72-cell set, but the higher amount of radiation transmitted to the back absorber resulted in a 5-10% higher thermal output and slightly higher outlet temperature (up to 0.7ºC). The peak PV temperatures for the 72-cell set were higher

by 0.6°C - 3.6°C, due to the higher radiation absorbed by a larger PV cell area. These results agree with previous investigations (Bloem, 2008; Vats et al, 2012). The choice of packing factor in a real application would depend on the desired electrical and thermal output.

4.2 Effect of second inlet and flow director

The introduction of the second inlet may increase the thermal output by up to 18% and the outlet temperature by 1°C (for a collector of 2 m height). The system's performance was further enhanced with use of a flow director, which directed the flow entering from the second inlet closer to the surface of the upper PV module, extracting more heat and further reducing its temperature. The electrical efficiency was marginally increased and the peak PV temperatures are lower by up to 1.6°C, depending on the flow rate. These results are in accordance with the experimental work of Yang & Athienitis (2014)

Figure 5 presents the electrical and thermal efficiencies and the peak PV temperatures for the three configurations at the 600 kg/hr flow air collection rate. The results were similar for the other flow rates tested, as well as for the 66-cell set.

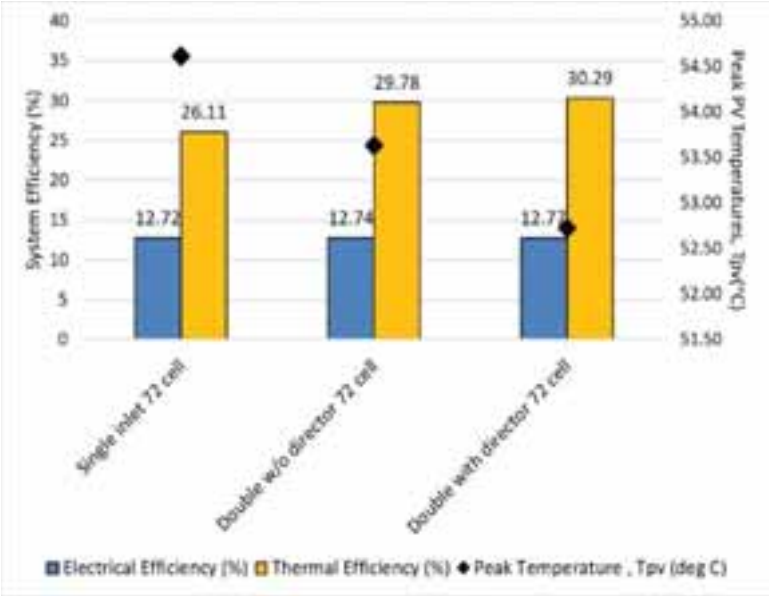

Figure 5: Electrical efficiency, thermal efficiency and peak PV temperature for the three configurations of the 72-cell set, at 600 kg/hr total mass flow rate (0.75 m/s average channel velocity)

5. Conclusion

This study focused on thermal enhancement techniques for air-based BIPV/T systems and presented the initial testing of a BIPV/T curtain wall prototype, with semi-transparent PV and multiple-inlets. The prototype has been developed to both provide design guidelines for fully integrated façade and roof BIPV/T systems and investigate the performance and applicability of various thermal enhancement techniques.

The initial testing of the prototype has shown that the introduction of a second inlet may increase the thermal output by up to 18%, decrease the peak PV temperatures by up to 3°C and marginally increase the electrical output, as opposed to the case of a reference single-inlet system. The double-inlet system's performance was further boosted by an air flow director element, which directed the flow closer to the surface of the second PV module. The use of higher transparency PV modules increased the thermal output, by 5-10% and the outlet air temperature but the electrical output was decreased by 10-11%. The differences in performance for the single and double-inlet systems are expected to be more prominent in larger scale applications.

This is part of a larger study involving the comparison of different enhancement techniques for air-based systems as well as the development of design guidelines for BIPV/T that may lead to a BIPV/T performance standard. Future work includes the investigation of more thermal enhancement techniques applied to the prototype, such as the use of fins and varying channel depth. A collective comparison of the tested methods will be carried at the end of the experimental procedure. Furthermore, models will be developed and validated according to the experimental results

for the simulation of full scale systems and the suitability of already developed convective coefficient relations will be evaluated.

Abstract

Singapore has committed to reducing greenhouse gases emissions as a part of the Paris Agreement. Increasing energy and food self-sufficiency through integration of solar and vertical farming systems into buildings' envelope could play a significant role in achieving Singapore's targeted reductions. This paper focuses on the design optimization of the façade systems that are to be installed at the Tropical Technologies Laboratory at the National University of Singapore. In particular, the paper presents the results related to five performance indicators which include solar energy and farming potential as well as the impact of the façade design on the indoor daylight conditions, shading and thermal performance. The multi-criteria decision analysis (MCDA) method VIKOR was adopted in the evaluation of the created design alternatives. The results from the computational simulations on radiation, daylight, and thermal conditions were used as inputs. Final optimal façade design is selected for four types of facades according to BIPV and farming systems arrangements for north and south orientations.

Keywords: BIPV, vertical farming, façade systems, solar architecture, tropical architecture

1. Introduction

Singapore has a high dependency on energy and food imports in order to cope with the growing domestic demand. Despite the currently favourable political and market conditions in the region, there are arguments, mainly for security reasons, for a gradual increase of locally produced food and energy in the future. Given the high population and urban density of the city-state, a limited land area available for conventional agriculture, as well as a lack of mineral resources, Singapore is seeking both the alternative solutions to reduce the dependency on imports and the means by which to meet the commitments of the United Nations Framework Convention on Climate Change Paris Agreement (United Nations, 2015) in combating the intensity of greenhouse gas (GHG) emissions and preventing them from peaking by 2030. Therefore, the contribution of the urban environment in increasing Singapore's self-sufficiency through the application of Building Integrated Agriculture (BIA) and Building Integrated Photovoltaic (BIPV) systems could play a crucial role in achieving those goals.

More than 90% of power production in Singapore is generated from fossil fuels. As for renewable energy sources, the rooftop integration of PV panels is very limited and does little to increase the share of renewable energy. Façade integration is therefore necessary to achieve a significant increase of solar energy production. Land in Singapore is scarce and expensive and although solar irradiation is much lower on vertical surfaces than on horizontal surfaces (at cca. -48.5% (for east) up to -64.3% (south)) (Khoo et al., 2014) façade integrations may justifiably present a sustainable solution. The design of façade integrations is a complex task requiring careful consideration and good optimization of various parameters such as: the tilt, shading effects, position, visibility from the inside and the outside of the building, accessibility, function, and overall aesthetics. Another factor to consider is that façade integration often relies on custom-made PV panels, hence, the attending costs, although exhibiting a gradual downward trend, still pose an important challenge in the design of façade integrations. Façade surfaces are visually more dominant than the rooftops of high-rise buildings and offer a

doi:10.18086/swc.2017.12.11 Available at http://proceedings.ises.org

wider range of aesthetically pleasing, high-quality solutions that can in turn serve as a positive influence on the behavior of the people and provide motivation for furthering similar projects.

Urban farming has recently come into attention since it represents a significant step towards reconnecting food producers and consumers. By shortening the food mile, urban farming saves time, reduces costs as well as GHG emission related to food transportation. At the same time, urban farming provides city residents with fresh ingredients, enabling a healthier life style and creating a more pleasant living environment. Urban farming also creates educational and interacting opportunities for city dwellers. Additionally, farming in the city may contribute to rainwater storage thus alleviating urban storm water flooding and run-off.

Several studies have been conducted on the integration of PV panels into building facades in Singapore (Luther and Reindl, 2014; Saber et al., 2014). The application of farming systems on building facades from the construction point of view was reported by Suparwoko and Taufani (2017) but there are no other references on the façade arrangement and the potential yield. The integration of both solar and farming systems on building facades was investigated by Tablada & Chao (2016) and Tablada et al. (2017) at the urban and façade scales respectively.

This paper therefore focuses on the design optimization of the productive solar façade (PSF) systems to be installed at the Tropical Technologies Laboratory (T2 Lab) located at the university campus. The research is based on the hypothesis that the performance of building facades should exceed the traditional functions of indoor–outdoor boundary and climatic regulation by also providing a portion of the energy and food that residential buildings demand. BIPV and vertical farming systems provide dual benefits: on one hand, they help produce electricity and food, and on the other, act as a passive device for solar gains reduction and the improvement of both visual and thermal comfort indoors.

The development of a PSF prototype involving both BIPV and BIA systems should employ a holistic iterative process that includes conflicting quantitative and qualitative parameters. The aim of the said process is to arrive at an optimal solution – a solution that meets and balances specific architectural and techno-economic requirements but also allows for different constraints that elements such as safety, accessibility and others may additionally impose. For the purposes of this study, the VIKOR method is employed (Opricović and Tzeng, 2004; Opricović and Tzeng, 2007). It is a multi-criteria compromise method that enables comparisons and assessment of otherwise incommensurable or conflicting criteria while offering relatively easy modelling and flexibility according to the preferences of the decision-maker (Kosorić et al., 2011; Krstić at al., 2012), especially if the decision maker has a complex structure and/or insufficiently clear preference in the optimisation process. MCDA VIKOR method used in this paper will therefore help provide a comprehensive evaluation and selection of the optimal design alternatives. Grasshopper parametric simulation tool (McNeel, 2010) is used together with necessary plug-ins to calculate several environmental performance criteria for the analysed cases on north and south façade orientations.

2. Method

2.1. Optimization method framework

Figure 1 presents the overall MCDA framework followed in this study. The first step is to define the potential façade components for the BIPV, vertical farming and the fenestration or voids. A series of preliminary simulations and technology selection is carried out for each system based on the available reference literature and discussions with local experts for both BIPV and BIA. Thereafter, the design strategy and decision goals are identified considering the potential PSF installation in residential buildings.

Quantitative and qualitative assessment criteria are also defined as well as the weights for each criterion. The impact of the façade design on sunlight availability for the BIPV and farming systems, as well as on indoor daylight conditions, shading and thermal performance are also taken into account by conducting computational simulations using Grasshopper's plug-ins.

While always accounting for the coherence with the overall building logic, mainly geometrical, functional and aesthetical characteristics of residential buildings, the design alternatives are then generated for two types of facades: (1) facade wall and (2) facade with balcony. Both façade systems are analyzed separately for four orientations: north, south, east and west. This paper presents the results for north and south oriented façade

walls. The façade design alternatives were developed according to the T2 Lab dimensions and layout. As shown in figure 2, eight test bed cells are located inside a 60 m2 building and are also used for other investigations of tropical technologies.

Optimal design alternatives are selected by means of the VIKOR (MCDA) method i.e the method was used to evaluate the PV integration design variants, rank determined alternatives, and then select a compromise solution Q from a set of m alternatives: A1, A2... Am, while those alternatives were evaluated on the basis of a set of n criteria functions. The alternative with the lowest Q value represents the compromise solution. This means that the said solution achieves a compromise between 2 decision making strategies: maximum group benefit defined by the value Sj (a better alternative is considered good according to the majority of criteria), and minimum of maximum deviation of ideal values defined by the value Rj (a better alternative must not be very bad according to any criteria). Vikor method also verifies "acceptable advantage" and "acceptable stability" of variant 'optimality' (Opricović and Tzeng, 2004). The details of the VIKOR method applied in this study can be found in Tablada et al. (2017).

