Abstract

The impact of low-speed filtration on the performance of salt water chlorinators, pool cleaners, and the pool water quality, based on experimental and modelled data, is investigated. Results show that a typical salt water chlorinator and pressure pool cleaner do not work well for flow rates of less than 1 litre s^{-1} and 1.3 litre s^{-1} respectively. With the implementation of a robotic pool cleaner, energy savings of more than 70% can be obtained by operating the filtration system at around 1 litre s^{-1} with a correctly adjusted chlorinator setting. This does not compromise the system performance and achieves a largely improved water quality. Furthermore, it is shown that a small photovoltaic system can provide nearly all the energy required by such energy efficient pool system. This PV powered pool filtration system achieves a discounted payback period (DPP) of 5.4 years in comparison to the grid supplied pool filtration system (the Business as Usual (BAU) scenario).

Keywords: low-speed pumping; pool chlorinator; pool cleaner; high-efficiency pool filtration.

1. Introduction

With the rapid growth of residential energy consumption and peak electricity demand, it is important to investigate the energy saving potential in households and so achieve higher energy efficiency. Studies have shown that households with a swimming pool have higher energy demand than households with no pools (Elnakat et al., 2015; Fan et al., 2015). The savings in pump energy used for solar pool heating was previously investigated by the authors and the results showed that operating the system at a lower flow rate reduced the pumping energy by 60%, without materially affecting the pool thermal performance (Zhao et al., 2018). This paper will investigate how to improve the energy efficiency of the pool filtration system by evaluating the performance of the whole system. Such system could achieve significant savings in energy and cost, which therefore enables its energy load to be supplied by a typical photovoltaic system.

2. Background

Presently, there are approximately 1.1 million residential pools in Australia (DEE, 2016) and the total annual electricity demand is estimated be 2100 GWh per year (EES, 2008). This corresponds to approximately 2 million tonnes of carbon emissions per year (DEE, 2017). Operating the pool filtration system under low flow conditions have been recognized as an energy efficiency retrofit by the industry and many swimming pool have adopted this measure (DOE, 2018). Further, numerous studies have investigated the operation of pool filtration under low pump speed (Springer and Rohe, 1996; Sproul, 2005; Cunio and Sproul, 2008; Hameiri et al., 2009) with reported savings of as much as 80%. In addition, the use of a small photovoltaic system to power the low-energy pumping system was examined by Sproul (2005) and the system achieved a 14 year payback period.

Although it is clear that significant amounts of energy could be saved by operating the pool filtration system under low flow conditions, the impacts on other system components such as the salt water chlorinators and the pool cleaners have not been widely reported. In addition to this, the associated effects on pool water quality yet have not been quantitatively examined. According to a recent report prepared for the Department of the Environment and Energy (DEE) of the Commonwealth of Australia, the most common type of Australian pool is a salt water pool (60%) which relies on a chlorinator for sanitation (Woolcott Research and Engagement, 2016). The electrolysis process in the salt water chlorinator has been studied by Khouzam

doi:10.18086/swc.2017.12.14 Available at http://proceedings.ises.org

(2008); this process produces two gases, hydrogen gas and chlorine gas. The hydrogen gas is not soluble in water and therefore gets carried out of the chlorinator by the water flow, into the pool, and eventually into the environment. On the other hand, the chlorine gas, which is highly soluble in water, reacts with water to produce the hypochlorous acid (HOCl). The hypochlorous acid is known as free chlorine, which is an effective disinfectant in the pool. As in most cases, the same pump is used to both filter and chlorinate the water. One possible problem of operating the standard salt water chlorinators at low flow rate is that as the water flow reduces, the hydrogen gas produced accumulates in the chlorinator instead of being flushed out into the pool. Typically, chlorinators are designed to detect this dangerous situation and will switch off the chlorinator and the pump. Hence under these conditions, the pool sanitation deteriorates.

Additionally, a pressure pool cleaner powered by the filtration pump is also susceptible to low water flow operation, as the flow through the cleaners is shared with the pool skimmers or returns. Thus, to fulfill the cleaning task, the pump needs to run at a high speed for a certain period of time, which limits the extent to which the pool filtration can be completed at low flow rate using high-efficiency pumps.

Thus, it is the aim of this study to estimate the energy savings of the pool filtration system by taking the whole system into consideration. In particular, the low flow operation of the salt water chlorinator and the pressure pool cleaner are investigated to examine potential efficiency gains. To the authors' knowledge, there is no information available regarding the minimum operating flow rate of the chlorinator as well as its energy usage. Furthermore, energy efficient operating scenarios are proposed and the feasibility of utilising a PV system is analyzed.

3. Experimental system

Experiments were carried out on an existing domestic pool filtration system in Sydney Australia (Figure 1). The system has an eight-star variable speed water pump (Viron eVo P280), a controller, a salt water chlorinator (Hurlcon VX11T), an oversized cartridge filter (Viron CL400), and a pressure pool cleaner (Polaris 360) operated by the filtration pump. During the experiment key system parameters were monitored, which included the electrical power of the pump and chlorinator; water flow rates through the pump and the pressure pool cleaner; the pressure drop across the pump and the filter. A manually adjustable 3-way valve is located at the discharge of the chlorinator, which can change the proportion of water flow into the cleaner.

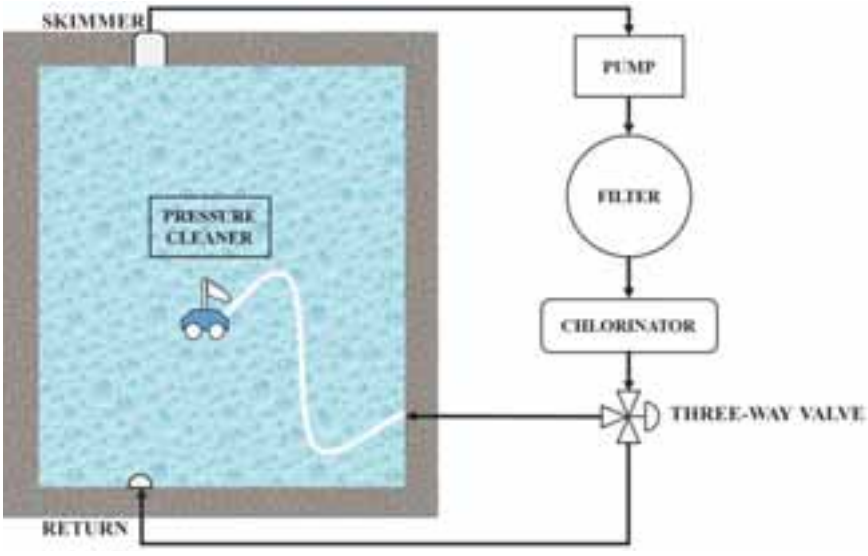

Figure 1: Pool filtration system layout.

The controller coupled to the pump was used to set the operating schedule as well as the pump speed so that the system performance could be investigated under multiple operating scenarios, with different pump speeds

and running times. The details of the operating scenarios are presented in Table 2. A robotic cleaner (Zodiac, 2017) was also retrofitted to replace the existing pressure cleaner in order to evaluate further energy saving opportunities.

Under each operating scenario, the water quality and cleaning effectiveness were examined qualitatively and quantitatively according to the requirements as per the Australian Standard AS3633 (1989) and NSW Government (2013) (Table 1). Based on the measured water quality, the chlorinator setting was adjusted manually using the controller until an acceptable water condition was obtained. Notice that as the pool water quality is affected by pool chemical levels as well as ambient factors including solar irradiance, the location of the pool, and its surroundings (Khouzam, 2008), the scenarios were varied out during the summer period to minimize variations due to the ambient weather conditions. Specifically, each scenario was carried out for 5 consecutive days with similar weather conditions (sunny and warm) and the daily water quality check was performed at 9 am.

Table 1: Recommended pool water chemical concentrations (Standards Australia, 1989; NSW Government, 2013).

Parameters	Recommended range	
Free chlorine (ppm[1])	Pool temperature < 26°C	> 2
	Pool temperature ≥ 26°C	> 3
pH	7 – 7.8 (Optimum: 7.2 – 7.6)	
Total alkalinity (ppm)	60 – 200	
Isocyanuric acid (ppm)	30 – 50	
Calcium hardness (ppm)	0 – 500	
Total dissolved solids (ppm)	1000 – 2000	
Turbidity	0.5 (NTU[2])	

4. Operating the whole pool filtration system at low flow

In order to assess the energy savings of running the variable speed pump at low speed, the comparison was made to the standard single speed pump investigated by Cunio and Sproul (2008). The Hurlcon 1500 W single speed pump was assumed to operate the same pool filtration system. The system operating point was obtained by overlaying the pump working curve with the measured system curve of the existing filtration system. The operating point was approximately 4.3 litre s^{-1} at a head of 18.5 m. For such a single speed pump to fully turnover the pool once every day as required by the Australian Standard AS3633 (1989), the daily pump energy is 3.6 kWh/day. This is comparable to the data reported by DEE (2016), which stated that "*Australian households with a pool use on average 1352 kWh per year (3.7 kWh/day) powering pool pumps used for filtration.*".

Figure 2 shows the daily required pump running time calculated based on one pool turnover and the measured pump efficiency (pump efficiency was calculated as the ratio of measured hydraulic and electrical power). Also shown is the daily pump energy savings in comparison to the single speed filtration by operating the variable speed pump over its flow rate range. Note that the daily energy consumption of the variable speed filtration was calculated based on the measured power usage and the required running time at each flow rate. As can be seen, lowering the flow rate leads to a significant increase in the daily running time while the pump efficiency decreases drastically. However, even at the minimum flow rate, one pool turnover can still be accomplished within 24 hours.

[1] Parts per million. One ppm is equivalent to 1 milligram of something per litre of water (mg/l).
[2] Nephelometric Turbidity Units.

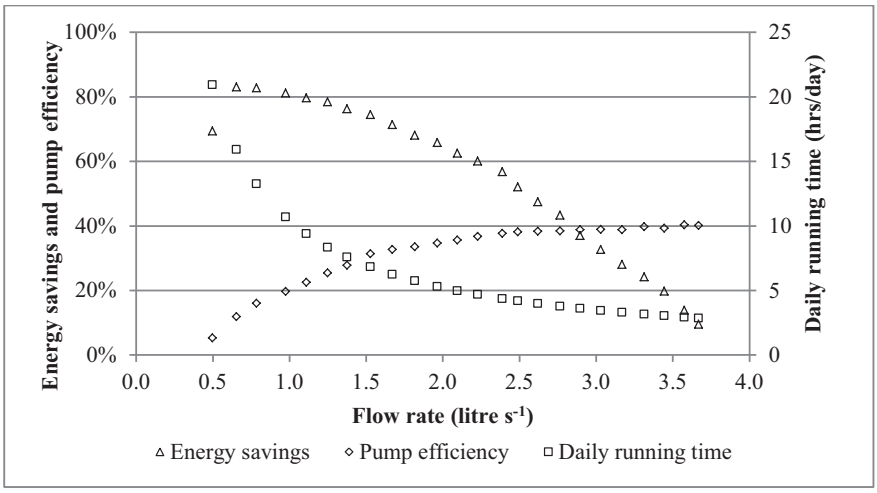

Figure 2: Pump energy savings in comparison to the BAU case, daily running time and measured pump efficiency.

Notice that even if the pump efficiency reduces by half, by operating the variable speed pump at a flow rate between 0.7 litre s^{-1} to 1 litre s^{-1}, pump energy savings of over 80% can still be obtained. This amount of pump energy savings matches the finding reported by Sproul (2005) and Cunio and Sproul (2008). However, the 80% energy savings were only contributed by the pool filtration pump, it is essential to adopt the whole system approach by taking other main system components into consideration, e.g. the pool chlorinator and the cleaner as shown in Figure 1.

Figure 3 shows the pressure drop across various system components. It can be seen that more than half of the total system pressure drop is due to the pipe and fittings. These include components that cause large pressure drop like the pool "eyeballs" (water inlet fittings), bends and tee pieces, and the three-way valve. It is also interesting to see that for flow rates below 1.7 litre s^{-1} (pump speed of less than or equal to the default low speed), the pressure drop across the oversized cartridge filter is very small and therefore can be neglected. This confirms that oversizing the pool filter could reduce the overall pressure loss and achieve a better energy efficiency (NRDC, 2013). In addition, the existing pressure pool cleaner accounts for noticeable pressure loss, which is about one-third of the total system pressure. In comparison to the filtration system without the pressure pool cleaner, this reduces the flow rate under a specific pump speed and leads to a longer daily filtration period to change over the same amount of water. Though the pump uses lower power, the daily energy is more.

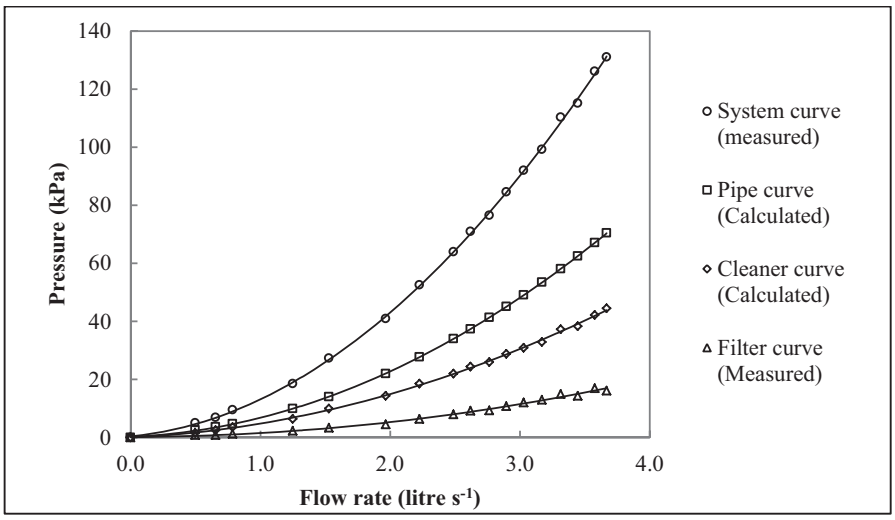

Figure 3: Pressure drop across the pool filtration system components.

By operating the pool filtration system under various scenarios, the energy savings achieved at low flow conditions can be examined along with the associated effects on key system components. Table 2 shows the experimental results obtained by operating the whole pool filtration system under 7 scenarios. Also shown is the chlorinator setting for maintaining an acceptable pool water quality as per the Australian Standard AS3633 (1989) for all scenarios. The Business as Usual (BAU) scenario is also presented, in which the variable speed pump was running at the highest speed and the chlorinator was at the highest setting. Notice that for scenario G, the pressure pool cleaner was disconnected and a robotic pool cleaner was used. Under this scenario, all flow was diverted through the pool returns by adjusting the three-way valve.

Table 2: Experimental results of the whole pool filtration system operating under different scenarios.

Scenarios	A	B	C	D	E	F (BAU)	G
Pump speed (RPM)	900	950	1150	1450	2075	2850	750
Cleaner type	Pressure cleaner						Robotic cleaner
Filtration time (hrs/day)	14 (11 for one turnover)	10	8	6	4	4 (2.8 for one turnover)	10
Schedule	5am – 7pm	7am – 5pm	8am – 4pm	9am – 3pm	10am – 2pm	10am – 2pm	7am – 5pm Robotic cleaner (11 am – 12 pm)
Flow rate (litre s^{-1})	0.97	1.03	1.30	1.73	2.58	3.67	1.07
Chlorinator working?	N	Y					
Chlorinator setting (out of 8)	N/A	3	4	5	8	8	3
Proportion of flow through pool returns	0%	0%	0%	24%	50%	65%	100%
Water chemistry	Poor	Good					
Water turbidity	3.2	0.82	0.45	0.41	0.43	0.4	0.24
Skimmer effectiveness and water clarity	Poor			Ok for small and lightly polluted pools.	Good		Perfect
Manual clean?	Y						N
Pool filtration system load (pump + chlorinator) (kW)				0.29	0.62	1.36	0.12 (before 11 am and after 13 pm) 0.19 (11 am to 13 pm)
Daily energy usage (kWh/day)				1.8	2.6	5.5	1.5

The pool chlorinator stopped working when the flow rate dropped below 1 litre s^{-1} due to insufficient flow and hydrogen accumulation. Hence under scenario A (flow rate of 0.97 litre s^{-1}), the pool water condition was heavily compromised – an unbalanced water chemical level and a turbidity of 3.2 NTU that was more than 6 times the recommended value of 0.5 shown in Table 1. This implies that 80% of savings of pump energy is actually not practical at a flow rate between 0.7 litre s^{-1} to 1 litre s^{-1}. This is due to the hydrogen accumulation in the salt water chlorinator, which is shut down under such circumstances.

In terms of the pressure pool cleaner, the operating flow rate for achieving the proper wheel rotations (28 – 32 RPM) was approximately 1.3 litre s^{-1} (Polaris, 2017). As seen from Table 2, under scenario A and B (flow rates of less than 1.3 litre s^{-1}), even if all flow was diverted into the pressure cleaner, its motion was still constricted and debris accumulated in the pool. By contrast, with proper adjustments of the existing three-way valve to meet the recommended flow range of the pressure cleaner, it was feasible to operate the pressure cleaner under scenario C to F. However for scenario C, the skimmer effects were heavily compromised since all flow was passed through the pressure cleaner. As a result, debris accumulated on the pool surface and this affected the pool clarity. The situation may get worse for heavily polluted areas.

From the whole of system performance perspective, it is more acceptable to operate the pool under scenario D (pump speed of 1450 RPM), where the three-way valve was adjusted to divert most of the flow (76%) through the pressure cleaner while still allowing some (24%) to allow the normal pool returns ("eyeballs"). This enabled the skimmer box and the pressure cleaner to be effective while running at the same time, therefore obtaining an appropriate pool condition. Notice that under scenario D, occasional manual cleaning was still needed to pick up the debris on the pool surface, especially during windy days.

After the robotic pool cleaner was retrofitted to replace the existing pressure cleaner, a significant improvement of pool cleanliness was observed (Figure 4). With the 4WD system, the robotic cleaner was able to climb on the pool steps and walls easily and perform cleaning without losing traction. In addition, since the water flow through the main pump was no longer needed to supply the pressure cleaner, all water flow was diverted via the normal pool returns and this allowed the skimmer box to operate more effectively. As a result, no manual work was required under this scenario to catch debris on pool surface nor to sweep the steps.

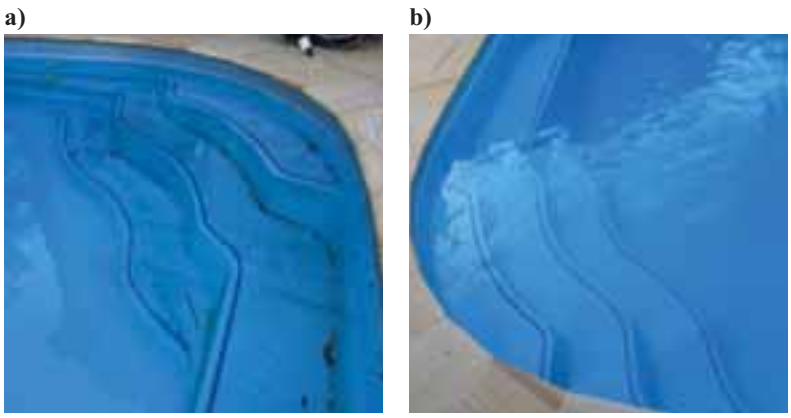

Figure 4: Conditions of pool steps when the filtration system was operating under a) BAU scenario with a pressure cleaner, b) scenario G with a robotic cleaner (both with no manual cleaning) after a 24-hour period.

Apart from the improved water clarity, it was also encouraging to see that the robotic cleaner was highly energy efficient and additional energy savings were obtained. Figure 5 shows the measured daily energy usage of the whole system operating under different scenarios. Notice that under these scenarios, all the system components were experimentally examined to work appropriately and the water quality was checked as acceptable.

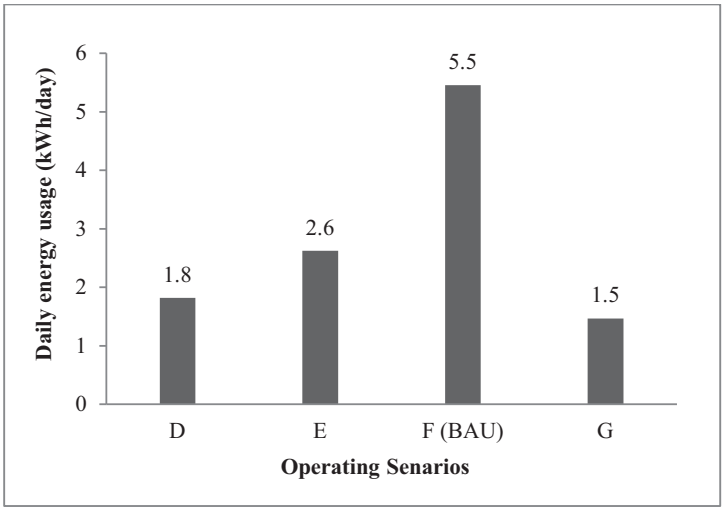

Figure 5: Measured daily energy usage of the whole pool filtration system operating under various scenarios.

For all scenarios with the pressure pool cleaner in use, the whole filtration system operating under scenario D consumed the least daily energy of 1.8 kWh/day. With a robotic cleaner in use (scenario G), the daily energy usage of the whole system was reduced to around 1.5 kWh/day. This is less than 30% of the BAU scenario (energy use of 5.5 kWh/day).