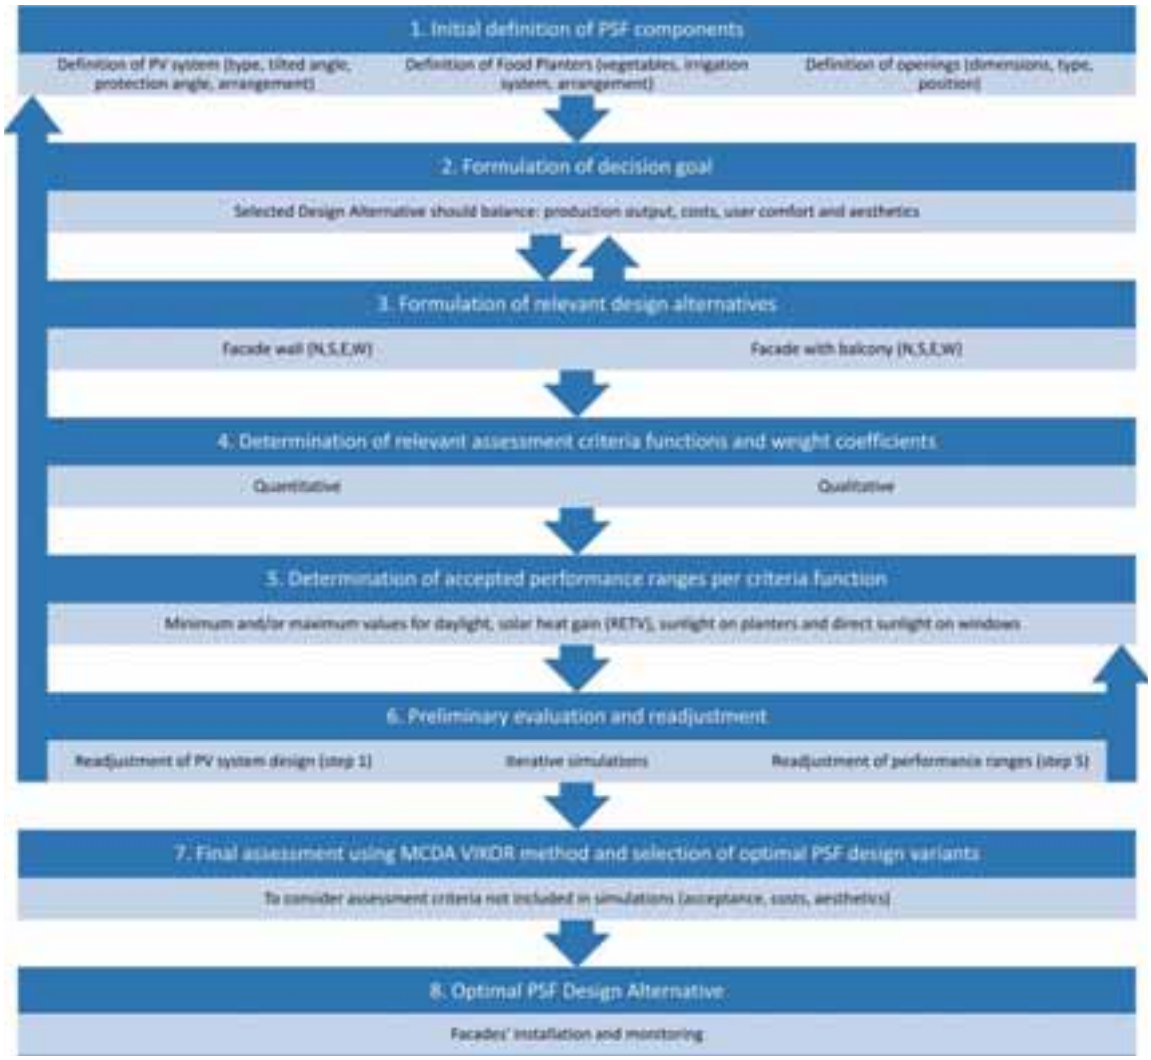

Fig. 1: Overall methodology for the development and optimization of the Productive Solar Façade (PSF) systems.

2.2. Model and simulation setup

Figure 3 presents four façade arrangements for façade wall and façade with balcony types. The façade arrangements are the following: façade with a single PV panels attached on top of the façade (I-F), façade with two PV panels attached to the top of the façade (II-F), façade with a single PV panel attached to the planter of the level above (I-P) and façade with two PV panels attached to the planter of the level above.

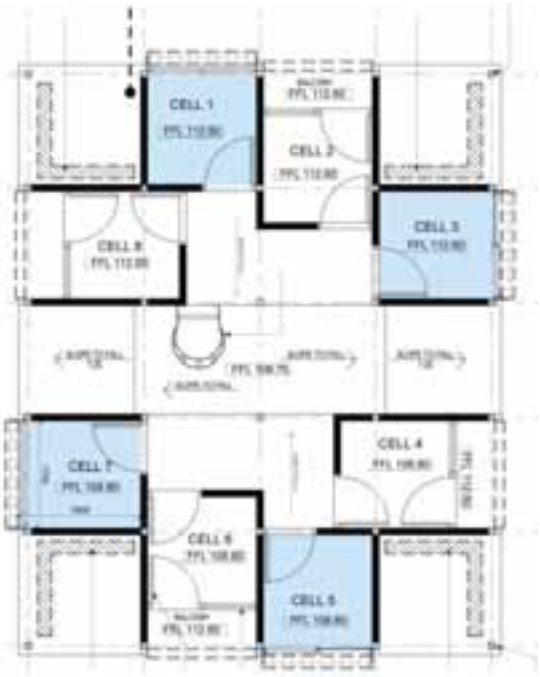

Fig. 2: Floor plan of the Tropical Technologies Laboratory (T2 Lab). Highlighted the cells analysed in this study. Adapted from: AWP Architects based on author's preliminary design.

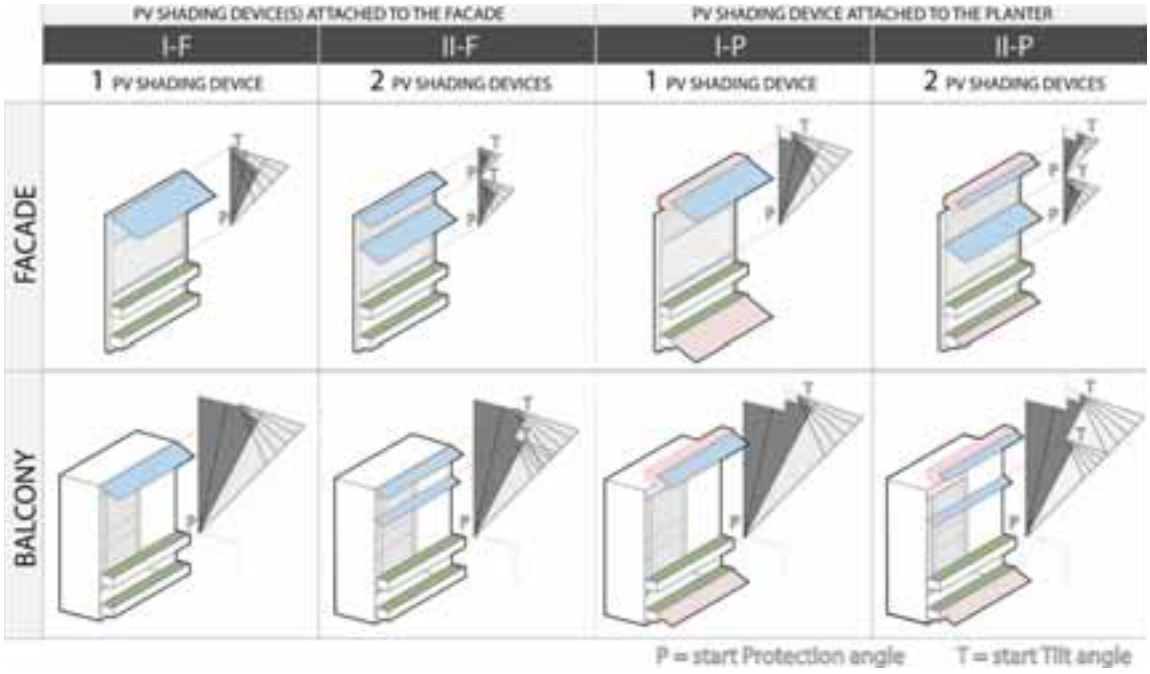

Fig. 3: Types of PV configurations and corresponding start of the protection and tilt angle.

A modular façade is used in order to obtain a high-quality sustainable solution: a cost-effective, time-efficient, and flexible multifunctional façade. Considering the restrictions of the building site - the typical floor to floor height of a Housing Development Board (HDB) flat of 2.8m, the module will be 2.8 m in height (2.6 m ceiling height) and 1.8 m in width. According to the Approve Document by the Building and Construction Authority (BCA) (BCA, 2017), the height of a barrier should not be less than 1.0m in order to protect people from falling from height. However, in order to have more design alternatives (e.g., to provide more space for planters installed at the lower part of the module), a window sill height of 1.1m is considered in this study which will

allow accommodating planters at the height of 100mm, 300mm, 500mm, 700mm and 900mm, in two or three rows, with a minimum height difference of 400mm between planters. A trapezoid cross-sectional planter will be used in the case of multiple-row planters, making it possible to provide more sunlight for lower level plants, while allowing more growing space for plants below. The size of the planter is set to be 190mm high and 150mm wide.

Optimizing the design of BIPV as shading devices on different façade orientations requires a careful definition of the objectives of the façade elements. The shading BIPV elements should be able to maximise the electricity generation and solar irradiance protection while allowing required illuminance levels in the interior, view towards the exterior and a minimum required amount of sunlight on the planters and BIPV on the same and lower stories respectively. The most influential geometrical parameter in achieving an optimal design alternative is the protection angle which together with the tilt angle defines the width of the BIPV shading element. The protection angle is defined as the angle between the vertical plane of the façade and the outside end of the BIPV shading element. The angle is taken from the bottom of the window for single shading and also on top of the lower shading for the cases with double BIPV shading as shown in figure 3. The protection angle should be understood as a response to the incidence angle; the angle of the sun to a specific target at a moment in time.

This study takes into account the minimum protection angle required by the Building Code Authorities of Singapore (BCA, 2008), through the Residential Envelope Transmittance Value (RETV) calculations. Additionally, for extreme incidence hours a minimum threshold of direct sunlight hours was set to before 8:30 and after 16:30. Lastly the minimum for the range of the protection angles was set so that no substantial impact on the operative temperature would be gained above a temperature of 28°C. Through this optimization the ideal intersection of protection and tilt angle of the shading device was arrived at. For the north and south orientation, protection angles from 28° to 37° met the specified requirements. For south the specific angle of 28° is only sufficient to comply with RETV requirements in combination with a tilt angle of 50°.