Assuming the pool filtration system is running year-round to maintain the pool conditions, the simple payback period of the whole system under the proposed energy efficient scenarios was calculated. Considering a variable speed pump (AU$1,500 including installation) as a retrofit option to the existing pool filtration system, operating the whole system at the minimum flow as required by the pressure cleaner (scenario D) has a simple payback period of approximately 3.4 years based on the electricity price of 0.323 AU$/kWh (Energy Australia, 2017). This is less than the average pool pump lifetime of approximately 7 years (DEE, 2016), making it an ideal energy saving option for pool owners. For the energy efficient scenario G where a robotic cleaner is retrofitted, it takes around 6.5 years to pay back the total capital cost of the variable speed pump and the robotic pool cleaner. This is nearly double the payback of scenario D since the robotic pool cleaner costs about the same as the variable speed pump (AU$1,550). If low-cost robotic pool cleaners were developed, operating a variable speed pump at the lowest flow that suits the chlorinator (scenario G) would obtain a lower payback and therefore become a better solution considering its superior cleaning quality as demonstrated above.

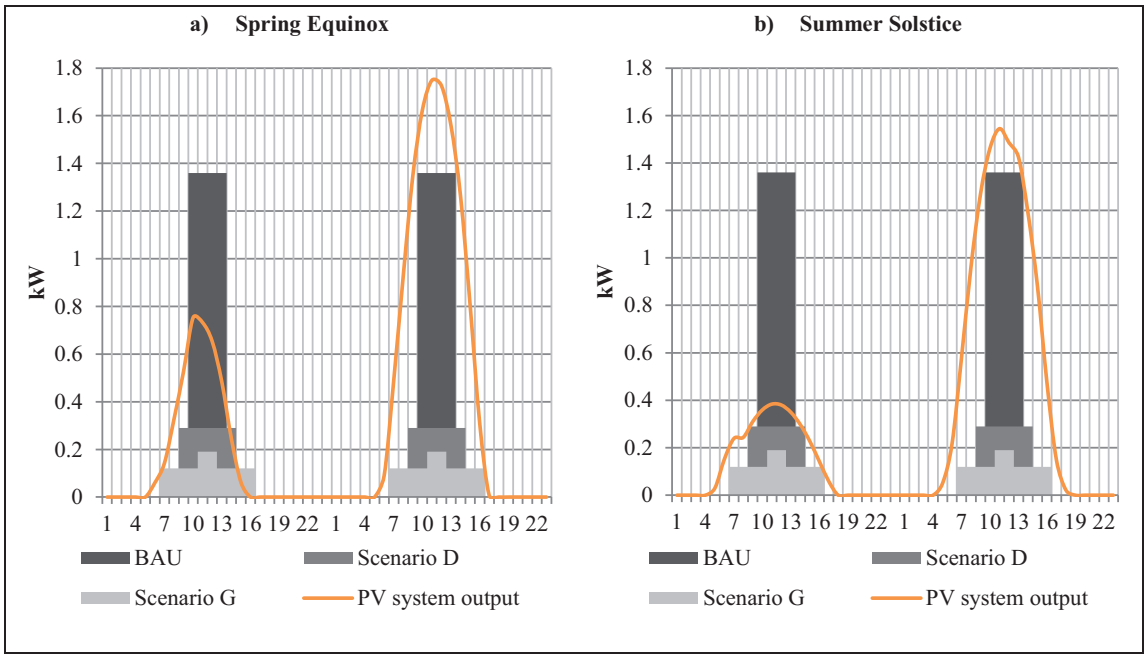
5. PV operated swimming pool filtration system

Previous results showed that operating the pool filtration system under energy efficient scenarios (D & G) achieves significant energy savings and acceptable paybacks in comparison to the BAU scenario. It is also interesting to investigate the feasibility of running the whole system from a PV array. The simulation was carried out using NREL's System Advisor Model (SAM) (NREL, 2017a) and the PV system was sized based on the BAU high-speed operation of the pool filtration system (scenario F in Table 2) in Sydney. The filtration system was assumed to operate year-round and the PV array was assumed to be connected to the grid. The key assumptions and parameters are shown in Table 3.

Table 3: Assumptions and parameters of the PV system sized based on the BAU scenario (F).

Nameplate capacity	2 kW
Array orientation	North
Array tilt	34°
PV module	Suntech Power STP250-20/Wd
Number of PV modules	8
Modules per string	8
Strings in parallel	1
Inverter	Solar Power: YS-2000TL 277V
Shading loss	0%
Soiling loss	5%
DC power loss	3%
AC loss	1%
Total module area	13 m^2

Figure 6 shows the power generated by the PV system at three different dates near to the: a) Spring (Autumn) Equinox, b) Summer Solstice, and c) Winter Solstice. Notice that two days around each date are presented to demonstrate the system performance under i) cloudy and ii) clear weather conditions. Also shown is the pool filtration system loads under BAU scenario, scenario D, and scenario G. The associated daily operating schedules and the energy loads are presented in Table 2.



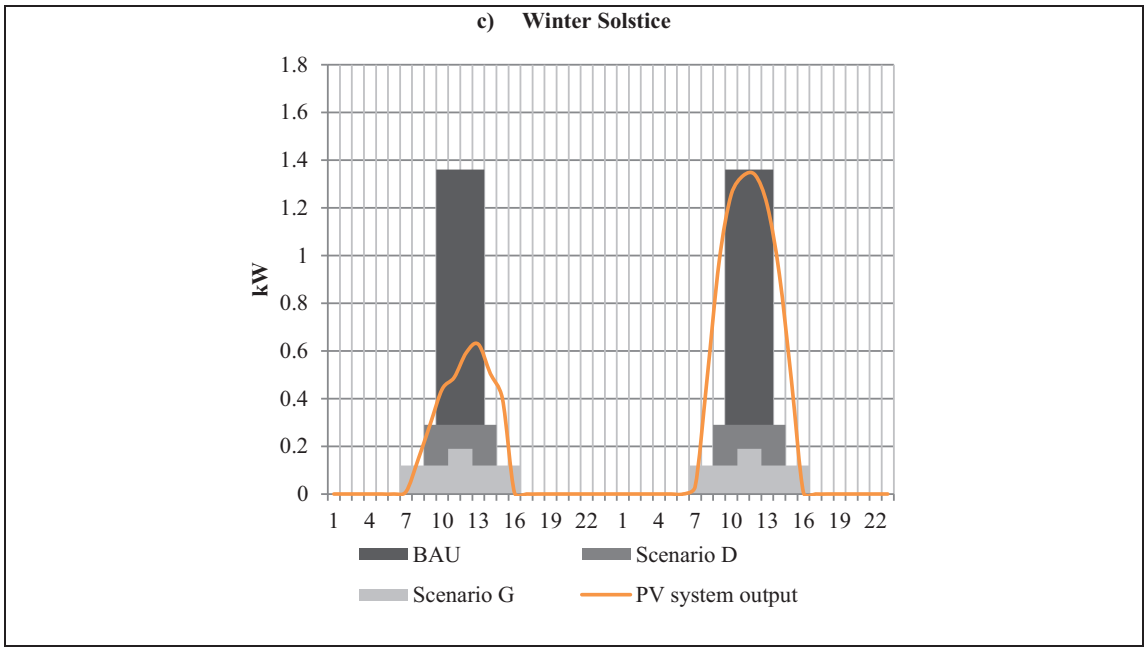


Figure 6: PV system output and pool load under scenario D, G, and BAU for different sun positions in the southern hemisphere (left: cloudy day; right: clear day).

It is clear from Figure 6 that on cloudy days, a majority of the pool load under the BAU scenario cannot be met by the PV system due to the significant decrease in the power generated. As seen from the SAM simulation results shown in Table 4, 423 kWh of electricity must be supplied annually by the grid under the BAU scenario and this leads to a PV fraction of only 45% (proportion of period where the pool filtration system load is completely covered by the PV system). By contrast, the same PV system is more likely to power the pool filtration system operating under energy efficient scenarios (D & G) even with bad weather. In both of these cases, only a small amount of electricity is sourced from the grid while the pool load can be fully supplied by the PV system for more than 90% of the total operating period (Table 4).

Table 4: SAM simulation results of the pool filtration system operating under BAU scenario (both grid and PV powered), scenario D, and scenario G.

	BAU+Grid	BAU+PV	Scenario D (PV+Variable speed pump+Pressure cleaner)	Scenario G (PV+Variable speed pump+Robotic cleaner)
PV system output (kWh/yr)	0	3017		
Excess PV output (kWh/yr)	0	1,454	2,391	2,547
Electricity from grid (kWh/yr)	1,986	423	9	19
Period with full load covered by PV (hrs/yr)	0	651	2,083	3,399
PV fraction	0	45%	95%	93%

Based on the results shown in Table 4, the net present values (NPV) and the discounted payback periods for the PV powered pool filtration systems were calculated relative to the BAU case: single speed pump, pressure cleaner, and grid-supplied system (BAU+Grid). The following parameters and assumptions were made for the calculations:

- Cost of system components:
  - Single speed pump: AU$ 775 (DEE, 2016).
  - Pressure pool cleaner: AU$ 720 (supplier).
  - Variable speed pump: AU$ 1,500 (supplier).
  - Robotic pool cleaner: AU$ 1,550 (supplier).
  - PV system: AU$ 5,868 (NREL, 2017a).
- The lifetime of both pool cleaners are assumed the same as that of a typical pool pump, therefore all need to be replaced every 7 years (DEE, 2016).
- All the PV electricity generated is assumed to be self-consumed by the household.
- The discount rate is 5% (Drury et al., 2011).
- The grid electricity price is 0.323 AU$/kWh (including GST) (Energy Australia, 2017)
- The grid electricity price is assumed to increase by 3% each year (Kai, 2017).
- The typical PV lifetime is 25 years (NREL, 2017b).

Table 5: Capital costs, net present values (NPV), and discounted payback periods (DPP) for PV powered pool filtration systems compared to BAU grid supplied system.

	BAU+Grid (Grid+Single speed pump+Pressure cleaner)	**BAU+PV** (PV+Single speed pump+Pressure cleaner)	**Scenario D** (PV+Variable speed pump+Pressure cleaner)	**Scenario G** (PV+Variable speed pump+Robotic cleaner)
Capital costs	AU$ 1,495	AU$ 7,363	AU$ 8,088	AU$ 8,918
NPV (relative to BAU+Grid)	AU$ 0	AU$ 13,288	AU$ 19,465	AU$ 17,649
DPP (years)		6.5	5.0	5.4

From Table 5, it can be seen that although the more efficient options have high upfront costs, the discounted payback periods for the two PV powered energy efficient systems (scenario D & G) are very attractive. In terms of scenario D, it has the highest NPV difference relative to the BAU grid supplied system and thus it is the most cost-effective solution. The whole system cost can be paid back in just 5 years, which is the shortest amongst three PV powered system considered. As for scenario G, due to the additional costs of the robotic pool cleaner and more electricity is purchased from the grid (Table 4), it needs around 5 months more for the whole system to pay back in comparison to scenario D. Nevertheless, it starts generating profits 1 year earlier than the BAU PV powered system (BAU+PV) and the discounted payback period is less than a quarter of the standard lifetime of a PV system. Considering that better pool quality and simpler pool maintenance can be achieved under scenario G, it is also an appropriate energy efficiency design of a residential pool filtration system.

6. Conclusion

The study presents for the first time the results of a typical residential pool filtration system operating under various scenarios. The water flow rate was varied under different scenarios and the pool chlorinator was adjusted accordingly to deliver different chlorine production rates. For lower flow rates and longer running times, the rate of chorine production was reduced in comparison to the high flow rate operation. The pool water was also tested to ensure that the key water chemistry such as free chlorine and pH levels met the Australian Standard AS3633 (1989) for all flow rates considered in this paper.

Experimental results revealed that over 80% of the pump energy could be saved by operating a variable

speed pump at flow rates of less than 1 litre s^{-1}. However, at such flow rates, the salt water chlorinator and the pressure pool cleaner were identified not working properly and this led to unsatisfactory pool water conditions. For the pool filtration system considered in this study (with the pressure pool cleaner in use), it is more appropriate and energy efficient to operate the whole system at a flow rate of 1.7 litre s^{-1} with a properly adjusted chlorinator setting (scenario D). The associated energy use is 1.8 kWh/day, which is approximately 33% of the energy use of the BAU scenario. In addition, the energy use reduces to 1.5 kWh/day with a robotic cleaner and the pool cleanliness is also substantially improved. For these energy efficient pool filtration systems, its load can be supplied by a small PV system. With no export of the PV electricity, it takes around 5 years and 5.4 years respectively for scenario D (pressure pool cleaner in use) and scenario G (robotic cleaner in use) to payback the initial investment (both refer to the discounted payback period with the replacement of pool system components taken into consideration). These discounted payback periods are less than 25% of the PV system lifetime.

Approximately 70% of the swimming pools in Australia are operated by single speed pumps (DEE, 2016). If all of these pools were retrofitted to the energy efficient scenarios considered in this study, total energy savings of more than 1000 GWh and carbon reductions of nearly 1 million tonnes could be obtained annually (DEE, 2017). Further, if all the low energy pool filtration systems were powered by PV systems where possible, total peak demand reductions of approximately 1 GW could be realized in Australia.

Except during periods of experimentation, the pool under study was operated under low flow conditions for approximately two swimming seasons. During this time water quality tests were undertaken, and readings were always in the acceptable range to maintain healthy swimming conditions as per the Australian Standard AS3633 (1989). In all circumstances, the filtration flow rates and pump run times were set so that the full volume of pool water was filtered once per day, as required by the Australian Standard AS3633 (1989). We would propose that provided this methodology was adhered to and that pool chemistry levels were maintained, the findings of this study should be generally applicable to different pool sizes, climates, and pool usage. However further studies of different pools would be useful to further verify the approach used in this paper.

Low to Medium Temperature Thermal Storage

Development and Testing of a Thermo-chemical Energy Store - Results of a Five year Research Project -

University of Stuttgart, Stuttgart (Germany)

Abstract

During the five-year research project EnErChem, a new solar heating system has been developed, aiming to supply the demand for space heating of energy efficient buildings completely based on solar thermal energy. Within the research project engineers and material scientists from universities and industry cooperated interdisciplinary. The aim was the further development of a concept of efficient long term heat storage based on improved storage materials. Composite storage materials based on the combination of hygroscopic salts and zeolite granulates have been developed. To fully use the properties of the developed storage materials a robust reactor design has been developed. Based on this design a prototype store has been built and experimentally investigated in a "hardware in the loop" (HIL) test environment. The developed design of the thermal energy store and the experimental results of the thermal energy store operation are presented in this paper.

Keywords: thermo-chemical heat storage, thermal energy store, adsorption, solar heating, high solar fraction, testing, hardware in the loop

1. Introduction

Solar assisted space heating systems are already well established on the market. These systems are usually able to cover between 30 % and 50 % of the building's total heat demand using solar radiation. To increase the solar fraction of space heating systems towards covering the complete heat demand using solar radiation as the only energy source, efficient heat storage is a crucial aspect. The main part of already well established systems is a sensible heat store based on hot water. Due to continuous heat losses during the storage period high efficient long term heat storage based on sensible heat is not possible.

For the purpose of highly effective long-term heat storage the technology of thermo-chemical heat storage has the advantage of high energy storage densities and minimal heat losses during energy storage over long time periods. Hence, adsorption heat storage, a sub category of thermo-chemical heat storage, has been under intensive research in recent years (Engel et al. 2017, Mette et al. 2014a, Kerskes et al. 2012, Cuypers et al. 2012, Zondag et al. 2012, Jähnig et al. 2006). Within the research project EnErChem, funded by the German Federal Ministry for Economic Affairs and Energy (BMWi), the development of this technology was conducted. In this project material scientists from ITC (Institute of Chemical Technology, University of Leipzig) partners from industry (Vaillant GmbH, Chemiewerk Bad Köstritz) and process engineers from TZS/ITW (Research and Testing Centre for Thermal Solar Systems, Institute of Thermodynamics and Thermal Engineering, University of Stuttgart) were working collaboratively on the development of enhanced sorption storage materials and on the development of the thermo-chemical heat store itself. Both scientific fields are crucial for the implementation of a thermo-chemical heat store with a high energy density.

Previous work on development of thermo-chemical heat stores stated the need for improvement regarding the robustness and efficiency of the charging and discharging process. Additionally enhanced sorption storage materials show a significant change of their thermal characteristics, influencing the charging and discharging process of the thermo-chemical heat store. This paper shows the improvement of the charge and discharge operation of the developed thermo-chemical heat store due to the newly developed reactor design and discusses the impact of the changed thermal characteristics of the storage material on the thermo-chemical heat store operation.

2. Enhanced sorption storage materials

With a commercial zeolite material as a basis, the sorption properties have been improved systematically by ion exchange and the impregnation with salts (Nonnen et. al. 2016). Figure 1 shows the energy storage density related to the material volume of the commercially available zeolite 13X (Na-X, KÖSTROLITH 13XBFK, Chemiewerk Bad Köstritz), the corresponding Ca^{2+}-ion-exchanged zeolite Ca-X, as well as the salt-impregnated zeolite composite 15 $CaCl_2$/Ca-X on the basis of the ion-exchanged zeolite Ca-X.

Due to the ion-exchange, the storage density Q_V of the zeolite can be increased by approximately 15 % to about 145-180 kWh m^{-3} (desorption at temperature of T = 110 °C and partial pressure of water vapor of $p_{w:}$ <0.2 mbar; adsorption at T = 30 °C/p_w: 5-25 mbar). Furthermore a profound understanding on the interaction between zeolite and salt could be obtained from investigations on the composite material (Nonnen 2016). Experiments at partial pressure of water vapor below the deliquescence of $CaCl_2$ show, that adsorption centers of the zeolite were covered by salt. Consequently, the storage density is decreased compared to the pure zeolite material. For water vapor pressures exceeding the deliquescence humidity of $CaCl_2$, the storage density of the composite material increases. Due to the formation of a salt solution, the energy storage takes place by simultaneous water adsorption by the zeolite and water absorption by the salt solution.

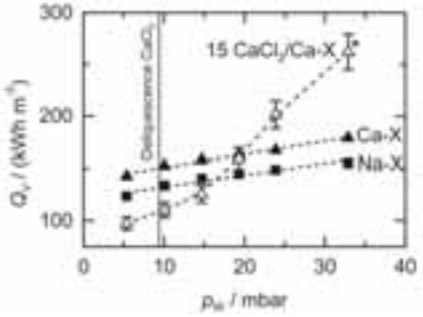

Fig. 1: Energy storage density Q_v of selected storage materials as a function of water vapor pressure p_w. Experimental conditions: desorption at 110 °C, < 0.2 mbar water vapor pressure, adsorption at 30 °C, 5-35 mbar water vapor pressure (Nonnen et al. 2016)

While the adsorption kinetic remained unchanged after the ion-exchange in the zeolite, the salt-impregnated zeolite changed its adsorption kinetic vastly. Figure 2 demonstrates this change, showing the results of an adsorption experiment in a packed bed reactor at a water vapor partial pressure of 24 mbar, an air mass flow rate of 0.3 kg h^{-1} resulting in a mass flow rate per cross section area storage material of 330 kg m^{-2} h^{-1}.

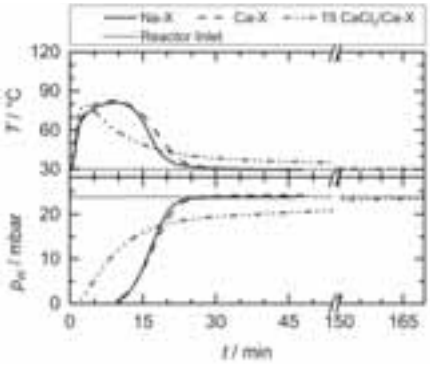

Fig.2: Comparison of a temperature T and water vapor pressure p_w at the outlet of a fixed bed reactor during adsorption for the storage materials Na-X, Ca-X and 15 $CaCl_2$/Ca-X (Nonnen et. al. 2016)

All three materials are showing a maximum temperature lift of about 50 K. While the water vapor breakthrough for the Na-X and Ca-X zeolites is begins after 9 min, it starts already after 2 min for the composite 15 CaCl2/Ca-X and extends over a time period more than 5 times as long as for the salt free zeolites. This characteristic is a challenge for the application of the material in a thermo-chemical heat store.

In addition to the steps of material development and laboratory characterization, the process for large-scale manufacturing of the composite has been developed by the industrial partner Chemiewerk Bad Köstritz. Material batches of 150 liters up to 200 liters have been produced. The produced material was inserted in the newly developed store and experimentally investigated in a “hardware in the loop“ (HIL) test facility under representative operation conditions described in section 5.

3. Development of improved storage design

The implementation of continuous charging and discharging process of the thermo-chemical energy store has been realized as an open adsorption process with material transport. The thermo-chemical energy store consists of three main parts: The storage vessel, a material conveyor system and an external reactor unit (cf. Figure 3). Charged and discharged material is stored separately in a thermally uninsulated, water vapor proof vessel. For charging and discharging the material is transported via the material conveyor system (e.g. vacuum exhauster transport system) to the external reactor unit. In the reactor unit the storage material flows gravity driven through the reactor and leaves the reactor unit at the bottom where it is collected and transported back to the appropriate part of the storage vessel.

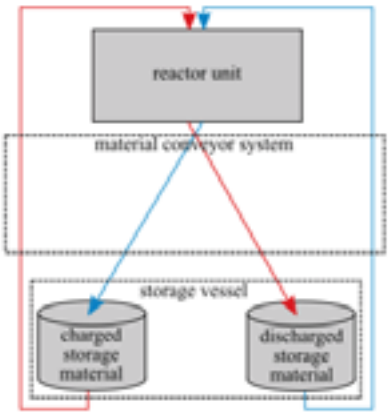

Fig. 3: Schematic view of the thermo-chemical store components

This concept has been applied by Kerskes et al. (2012) and Mette et al. (2014a). It shows a great potential for the realization of a high thermal performance thermo-chemical heat storage. The earlier work also addresses challenges regarding the robust operation and efficiency during charging and discharging of the storage material in the external reactor. A semi batch operation mode has been suggested by Kerskes et al. (2012) to implement an interruption-free operation. The experimental work on the semi batch operation has been limited to operation modes with a constant storage material mass flow rate. An introduction of a process controlled storage material mass flow rate based on the temperature measured in the reactor has been identified as the most promising improvement for a stable reactor operation. The implications resulting from a temperature based storage material mass flow control in a single stage reactor as used in previous work and further challenges regarding the efficiency of the charging and discharging process led to the development of an improved reactor design based on a two stage reactor.

Improvement of the reaction behaviour through reactor splitting

During charging and discharging the reactor is operated in a semi batch operation mode (see figure 3 left). Small portions of storage material are extracted discontinuously at the bottom of the reactor. Fresh storage material falls from a buffer vessel at the top of the reactor into the reactor bed. The air streams through the reactor bed in cross flow.

To ensure that the storage material always leaves the reactor completely charged/discharged it has to stay in the reactor bed until the adsorption process is completed everywhere in the material batch. In practice this state is hardly achievable. Due to grain size deviations, zones with unevenly distributed air flow are present. The increased friction between the storage material and the reactor walls creates zones with lower material flow. These influences lead to different timings of water vapor breakthrough in different parts of the reactor. Therefore a buffer zone at the bottom of the reactor is necessary where the charging/discharging of all parts of the material is completed. Furthermore the buffer zone provides the possibility to transfer the sensible heat of the storage material to the air stream during discharging.

The impact of introducing a buffer zone in a single stage reactor shall be explained with an adsorption example. The example sequence is based on a dynamic simulation of the adsorption process. The used storage material is the zeolite Na-X. The storage material enters the reactor with a temperature $T_{s\text{-}in}$ = 20 °C and a water loading of X_s = 84 g/kg. The reactor is crossed with a humid air stream with a mass flow rate of $\dot{m}_f$ = 300 kg/h. The humid air enters the reactor with a temperature of $T_{f\text{-}in}$ = 30 °C and the specific humidity of $x_{f\text{-}in}$ = 6 g/kg corresponding to water vapor pressure of approximately 9.4 mbar. At the beginning of the adsorption sequence the reactor is completely filled with fresh storage material. The reactor control initiates an exchange of one storage material portion (1.0 liter) if the trigger

temperature T_{ME} is lower than $T_{f\text{-}in}$ + 1.8 K. Figure 3 shows a scheme of the single stage reactor as well as the time series for specific humidity, temperatures and the binary signal for storage material exchange (ME) in the reactor.

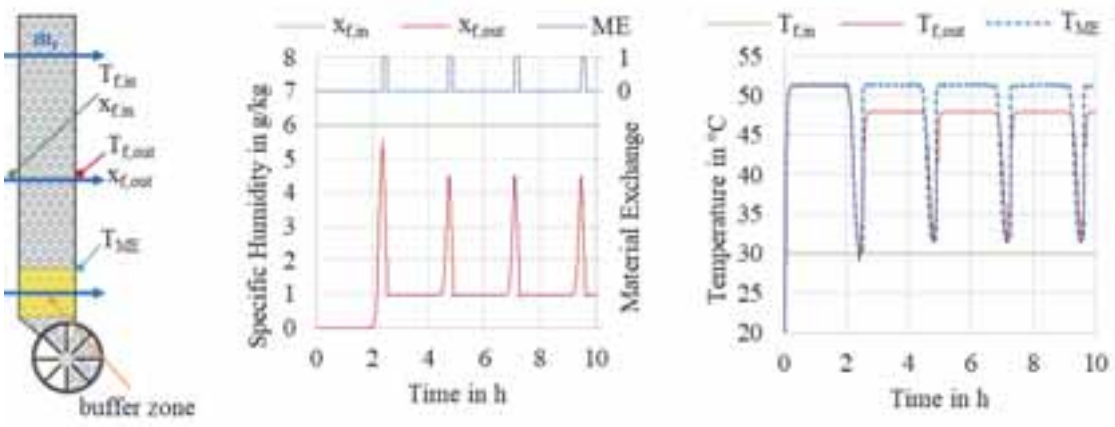

Fig. 3: Simulation results of an adsorption sequence in a single stage reactor

The process illustrated in figure 3 shows that in a single stage reactor the introduced buffer zone has multiple disadvantages. Since the reactor depletes as a whole, all storage material portions above the buffer zone are exchanged after each other. This leads to a short drop of the outlet temperature $T_{f,out}$. Since the buffer zone is not filled with fresh material the specific humidity of the air stream is not adsorbed in the buffer zone. Therefore after the initial period the specific humidity in the mixed air stream behind the reactor has a value of at least 1.0 g/kg. Since there is no temperature lift in the buffer zone the temperature in the mixed air stream behind the reactor ($T_{f,out} \approx 48$ °C) is also lower compared to the temperature during the initial period of 51 °C.

To overcome the disadvantages of the single stage reactor the reactor has been split up into two stages: a main reactor and a pre-reactor (see figure 4 left). In this two stage reactor the air first flows through the pre-reactor, is redirected at the outlet of the pre-reactor and then enters the main reactor. The storage material enters the main reactor first and is moved to the pre-reactor after leaving the main reactor. The introduced buffer zone is now placed in the bottom part of the pre-reactor. Analog to the single stage reactor the storage material portions will be exchanged based on the trigger temperature at the top of the buffer zone.

For the comparison of the single stage reactor with the double stage reactor the same adsorption sequence has been applied. The sum of the reactor bed thickness of the double stage reactor equals the reactor bed thickness of the single stage reactor. The cross area of each, the main reactor and pre-reactor is equal to the cross area of the single stage reactor. Therefore the pressure drop over the whole reactor remains similar. Figure 4 shows the calculation results. In the double stage reactor the specific humidity and the temperature at the outlet of the pre-reactor are specified in addition to the quantities at the inlet and outlet of the whole reactor.

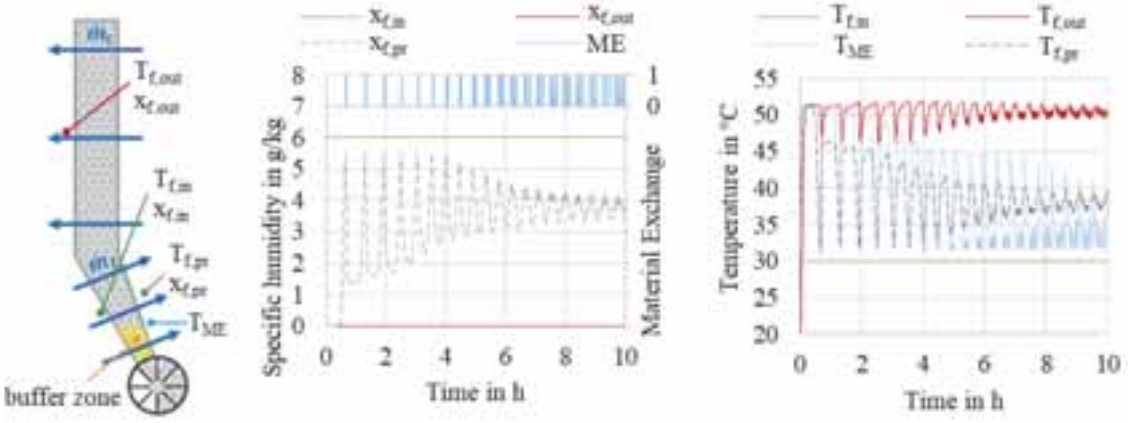

Fig. 4: Simulation results of an adsorption sequence in a double stage reactor

Due to the lower reactor bed thickness of the pre-reactor the specific humidity at the outlet of the pre-reactor rises and the temperature falls already after a period of about 0.5 h. The adsorption in the pre-reactor is completed and the first storage material portion is exchanged. Since the main reactor is still filled with fresh material this has no impact

on the specific humidity at the outlet of the reactor. The exchange of the storage material portion causes a short reduction of the outlet temperature. The entering storage material in the upper part of the reactor has a temperature of 20 °C and has to be heated up to the process temperature. During the whole sequence the water vapor is completely adsorbed in the two stage reactor and the mixed air stream temperature at the reactor outlet remains nearly at the maximum of 51 °C. In this way the introduced buffer zone does not have a negative impact on the reactor performance.

4. Experimental investigation of the improved storage design

For demonstration and performance testing of thermo-chemical energy storage device with the newly developed reactor unit with a two stage reactor, a “hardware-in-the-loop” (HIL) test facility has been built. The HIL test facility consists of an air loop, a heat load emulation loop and an electrical power source. With the air loop a humid air stream with a defined specific humidity in the range from 3 to 16 g/kg, a temperature in the range of 15 to 30 °C and a mass flow rate up to 200 kg/h can be provided to the reactor of thermo-chemical energy store. In the heat load emulation loop thermal oil is circulated with a mass flow rate between 100 and 250 kg/h. For tempering of the oil an electrically heated thermostat is used for heating with a power up to 4 kW and for cooling with a power up to 2.5 kW in a temperature range from 20 to 200 °C.

In the HIL test facility the thermo-chemical storage has been operated under real application conditions. Adsorption and desorption experiments have been carried out in application scale. All ingoing and outgoing energy fluxes were measured based on the measurement of temperatures, mass flow rates and humidities, which allowed an energetic balancing under dynamic operating conditions.

Developed reactor unit with a two stage reactor

The newly developed reactor unit consists of four key components: the two stage reactor (consisting of main and pre reactor), air heat exchanger, charge heat exchanger (or electrical heating rod) and discharge heat exchanger. All key components are placed in a common thermal insulation (cf. Figure 5). During operation ambient air enters the reactor unit through the air heat exchanger and is preheated by the exiting air stream. Thus the air heat exchanger decouples the reactor operation temperature level from the ambient temperature. Afterwards the air flows through the charge heat exchanger, which is only active during charging, and enters the reactor through the pre-reactor. The air steam is deflected in a duct behind the pre-reactor and led through the main reactor. Finally it flows through the discharge heat exchanger, only active during the discharge operation, which is placed directly after the main reactor.

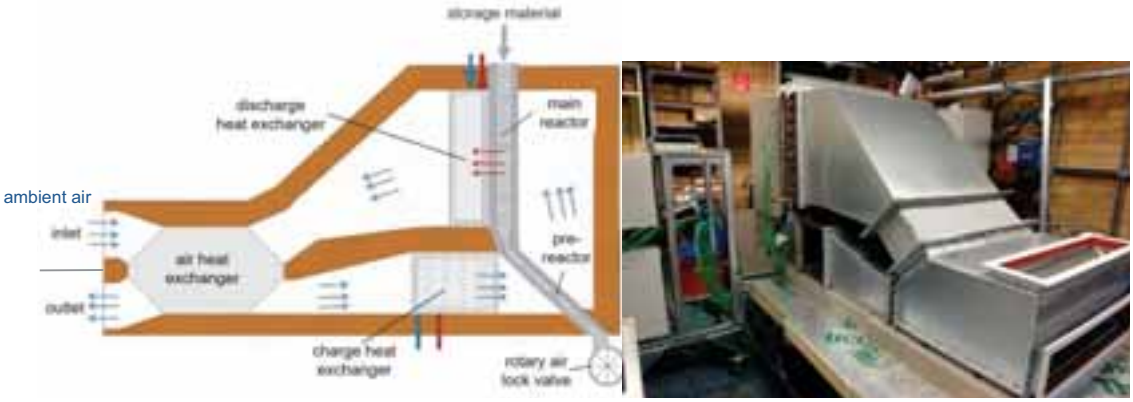

Fig. 5: Sketch of the reactor unit with a two stage reactor (left) and the reactor unit during construction integrated in the “hard ware in the loop” (HIL) test environment (right)

The reactor accommodates approximately 24 liters of storage material. The pre-reactor has a cross area of 0.245 m^2 and a bed depth of 0.02 m. The main reactor has a cross area of 0.49 m^2 and a bed depth of 0.05 m. A buffer vessel at the top of the reactor unit contains additionally 90 liters of storage material. The storage material enters the reactor unit from the buffer vessel and is conveyed through the reactor driven by gravity. The dosing of the storage material is handled by a customized rotary air lock valve. The rotary air lock valve is operated discontinuously triggered depending on the temperature behind the pre-reactor. The volume of each rotary air lock valve chamber is 0.7 liters, which corresponds to the storage material portions which are extracted at once.

In the experimental setup a vacuum exhaust transport system has been added at the outlet of the rotary air lock valve.

This system transports the charged/discharged storage material into a storage vessel, where it is stored water vapor tight until the next test sequence. As storage vessels for the charged and discharged storage material two metal bins have been used. The transport from the storage vessel to the buffer vessel is done manually before the beginning of a test sequence.

The newly developed reactor unit has been operated in a fully automated mode under realistic conditions in approximately 50 adsorption and desorption experiments, each with a duration between 4 and 20 hours. During discharging the set value for the reactor unit is the flow temperature of the heat load emulation loop. The reactor control adapts the air mass flow rate through the reactor to match the reactor adsorption output to the heat demand of the discharge heat exchanger. The mass flow rate and the return temperature of the heat load emulation loop were applied as boundary conditions. During charging the temperature at the inlet of the pre-reactor is the set value. To attain the required pre-reactor inlet temperature in this operation mode the air mass flow rate is adapted to the available charging power and the outlet temperature of the main reactor.

5. Results of HIL experiments

The following questions have been experimentally investigated in the HIL test facility:

- Is the reactor unit able to provide the expected thermal power?
- Is the reactor unit operating robust when dynamic heating demand is applied during discharging?
- Can the theoretically available energy storage density of the storage material be fully used in the reactor unit?
- Is efficient operation with the commercially available Na-X zeolite and the newly developed composite material 15$CaCl_2$/Ca-X in the reactor unit possible?

Reactor unit operation with different storage materials

A series of adsorption and desorption experiments have been successfully conducted with the commercially available zeolite Na-X and with the newly developed composite material 15 CaCl2/Ca-X.

In the results of the desorption experiments shown in figure 6 the storage material is desorbed at a temperature of 180 °C. The air mass flow rate through the reactor unit is controlled to provide a defined fluid temperature measured at the reactor inlet of $T_{f\text{-}in}$ = 192 °C. A portion of the storage material is released, when the fluid temperature measured at the outlet of the pre-reactor bed $T_{f\text{-}pr}$ reaches 180 °C. Figure 6 shows the temperatures and the specific humidity during desorption of the zeolite Na-X and during desorption of the composite material 15 $CaCl_2$/Ca-X.

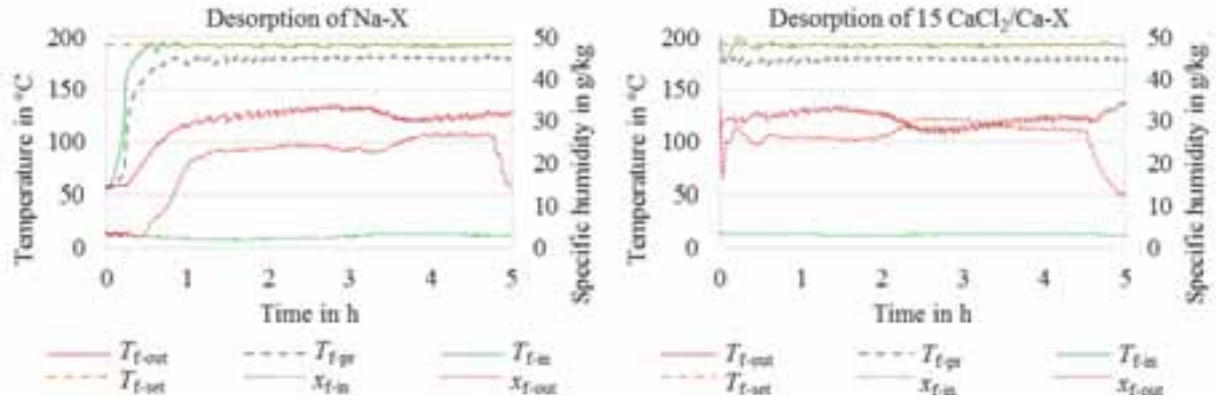

Fig. 6: Mean temperatures in the reactor unit as well as specific humidity and temperatures at the inlet and outlet of the reactor unit during a stationary desorption of Na-X zeolite (left) and the composite 15CaCl2/Ca-X (right)

As shown in figure 6 a stable desorption process continues over a period of about 5 hours for both storage materials. In both sequences similar fluid output conditions are reached over the major part of the shown period. The fluid temperatures at the reactor outlet ($T_{f\text{-}out}$) are in both cases in the range from 110 °C to 140 °C. The reactor outlet specific humidity is in both experiments in a similar range from 22 g/kg to 30 g/kg. After a starting period of approximately 1 hour (not included in the shown desorption of 15 $CaCl_2$/Ca-X) a stationary operation of the reactor is reached and continues until the buffer vessel at the top of the reactor runs out of storage material.

In the adsorption experiments shown in figure 7 the storage material has been discharged during an adsorption process with an air mass flow rate through the reactor unit of approximately 110 kg/h. The mean thermal output

power of the reactor unit during the adsorption process was 680 W. Due to control errors the specific humidity deviates slightly in the two shown experiments resulting.

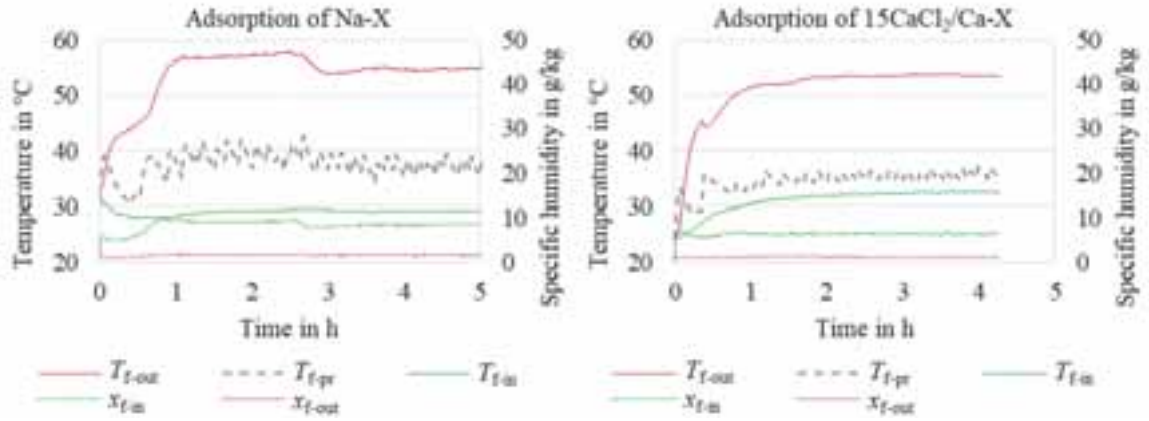

Fig. 7: Mean temperatures in the reactor unit as well as specific humidity and temperatures at the inlet and outlet of the reactor unit during a stationary adsorption of Na-X zeolite (left) and the composite 15CaCl2/Ca-X (right)

As shown in figure 7 in both experiments a stationary outlet temperature of approximately 54 °C has been reached after 3 hours of operation. After a period of approximately 20 to 30 minutes the material exchange starts in both cases. The process is stationary after approximately 1 hour. The temperature $T_{f\text{-}pr}$ at the outlet of the pre-reactor is slightly lower during the adsorption of the 15 $CaCl_2$/Ca-X compared to the adsorption of Na-X. This behavior is consistent with the results measured in a fixed bed reactor, which have been shown in figure 2. Although the zeolite-salt composite 15 CaCl2/Ca-X has a slower reaction kinetic, the double stage reactor design compensates this limitation and allows a stationary charging and discharging process.

Measured reactor unit output power

To determine if the reactor unit is able to provide the expected heat flow rate, multiple adsorption experiments have been conducted. In this series of experiments the specific humidity has been varied in the range from 5.5 g/kg to 13.5 g/kg. The heat load demand has been varied in the range from 500 W to 1800 W. As reference the theoretical heat flow rate is used which is calculated based on the measured water uptake from the air stream and the standard adsorption enthalpy of the Na-X zeolite of h_{ads} = 3456 kJ/kg determined by Mette et al. (2014b). The reactor unit output power is determined based on measured inlet and outlet temperatures and mass flow rate of the heat load emulation loop. Figure 8 shows the comparison between the theoretical heat flow rate and the measured reactor unit output power.