2.3. Farming considerations

A selection of leafy vegetables and herbs was deemed suitable for cultivation on building façades since the whole final produce is edible and usually shallow-rooted which makes it space-efficient. Additionally, leafy vegetables and herbs are less prone and less vulnerable to the attack of pests than fruited vegetables.

There are several factors affecting the growth of vegetables, including light, temperature, water and cultural practices. Among them, light is the key factor as it drives photosynthesis and affects plant development, morphology and yield (Inada and Yabumoto, 1989). With regards to the building façade farming, the demand for light is the most crucial factor to be considered due to the inconsistent light condition of building façades. Among the most common locally grown leafy vegetables, shade-tolerant crops with a lower daylight demand like Leaf Lettuce (Lacttuca Sativa) and Kangkong (Ipomea Aquatica), should ideally be grown on building facades. Also, most species of herbs like sage and basil are also quite suitable for the building façade cultivation.

Daily light integral (DLI), expressed in mol/m²· day, is defined as the total number of photo-synthetically active photons that plants receive in 1 sqm of growing space in one day. DLI reflects the combined result of the light intensity and duration of the photoperiod. Compared to other measuring methods, DLI is more accurate in determining the exact lighting condition for plants and is therefore commonly used in the agricultural industry. Commercial farms aim to keep minimum DLI of 10-12 mol/m²· day for optimum growth of plant (Morgan, 2016). A DLI of 12-13 mol/m²· day or higher is generally required for lettuce production (Dorais, 2003). The optimal DLI for production of sweet basil is about 28.8 mol/m²· day (Beaman, Gladon, & Schrader, 2009). Although leaf lettuce normally needs 12-13 mol/m²· day or more to achieve maximum production, it can still be grown with as little as 4-10 DLI. However, its quality is usually low below 8 mol/m²· day (Schiller, 2017)(Glenn, Cardran, & Thompson, 1984). Hence, 8 mol/m²· day is set as the minimum DLI requirement for lettuce growth. Converting the DLI to illuminance levels, this is equivalent to 10 000 lux.

2.4. Simulation settings

Combining the 3d-modeling software Rhinoceros with the programming software Grasshopper supports the parametric design generation. Utilizing these combined instruments the results of over 1.000 plausible cases can be approximated precisely, without requiring intermittent manual interference. The plug-ins Ladybug and Honeybee (Roudsari & Pak, 2013; Grasshopper3d.com, 2017) utilize the flexibility of Grasshopper to read local

weather data, add detailed design information and run these through validated software such as Daysim (Reinhart and Walkenhorst, 2001) (Lagios et al., 2010), Radiance (Ward and Shakespeare, 1998) and Energyplus (Crawley et al., 2011) (Jakubiec & Reinhart, 2011), In return these results can be read, disseminated, organized and visualized by Ladybug and Honeybee in Grasshopper.

Since PSF has multiple quantifiable performance indicators, a multi-objective optimization process was chosen supported by VIKOR. This method chooses the optimal result by balancing 5 conflicting performance indicators: daylight autonomy (DA), energy flow, electricity potential of the PV shading device(s), farming potential and view angle. A fitness value indicating the performance of each case on each indicator is established by comparing their results with the highest (100%) and lowest value (0%) returned by all cases. Strict requirements were predefined for each performance indicator according to literature and local regulations. This ensured overall quality of all cases within the VIKOR optimization process and reduced the total amount of cases by around 90%.

DA is defined as the percentage of time during the year in which a certain pre-defined illuminance value (200 lux) is achieved from 8 AM till 5 PM. Since the size of the testbed cell is reduced in comparison to actual room dimensions in residential buildings, an equivalent DA was used instead of the actual values obtained in the simulations. The energy flow is defined as the interior net heat gain (heat gain minus heat loss, kWh). Electricity potential is defined as the potential electricity generation from the PV panel taking the lowest incident radiation on the PV multiplied with the total area of the shading device, as the PV cells are connected in series. At this stage no definition was made regarding the type of PV and also other performance coefficients affecting electricity generation were not considered. Farming potential is defined as the percentage of days per year where planter area receives DLI > 8 mol/m²· day. View angle is defined as the average view angle from two points inside the testbed cells towards the exterior. The two points are located at 1.5m from the façade at 1.17m and 1.56m height from the floor, which correspond to sitting and standing viewing height for an overall height of 1.68m. The obstruction effect from the planters and the PV panels are taken into account. A minimum of 20° was set as required for all cases.

3. Results

This section summarises the results obtained for the north and south oriented Façade Wall. Figure 4 presents the preliminary design of the optimal cases for four types of façade arrangements: I-P, I-F, II-P and II-F (see figure 3 for nomenclature). For the 4 façade types the optimal position of the planters is at 100mm and 700mm from the floor level. This assure the best sunlight access to both planters disregarding the dimensions and positions of the PV panels. The optimal position of the planters for the 4 façade types stands at 100mm and 700mm from the floor level respectively. This ensures the best access of sunlight to both planters disregarding the PV panel dimensions and position. The optimal solution for north and south orientation is the same - a single PV attached to the planter above with a protection angle of 28° and a tilt angle of 50°. Higher position of the PV panel with respect to the upper window allows higher value of Daylight Autonomy (DA), however, in order to achieve the required solar protection according to the RETV, the tilt angle should be larger than the recommended 30° from the horizontal position (Luther and Reindl, 2014) (Saber et al., 2014) for Singapore facades. The second and third best cases for south and north oriented façades respectively are those with a single PV attached to the top of the façade. Double PV configurations are not favourable for any of the two façade orientations, especially for the north façade. The small dimension of the upper PV panel results of in the need to avoid overshadowing on the panel underneath. However, such small dimension may not be feasible and cost-effective.

Figure 5 presents the results of five performance indicators for each optimal case of the four façade arrangement types. The left-side axis displays actual values of each performance indicator while the right-side axis presents fitness values relative to the best and worst cases per façade type. The fitness value (Fv) is defined as:

$$Fv = (PI - Min) * (100 / (Max - Min) \quad \text{(eq. 1)}$$

Where PI is the obtained value per performance indicator, Min and Max are the minimum (worst) and maximum (best) values on the list of cases per façade arrangement type.

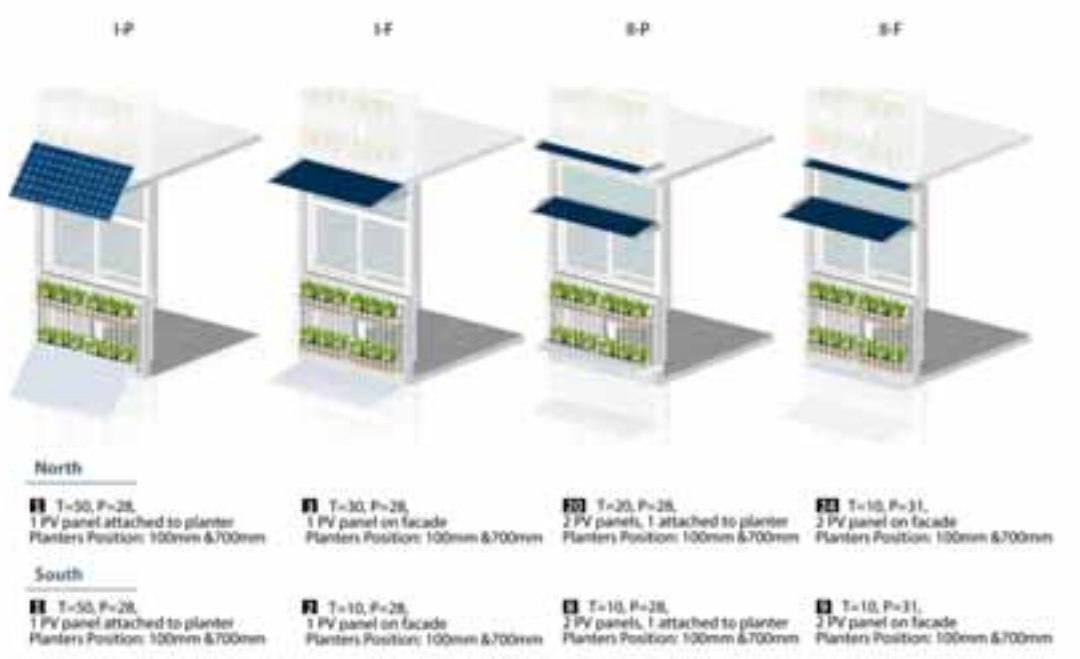

Fig. 4: Best cases per type, with overall rank and specifications for north and south orientations.

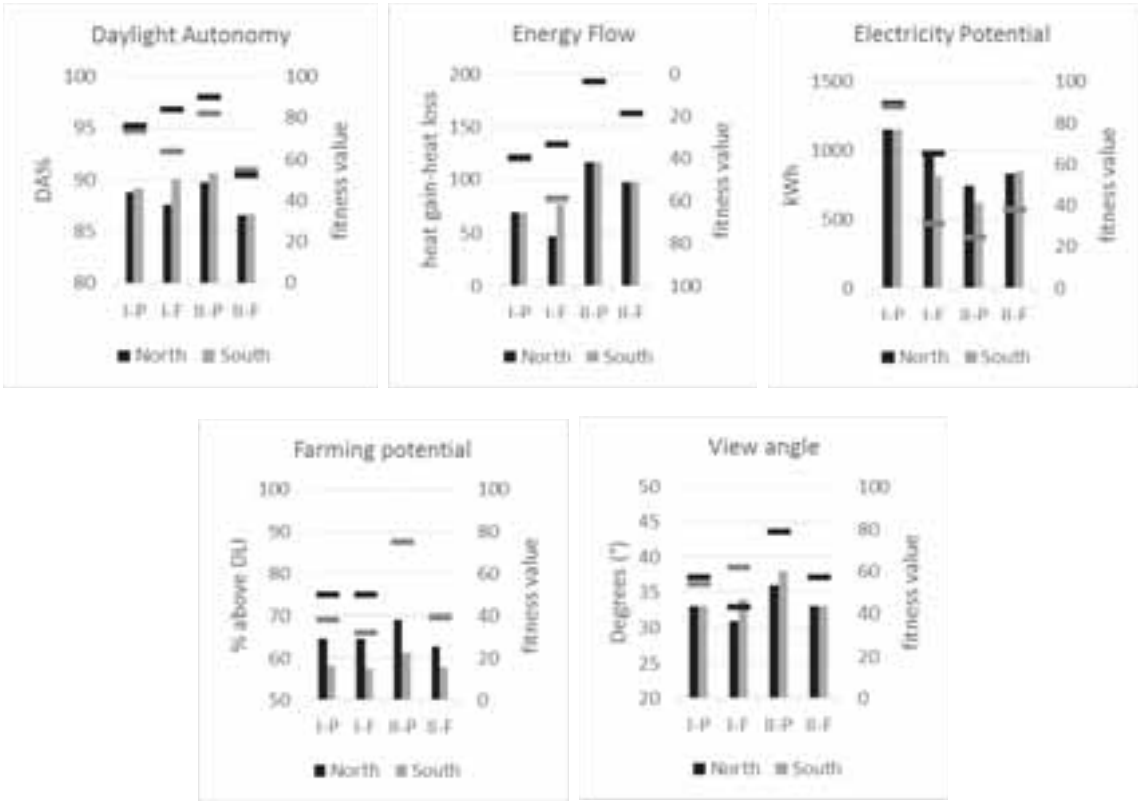

Fig. 5: Performance indicators for four façade types on north and south orientations. Bars correspond to left-axis values and lines represent fitness value.