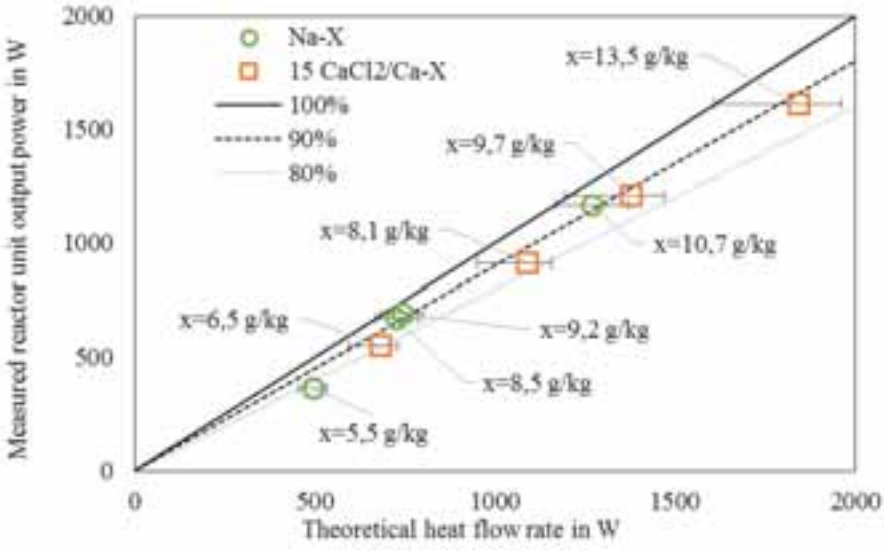

Fig. 8: Comparison of the measured reactor unit output power to the theoretical heat flow rate or power respectively obtainable for Na-X zeolite and the composite 15CaCl2/Ca-X at given boundary conditions

As shown in figure 8 in the most experiments the measured reactor unit output for the zeolite Na-X has reached

approximately 90 % of the theoretical heat flow rate. Operation conditions with lower humidity and operation with the zeolite salt composite 15 $CaCl_2$/Ca-X leads to a slight degradation of the efficiency. In this cases the measured reactor unit output is about 80 % of the theoretical heat flow rate.

Robustness of reactor unit operation

To ensure a robust operation of the reactor unit adsorption experiments with varying heat demand have been conducted. The heat demand variation has been applied through variation of the mass flow rate in the heat load emulation loop. Small deviations of the specific humidity in the air stream entering the reactor constitute an additional disturbance representing a dynamic environment. Figure 9 shows the results of an adsorption experiment.

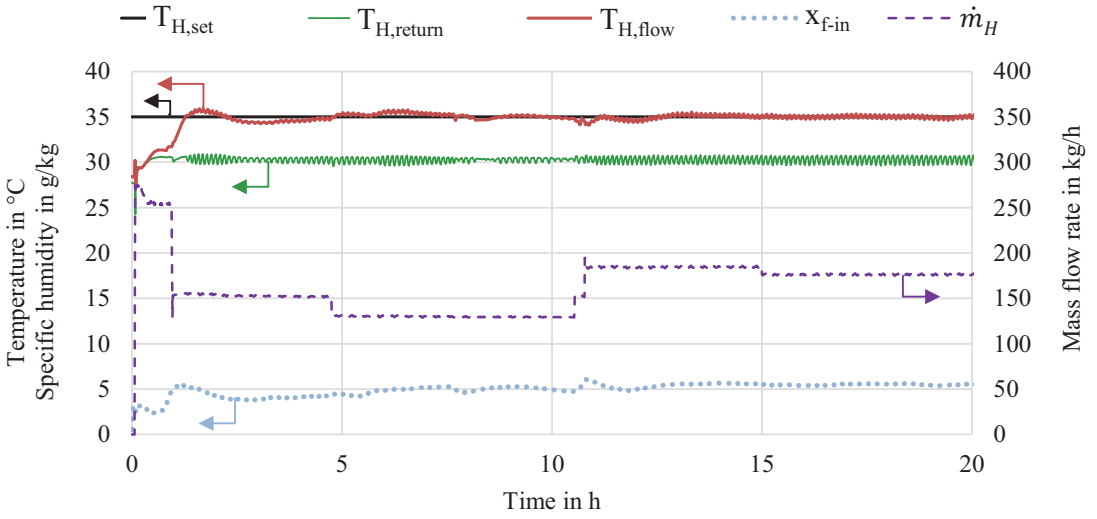

Fig. 9: Temperatures and the mass flow rate in the heating loop of the reactor unit and specific humidity at the inlet of the reactor unit during adsorption of Na-X zeolite with variations of the heat demand

The results show that the reactor unit managed to provide the required flow temperature of $T_{H\text{-}set}$ = 35 °C with only small deviations. The reactor unit control adapted the mass flow rate of the air through the reactor adequately and with it the required thermal power of the reactor. Thus both deviations due to the variation of the humidity and the variation of the heat demand were compensated.

Degree of storage material capacity utilization

The introduction of a pre-reactor with a buffer zone at the bottom theoretically allows to utilize the full storage material capacity. Therefore experiments have been conducted to investigate the degree of storage capacity utilization.

During adsorption and desorption operation of the reactor unit in the HIL test facility material samples of approximately 10 g have been extracted for analyses from the storage vessel. The samples have been taken from the storage vessel after finishing the experiment from volume portions of 10 l each. The water loading of the samples has been determined using a halogen moisture analyzer from the manufacturer Mettler Toledo. All samples were desorbed in the moisture analyzer to reference conditions (T_{ref} = 180 °C, $x_{f\text{-}ref}$ = 7.2 g/kg), where the change of the water loading between the state after the experiment and the reference conditions has been measured. From the change in the water loading the water loading at the end of the experiment has been calculated.

The theoretical storage capacity of the storage material is being utilized when the material reaches the equilibrium water loading at the given conditions. The equilibrium water loading has been calculated from the isotherms (Mette et al. 2014b) of the zeolite Na-X for each sample. The equilibrium was calculated according to the conditions ($T_{f\text{-}pr}$, $x_{f\text{-}in}$) in the lower part of the pre-reactor during the residence time of the material sample in the pre reactor. Figure 8 shows the results of the comparison of water loading X_s measured in samples and the calculated equilibrium water loading during an exemplary adsorption and desorption sequence. The samples are displayed over the normalized volume fraction. The normalized volume fraction is the total storage material volume used in the sequence divided by the reactor volume.

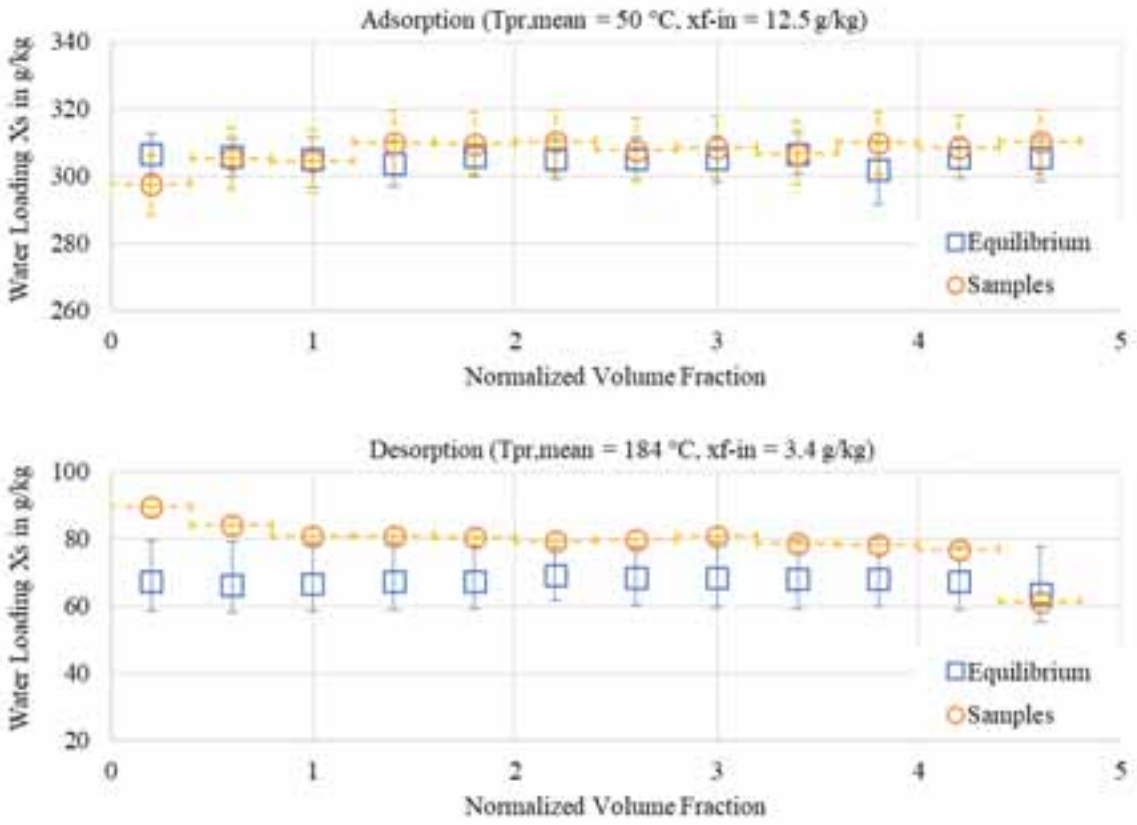

Fig. 1: Measured water loading of Na-X after an adsorption and desorption sequence in the reactor unit compared with the water loading of Na-X reached in equilibrium

The results for the adsorption experiment show that the measured and calculated equilibrium water loading matches well within the error margin of the experiment. In the shown desorption sequence the measured water loading is approximately 10 g/kg higher than the calculated equilibrium water loading. The measured water loading lift between the shown desorption and adsorption is 228 g/kg. Compared to the maximum water loading lift of 238 g/kg this shows a 96 % degree of storage capacity utilization. This experiment shows further that the charging and discharging of the storage material is robust over multiple filling volumes of the reactor. Only the first probe shows lowered water loading compared to the average values.

The shown experiment has been conducted for a combination of more than 10 adsorption and desorption sequences. The degree of storage capacity utilization in all experiments is in the range from 92 to 98 %.

6. Conclusions

Zeolites and zeolite salt composites are promising energy storage materials applicable for seasonal heat storage. Both storage materials have a high energy storage density but show different characteristics regarding the adsorption kinetic. Therefore a new reactor unit design has been developed. In this design the reactor is split into two stages: the main reactor and the pre-reactor. This two stage reactor allows an efficient and robust charging and discharging of the storage material under dynamic operation conditions.

For experimental investigation of the newly developed reactor unit a HIL test facility has been built up. The experiments carried out in the HIL test facility are an important step from laboratory to demonstration scale. The developed thermo-chemical store has been operated in the HIL test facility in a fully automated mode under realistic conditions. In stationary adsorption and desorption experiments using the pure zeolite Na-X and the zeolite salt composite 15 $CaCl_2$/Ca-X the expected operation behavior of the reactor unit has been confirmed. During discharging the rector unit shows an efficient operation: More than 80 % of the theoretical rector unit output power has been obtained for all investigated settings of humidity. Furthermore it has been shown, that approximately 95 % of the theoretical value of energy storage density provided by the storage material could be utilized with the newly developed two stage reactor design.

Abstract

A seasonal heat storage with phase change material (PCM) for a solar space heating and domestic hot water combisystem was tested in automated operation during charge with solar collectors. A water tank was operating as buffer heat storage. Based on measurements during a representative day with sunshine, the storage system performance was evaluated regarding charge with solar heat. It shows the system behavior during typical operation resulting from the control strategy. Heat transfer rates from the solar collector array (22.4 m^2 aperture area) to the heat stores reached a peak of 19 kW, when PCM was melted. 30 kWh of heat was transferred to the 750 l water volume as it heated up. Afterwards 46 kWh of heat was transferred to the segmented PCM storage. In total 56 % of the total irradiation on the tilted collector plane was utilized to heat the storage units. During PCM charge heat transfer fluid temperatures were increasing with the state of charge. This is in contrast to maximization of solar yield. However, the energy conversion efficiency (65 %) of the collector array was satisfying. By considering pump electricity consumption, an overall performance ratio of 30.8 was obtained.

Keywords: Solar combisystem; Seasonal heat storage; Demonstrator; Performance evaluation; Measurement.

1. Introduction

Sodium acetate trihydrate (SAT) can be utilized for heat storage in a solar combisystem for space heating and domestic hot water supply. It can be melted in sunny periods with solar heat, the PCM can cool down to the ambient temperature without solidifying and remain stable in supercooled state. The solidification can be initiated and the heat of fusion released later when heat is in demand. This concept was successfully applied to flat prototype heat storage units (Dannemand et al., 2016). SAT has a melting point of 58°C and a latent heat of fusion of 264 kJ/kg (Meisingset & Grønvold, 1984). The heat content of SAT composites was experimentally investigated by Kong et al. (2016).

A seasonal PCM heat storage demonstration system (Fig. 1) was designed based on calculations with a TRNSYS model (Dannemand et al., 2015). Four 150 l heat storage units have been assembled to a latent heat storage stack. They were tested for their ability to supercool in a stable way after being charged with a fluctuating heat source (Englmair et al., 2016). The system was built at the solar heating test facility of the Technical University of Denmark. Heat from a solar collector array, 7 panels of evacuated tubular collectors with an aperture area of 22.4 m^2, was used to charge a 750 l water tank (buffer storage). The excess yield of the collector array was utilized to heat up the latent heat storage. This additional storage volume aims to preserve heat for periods with shortage of solar energy supply.

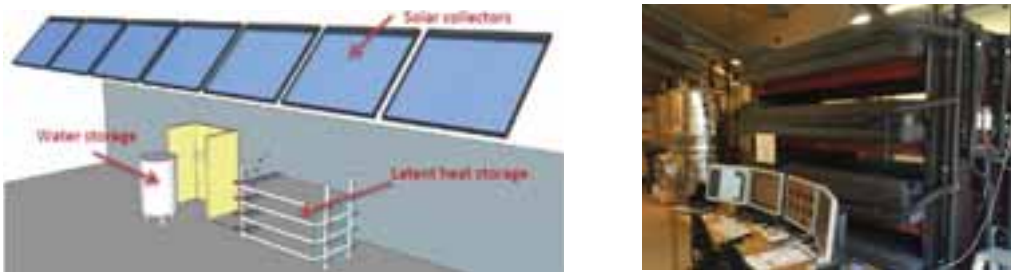

Fig. 1: Overall system design: Schematic drawing (left); Photography of water tank and PCM heat storage (right).

doi:10.18086/swc.2017.13.02 Available at http://proceedings.ises.org

Using evacuated tubular collectors as a heat source for seasonal PCM heat storage is a novel approach. The heat transfer to the buffer storage and the PCM units are of special interest, since the solar source is fluctuating and therefore an optimized control strategy has to be found. Therefore data from a sunny day (9th of September 2015) where the system was operating with the designed control strategy was analyzed. The performance evaluation was based on measured heat transfer rates and monitoring of pump electricity consumption.

Nomenclature:

Symbol	**Quantity**	**Unit**
G	global irradiance	[W/m^2]
H	global irradiation	[Wh/m^2]
P	electrical power	[W]
PR	performance ratio (daily)	[-]
$\dot{Q}$	heat transfer rate	[W]
Q	heat	[Wh]
T	temperature	[°C]
W	electrical work	[Wh]
η	efficiency	[-]

Subscript	**Quantity**
aperture	aperture area (collector field)
charge	buffer charge and PCM charge loops
charge buffer	buffer charge loop
charge PCM	PCM charge loop
coll	solar collector
coll loop	solar collector loop
P	pump
total	tilted surface (collector field)

2. Method

2.1 Hydraulic configuration

The solar collector array was formed with 7 panels of Thermomax HP 450 (heat pipe evacuated tubular solar collectors) from Kingspan Renewables. Each panel consisted of 30 tubes. The 7 panels were connected in 2 parallel circuits. One circuit with 4 panels in series and one with 3 panels in series as illustrated in Fig 2. Equal fluid flow rate in each collector panel was realized by means of regulation valves. A CM3 pyranometer from Klipp & Zonen was used for G_{total} measurements in between the two parallel collector circuits (location marked with the green star). A copper-constantan thermocouple (TT-type) was used for measurement of the collector outlet temperature (location marked with the red star). Because of its location in Denmark (latitude: 55.89), an inclination angle of 45° was chosen. The azimuth angle of the collector array was 12° towards east.

Fig. 2: Collector setup (schematic drawing).

Inside the building heat was transferred from the collector loop via a plate heat exchanger, operated in counter flow. At the secondary side, 2-way control valves were set in order to realize either buffer storage or

PCM charge. TYFOCOR LS (propylene-glycol and water mixture) was used as solar collector fluid and water was filled in the secondary side. In Fig. 3 operation schemes for the operation modes are drawn. Active pumps and open valves are marked in green; inactive pumps and closed valves in red.

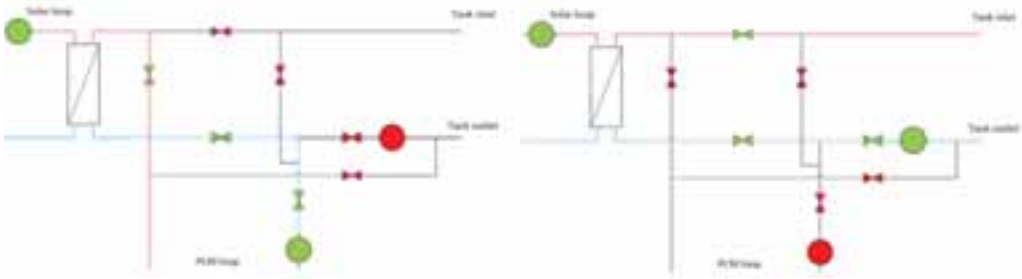

Fig. 3: Operation scheme with marked active components: PCM charge (left); buffer storage charge (right).

The forward pipe from the heat exchanger to the collector array was 21.5 m, the return pipe was 14 m. 8 meters of the forward and of the return pipe was inside of the building of the demonstration system and the rest was outside the building. Forward and return pipe in between the heat exchanger and the water tank were both 4.5 m long. From the heat exchanger to the PCM heat storage units the forward pipe reached 7-9 m and the return pipe reached 10-12 m, depending on the number of PCM units in charge. 20 mm (outer diameter) copper pipes in the collector loop and ¾" carbon steel pipes in the secondary loops were installed. Pipework, valves and the heat exchanger were insulated with 19 mm of elastomeric foam.

All hydraulic loops were equipped with magnetic induction flow meters (class 2) in the return flow, copper-constantan thermocouples (TT-type) for temperature measurements, thermopiles (TT-type) for temperature difference measurements and motor valves. Regarding to the norm (EN 1434), the maximum measurement error of class 2 flow sensors was 2.5 % in the operation range. This accuracy was proved by tests for all flow meters installed. Electricity consumption was detected by an installed wattmeter for each pump.

2.2 Operation sequence

The collector loop pump was activated when the temperature difference between the collector outlet temperature and the temperature at the bottom of the water storage exceeded 10 K (lower threshold value). The water tank was charged until a temperature of 55°C was reached in the middle of the water tank. This value was chosen as the upper threshold value for the control. Buffer storage charge stopped 5 minutes after either the lower or upper threshold value was met.

When the upper threshold for the buffer storage was met, collector loop circulation stopped until a collector outlet temperature of 70°C was measured. Then the PCM charge mode was activated. Melting of SAT composites required higher temperature, therefore previous buffer storage charge was beneficial. In order to achieve the full melting of the PCM, which is required for stable supercooling, inlet temperatures to the PCM units of up to 93 °C and high water flow rates were applied.

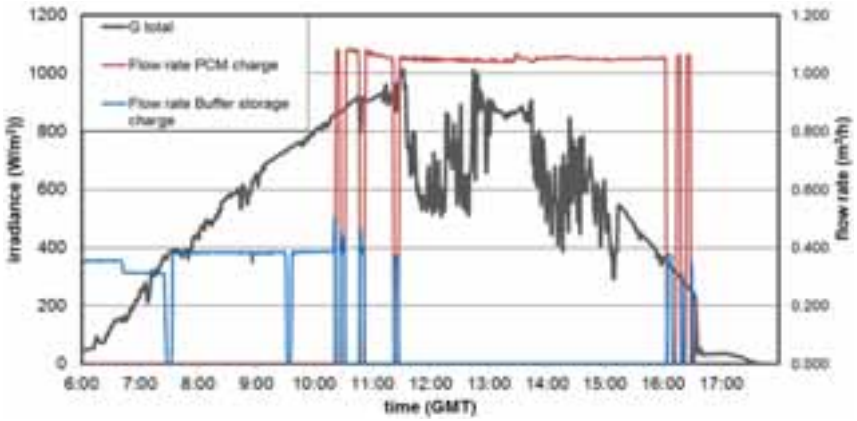

Fig. 4: Development of irradiance on the collector array and water flow rates applied.

Fig. 4 shows the flow rates applied on the secondary side of the plate heat exchanger. At 7:30 h the operation mode was switched from manual to automated control. The buffer storage was charged with a flow rate of 6.3 l/min (blue curve). Although at 10:15 h the buffer storage was already heated up, some periods of additional demand around noon and in the evening were detected by the control system. The collector array was shaded from 16:20 h on. As a consequence, the operation stopped with a short delay. A water flow rate of about 16.5 l/min (red curve) was applied when the PCM storage was charged. Due to the limited heat exchange capacity rates of a single PCM unit (Englmair et al., 2016) the units were charged in parallel.

2.3 Performance evaluation

The evaluation was based on heat transfer rates in the charging loops. In Fig. 5 the thermopiles (TP) mark the location where the heat transfer rates were evaluated. Also inlet-and outlet temperature measurements were located there. Beside temperature difference, measured flow rates, temperature dependent densities and specific heat capacities (resulting from temperature measurements) of the heat transfer fluids (solar collector fluid and water) were used for calculation.

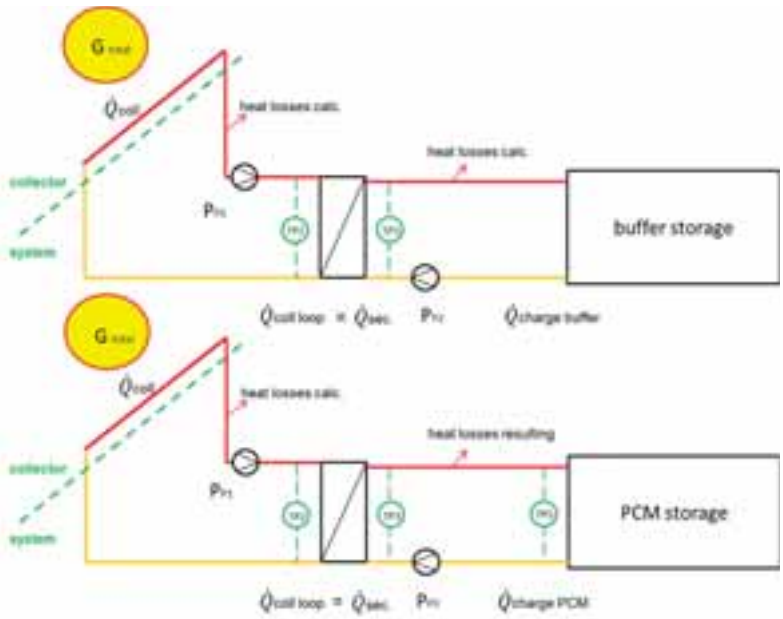

Fig. 5: Schematic evaluation model.

Pipe heat losses between the solar collector and the heat exchanger and between the heat exchanger and the buffer storage are included in the analyses. The heat loss in the solar collector loop was determined by calculations based on length, diameter and insulation thickness for the pipes and on measured temperatures. The heat loss in the PCM charge loop was resulting from the difference of heat transfer rates between TP3 and TP5. Thermal collector power was resulting from adding pipe heat losses to the calculated heat transfer rates at the plate heat exchanger.

Transferred heat was resulting from integration of heat transfer rates over time, considering the duration of each charging period.

As reference for evaluation, the solar potential was defined by the daily solar irradiation ($H_{aperture\ total}$) on the aperture area of the tilted collector surface. The course of the solar irradiance (G_{total}) is drawn in Fig. 4 (grey curve). The overall energy conversion efficiency was defined by the ratio of heat transferred to the sink (Q_{charge}) and the solar potential (formula no. 3).

$$\eta_{collector} = \frac{Q_{coll}}{H_{aperture\ total}} \quad (1)$$

$$\eta_{system} = \frac{Q_{charge}}{Q_{coll}} \quad (2)$$

$$\eta_{overall} = \frac{Q_{charge}}{H_{aperture\ total}} \quad (3)$$

Energy conversion efficiency at the collector (formula no. 1) and heat transfer efficiency in the system (formula no. 2) were based on the system border to the collector array, defined in Fig. 5. This approach enabled a closer look on the dependency of heat losses to the water temperatures during the two charging modes.

In terms of electrical power, control plays a minor role in solar heating systems. Therefore the consumption of pumps (marked in Fig. 5) was evaluated with the following performance ratios:

$$PR_{charge\ buffer} = \frac{Q_{charge\ buffer}}{W_{P1\ charge\ buffer} + W_{P2}} \quad (4)$$

$$PR_{charge\ PCM} = \frac{Q_{charge\ PCM}}{W_{P1\ charge\ PCM} + W_{P3}} \quad (5)$$

$$PR_{charge\ overall} = \frac{Q_{charge\ buffer} + Q_{charge\ PCM}}{W_{P1} + W_{P2} + W_{P3}} \quad (6)$$

As reference, their electrical work was logged during charging periods (indicated by the flow rates in Fig. 4). The collector loop pump (P1) was in operation during all periods, while P2 operated during buffer storage charge and P3 during PCM storage charge.

3. Results and discussion

On the selected day, the system was only in charging operation. Heat transfer rates, the daily energy balance as well as efficiency values were evaluated.

3.1 Heat transfer rates

In Fig. 6 the development of heat transfer rates of the collector loop (black marks), of the buffer storage charge loop (blue marks) as well as of the PCM charge loop (red marks) are drawn over time. The collector loop power followed G_{total} (grey curve in Fig. 4). During PCM charge peak values of up to 19 kW were reached when the mode has been activated (10:15 h), as well as during cascading of the number of PCM units (13:30 h – 14:00 h) in the charging loop.

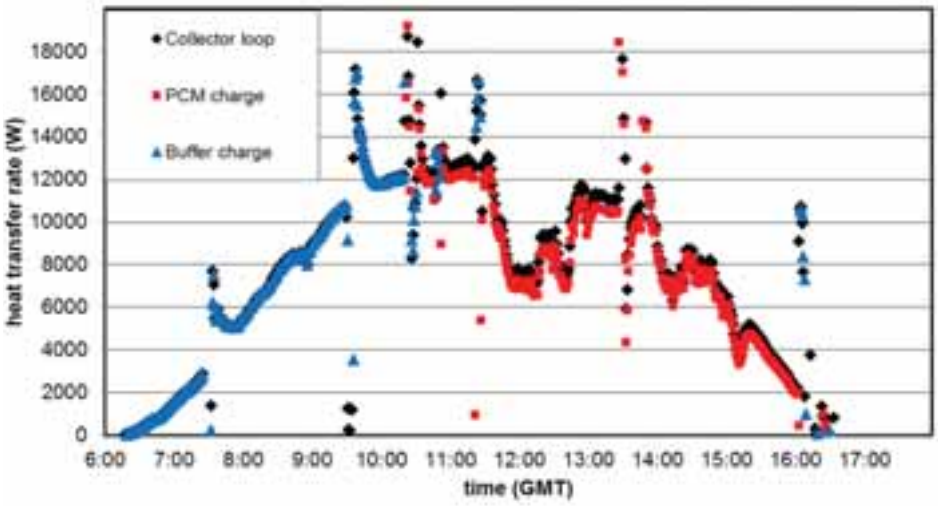

Fig. 6: Heat transfer rates during the course of the day.

Because the buffer storage is situated close to the plate heat exchanger, the collector loop power almost equaled to the heat transferred to the water tank. Buffer storage charge was interrupted two times before noon. Significant heat losses occurred in the PCM charge loop. The total duration of heat transfer was 10 hours.

The data were noisy through to the setting of the control system. Cascading of PCM units during PCM storage charge is necessary to match the fluctuating collector power with the limited heat transfer capacity of

PCM units. In contrast, intermediate buffer storage charge during periods of PCM storage charge only happened due to small internal temperature changes in the water tank. This cooled down the collector array and system components (collector loop, plate heat exchanger, pipework). Therefore a temperature hysteresis for full buffer charge (end criterion: 60°C, start criterion: 50°C) was implemented in the control after the present initial tests.

3.2 Daily energy balance

The energy balance was analyzed by integration of the heat transfer rates over time. Fig. 7 shows the solar potential (black curve) compared to the transferred heat during the course of the day. The difference between the collector loop energy (red curve) and the calculated collector output (red dotted curve) was a result of the pipe heat losses in the collector loop. During the total period of operation, the solar potential was 135 kWh. From this potential 79 kWh of energy was supplied by the collector loop to the heat storage system. 76 kWh (53 % of the solar potential) of heat was stored. Most heat was transferred to the PCM modules (46 kWh) in the period from 10:30 h to 16:00 h. This means an average net heat transfer rate of 9 kW. To the buffer tank (green curve) the highest share of energy (25 kWh) was transferred until 10:00 h, while the rest was transferred later, in four short periods.

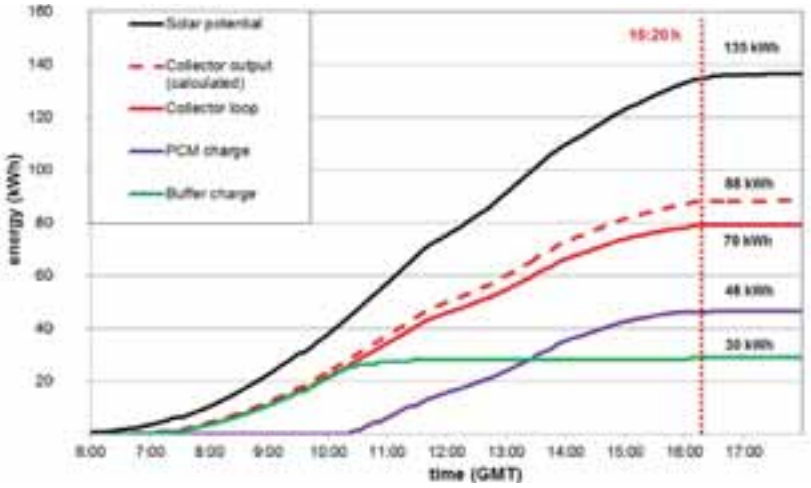

Fig. 7: Development of heat transfer during the course of the day.

During buffer storage charge only minor heat losses occurred in the system (collector loop and charging loop), while significant heat losses (8 kWh) occurred during the charge of the PCM units with high solar collector fluid and water temperatures.

The buffer storage charge means an average temperature increase of 35K in the water tank (750 l), which was considered to be sufficiently high to cover the heat demand of an energy efficient single family house throughout the following day. Full charge of a single PCM unit (from solid state at ambient temperature) required 27.4 kWh (Englmair et al., 2016). However, since up to 3 PCM units were charged in parallel, 2 consecutive sunny days are assumed to be necessary to ensure full PCM unit heat up to a uniform temperature of 80°C. Only in this way the supercooling ability of charged PCM units can be enabled.

3.3 Energy efficiency

Based on the daily energy balance, average energy efficiency factors are obtained:

$$\eta_{collector} = 0.65; \qquad \eta_{system} = 0.86; \qquad \eta_{overall} = 0.56$$

As a result of energy conversion of the collector, 65 % of the solar potential was transferred in form of heat to the system. The system efficiency was 86 % on the reference day. 10 % of heat in the collector loop and 4 % of heat in the secondary loop were dissipated via heat losses to the ambience. So, in total 56 % of the solar potential was transferred to the heat sink.

Further information can be seen from the course of energy efficiencies in context to the collector outlet temperature in Fig. 8. The energy conversion efficiency at the collector (grey scattered curve) was low until

9:00 h. During this period and all components of the collector loop as well as the heat transfer fluids were heating up. Peak values occurred due to changes of operation modes. After 9:00 h $\eta_{collector}$ reached a level of above 65 %. Because of rising heat transfer fluid temperatures (indicated by the collector outlet temperature – red curve) $\eta_{collector}$ fell throughout the day. Shifts between buffer and PCM charge modes (Fig. 4) caused collector outlet temperature jumps. During PCM charge the heat transfer fluid temperatures were coupled to the state of PCM unit charge.

After 15:00 G_{total} and the efficiency values fell down dramatically and the heat transfer fluid temperatures remained high. When the operation stopped, heat remained in the hot heat transfer loops and in the solar collector.

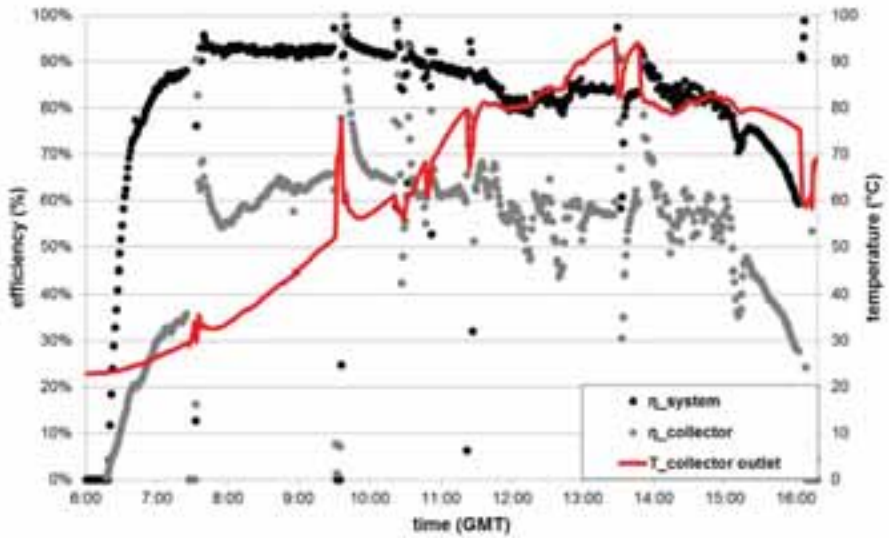

Fig. 8: Development of system efficiency, energy conversion efficiency at the collector and collector outlet temperature during the course of the day.

The system efficiency (black scattered curve) showed similar behavior. After the pipework was heated up (until 7:30 h), η_{system} remained above 90 % during buffer storage charge. During PCM charge, when heat transfer fluid temperatures raised and a longer pipework was used, η_{system} was in the range of 80-90 % for long time. Lower values were observed around noon, when G_{total} was fluctuating at lower level than before noon. Decreasing system efficiency after 15:00 h was a result of lower heat transfer rates at high fluid temperatures. This means that during that period a high share of heat was dissipated to the ambience.

Longer periods of buffer storage charge (lower heat transfer fluid temperatures) at the end of the day (when G_{total} is decreasing) would maximize the daily energy yield. Increased η_{system} and $\eta_{collector}$ values would be resulting. However, PCM unit charge is beneficial after the buffer heat storage is sufficiently heated for domestic heating applications.

3.4 Pump efficiency

The secondary loop pump (P2) was powered with 8 W to achieve the set water flow rate during buffer charge. To match the heat transfer capacity rate of the solar collector fluid at the heat exchanger to the water, a collector loop pump power of 70 W was required. During PCM charge the pumps were set at 90% of their maximum operation speed to enable high fluid flow rates. The collector loop pump power reached 390 W and the secondary loop pump (P3) was operating at 120 W. The resulting electricity consumptions are given in Tab. 1:

	W_{P1} (Wh)	W_{P2} (Wh)	W_{P3} (Wh)
Buffer charge	167	22	none
PCM charge	1716	none	548
Overall charge	1883	22	548

Tab. 1: Pump electricity consumption during charging periods.

The electrical power consumption of pumps during PCM charge (about 5 hours of operation) was 2.5 kWh, while for buffer storage charge only 0.2 kWh were consumed. Based on the previous definitions, the following performance ratios were resulting:

$PR_{charge\ buffer}$ = 154; $PR_{charge\ PCM}$ = 19.1; $PR_{charge\ overall}$ = 30.8

The highest performance ratio was occurring during buffer storage charge (154), while the performance ratio during PCM module charge was about 8 times lower. The overall charge performance ratio was 30.8. It was found that the electricity consumption for PCM charge can be lowered by application of different pump types. Also, a reduction of flow rates during PCM charge could lower the electricity consumption. However, this would lower the heat transfer in the PCM units.

4. Conclusions

A demonstration system on seasonal heat storage, utilizing the principle of stable supercooling of SAT, was tested for its functionality during charge on a representative sunny day. System control enabled interplay between solar collectors, buffer heat storage and PCM heat storage:

- The applied collector array enabled sufficiently high heat transfer for both, buffer storage and PCM charge. The heat transfer reached peak values of more then 12 kW in both operation modes. When modes were changed or interrupted, heat transfer rates of up to 19 kW occurred.
- During PCM charge the HTF temperatures were increasing with the state of PCM charge. This is in contrast to maximisation of solar yield. Since the number of PCM units in operation was variable, no restrictions for heat transfer from the collector array were observed.
- Regarding to the required high collector outlet temperatures (up to 95°C) during PCM charge, the energy conversion efficiency of the collector array was satisfying. 65 % of the solar potential was converted into heat and transferred to the system.
- 76 kWh (86 %) of available heat was stored. During buffer storage charge only minor pipe heat losses occurred. 46 kWh of heat were charged to the PCM storage when 8 kWh (10% of available heat) were dissipated via hydraulic components to the ambience.
- The PCM charge performance ratio (19.1) and therefore also the overall performance ratio (30.8) were quite low, although standby consumptions of pumps and of the control system were not considered in their calculation.

The resulting operation sequence proved functional system behavior. Significant heat losses due to a long pipework, frequent mode-switches and rather high pump electricity consumption during PCM charge were identified as areas for potential improvements.

EXPERIMENTAL AND THEORETIC INVESTIGATIONS OF THERMAL BEHAVIOR OF A SEASONAL WATER PIT HEAT STORAGE

Jianhua Fan[1], Junpeng Huang[1], Angelos Chatzidiakos[1], Simon Furbo[1]

[1] Department of Civil Engineering, Technical University of Denmark, Kgs. Lyngby, Denmark

Abstract

Seasonal heat storages are considered essential for district heating systems because they offer flexibility for the system to integrate different fluctuating renewable energy sources. Water pit thermal storages (PTES) have been successfully implemented in solar district heating plants in Denmark. Thermal behavior of a 75,000 m^3 water pit heat storage in Marstal solar heating plant was investigated experimentally and numerically. Temperatures at different levels of the water pit storage and temperatures at different depths of the ground around the storage were monitored and analyzed. A simulation model of the water pit storage is built to investigate development of temperatures in and around the storage. The calculated temperatures are compared to the monitored temperatures with an aim to validate the simulation model. Thermal stratification in the water pit heat storage and its interaction with the ground are elucidated by calculations using the validated CFD model.

1. Introduction

Heat storages are considered essential for a district heating system with a large share of renewable energies due to the flexibility they offer to accommodate the fluctuating nature of the renewable energy sources such as wind and solar energy. The most promising heat storage solutions are tank storage systems, water pit thermal storage (PTES), aquifer thermal energy storage (ATES), borehole storage (BTES) and water-gravel pit storage (Pavlov and Olesen 2012, Heller 2000). Moreover, cases of latent heat storage using phase change materials are also investigated but there are still some barriers to overcome before applying them to large scale (Sharma etc 2009). Large scale water pit thermal energy storages are viable solutions both economically and environmentally since these stores are simple in construction and relatively cheap. Larger storage volumes lead to increased efficiency in practice, since the heat losses do not increase with the volume proportionally. With a large water pit heat storage, solar fraction of a district heating system could be significantly increased to for example 50% of the heat demand of the district heating network. PTES have been successfully used in district heating plants in Denmark, for example, in Marstal (75,000 m^3), Dronningland (60,000 m^3), Vojens (200,000 m^3) and Gram (120,000 m^3).

Thermal behaviors of water pits as seasonal heat storages have been investigated both experimentally and theoretically. Kielsgaard Hansen et al. (1983) investigated first a small 500 m^3 pilot water pit heat storage at the campus of the Technical University of Denmark. Later, Kübler et al. (1997) presented investigations on a pilot heat storage with about 600 m^3 volume built in Rottweil. The pilot heat storage was applied as short term storage in connection with a combined heat and power (CHP) plant. The storage container was made of concrete with a stainless steel liner and mineral wool as insulation. The aim of the paper was to demonstrate the feasibility of the technology and to gain practical experience for the construction of larger stores. A gravel /water storage pit was built in Steinfurt, Germany (Pfeil M. 2000). The ecological compatibility of the used materials in the storage was proved. Another focus of the paper was analysis of the cost-reduction potential of the PTES (Pfeil M. 2000). Thermal behavior of a model PTES was experimentally investigated in a test rig and numerically investigated by means of CFD simulations (Change and Wu, 2017). The investigated PTES was a scaled down model that facilitates measurements in a test rig. Thermal behaviors of PTES in real operation with a volume as large as 70,000 m^3 was not found.

Marstal's PTES was developed, based on the experience from the small demonstration water pits, and funded under the SUNSTORE 4 project, as part of the "EU flag projects" (Kate 2013). Its aim is to increase the solar fraction of the plant up to 55% of the thermal energy production, focusing on sustainability, increased efficiency and low costs.

doi:10.18086/swc.2017.13.03 Available at http://proceedings.ises.org

Marstal's 75,000 m^3 PTES was commissioned in 2012 and it has a capacity of 6.96 GWh according to PlanEnrgi (Jensen 2014). The operating temperatures vary depending on the season and the depth of the water layer, however the pond is designed to operate in a range of 10-90 °C.

The aim of the paper is to investigate thermal behavior of the large water pit heat storage in Marstal solar heating plant. Temperatures at different levels of the water pit storage and temperatures at different depths of the ground around of the storage were monitored and analyzed. A simulation model of the water pit storage is built to investigate development of temperatures in and around the storage. The calculated temperatures are compared to the monitored temperatures with an aim to validate the simulation model. Thermal behavior of the water pit heat storage and its interaction with the ground are elucidated.

2. Measurements of the PTES in Marstal

Located in a small island Ærø in the southern part of Denmark, the 75,000 m^3 water pit heat storage has an outer dimension of 98 m × 98 m excluding the dam around the storage, see Fig. 1. The depth of water in the storage is 16 m. An illustration of the design of the water pit thermal energy storage is given in Fig. 2. After commissioning of the PTES in 2012, detailed measurement have been carried out in in the period 2014-2016 to evaluate thermal performances of the storage. The following monitoring equipment is installed on the water pit heat storage:

‹ Temperature and volume flow sensors in inlet/outlet pipes
‹ Temperature sensors inside the water storage at different levels
‹ Temperature sensors in the ground at different depths
‹ A heat flux sensor in the floating top cover

Fig. 1: Bird view of the water pit heat storage in Marstal Solar heating plant

The sensors in the inlet/outlet pipes are located at the end of the transmission pipes 300 m away from the pit storage. The volume flow rate is measured with flow meters in m^3/h with an accuracy of 2% (Schmidt 2013). The temperature sensors are PT resistance thermometers with an accuracy of +/- 0.1 K (Schmidt 2013).