Regarding DA, all cases achieve values above 85% representing the time period in a year with the average illuminance levels above the threshold of 200 lux. The performance in two cases when PVs are attached to planters above (I-P and II-P) is better (fitness value > 75%) than in the two cases where PVs are attached to the

highest point of the façade. Larger separation of PVs from the upper window allows higher penetration of diffuse daylight. South façade arrangements receive higher illuminance levels than north façade arrangements.

With regards to the energy flow indicator, the lower the value of the net heat gain from the exterior, the better its performance and fitness value. Also, in terms of this indicator, the number of PV panels has a higher impact than their position on the façade. A single panel will provide better protection from solar radiation than two panels. Sunlight inter-reflection between the two panels and the reflection of the lower panel towards the interior may be the reason for the higher heat gain. Only in cases when a single PV is attached to the façade, substantial differences on energy flow exist in relation to the facade orientation.

As for electricity potential, once again, a single PV panel will perform better than two panels. If two PV panels are utilized, then the top device, although small, shades the bottom one during the hours in which the incidence angle is smaller than the protection angle. Since PV cells are connected in series, the shaded cell will define the overall electricity production by lowering it. The differences are more evident between the cases I-P and II-P with fitness values around 90% and 25% respectively. The electricity potential on the north façade is overall higher, most likely due to frequently clear skies from March to September equinoxes. If we consider a conventional 13% efficiency Si-monocrystalline PV module the estimate of electricity generation of the optimal cases of north I-P, I-F, II-P and II-P are 150 kWh, 130 kWh, 97 kWh and 108 kWh respectively which represent 48%, 48%, 33% and 34% of the same PV module type and area located on a rooftop without obstruction.

The four façade types exhibit smaller differences regarding the farming potential. In all cases the percentage above the required DLI is not higher than 70%. However, DLI values are substantially higher for the north than the south façade orientation. For the latter, the fitness values are around 40% or below except in the II-P case. The last performance indicator considered at this stage of the study is the view angle from the interior. Facades with PV panels attached on the planters above provide higher view angles, which is well within expectations considering the higher position of the panels with respect to the upper window.

Figures 6 presents fitness value for all façade types facing north and south respectively. The average fitness value of the optimal case I-P is 62.0% and 59.1% for north and south orientations respectively. The average fitness values for the second best façade type are 56.0% and 48.5% for north and south orientation respectively. Figure 7 presents the fitness values of the two best and worst cases for north façade orientation.

At this stage, the strategy to determine the best among facade types presupposes that all criteria used are of equal importance. Consequently, since the selection of the optimal solution strongly depends on the criteria weight coefficients, all five criteria used were allocated the same weight of 0.2. However, different weights may be applied for east and west façade orientations given the larger exposure of glass windows to direct solar radiation. For these orientations, the weight of criteria functions with larger value variation –for example, those related to the energy flow- will be proportionally higher than the weights of criteria functions with smaller variation.

4. Conclusions

This paper describes the design optimization of SPF facades with the integration of PV and farming systems and analyses the performance of four façade types for north and south orientations. The facades systems are to be installed at the Tropical Technologies Laboratory at the National University of Singapore. The impact of the façade design on five performance indicators - daylight autonomy, energy flow, PV electricity potential, farming potential and view angle - are obtained from computational simulations and subsequently used as inputs in the MCDA method VIKOR.

The above results reflect the values relative to facade types deemed to be the best, and are not representative of all instances. However, a comparison with the fitness values of other cases of the same type has served as a confirmation of trends. With these practical considerations in mind, the following conclusions can be made:

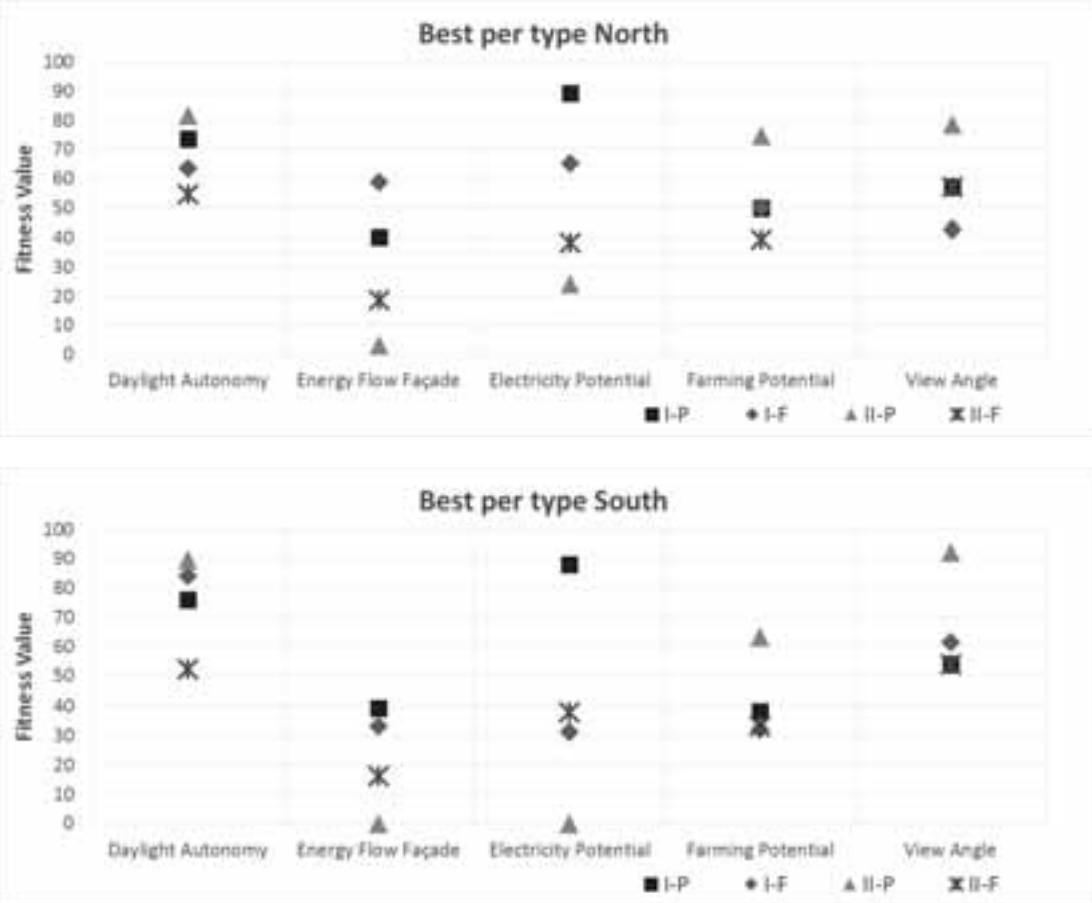

Fig. 6: Performance indicators of the optimal facade designs for north (top) and south (bottom) orientations

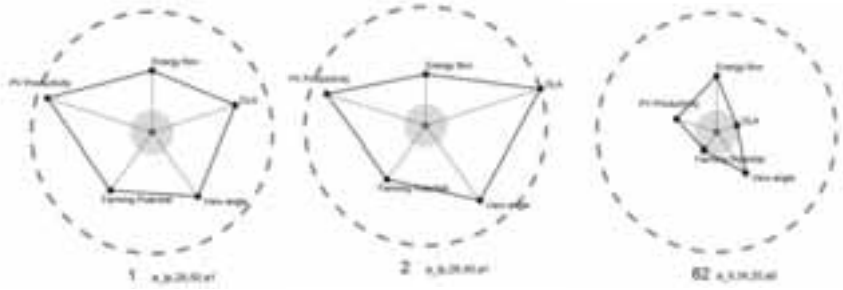

Fig. 7: The two best and worst cases for north, small (0%) to large (100%) circle represents fitness value.

- The optimal position for BIPV shading device is next to the planters at the above level. This position maximizes solar energy yield while also achieving a high fitness value for other four performance indicators related to food production and indoor visual and thermal conditions. The result indicates that even with no farming system installed, the best compromise between solar energy yield and indoor conditions is achieved by using the lower portion of the façade of the level above for the installation of larger sun-exposed PV panels.
- For north and south façade orientation, systems with two rows of PV panels will produce less electricity than the system with one row of PV panels. With two PV shading devices, the topmost device shades the bottom one during the hours in which the incidence angle from the vertical plane is smaller than the protection angle. It should be noted this occurs around midday when the incident solar radiation is at its highest.

- Overall, north facades achieve slightly higher fitness value than south facades. Farming potential on north facades is higher than on south facades as the planter area receives the required Daily Light Integral for longer periods of time during the year. Similar trend is observed for the electricity yield potential although not for all cases.

The results of the study prove the importance of using a holistic approach and a multiple objectives criteria analysis in the design of such complex façade systems, especially for BIPV and BIA systems which compete for receiving the maximum sunlight. The VIKOR optimization method helped obtain a solution according to a tight set of requirements. It also created a framework that enabled iterative strategic learning based on reciprocity and the understanding of project strengths and weaknesses. The impact of the façade systems on indoor visual and thermal conditions in residential buildings are also crucial and are not to be ignored or underestimated. Otherwise, the benefits of the electricity and vegetable production are minimised or reversed.

The study will continue with further analysis aimed at finding the optimal façade design alternatives for east and west orientation. In addition, the same optimisation process will be applied for the façades with balcony that already have solar protection to a certain degree. Different BIPV configurations and dimension are expected for those façade types and orientations. In this first part, the design process of SPF was focused and based mainly on quantitative parameters, resulting in optimal solutions with balanced technical performance. The subsequent steps will include costs and qualitative criteria, which will ensure sophisticated sustainable high-quality solution in terms of both techno-economic performance and architectural value.

Abstract

Existing non-residential buildings represent a valuable asset in Europe. These buildings account for 25% of the total building stock in Europe and comprise a more complex and heterogeneous sector compared to the residential one. The public non-residential building stock represents an average 31% of the total non-residential sector in Europe. Understanding the energy use and CO_2 emissions in the non-residential sector is complex as end-uses such as lighting, ventilation, heating, cooling, refrigeration, IT equipment and appliances vary greatly from one building category to another within this sector. The average specific energy consumption in the non-residential EU27 sector is 280kWh/m^2 (covering all end-uses). A retrofitting solution package for existing public-owned non-residential buildings is needed in order to achieve a drastic reduction of the energy consumption (beyond 50%) and GHG emissions in this sector. This retrofitting package is based on; Envelope retrofitting solutions for demand reduction through made-to-measure façades, innovative insulation materials and high performance windows and zero emissions energy production technologies based on a cogeneration system fed with locally available and clean renewable sources. The retrofitting solution package is implemented in three real demonstration multi-buildings complexes, located in different climate conditions in three different European Countries and with different end-uses: Sanitary, Educational and Administrative.