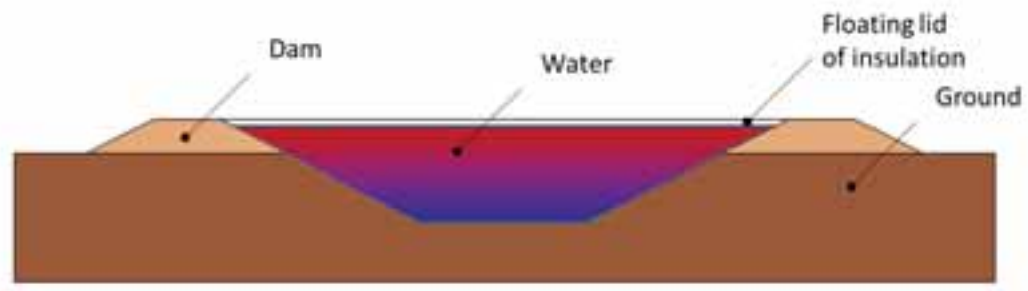

Fig. 2: Illustration of the design of a water pit thermal energy storage

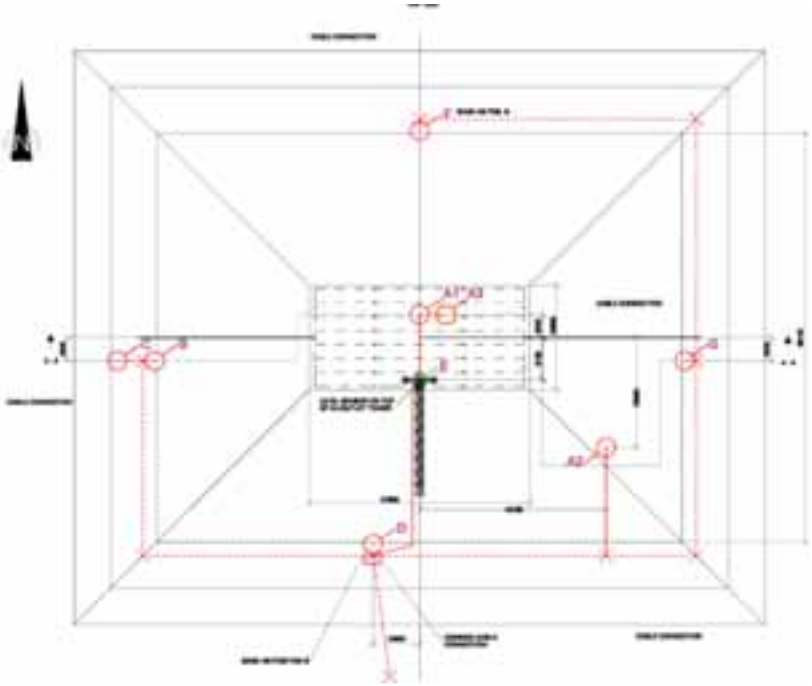
The placement of the sensors in the water pit heat storage are indicated as circles in Fig. 3, where sensors A1 and A2

measure water temperatures of the store at different depths, while the sensors B, C and G measure temperatures of the ground at different levels. Moreover, at A1 a heat flux sensor is installed in the lid including one temperature sensor on the top and one temperature sensor on the bottom surface of the insulation layer.



(A)

Fig. 3: Schematic illustration of the measurement sensors

3. Numeric method

A simplified CFD model of the water pit heat storage in Marstal is built using a commercial CFD software Ansys Fluent (Ansys 2016). The model includes the water volume in the store and the inlet/outlet openings. An inlet/outlet pipe with three inlet/outlet openings is placed in the middle of the PTES. Fig. 4 shows mesh of the simplified CFD model of the PTES. Grid lines on the side and the bottom surfaces of the PTES and grid lines on two vertical cut planes across the middle of the inlet/outlet pipe are presented. In the area around the inlet/outlet pipe, a denser mesh is assigned in order to better resolve fluid flow and heat transfer caused by inlet and outlet flows. In total 1.6 million hexahedron elements were used to mesh the model.

Fig. 4: Mesh of the simplified CFD model of the PTES in Marstal

Heat loss coefficients for the top cover is determined based on given design of the floating lid and on measurements by a heat flux sensor at A1 while heat loss coefficients and boundary conditions for the side and the bottom surfaces of the store are evaluated by transient simulations using a simplified 2D CFD model of the ground around the store. Fig. 5 shows the 2D model of the water pond and the ground around the pond. It is assumed that the pond is symmetrical therefore only half of the water pond is modelled. The whole model has a dimension 74 m * 41 m with an aim to minimize the thermal influence of the pond on the bottom and the side boundary surfaces. Since temperature at the bottom and the side boundary surface of the 2D model is not influenced by the pond during the investigated 4 months period, these boundary surfaces are defined as adiabatic walls.

The 2D model calculates the heat transfer between the water pond surface and the ground around the store, which is used to determine heat loss coefficients of the bottom and the side surface of the PTES. The obtained heat loss coefficients are used as input in calculations using the 3D CFD model of the PTES.

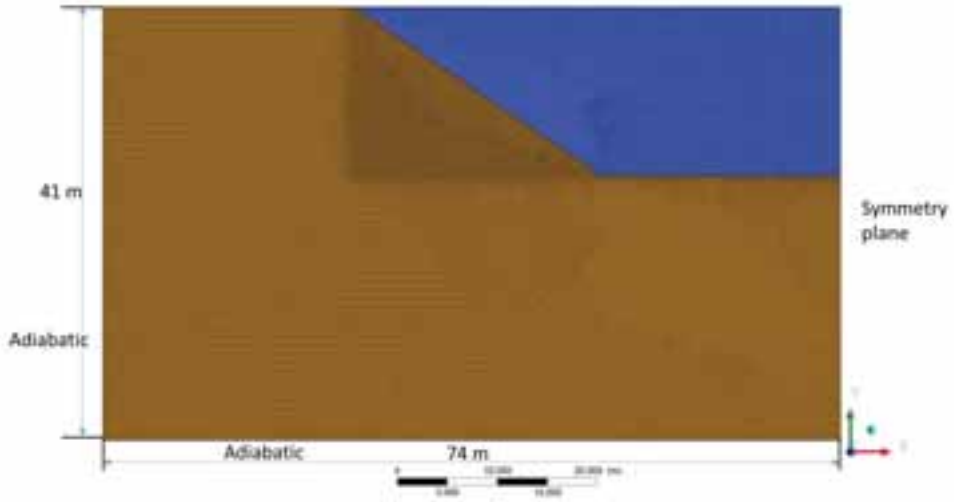


Fig. 5: A 2D ground model including the water pond and the ground around the pond

Water is used as the heat storage media. Properties of water and their dependences on temperature are shown as follows:

Density, [kg/m^3] $$\rho = 863 + 1.21 * \mathrm{T} - 0.00257 * \mathrm{T}^2 \quad (1)$$

Dynamic viscosity, [kg/(ms)] $$\mu = 0.0007 * (\frac{T}{315})^{-5.5} \quad (2)$$

Thermal conductivity, [W/(mK)] $$\lambda = 0.375 + 8.84 \times 10^{-4} * T \quad (3)$$

Specific heat, [J/(kgK)] $$Cp = 4432.6 - 1.819 * \mathrm{T} + 0.0033 * T^2 \quad (4)$$

where T is fluid temperature, [K].

Calculation of Rayleigh number shows that the flow in the PTES is laminar in most parts of the store, therefore the laminar model is used in the calculation. Transient CFD calculations are performed with Boussinesq approximation. The PRESTO and second order upwind method are used for the discretization of the pressure and the momentum/energy equations respectively. The SIMPLE algorithm is used to treat the pressure-velocity coupling. The transient simulations start with a temperature distribution in the PTES determined by measurements. A zero velocity field is assumed at the start of all simulations. The calculation is considered convergent if the scaled residual for the continuity equation, the momentum equations and the energy equation are less than 10^{-3}, 10^{-3} and 10^{-6} respectively. The simulation runs with a time step of 5 s and a duration of 7-10 h.

4. Heat losses from the store

One important boundary of the model is thermal losses of the store which consists of two heat losses: losses from the top floating cover to the ambient air and losses from water in the pond to the ground. Heat loss from the top cover of the store is determined based on measurement by a heat flux sensor placed on the cover and properties of the

insulation material, see location A1 in Fig. 3. Since it is only a single point measurement at a fixed location, precise measurement of heat losses for the whole cover is difficult. For instance, the measurement is not able to measure extra heat losses caused by periodic ventilation of the top cover, thermal bridges through the manhole, joints and extra heat losses caused by decreased insulation property of deformed insulation material observed in some places of the cover. The measured heat loss from the cover is therefore modified with an aim to achieve an energy balance of the water pond in a measurement period of one year. The heat fluxes of the floating cover used in the paper are in the range of 22-34 W/m^2.

Tab. 1: Heat fluxes from the top floating cover

Days calculated by the 3D CFD model	Heat flux from the top cover [W/m^2]
October 07	34
August 03	24.2
February 18	22
April 22	24.2

From Table 1, it can be seen that among the four days investigated, the heat flux is the largest on October 07 and the smallest on February 18. It can be explained by the temperature difference between the water at the top layer of the pond and the ambient air. On October 07, the water pond had a relatively higher temperature due to charging during the summer while the ambient air temperature is around 10-20ºC. In February 18, the ambient air temperature is much lower and the temperature at the top layer of the pond was significantly decreased due to discharge of the PTES throughout the winter.

Heat losses from the PTES to the ground are more difficult to measure since it is influenced not only by yearly fluctuation of the ambient air temperature, but also by heat transfer in the soil. In order to locate a ground boundary of the water pond that is not influenced by temperatures of the water pond, a large amount of soil volume has to be included in the CFD model. As a result, the CFD model might be extremely large, making it too time consuming to carry out CFD simulations. In this paper, heat transfer between the water pond and the ground is calculated in a separate 2D model, see Fig. 5. In the 2D model, measured temperatures at different layers of the water pond were used as initial conditions of the store. Fig. 6 shows temperature distribution in a vertical cut plane of the ground around the PTES. View of the whole water pond is shown in the figure to the left while a magnified view of the upper corner of the PTES is shown to the right.

The 2D ground model calculates the heat transfer between the water pond surfaces and the ground around the store, which is used to determine heat loss coefficients of the water pond surfaces. The heat loss coefficients are used as input in the 3D CFD model of the PTES.

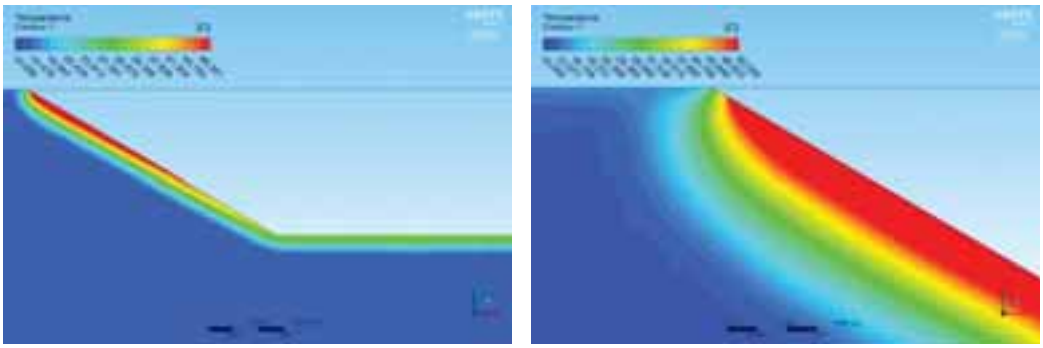

Fig. 6: Temperature distribution in a vertical cut plane of the ground around the PTES (left: side and bottom surface, right: a magnified view of the upper corner of the PTES)

Fig. 7 shows the calculated heat transfer coefficients between the sides of the water pond and the ground soil. The blue curve and the orange curve show respectively the heat transfer coefficients obtained by the simplified 2D model and the coefficients used in the 3D CFD model by means of a user defined function. As shown in Fig. 7, the heat loss coefficient of the sides of the PTES is around 0.15 W/m^2/K at a depth of 16 meters. The heat loss coefficient increases slightly with a decrease of the depth. At a depth of 2 meters, the heat loss coefficient is around 0.2 W/m^2/K. For surface area within 2 meters deep, the heat loss coefficient increases significantly due to the influence of ambient

conditions. At the bottom surface of the PTES, the heat loss coefficient is found to be 0.1 W/m^2/K.

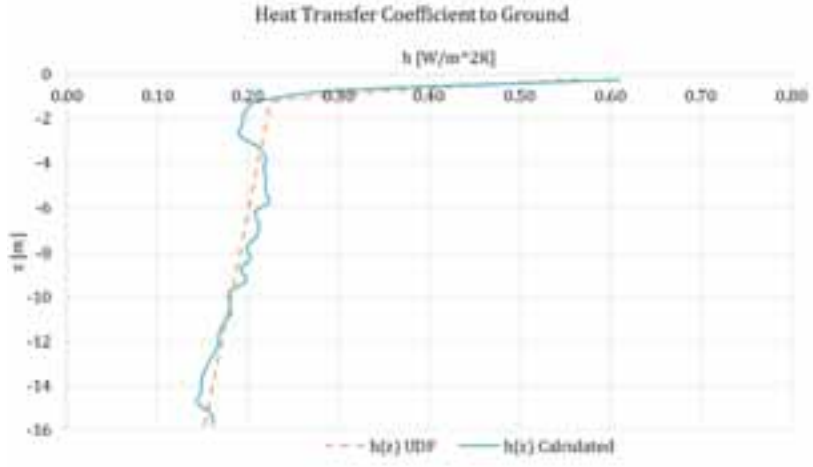

Fig. 7: Heat transfer coefficients between the sides of the water pond and the ground soil.

The 2D ground model was also used to determine soil temperature around the water pond. Since temperature of the ground around the store depends on both the depth of the soil and the time of the year, the distribution pattern of the temperatures was determined by calculation using the 2D ground model, while the absolute level of the temperature was determined by measurements at the location B.

Fig. 8 shows ground temperatures on the side of the water pond in different times of the year. Among the investigated four periods, the ground soil temperature is the highest in October and the lowest in February, which indicates a strong influenced by the temperatures of the pond and the ambient air. A clear pattern can be seen from the curves: relatively lower temperature at both the top and the bottom of the pond and higher temperature around 6 m below the ground surface. A lower temperature at the bottom of the pond could be explained by strong thermal stratification in the pond. Due to thermal stratification, temperature of water layer at the bottom of the pond is relatively lower, therefore a lower temperature is observed at 16 m below the ground surface. While a lower temperature close to the ground surface could be explained by cooling of soil by the ambient air with a lower temperature.

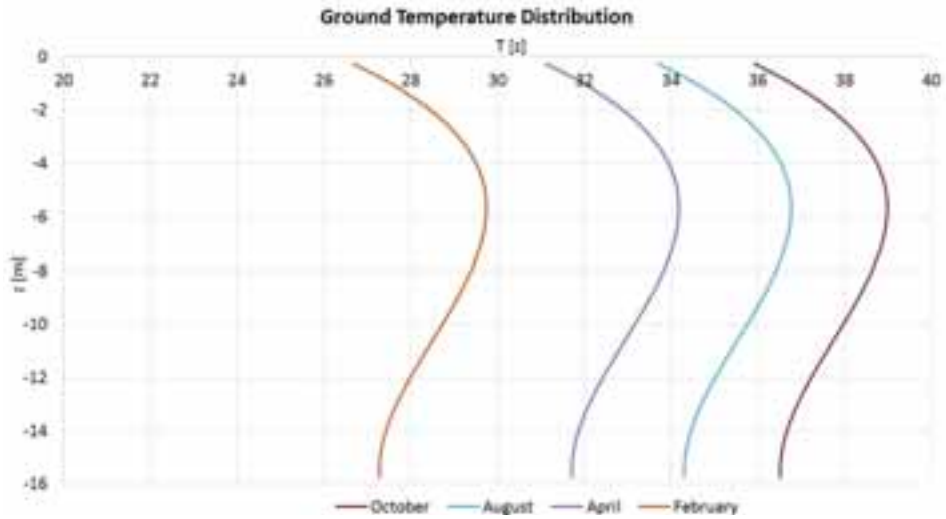

Fig. 8: Ground temperature on the side of the water pond

5. Thermal stratification in PTES

Validity of the CFD model is investigated by comparing the CFD calculated thermal behaviors of the PTES with the measurements. The investigation was carried out for 4 scenarios including two discharges and two charges of the PTES, see Table 2. In the CFD simulations measured temperatures of the water pond and the ground were used as initial conditions of the PTES. The transient flow rate and temperature of the inlet flow to the PTES were measured

and used as boundary conditions for the inlets by means of user defined functions. During charge of the PTES, the average temperatures of the inlet flow are 83.3ºC and 77.3ºC on August 03 and April 22 respectively. The average discharge temperature are 44.4ºC and 36.5ºC respectively on October 07 and February 18. The CFD calculated temperatures at the outlet and at different levels of the pond were compared to the measured ones.

The CFD model is able to calculate heat transfer and the convective, buoyance driven flow in the PTES. The development of water temperature is elucidated by means of the transient CFD simulations. Thermal stratification in the store during charge and discharge of the store is evaluated.

Tab. 2: Heat fluxes from the top floating cover

Days calculated by the 3D CFD model	Initial pond T at the bottom, ºC	Initial pond T at the top, ºC	Average ground T 2.5 m from pond surface, ºC	Average inlet T, ºC	Measured energy, MWh
October 07	44	82	37.8	Discharge, 44.0	24.2
August 03	52	79	35.6	Charge, 83.3	68.9
February 18	30	51	33.0	Discharge, 36.5	14.6
April 22	33	71	28.5	Charge, 77.3	95.3

5.1. Charge of the PTES

Fig. 9 shows the measured and the CFD predicted charge power of the PTES for the charge case on August 3. There is a satisfactory agreement between the CFD model and the measurements. The difference between the measured energy flow and the calculated energy flow is within 10%.

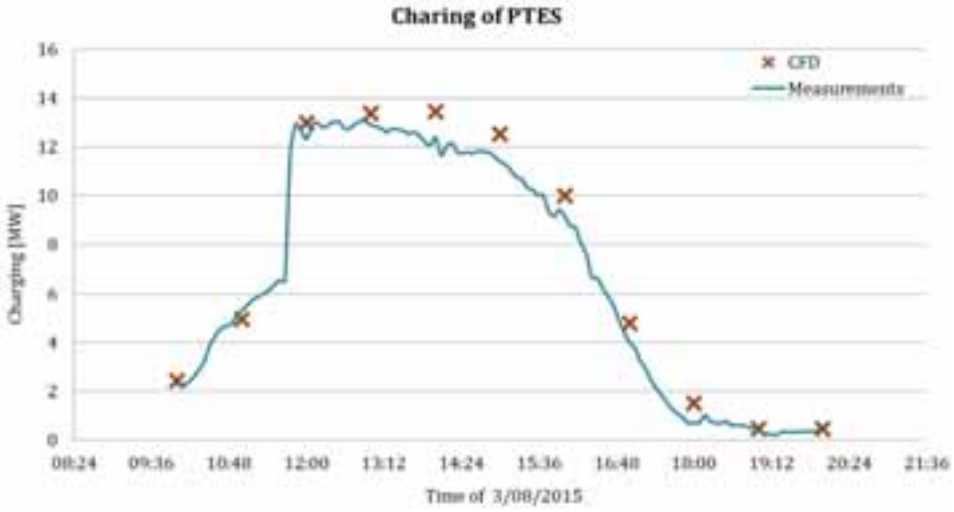

Fig. 9: Measured and CFD predicted charge power of the PTES for the case on August 3

Fig. 10 shows the measured and the CFD predicted temperature distributions in the PTES for the case on August 3. Both the initial temperatures and the temperature distribution of the pond at the end of the calculation are presented. The measured temperatures are shown as scatted dots while the CFD calculated temperatures are shown as curves. A comparison between the measured and the CFD calculated temperatures is shown for the location A1 and A2 respectively in the figure to the left and the figure to the right. Since the depths of the water are 16 meter at the location A1 and 8 meters at the location A2, the scales of the two figures are different. It is shown that water at the same level of the pond has almost identical temperatures. Based on the measured initial temperatures at different levels of the water pond in the start of the charge period, a regression is made to find a function between the water temperature and levels of the pond. The function is used as initial conditions in the CFD model by means of user defined functions.

There is generally a good agreement between the measured and the CFD calculated temperatures at the end of the charge period (20:00) at different locations of the pond. An exception is found at the level of 4 m below the ground surface on the location A2 where the water temperature was measured to be approx. 85ºC in comparison to a CFD calculated temperature of around 75ºC. A likely cause of the big difference could be false measurement of the sensor.

As water temperatures at the top of the pond are approx. 80ºC, it is very unlikely that temperature of the water 4 meter below the surface has a temperature higher than temperature of the water on the top of the pond. Therefore measurement data of the false sensor was not included in the investigations.

In the right figure of Fig. 10, it is shown that measured temperature of water at the top surface of the pond has a lower temperature than water 1-4 meter below the water surface, indicating a higher heat loss from the top cover at the location A2 than the average heat loss used in the CFD model.

It should be noted that temperature of the water pond increases slightly during charging in the investigated period. Such a change of temperature during charge in one day is too small to fully validate the CFD model. CFD calculation of charging in more than one day would better elucidate validity of the CFD model but the corresponding simulation time would increase significantly, therefore was not applicable for the present study. However such long term calculations are recommended for the future by means of parallel computing on super computers.

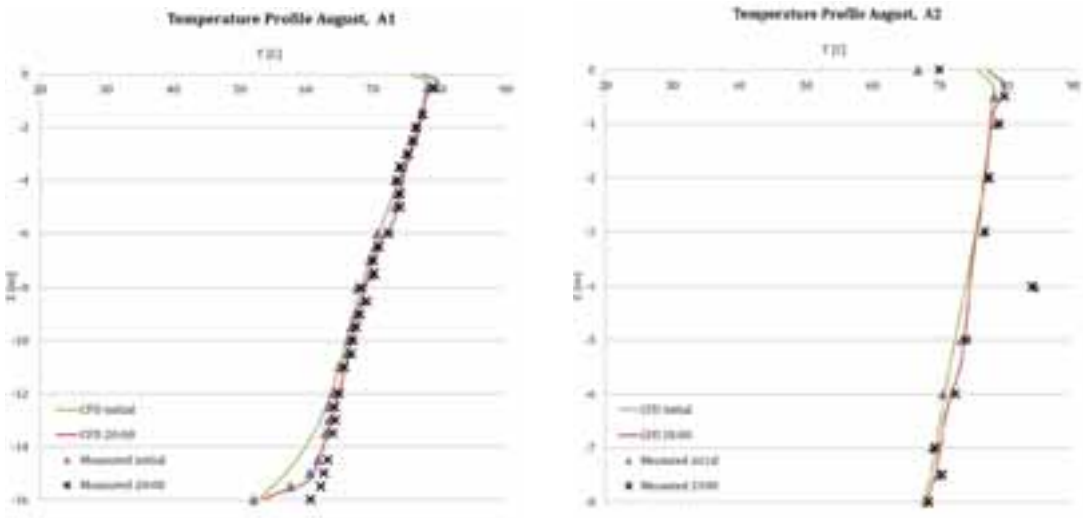

Fig. 10: Measured and CFD predicted temperature distribution in the PTES for the charge case on August 3

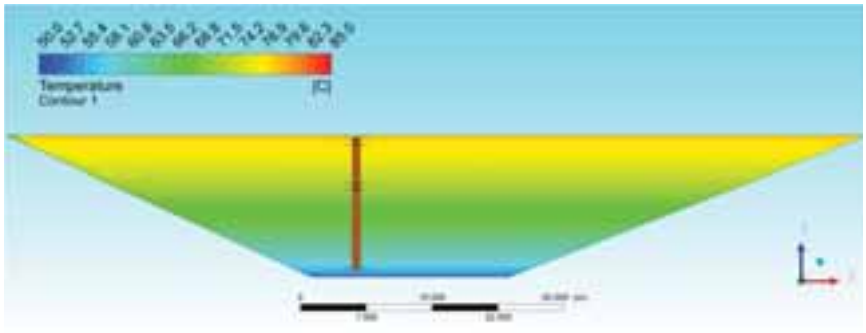
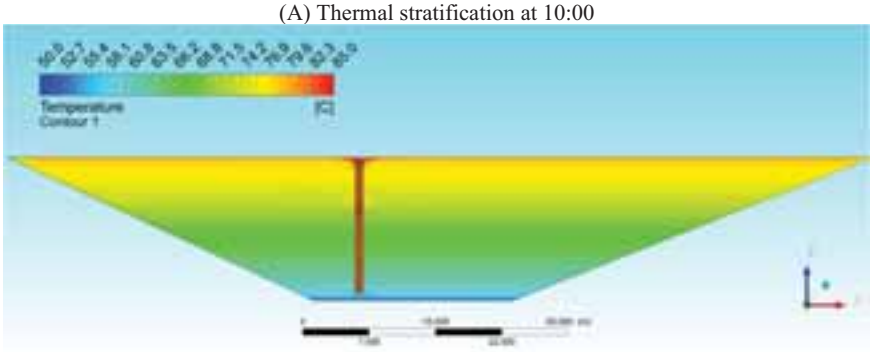
Fig. 11 shows temperature plots in the water pond at different times of the day. Temperature distributions at the start of the charge period (10:00) and in the middle of the day (14:00) are shown respectively in Fig. 11A and 11B. As shown in Fig. 11B, there are inlet flows with a temperature of 85ºC in the top inlet and in the middle inlet. After entering the top inlet opening, the hot fluid rises up and tends to flow along the top surface of the pond. Around the middle inlet opening, the inlet hot fluid mixes with relatively colder water in the PTES, resulting in a mixing region above the inlet opening. The mixing region is limited to a small area around the inlet disc indicating a good conservation of thermal stratification in the pond.

Fig. 12 shows regions in the pond where there is a larger fluid movement. Not surprisingly, larger fluid movement is observed in the three regions: around the top inlet opening, the middle inlet opening and the exit. The fluid velocity close to the inlets are in the range of 4-8 cm/s, which are considered to be higher enough to destroy thermal stratification. Since the region with a disturbing fluid velocity is rather limited, thermal stratification in the pond is kept during charge of the pond. It is interesting to note that around the top inlet opening the region with a higher fluid movement looks like a disc, indicating spreading of the hot fluid along the top surface of the PTES. That fluid pattern means well function of the inlet opening since the hot fluid has a higher temperature than the water temperature at the top of the pond and therefore should be directed by the inlet to the very top of the pond.



(A) Thermal stratification at 10:00



(B) Thermal stratification at 14:00

Fig. 11: Temperature plots of the water pond during charge on August 3

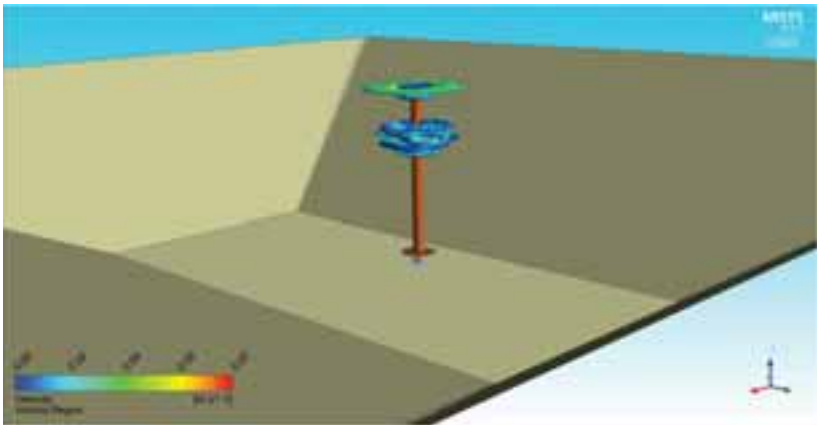


Fig. 12: Illustration of regions with a larger fluid movement for the charge case on August 3

5.2. Discharge of the PTES

Fig. 13 shows the measured and the CFD predicted discharge power of the PTES for the discharge case on October 7. There is a satisfactory agreement between the CFD model and the measurements. The difference between the measured energy flow and the calculated energy flow is within 5% except at the very start of the simulation. There is a large difference of approx. 0.4 MW between the measured and the calculated discharge power. A large deviation at the start of the simulation could be due to over simplified initial conditions of the PTES in the CFD model.

Fig. 13: Measured and CFD predicted discharge power of the PTES for the discharge case on October 7

Fig. 14 shows temperature distribution in the water pond at 21: 00 October 7. A clear thermal stratification in the pond can be observed. At the start of the October the pond was already quite fully charged. Water temperatures are 80-87ºC in the top of the pond, 70-76ºC in the middle and 40-45ºC at the bottom of the pond. During discharge, hot water is taken from the top of the pond, cooled down by the district heating network and returns through the bottom inlet of the pond. Since the inlet water is around 44ºC, close to the water temperature at the bottom of the pond, there is almost no mixing induced by the inlet flow. It is also confirmed by Fig. 15 where regions with a fluid velocity larger than 3 cm/s can be seen. Around the inlet opening at the bottom, the mixing region is very much limited. It can concluded that the current inlet/outlet design is able to minimize mixing during discharge from the top and the bottom openings when the PTES is fully charged.

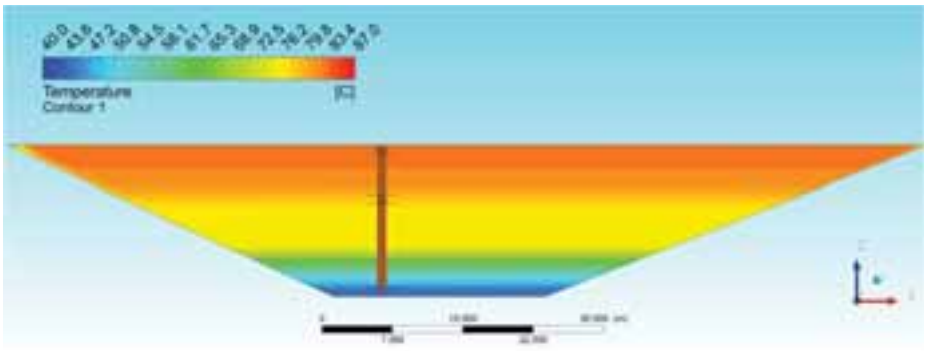

Fig. 14: Temperature plot of the water pond at 21:00 for the discharge case on October 7

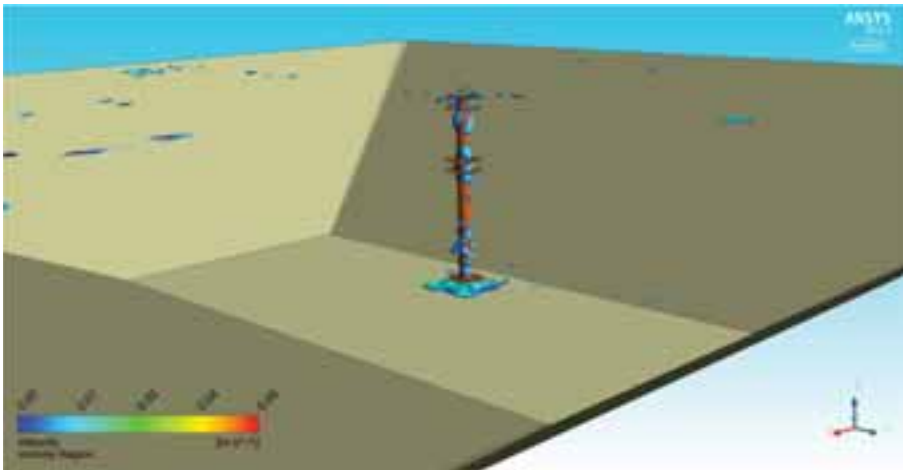

Fig. 15: Illustration of regions with a larger fluid movement for the discharge case on October 7

Fig. 16 shows temperature distribution in the water pond at 6:00 February 18 during discharge. After discharge throughout the winter, temperature of the pond was significantly decreased. Water temperature at the top of the pond was decreased to 48-53ºC while the water temperature was in the range 28-32ºC below the middle opening. During

the discharge, heat is taken from the top of the pond as for instance heat source of a heat pump. On the hot side of the heat pump, the district heat water is heated from 40ºC to 80-85ºC. On the cold side the heat pump, water is cooled down from 48-53ºC to around 40ºC before flowing back to the pond through the bottom inlet opening. Since the inlet water temperature is higher than the water temperature at the bottom of the pond, a significant mixing at the lower part of the pond is observed, see Fig. 17. Due to buoyancy forces, the incoming water with a higher temperature rises along the inlet/outlet pipe while water on the edge of the pond with a relatively lower temperature flows down to the bottom of the pond, creating a big circulation and a quite uniform temperature at the lower part of the pond. The circulation is shown by the stream lines in Fig. 18.

Velocity vectors in the water pond during discharge on February 18 are shown in Fig. 18. A clear uprising flow is seen along the inlet/outlet opening. After reaching the middle opening where there is a water layer with higher temperature, the flow turns to flow horizontally.

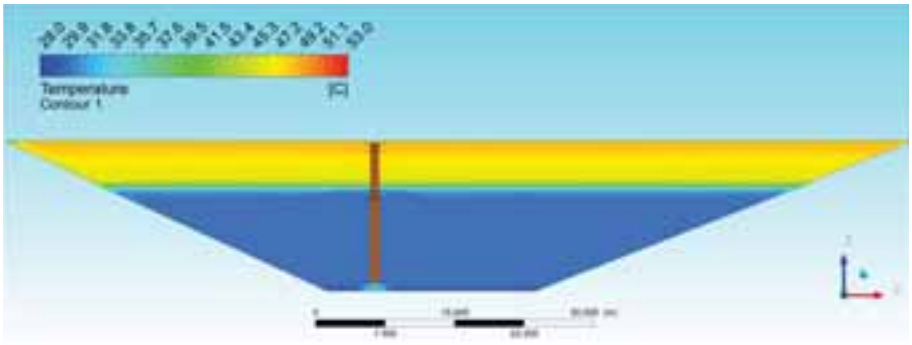

Fig. 16: Temperature plot in the water pond at 6:00 for the discharge case on February 18

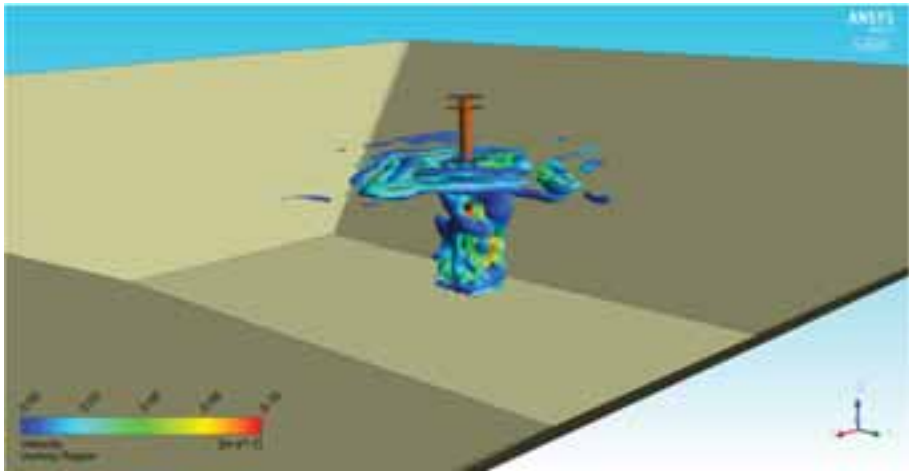

Fig. 17: Illustration of regions with a larger fluid movement for the discharge case on February 18

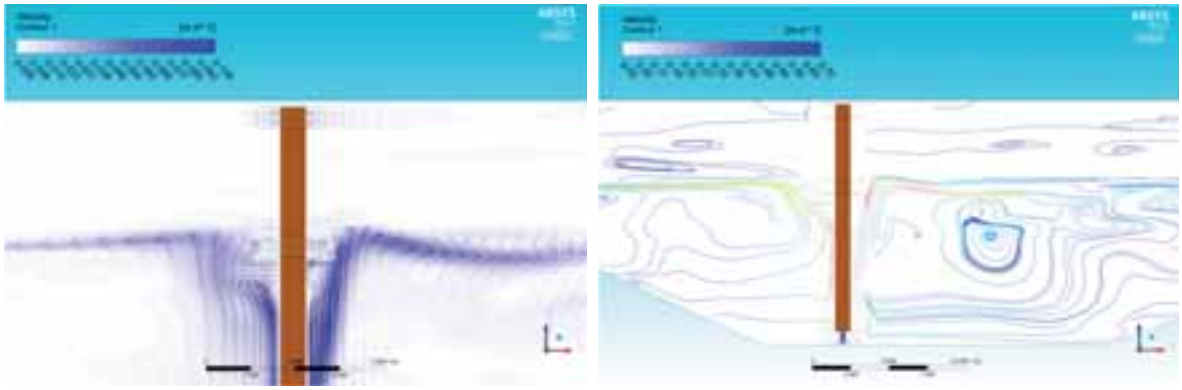

(A) Velocity vectors showing the uprising flow (B) Stream lines shown a big circulation

Fig. 18: Velocity vectors and stream lines in the water pond during discharge on February 18

For the investigated scenario, the inlet temperature is much higher than the temperature at the bottom of the pond,

thus creating strong mixing and destroying stratification at the lower part of the pond. If the middle inlet opening was used as inlet, a better thermal stratification in the pond could be achieved. However it should be mentioned that temperature of water from the heat pump varies depending on operation conditions of the heat pump. The return temperature could be much lower under some conditions, for instance a return temperature from the heat pump in the range of 15-25ºC is likely to happen. Consequently it will be advantageous to have the inlet at the bottom inlet opening. It is therefore interesting to investigate these scenarios in detail in the future.

6. Conclusions

Thermal behaviors of the 75,000 m^3 water pit heat storage in Marstal solar heating plant were investigated experimentally and numerically. Temperatures at different levels of the water pit storage and temperatures at different depths of the ground around the storage were monitored and analyzed. A simulation model of the water pit storage is built to investigate development of temperature in and around the storage. The calculated temperatures are compared to the monitored temperatures with an aim to validate the simulation model. The results show that the CFD models predict satisfactorily temperatures in the PTES for both charge and discharge operations. However it is recommended for the future to carry out a long term simulation in order to achieve a more detail validation of the CFD models.

Calculations of fluid flow and heat transfer in the PTES by the CFD model show that the inlet/outlet openings work properly during charge with minimal mixing region created in the PTES around the inlet/outlet openings. While for discharge of PTES, the ability of the inlet/outlet arrangement to keep thermal stratification strongly depends on temperature of water returned to the PTES. If temperature of the flow back to the PTES is much higher than the temperature at the bottom of the pond, strong mixing will be created, thus destroying stratification at the lower part of the pond. If the return temperature is lower than temperature at the bottom part of the PTES, it will be advantageous to have the inlet at the bottom inlet opening. It is therefore recommended to investigate these scenarios in future studies.

RADIAL DIFFUSERS IN STRATIFIED HOT WATER STORES: GEOMETRY OPTIMIZATION WITH CFD

Fabian Findeisen[1*], Thorsten Urbaneck[1], Bernd Platzer[1]

[1] Chemnitz University of Technology, Department of Mechanical Engineering, Institute of Mechanics and Thermodynamics, Professorship Technical Thermodynamics, 09107 Chemnitz, Germany

Abstract

This abstract deals with thermal energy stores for solar and district heat supply systems and presents numerical results for the performance of radial diffusers in a new type of overground storage tank which has a floating ceiling. The influence of the position of the radial diffuser in the thermal store was investigated revealing significant potentials regarding thermal stratification and storage efficiency. The optimization of the diffuser geometry led to a new free-form radial diffuser, which allows charging temperatures up to 98 °C. A Large Eddy Simulation (LES) illustrated the development of the stratification.

Keywords: CFD, district heating, floating ceiling, geometry optimization, heat supply, hot water, LES; charging device, radial diffuser, solar heating, thermal energy storage, thermal stratification

1. Introduction

Sensible thermal energy stores can make heat surpluses available to the consumer if necessary. A thermal stratification inside the storage tank is achieved by separating water with different temperatures through buoyancy. In a store operating according to the displacement principle, a water exchange takes place by direct charging and discharging. Radial diffusers can serve as charging devices. They consist of radial plates guiding the flow through a narrow gap horizontally into the cylindrical storage tank. For use in solar thermal systems an operation via matched flow is recommended to realize constant loading temperatures.

Numerical results will be presented for a new storage design proposed by Urbaneck et al. (2016) offering numerous benefits compared to other storage types. Here especially the effect on the temperature distribution inside this storage tank will be discussed using Computational Fluid Dynamics (CFD). The main novelty of the construction is an indoor protected floating ceiling, with the upper charging device directly attached to it. A flexible connection allows the free movement of the floating ceiling between a top and bottom dead center. During charging of the tank a gravity current occurs directly at the ceiling, which is an essential prerequisite for a good thermal stratification as will be shown later in this paper. The design is illustrated in fig. 1c. In comparison, fig 1a and 1b show examples of conventional storage types where the radial diffuser is mounted in a fixed position resp. floating (e.g. Hedbäck, 1993).

A demonstrator of the new storage design was already built in cooperation with industrial partners. By now, experiments are in progress to prove the high stratification quality and the very low heat losses. The investigations are part of the OBSERW project (Urbaneck et al., 2017).

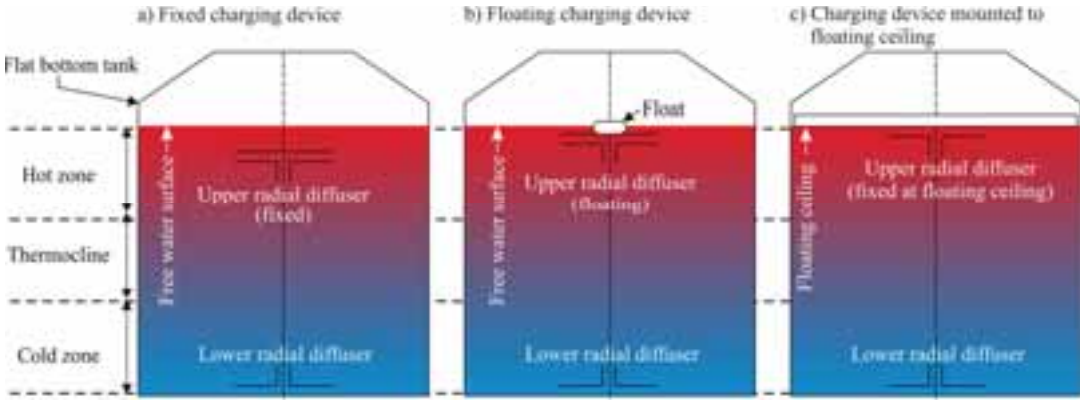

Fig. 1: Thermal energy storage with different possibilities of mounting the charging device in the store

doi:10.18086/swc.2017.13.04 Available at http://proceedings.ises.org

2. CFD model and boundary conditions

A two-dimensional axisymmetric model was used to perform the simulations with Ansys CFX. The CFD model takes buoyancy into account. The k-ω-SST model serves as a turbulence model. Additional production and dissipation terms capture the effects of density gradients on the turbulent flow. Fig. 2 presents the simulation model. Findeisen et al. (2016) describes the modeling in detail. The boundary conditions at the inlet as well as the initial condition in the tank are determined by the operating conditions in tab. 1 (assumption: constant volume flow and constant charging temperature).