Keywords: Energy efficiency, Renewable energies, Tri-generation, Zero energy buildings

1. Introduction

Existing non-residential buildings represent a valuable asset in Europe. These buildings account for 25% of the total building stock in Europe and comprise a more complex and heterogeneous sector compared to the residential one. The retail and wholesale buildings comprise the largest portion of the non-residential stock, while office buildings are the second biggest category with a floor space corresponding to one quarter of the total floor space. Understanding the energy use and CO2 emissions in the non-residential sector is complex as end-uses such as lighting, ventilation, heating, cooling, refrigeration, IT equipment and appliances vary greatly from one building category to another within this sector. The average specific energy consumption in the non-residential EU27 sector is 280kWh/m^2 (covering all end-uses).

Over the last 20 years in Europe, electricity consumption in European non-residential buildings has increased by a remarkable 74%. This is compatible with technological advances over the decades where an increasing penetration of IT equipment, air conditioning systems etc. means that electricity demands within this sector is on a continuously increasing trajectory. Buildings vary remarkably in terms of size where large variations are expected in the non-residential categories.

The ownership profile in the non-residential sector is heterogeneous. Private ownership can span from as low as 20% to 90% from country to country and also from one building type to another. The public non-residential building stock represents an average 31% of the total non-residential sector in Europe (Based on the survey "Europe´s buildings under the microscope" by BPIE in 2011.).

On the other hand, the heating and cooling of buildings take a large share in the energy consumption. The average energy consumption in the non-residential sector, such as public and industrial buildings, is estimated to be at least 40% greater than in the residential sector in Europe. Some reasons for this general increase are for example an increase in comfort habits, currently still low energy costs, architectural trends (glazed areas in

doi:10.18086/swc.2017.12.12 Available at http://proceedings.ises.org

buildings) and slowly changing in climate conditions. This rising demand for cooling and air-conditioning in buildings involves unfavourable fossil fuel consumptions as well as upcoming stability problems in the electricity supply in Mediterranean countries, which in turn demands for costly upgrading of the grids to handle electricity peak power demand situations.

Therefore, integrating technologies to make existing buildings more energy efficient is the challenge that the EU-funded BRICKER research project is addressing. The project consists of retrofitting showcase public buildings in Spain, Turkey and Belgium to achieve at least 50% reduction in energy consumptions compared to the values before renovation.

2. Demonstration buildings

The demonstration buildings are in use and the goal is to demonstrate the performance of the technologies and systems developed within the project. BRICKER combines various active and passive technologies to achieve energy efficiency in innovative ways. (In this case a tri-generation system capable of providing power, heating and cooling simultaneously). The system's activation heat will be produced using parabolic solar collectors working on a high temperature and biomass boilers adapted to the specificities of each demo site and its surroundings.

The demonstration buildings of this project BRICKER are 3, and are located in the geographical areas trying to cover the diversity of Europe. These buildings can be seen in Fig. 1 and are concretely located in Caceres (Spain), Liege (Belgium) and Aydin (Turkey). The idea behind the project is to demonstrate the operation of the technologies and systems developed and to achieve energy savings of more than 50% compared to the initial values prior to renewal. The investment costs associated are expected to be at most 20% of the total costs of a building compared to those due to a new one located on the same site, and return of investment around 7 years. All this can be seen reflected for each concrete case of each demonstration building below.

Fig. 1: Location of demonstration buildings in the BRICKER project

2.1. Demonstration building in Caceres:

- Building: Administrative offices of the Government of Extremadura.
- Renovation: 1 administrative building of a set of 7 buildings.
- Useful area: 8,480 m^2.
- Occupation: 300 workers.
- Electrical savings: 60%.
- Return of investment: 7 years.
- Associated investment cost: 13.4%.

Fig. 2: Administrative offices in Caceres

2.2. Demonstration building in Liege:

- Building: School of Engineering of the University of Liege.
- Renovation: 2 blocks of an academic complex formed by 7 buildings.
- Useful area: 23,000 m^2.
- Occupation: 1,200 students.
- Electrical savings: 86%.
- Gas savings: 75%.
- Return of investment: 7.2 years.
- Associated investment cost: 9%.

Fig. 3: School of Engineering in Liege

2.3. Demonstration building in Aydin:

- Building: AHU Hospital; Adnan Menderes University.
- Renovation: 1 building of the university hospital complex composed by 4 blocks.
- Useful area: 19,467 m^2.
- Occupation: 600 patients y 450 workers.
- Energy savings: 51%.
- Return of investment: 7 years.
- Associated investment cost: 10%.

Fig. 4: AHU Hospital in Aydin

3. Core of BRICKER project

Tri-generation concept or CCHP (Combined Cooling, Heating and Power) is the simultaneous production of mechanical power, heating and/or cooling from one primary fuel by coupling with thermally activated cooling technologies that take the waste heat from CHP for producing cooling.

Thermally activated cooling utilized for CCHP systems primarily refers to sorption refrigeration; it employs waste heat produced in the process of power generation as the driving force to power a sorption refrigeration device. Some energy demand for refrigeration is thus shifted from electrical to thermal energy, and primary energy consumption is also reduced. Another difference between sorption systems and conventional vapour compression systems is the working fluid used. Most vapour compression systems commonly use chlorofluorocarbon refrigerants (CFCs), because of their thermo-physical properties. It is through the restricted use of CFCs, due to depletion of the ozone layer that will make sorption systems more prominent. However, although sorption systems seem to provide many advantages, vapour compression systems still dominate all market sectors. In order to promote the use of sorption systems, further development is required to improve their performance and reduce cost.

Power generation system is an Organic Rankine Cycle (ORC) whose operation principle is the same as the conventional Rankine cycle, but in this case, the working fluid is an organic compound of low boiling point instead of water, thus decreasing the temperature needed for evaporation. A pump pressurizes the liquid fluid, which is injected into an evaporator (heat source) to produce a vapour that is expanded in a turbine connected to a generator. Finally, the output vapour is condensed and sucked up by the pump to start the new cycle. ORC heat source could come from renewable sources (solar, biomass, geothermal…), the ORC unit is able to produce electricity (DC) for self-consumption or for the grid, and another heat source at lower temperature (from the condensation side) than can be used for heating. If the heat source from the condensation is also used for cooling (using a sorption machine), we have a tri-generation system.

Most of the commercial installations of concentrating solar collectors are for large scale solar power generation in steam turbines. Large collectors and systems with high operating temperatures are targeted for optimal steam cycle efficiency. However, Parabolic Trough Collectors (PTCs) are also suitable for the medium temperature and medium size applications and for industrial process heat, desalination, solar air conditioning and distributed power generation with Cogeneration turbines or internal combustion engines. For state of the art, we refer to small (roof mountable) parabolic trough collectors commercially available today, because the larger parabolic trough can simply not be used on rooftops. These small parabolic troughs are optimized for the temperature range 100-200°C. This temperature range has a very large potential for industrial process heat and solar cooling. For small power plants where ORC and solar are combined, the temperature range should be increased up to the temperature range 250 to 300°C, i.e. at least 50°C above the current optimization range. Therefore, in the framework of the BRICKER project, the development, testing and integration of a parabolic through collector and whole solar fields to feed the cogeneration unit that works with a heat source of 250 +/- 30ºC, is also developed.

Several factors such as the heat sources available, the existing conventional systems and the new energy systems to be installed in the buildings within this project, the economic restrictions and the cooling and heating needs among others has been studied and has allowed to identify which of the solutions/configurations fitted better within the BRICKER concept. As has been mentioned before the main objective of BRICKER is the installation of a tri-generation system to provide energy in an optimal way to the building, so for that and following the original concept of a tri-generation system, the unique option is limited to use the residual energies coming from the BRICKER energy system to produce in this case cooling, and in this particular case has been concluded that the only option available is the utilization of the residual heat coming from the ORC in form of water condensation to feed the chiller unit as primary heat source. This limitation together with the need to produce chilled water at certain range of temperatures to feed the terminal units already installed has reduced the possibilities to only two, which are the installation of an adsorption chiller unit (Fig. 5) or on the other hand the installation of a single effect absorption chiller unit (Fig. 6). These two possibilities can be seen in the pictures below.

Fig. 5: Integration of an adsorption chiller

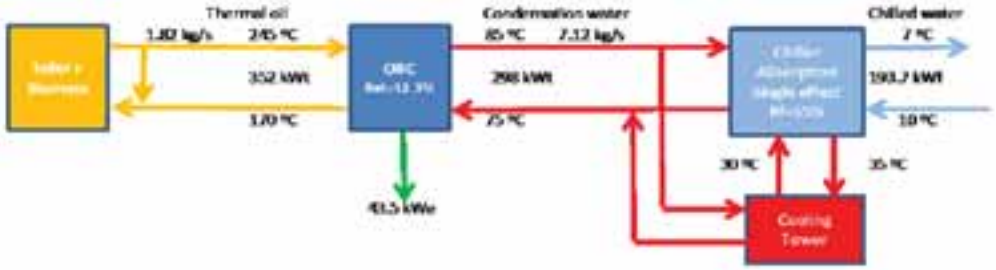

Fig. 6: Integration of an absorption chiller

The difference between them is mainly the activation requirements but also the working principle as one is using a liquid as sorption material and the other is using a solid.

Demo cases analyzed are two public buildings located in Spain (Caceres) and Turkey (Aydin). The first one is an administrative building of around 8,150 m^2 while the second one is a big hospital with a surface of more than 50,000 m^2. Due to their similar weather conditions (both located in the south of Europe) with hot summer periods, but also in the case of the hospital due to their specific conditions with cooling needs during the whole year, it is assumed the necessity of systems which provide the buildings with cooling capacity. In both cases original cooling systems are based on conventional heat pump systems which consume high amounts of electricity. So the idea is with the implementation of thermally activated cooling technologies within the BRICKER system to cover cooling needs of the buildings with the corresponding reduction of electricity consumption due to the less use of the conventional systems.

Many options are available and have been studied in terms of thermally activated cooling technologies, each of them with their own characteristics and limitations. After analyzing the different options and taking into account the boundary conditions imposed by each demo case has been concluded that the most suitable option is to install an adsorption chiller unit for both buildings. This selection has been due to the necessity to meet the original concept of tri-generation, in which is needed to make use of the residual energies coming in this specific project from the ORC water condensation at low temperature (70 ºC in cogeneration mode) as primary heat source. This limitation of temperature together with the possibility to get higher electrical performances in the ORC in comparison with the other thermally activated technologies (lower temperatures in the condensation side, makes the ORC to work with higher electrical performances), makes this selection as the most suitable. Other options such as the open cycle systems have been discarded due to the necessity to feed the terminal units at a given temperature (10 - 15 ºC). In the same way, the absorption units have been discarded due the operating limitations to work below 80 ºC in which the ORC develops their full potential in cogeneration mode. In addition, these machines have lower performances at working temperatures in the range between 80 - 90 ºC.

Although the selected technology has been the same for both demo cases (an adsorption chiller unit), it could be noticed that each has their own peculiarities. In the case of the Spanish demo case, the chiller unit has been dimensioned with the idea to cover all the cooling needs of the building, accomplishing the project economical restriction (only requiring additional support during occasional peak loads through a conventional heat pump system). In the Turkish demo case, due to their higher demand in terms of cooling, the idea is to cover only a little portion of it, so the selection is only based on the restrictions coming from the ORC (thermal energy limitations) and the economical ones.

4. Conclusions

Finally, two main conclusions can be drawn:

1. Energy use in public non-residential buildings represents a high proportion of the EU energy consumption and CO_2 emissions for the non-residential sector. In particular, hospitals, offices and educational buildings represent the highest levels of energy intensities of public-owned buildings.

2. Concerning the energy retrofitting solutions to be proposed for this target group, aiming at achieving nearly zero energy buildings, the scope must be related to systemic and integrated approaches involving:

a. Energy demand reduction by envelope optimization techniques (to decrease electrical and gas dependence).

b. Development and integration of Combined heat and Power (renewable based) solutions to produce both distributed heat and electricity at building and district level, according to the locally available resources.

c. Integration and optimization of the systems and its operation in cost effective way for the life cycle.

To sum up, the heart of this project is the development of innovative Combined Heating, Cooling and Power (CHCP) systems tailored to the specific needs of each demo building combining and adapting in the best way different subsystems (ORC units, parabolic through collectors, biomass boilers, sorption units) and locally available renewable sources (solar and/or biomass) as an example of high efficiency and renewable energy alternative, suitable for those buildings and districts with relevant electricity, heating and/or cooling needs.

Abstract

Both electrical power and useful thermal energy can be obtained from building-integrated photovoltaic/thermal systems (BIPV/T) which have the potential to reduce the energy consumption of buildings. Double-skin façades (DSF) have been implemented for enhancing energy efficiency as well as improving indoor thermal comfort. This paper explored the performance of a combination of BIPV/T and DSF, which included the thermal performance of this novel building envelope as well as the indoor comfort performance through a simulation analysis for a test building in Sydney, Australia. To date, the work has focused on two operation modes of the BIPV/T-DSF system comprising fan-driven ventilation mode in summer time and non-ventilation mode in winter. A comparative simulation analysis of the two operation modes and the building without adopting the BIPV/T-DSF system was presented in terms of the thermal response of the indoor space.

Keywords: Building-integrated Photovoltaic/Thermal System, Double-skin Façade, Commercial Building, Energy Efficiency, Indoor Thermal Comfort

1. Introduction

The world is in the process of rapid development, with increasing heavy industrial production as well as increasing building construction, all of which is contributing to the rapid increase of energy consumption. Energy demand from the building sector accounts for 40% of energy consumption globally and consequently emits approximately 1/3 of the greenhouse gas emissions (United Nations Environment Programme, 2016). The total energy consumption of commercial buildings in Australia was 3.5% of the national gross energy consumption in 2009 and this proportion is expected to rise by 24% over the period 2009 to 2020 (Council of Australian Governments, 2012). Building façades are a key component linking buildings and the outdoor environment, which significantly affects air-conditioning energy use for heating and cooling (Peng, Lu, Yang, Song, & Ma, 2015). High heating and cooling energy consumption is due to the poor thermal insulation properties of building façade (Papaefthimiou, Syrrakou, & Yianoulis, 2006). Thus, exploring high performance building façades is important to improve energy efficiency of commercial buildings.

The utilization of renewable energy technologies in buildings is an effective solution to combat the increase in energy consumption (Chwieduk, 2017). Solar energy is one of the most widely applied renewable energy approaches for increasing energy sustainability in the building industry (Mekhilef, Saidur, & Safari, 2011). Solar photovoltaic/thermal (PV/T) systems, integrated into building façade, can form a cohesive design, construction and energy solution for buildings (M. D. Bazilian, Leenders, Ree, & Prasad, 2001). Both electrical power and useful thermal energy can be obtained from the PV/T system hence contributing to the reduction of

[1] Corresponding author. Tel.: +61 (02) 9385 6372; Mob.: +61 (0) 415 680 589.

doi:10.18086/swc.2017.12.13 Available at http://proceedings.ises.org

the energy consumption of a building (Yang & Athienitis, 2012). Double skin façades, have been effective for enhancing energy efficiency as well as improving the indoor thermal comfort (Marques da Silva, Gomes, & Rodrigues, 2015). This type of façade solution has become a globally widespread option for implementing sustainable energy and an architecturally attractive option for the building envelope (Ghaffarianhoseini et al., 2016). Quite a few researchers have generally reported the factors of that affecting the power efficiency of the BIPV system (e.g. typology of the materials, PV module temperature, and packing factor of PV module) (M. Bazilian, Kamalanathan, & Prasad, 2002; Oliver & Jackson, 2000; Vats, Tomar, & Tiwari, 2012). A few studies have reported both the thermal and electrical efficiency of the BIPV/T system but, the outcomes in cold climates have predominated and only a small number investigated a range of climatic conditions (Athienitis, Bambara, O'Neill, & Faille, 2011; Chen, Athienitis, & Galal, 2010; Chow, Hand, & Strachan, 2003; Pantic, Candanedo, & Athienitis, 2010; Yang & Athienitis, 2015). Further a few studies lately reported the performance of PV efficiency of a BIPV/T-DSF envelope, but little research has been done on understanding of indoor thermal comfort and energy performance of the building adopting BIPV/T-DSF system (Charron & Athienitis, 2006; Peng, Lu, & Yang, 2013; Saadon, Gaillard, Giroux-Julien, & Ménézo, 2016). Most of field studies were conducted under the indoor test conditions, which were not absolutely reliable (Fossa, Ménézo, & Leonardi, 2008; Yang & Athienitis, 2015).

Neither building-integrated photovoltaic/thermal (BIPV/T) nor double-skin façade (DSF) is novel. However, little research or real application of the hybrid mechanism of BIPV/T and DSF has been conducted in both academic and industrial settings (Peng, Lu, Yang, & Han, 2013). Therefore, this research project aims to investigate the overall performance of a BIPV/T system integrated with a DSF. In particular the electrical and thermal performance of this novel building envelope as well as the impact of this envelope solution on indoor thermal comfort performance of the commercial buildings is investigated.

2. Methodology

This paper examined both experimental field measurements and computational simulation for building-integrated photovoltaic/thermal double-skin façade (BIPV/T-DSF). The computational model was validated against experimental results reported in the literature. This model was then used to simulate a commercial building in Australia. The system parameters were adjusted to optimize the performance of the BIPV/T-DSF and the indoor thermal condition of the building. A long-term system performance and indoor thermal comfort then can be predicted confidently by using the validated computational model.

The building with BIPV/T-DSF system was modelled in TRNSYS (thermal modelling software). TRNSYS is widely used visual based software for transient simulations of solar thermal energy systems and any dynamic simulation including buildings (Kamel & Fung, 2014).

A model of the BIPV/T-DSF was developed in TRNSYS and validated by using experimental results taken from the existing published studies by Peng et al. (Peng et al., 2016; Peng, Lu, & Yang, 2013; Peng, Lu, Yang, & Ma, 2015). They have conducted the series field studies of a test bed with a ventilated BIPV/T-DSF under different ventilation modes in Hong Kong. This BIPV/T-DSF system uses a double-glazed semi-transparent a-Si PV module (Peng, Lu, & Yang, 2013). The diagram of the BIPV/T-DSF is shown in Fig. 1. As can be seen, the DSF consisted of two cavities which were separated by a vertical insulation board; at this point, the two air cavities were used for the comparative analysis for different modes of ventilation without affecting one another. Two ventilation modes used for model simulation and model validation, are shown in Tab. 1.

Tab. 1: Specifications of the selected ventilation modes for model validation (Peng, Lu, & Yang, 2013).

Ventilation Modes	Specifications
Non-ventilated mode (mode 1)	All inlet and outlet louvers were closed and the internal windows were opened, air-conditioner was turned off.
Buoyancy-driven ventilation mode (mode 2)	The inlet and outlet louvers on left hand side (cavity 1) were closed, while the inlet and outlet louvers on right hand side (cavity 2) were opened; all internal windows were closed; indoor air temperature was maintained at 22°C by use of the air-conditioner.

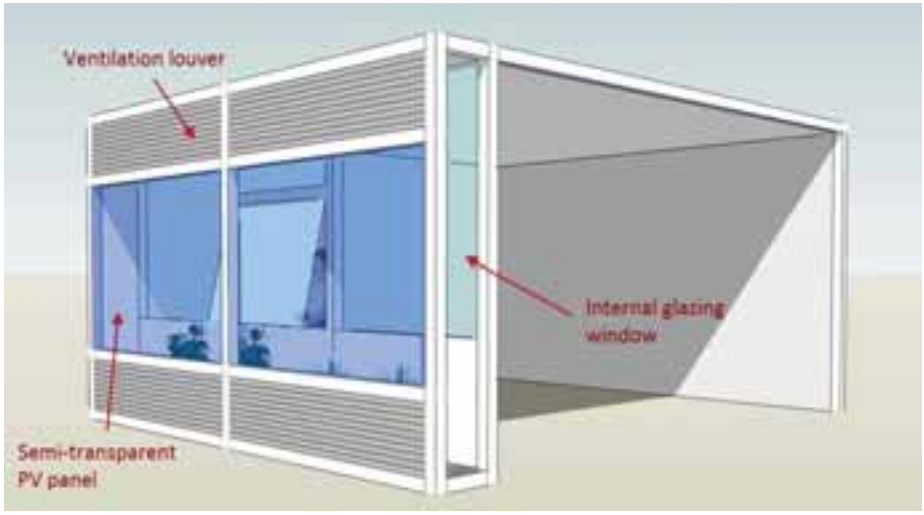

Fig. 1: Schematic diagram of the BIPV/T-DSF system for the test bed (Peng et al., 2016).

3. Modelling and Model Validation

The key dimensions of the BIPV/T-DSF system and the physical characteristics of the PV panel (semi-transparent) used are given in Tab. 2 and Tab. 3 respectively.

Tab. 2: Key dimensions of the BIPV/T-DSF system (Peng et al., 2016).

Parameters	Values
Width of PV panel	1.1 m
Height of PV panel	1.3 m
Thickness of PV module	0.006 m
Width of louver	1.1 m
Height of louver	0.5 m
Depth of air flow duct (air cavity)	0.4 m
Dimension of the test bed (W x L xD)	2.4 x 2.5 x 2.3 m
Orientation	Due south

Tab. 3: Physical characteristics of the semi-transparent a-Si PV panel (Peng et al., 2016).

Parameters	Values
Maximum power under STC (W_p)	85
Open circuit voltage, V_{oc} (V)	134.4
Short circuit current, I_{sc} (A)	1.05
Voltage at the maximum power point, V_{mp} (V)	100
Current at the maximum power point, I_{mp} (A)	0.85
Efficiency, η (%)	6.2
Power temperature coefficient, T_k (%/K)	-0.21
Dimensions (L x W x D), (mm)	1300 x 1100 x 6
Transmittance in visible lighting range (%)	7
Thermal conductivity, ($Wm^{-1}K^{-1}$)	0.486
Infrared emittance	0.85

The test model was established in TRNSYS based on the experimental parameters provided in Tab. 2 and Tab. 3. Real-time meteorological data (on-site historical weather data for Hong Kong) of the site during the experiment was provided by the authors (Peng et al.), which was used for the TRNSYS simulation. Fig. 2 shows the model of the BIPV/T-DSF in the TRNSYS Simulation Studio (the user interface to create the simulation model).

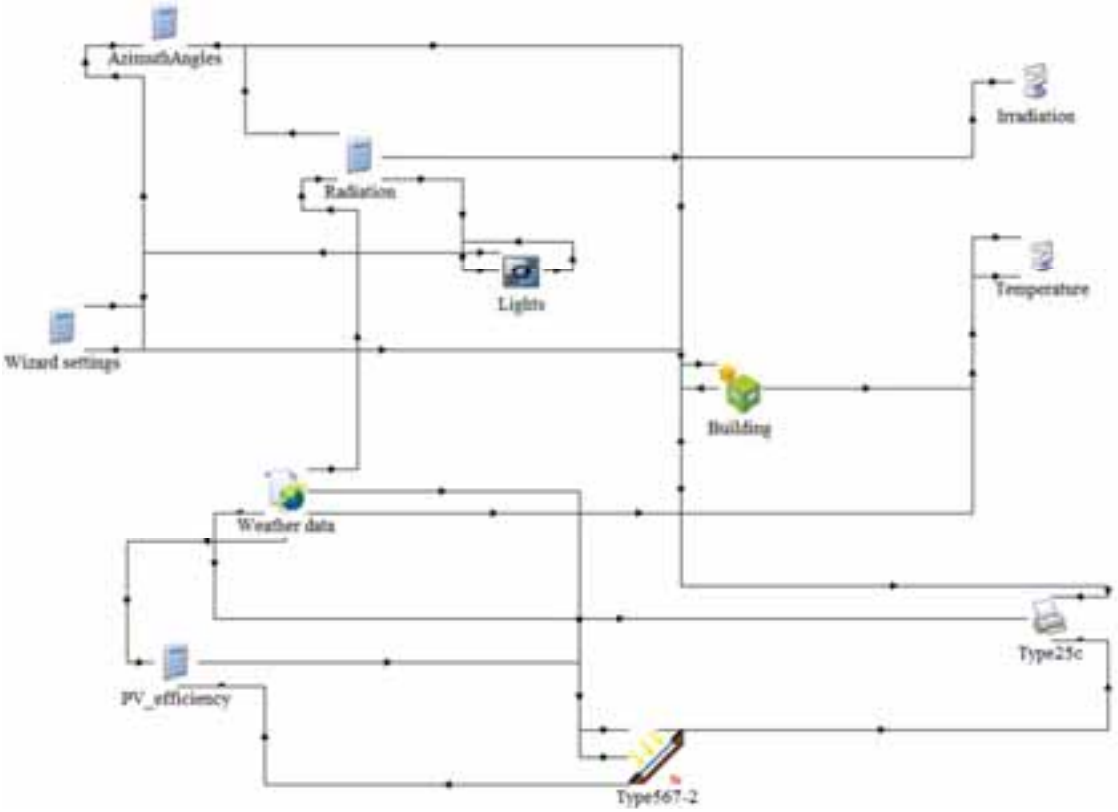

Fig. 2: Schematic of the testing building model integrated with the BIPV/T-DSF system in TRNSYS.

Type 56 (the "building" icon in Fig. 2) included the details of the building model such as building geometry, type of construction, and optical data of the window glazing. The glazed semi-transparent PV panel used in the test bed was symbolized by Type 567-2 (the corresponding PV module in TRNSYS) which was connected to the test bed (Type 56) in the TRNSYS model. Because the semi-transparent PV panel model is not available in TRNSYS, a glazing model with the exact identical thermal and optical properties of the semi-transparent a-Si PV panel was created and replaced the outer window on the DSF. As such, the electricity production of the PV was calculated separately.

3.1. Validation of the Model in Non-Ventilated Mode

The PV module (back-surface) temperature is a major feature that is closely related to the output power of the PV panel, which is mainly affected by the ambient conditions, primarily the solar radiation as well as the ambient temperature (Chikate & Sadawarte, 2015). Therefore, the PV module temperature of the BIPV/T-DSF system from the simulation was compared with the experimental result (Peng, Lu, & Yang, 2013). In addition, the indoor air temperature is a crucial indicator for indoor thermal comfort which was also compared accordingly. The available experimental results of the non-ventilated mode (mode 1) were from Jan 5 to Jan 7, 2013. The simulation in the TRNSYS model was in accordance with the same time period and the comparative results are shown in Fig. 3 and Fig. 4 accordingly.

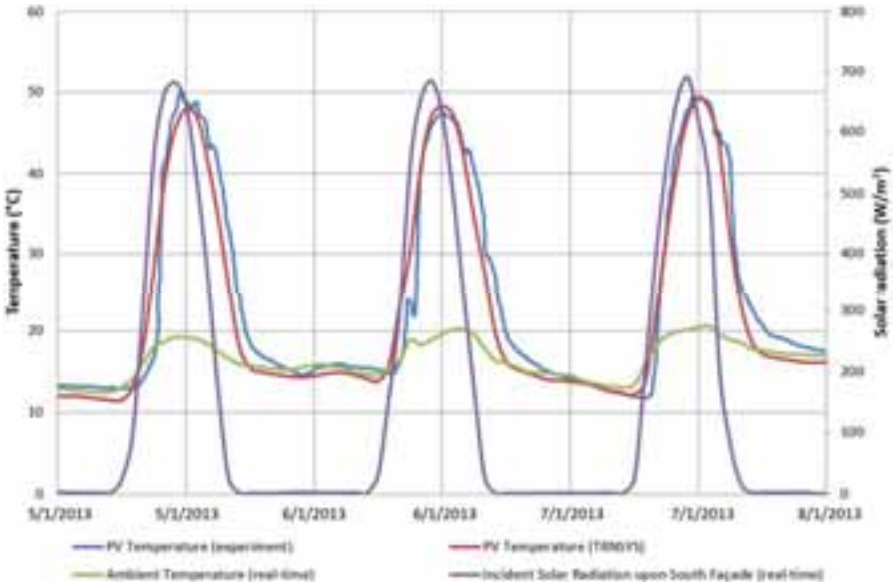

Fig. 3: PV module temperature comparison in Mode 1 (non-ventilated).

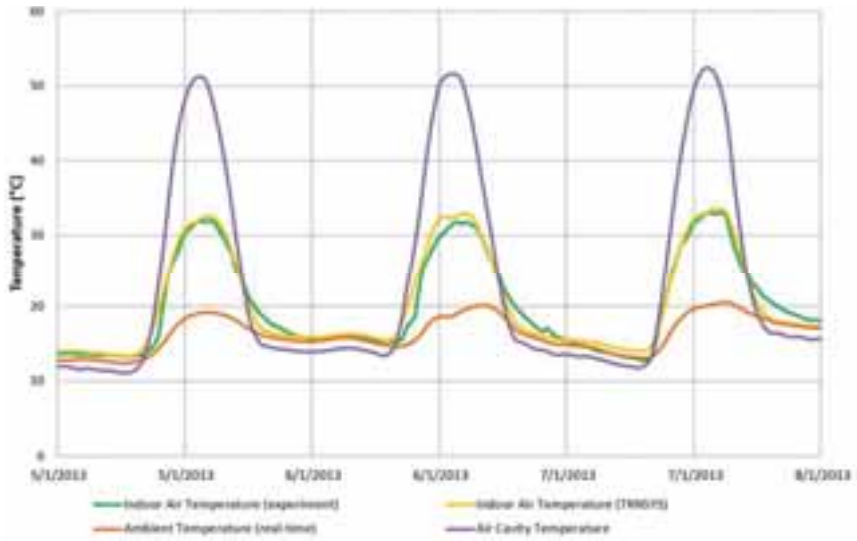

Fig. 4: Indoor air temperature comparison in Mode 1 (non-ventilated).

As can be observed in Fig. 3, the simulated PV module temperature and the measured PV module temperature (72 hours' results) show good agreement although a certain extent of discrepancy exists. The hourly Mean Bias Error (MBE) and Cumulative Variation of Root Mean Squared Error (CVRMSE) (ASHRAE, 2002) were used as the criteria for assessing the acceptability of the agreement between simulated and measured data. The MBE and CVRMSE are calculated as:

$$\boldsymbol{MBE} = \frac{\sum_{i=1}^{Np}(\boldsymbol{M_i}-\boldsymbol{S_i})}{\sum_{i=1}^{N_P}\boldsymbol{M_i}} \qquad \text{(eq. 1)}$$

$$\overline{\boldsymbol{M_P}} = \frac{\sum_{i=1}^{N_P}\boldsymbol{M_i}}{\boldsymbol{N_P}} \qquad \text{(eq. 2)}$$

$$\boldsymbol{CVRMSE_{(P)}} = \frac{\sqrt{\sum_{i=1}^{N_P}((\boldsymbol{M_i}-\boldsymbol{S_i})^2/\boldsymbol{N_P})}}{\overline{\boldsymbol{M_P}}} \qquad \text{(eq. 3)}$$

Where M_i and S_i are measured and simulated data at instance "i" respectively; p is the interval (e.g. monthly, weekly, daily and hourly); N_p is the number of values at interval p (e.g. $N_{month} = 12$, $N_{day} = 365$, $N_{hour} = 8760$) and $\overline{M_p}$ is the average of the measured data (Raftery, Keane, & Costa, 2011). The both hourly acceptance

thresholds of MBE and CVRMSE are ±10% and ≤30% respectively. For the PV module temperature, the MBE and CVRMSE were 4.55% and 14.48% respectively, so the simulated results of PV module temperature were acceptable. Similarly, as shown in Fig. 4, the hourly values of indoor air temperature also show good agreement with the experimental results and the corresponding hourly MBE and CVRMSE were -1.02% and 5.5% respectively. Thus, the TRNSYS model for mode 1 was deemed validated.

3.2. Validation of the Model in Buoyancy-Driven Ventilation Mode

The available experimental results for the buoyancy-driven ventilation mode were from Jan 28 to Jan 31, 2013. The right-hand side cavity (cavity 2) was selected. As the indoor condition was constantly maintained at 22°C through air-conditioning, the indoor air temperature in this operation mode was not be analyzed. The PV module back surface temperature on this cavity (PV module 2) and internal surface temperature of the corresponding internal window (window 2) were selected and simulated in the TRNSYS model through the same time period of the experiment and the comparative results are shown in Fig. 5 and Fig. 6 accordingly.

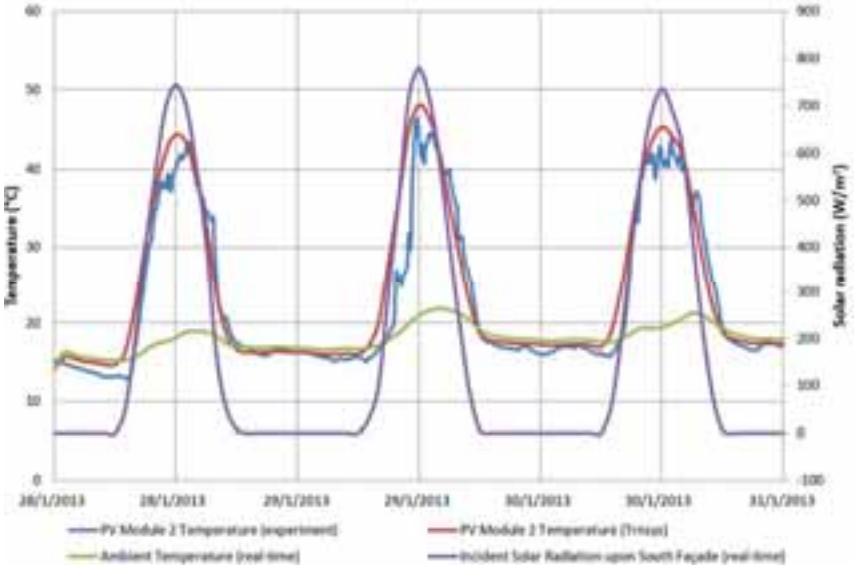

Fig. 5: PV module temperature comparison in Mode 2 (buoyancy ventilation).

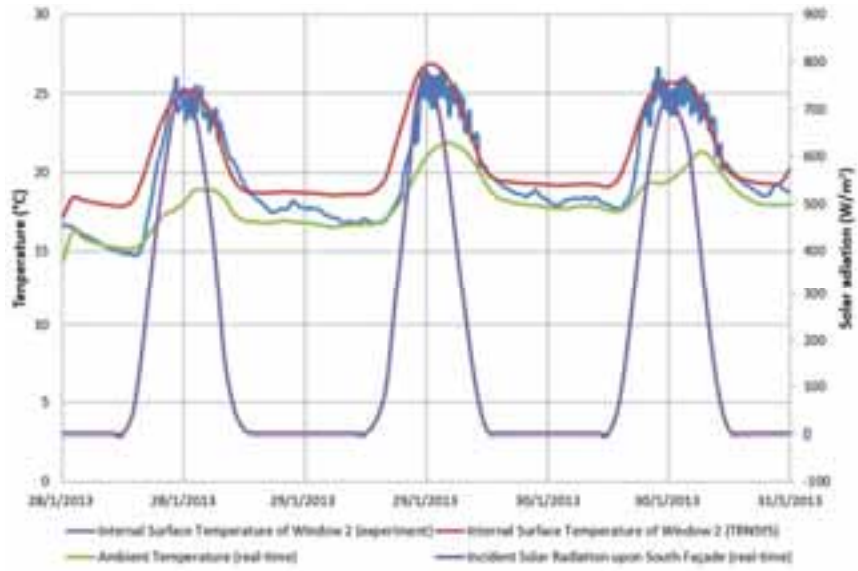

Fig. 6: Comparisons for internal surface temperature of Window 2 in Mode 2 (buoyancy ventilation).

As shown in Fig. 5, the hourly values of PV module temperature show acceptable agreement with the

experimental results and the corresponding hourly MBE and CVRMSE were -4.85% and 11.6% respectively. Comparison of the simulated and measured hourly internal surface temperature of window 2 shows obvious differences during the troughs, in which the simulated values are consistently exceeding the measured values and the biggest difference reached about 3°C in Fig. 6. A likely explanation is the different thermal behaviors between the used window glazing in TRNSYS and the experiment as the experimental information of the window was not available (Peng, Lu, & Yang, 2013), a float glass was assigned to window 2 in the TRNSYS model. In addition, it is difficult to model natural ventilation directly in TRNSYS. This could be done by coupling with the external plug-in such as TRNFlow and CONTAM, but it is outside the scope of this stage of study. As an alternative, the buoyancy-driven ventilation in the cavity was modelled in terms of the constant mass flow rate as the window speeds during the 72 hours were basically floating at 2m/s according to the real-time weather data, so the simulated curve (internal surface temperature of window 2) was much steadier than the curve of measured values. Moreover, the related MBE and CVRMSE were -5.51% and 7.28% respectively, which were acceptable and hence the TRNSYS model for mode 2 was deemed validated.

4. Preliminary Numerical Simulation Model for the BIPV/T-DSF in Australia

In terms of the validated TRNSYS model, a preliminary numerical simulation model has been developed for investigating the thermal performance of the novel BIPV/T-DSF system and its impact on indoor thermal comfort of a commercial building in Sydney, Australia. A building model was built in TRNSYS which was based on the experimental test bed but facing due north in Sydney. The building fabric, except for the PV glazing of the simulation model was modified in the generic design for a better evaluation of the indoor thermal response by use of the BIPV/T-DSF. In order to understand the performance of the BIPV/T-DSF system, the indoor air temperature under the typical days in summer and winter were analyzed accordingly.

4.1. Fan-Driven Ventilated Operation in Summer

A fan-driven ventilating operation for the model building in Sydney was modelled in TRNSYS using a constant mass flow rate (1.35 kg/hour from the validated model in section 3.2) for a steady state of analysis for 72 hours' simulation. In this operation mode, there was no air-conditioning in the building model, the inlet and outlet louvers on the both cavities were opened to allow buoyancy ventilation, which was then compared to the building model operated without the BIPV/T-DSF system. In order to eliminate other uncertainties which might interfere the simulation results, the internal gains from people, equipment and lightings were not included in the models.

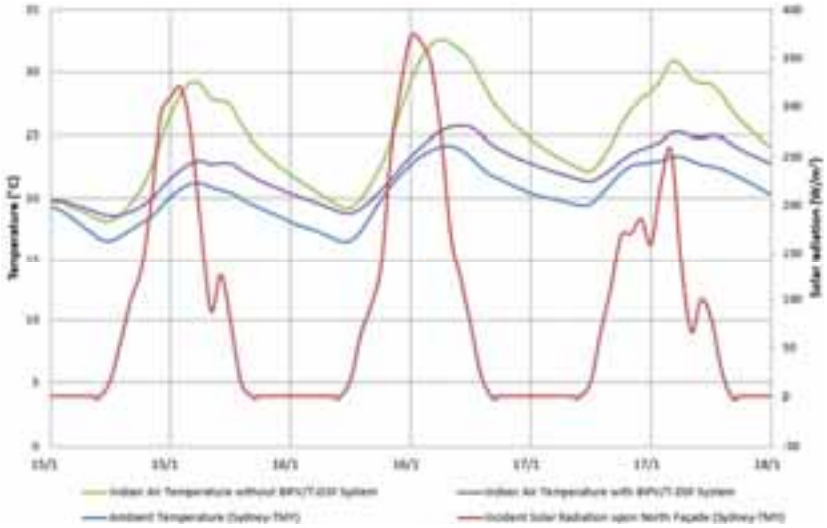

Fig. 7: Comparisons for indoor air temperature with/without BIPV/T-DSF system in summer.

Fig. 7 presents the indoor air temperatures with/without the application of BIPV/T-DSF system for the building model from Jan 15 to Jan 18 in the typical summer days in Sydney. It was found that the indoor air temperature of the building either with or without the BIPV/T-DSF system was always higher than the ambient temperature

throughout the day. The main reason is that the accumulations of solar heat gain led to a higher indoor air temperature than ambient temperature. However, the building model that utilized the BIPV/T-DSF system has significantly lower indoor air temperature than the building model without a BIPV/T-DSF and reached a maximum temperature of 6°C lower during the daytime. This indicated the BIPV/T-DSF system can reduce the indoor air temperature and assist in reduce the thermal load on the mechanical cooling system.

4.2. Non-Ventilated Operation in Winter

Based on the results in section 4.1, all the louvers and windows of the BIPV/T-DSF system were closed for winter to avoid the heat loss through the ventilation. The comparisons between the building adopting and not adopting the non-ventilated BIPV/T-DSF system were compared from Aug 15 to Aug 18 for typical winter days in Fig. 8. It can be seen that the indoor air temperature of the building model either with or without BIPV/T-DSF system was always higher than the ambient temperature, and the indoor air temperature can be maintained at a comfort level during the daytime. Clearly, the temperature drops at night time due to the heat loss through the building fabric, while the BIPV/T-DSF system brought the thermal buffer benefit that played a passive heating role in winter, but the ventilated operation of the cavity can be used for the higher solar radiation days (i.e. Aug 15 and Aug 17) to maintain a lower and comfort indoor air temperature. The non-BIPV/T-DSF case has an overheating issue during the peak daytime and the highest indoor temperature reached about 42°C on Aug 15.

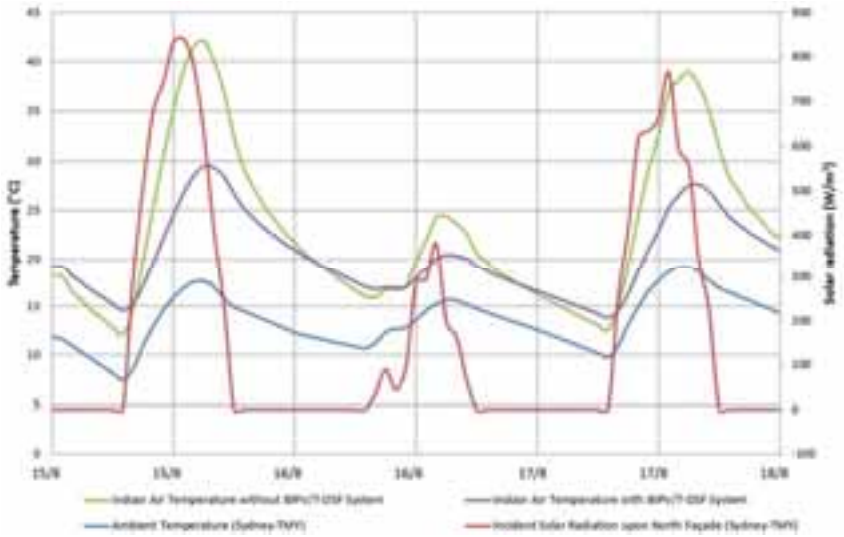

Fig. 8: Comparisons for indoor air temperature with/without BIPV/T-DSF system in winter.

5. Conclusions

The simulation results show that BIPV/T-DSF system gives not only good thermal performance in terms of buffering the building from summer heat gains, but reduces heat loss as well as overheat of building during winter time in the subtropical climate areas in southern hemisphere like Sydney. These are preliminary studies of the novel building façade technology that remains provisional since they are parts of the ongoing research. Further studies will concentrate on developing the specific strategies for maximizing its thermal and electrical performance, and optimizing the long term indoor thermal comfort using the strategies.