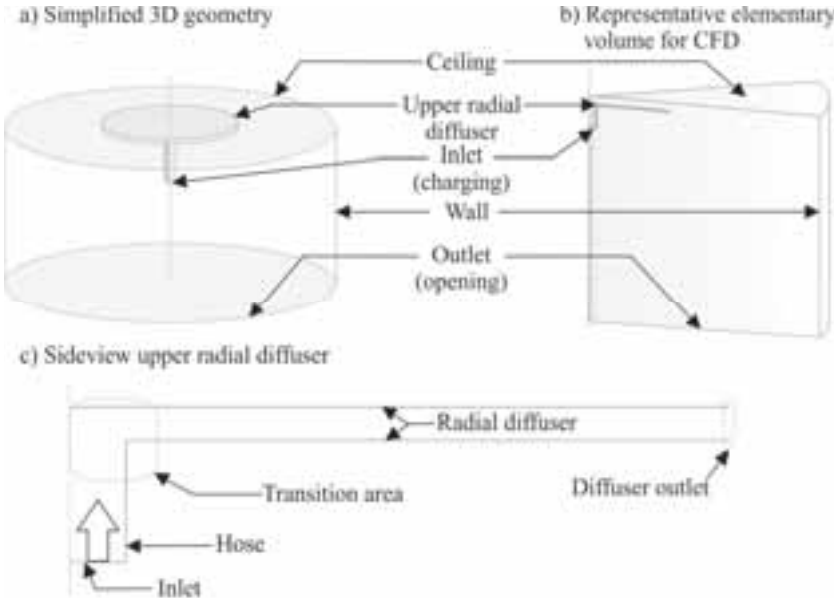

Fig. 2: Schematic view of the simulation model

Tab. 1: Operation conditions and geometrical parameters of the demonstrator

$\dot{V}_{in}$ [m³/h]	19.44	T_{in} [°C]	70	$h_{diffuser}$ [mm]	40	d_{store} [m]	5.12
V_{store} [m³]	116.76	T_{store} [°C]	40	d_{hose} [mm]	68.8	$d_{diffuser}$ [m]	0.96

3. Influence of the position of the charging device

Radial diffusers in flat bottom tanks are usually floating or mounted fix in the store without any moving parts (fig. 1a, b). Thus, the diffusor is located below the water surface, resp. the storage ceiling. To investigate the influence of reducing this distance, especially by mounting the charging device directly to the ceiling, a simplified simulation model was used, which does not consider a free water surface. It assumes a constant velocity profile at the entry of the tank (corresponds to the outlet of the charging device). Hence, the radial diffuser is not yet simulated.

Fig. 3 illustrates the calculated temperature fields for three different cases. As the distance towards the ceiling increases, the thermocline grows and the average temperature in the hot zone decreases while an unfavorable non-isothermal free stream due to convection develops. This free stream causes strong mixing of hot charging fluid and cooler storage fluid significantly reducing the layering quality.

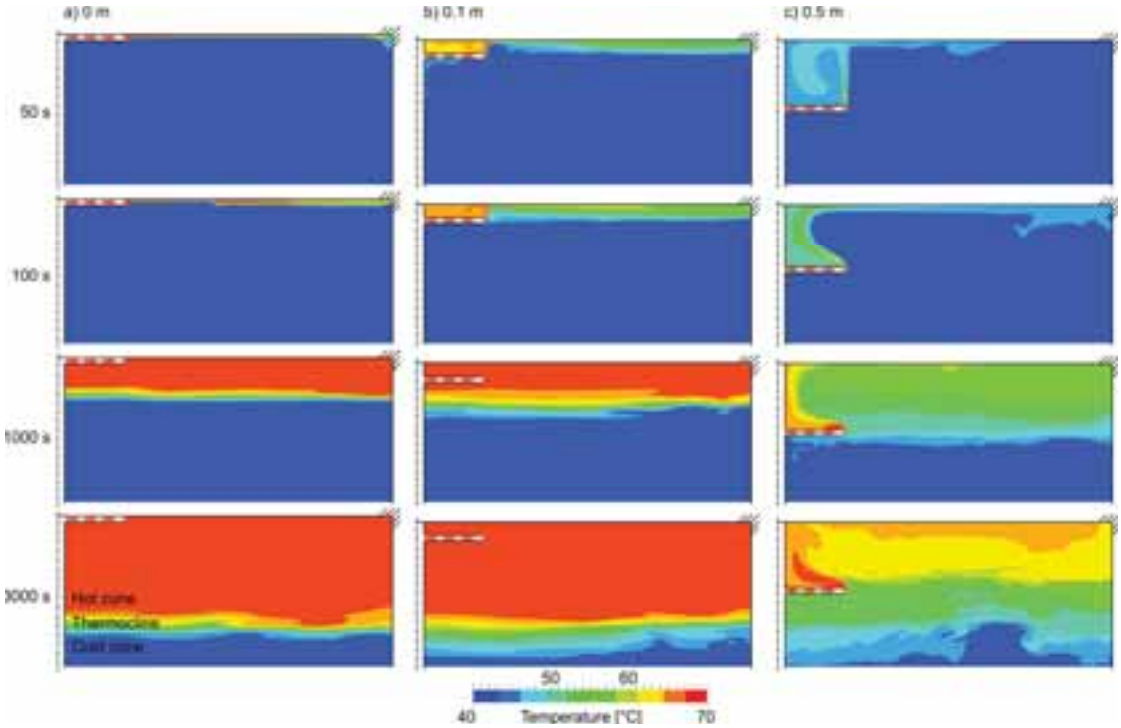

Fig. 3: Evolution of the calculated temperature field inside the storage tank for different distances between the charging device and the ceiling

To determine the quality of the stratification the volume averaged temperature in the hot zone as well as the average height of the thermocline are used for evaluation. The height corresponds to a volume averaged height over the entire radius of the simulation model according to the 90/10%-principle (Findeisen et al., 2016). Tab. 2 compares the results obtained. The thermocline doubles its height if the distance between diffuser and ceiling increases to 10 cm and is more than tenfold its height if the distance is 50 cm. At the same time the average temperature in the hot zone drops to 69.64 °C, resp. 67.42 °C. Thus, the stratification quality strongly depends on the position of the charging device.

Tab. 2: Results for different distances between the radial diffuser and the ceiling after 3000 s of charging

Distance between radial diffuser and storage ceiling [m]	0.0	0.1	0.5
Average thermocline height (90/10%-Method) [m]	0.09	0.18	0.99
Average temperature in the hot zone [°C]	69.99	69.64	67.42

Furthermore, since the hot fluid cannot be removed from above the charging device, the corresponding storage volume as well as the heat stored there is unusable. In addition, as soon as the hot fluid cools down, thermal inversion can permanently destroy the stratification in the tank. Charging directly along the storage ceiling completely eliminates these drawbacks and therefore promises substantial improvements, also because the floating ceiling is well insulated.

4. Investigation of the discharging- and charging behaviour

With a minimal distance between the charging device and the floating ceiling, hot water is sucked in directly along the ceiling in case of discharging, which allows the full use of the hot zone. But mounting the charging device to the ceiling goes along with an elimination of a hydrostatic pressure relief above the charging device. Since the store operates with a maximum temperature up to 98 °C this means that there is a risk of falling below the steam pressure limit. The pump is in feed mode, the charging device sucks in and thus discharges the storage tank. Hereby, the flow can be disrupted by local steam formations (e.g. cavitation) or other transient effects, which can lead to operational failures or even a breakdown of the entire discharging system. In order

to ensure operational safety during discharging, it is therefore necessary to optimize the diffuser geometry in order to minimize the local pressure drop. There is usually no risk for the charging behavior. Instead, for this operational case the influence of different diffuser geometries on the quality of the thermal stratification will be investigated.

The various geometries of charging and discharging systems (CDS) are shown in fig. 4. Starting from a reference case with a sharp edge from the connection hose to the diffuser and straight diffuser walls (CDS_0) the transition area between the hose and the radial diffuser will be modified. Hence, CDS_1 has a round transition with a constant radius and CDS_2 to CDS_4 have a free from transition area. Furthermore, different diffuser styles (CDS_2a/b) as well as build-in parts (CDS_5) and guiding plates at the outlet are part of the study. Besides of the demonstrator (tab. 1) the investigation also considers three representative storage sizes (tab. 3).

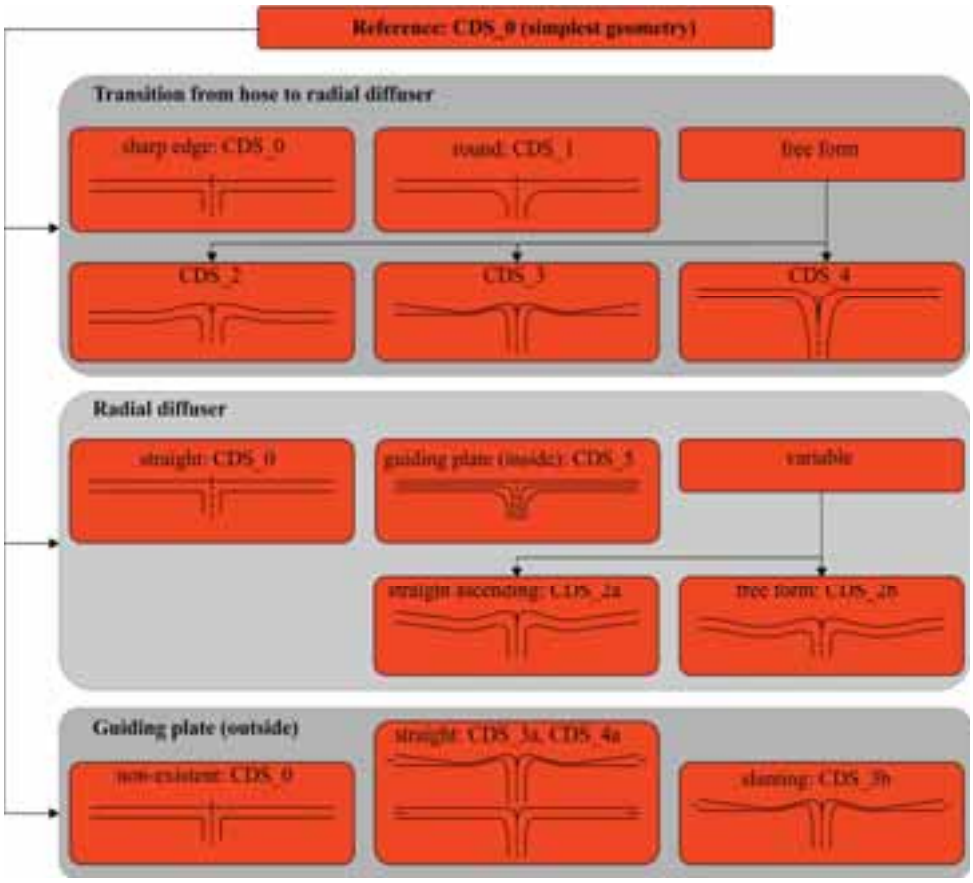

Fig. 4: Investigated diffuser shapes

Tab. 3: Overview of simulated storage sizes

Name	V_{store} [m³]	d_{store} [m]	$d_{diffuser}$ [m]	$h_{diffuser}$ [mm]	d_{hose} [mm]	$\dot{V}_{in}$ [m³/h]	*Fr* [-]	*Re* [-]
demon-strator	116	5.12	0.96	40	68.8	20	0.57	4209
store 1	1000	10.84	2.00	80	200.0	167	0.86	17658
store 2	3500	16.46	3.60	120	371.0	583	0.91	34334
store 3	6000	19,69	5,00	120	486,0	1000	1,12	42378

4.1 Discharging behaviour

Aim of the study is to improve the flow inside the charging device since the pressure in the radial diffuser must not fall below the steam pressure limit. Thus, it is important to minimize the local pressure drop. Besides of different storage sizes the investigation also takes into account different atmospheric pressure levels.

The minimum absolute pressure inside the charging device for three different atmospheric pressure levels and the steam pressure limit for 95 °C, resp. 98 °C is illustrated in fig. 5 for selected geometries. Whether the pressure falls below the steam pressure of 98 °C strongly depends on the atmospheric pressure. Whereas for 0 m above sea level (a.s.l.) there is only a risk for the reference diffusor with a sharp edge (CDS_0), in case of 500 m a.s.l. nearly every simulated geometry case, except of the optimized free form CDS_4, falls below the limit. For an atmospheric pressure level according to 1000 m a.s.l. the pressure in CDS_1, resp. CDS_4 is above the steam pressure only if the liquid temperature is reduced to 95 °C.

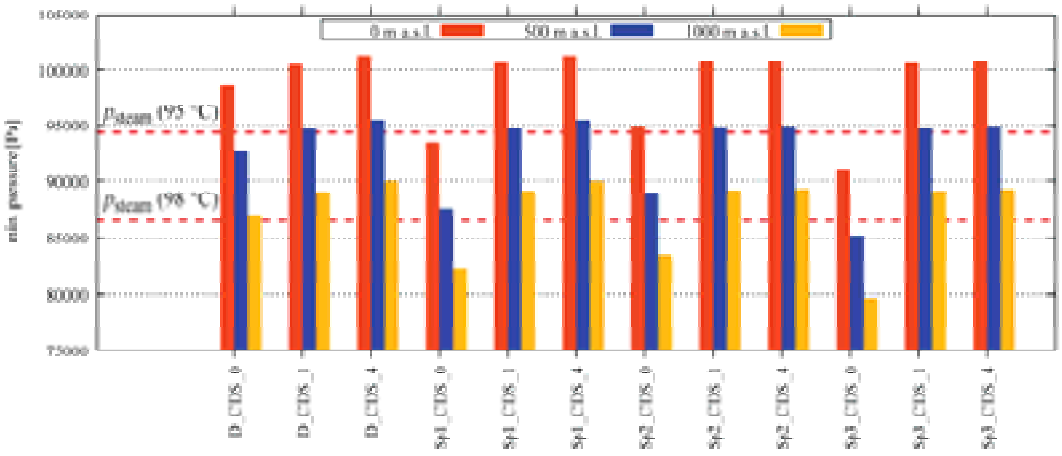

Fig. 5: Minimum static pressure inside the radial diffuser for different atmospheric pressure levels

Fig. 6a shows the pressure field for the reference radial diffuser CDS_0 with a sharp edge between the connection of the hose and the radial diffuser, where the pressure drops locally for about 10 kPa. As a result of the geometry optimization, the free form diffuser CDS_4 (fig. 6b) reduces the local pressure drop to 1.2 kPa. This value corresponds exclusively to the dynamical pressure conversion due to the acceleration of the fluid. Thus, by using a free form diffuser the local pressure drop inside the charging device can be minimized.

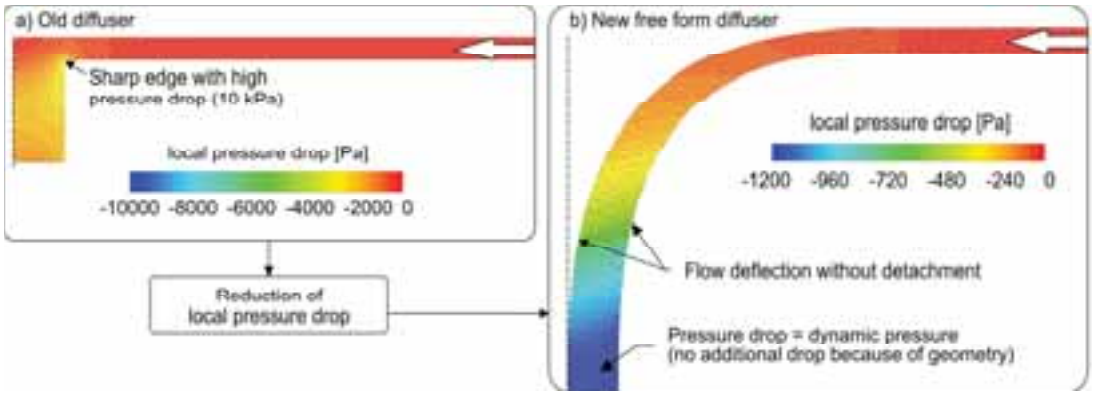

Fig. 6: Local pressure drop in a radial diffuser during discharging with 98 °C hot water; CDS_0 (a) and CDS_4 (b)

4.2 Charging behaviour and development of the thermal stratification

The diffuser shapes were also investigated regarding their performance during charging of the tank. Fig. 7 displays the temporal evolution of the averaged height of the thermal stratification using the example of the demonstrator. It is important to notice, that the criteria is not valid until the thermal stratification is fully developed. This is the case during the first 500 s. In the further development no significant differences can be observed between the investigated diffuser shapes. The same yields for the other simulated stores (fig. 8). There is no remarkable difference between the geometries. Since the stratification quality is already very high

due to the direct mounting of the diffuser at the ceiling no further improvements can be observed. Thus, a very high stratification quality is possible and independent of the diffuser geometry. But, as test simulations with different diffuser heights suggests, this counts only as long as there are no negative velocities at the diffuser outlet because of suction effects. The dimensioning of the radial diffuser is therefore still important.

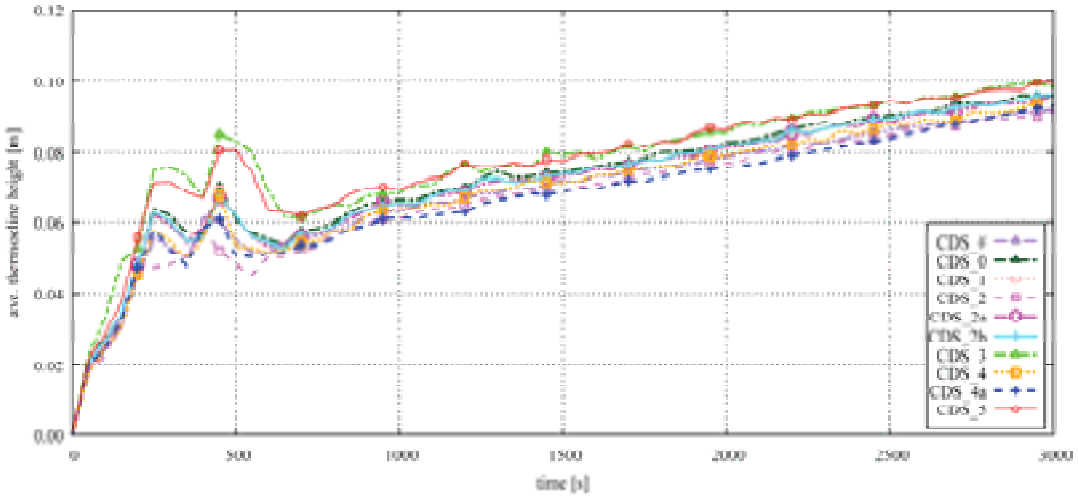

Fig. 7: Temporal evolution of the average height of the thermocline for different diffuser geometries in the demonstrator

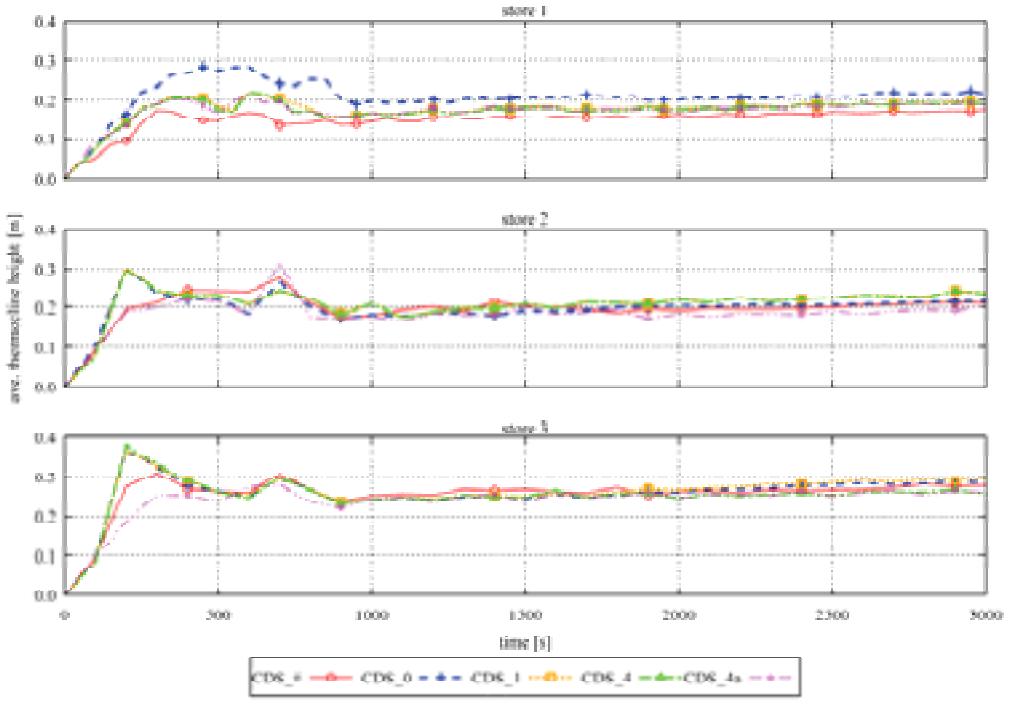

Fig.8: Temporal evolution of the average height of the thermocline for selected diffuser geometries in stores with a volume of 1000, 3500 and 6000 m³

To understand the underlying mechanisms and to illustrate and clarify effects that determine the resulting thermocline height a Large Eddy Simulation (LES) was performed. Fig. 9a shows the density current with its characteristic properties. The result pointed out, that there are mainly two mixing areas. The first one is situated along the height of the radial diffuser (fig. 9c) and the second one is located below the radial diffuser (fig. 9d). Interesting is, that, at least in flat bottom tanks with relatively high diameters, the collision of the density current against the side wall did not significantly influence mixing.

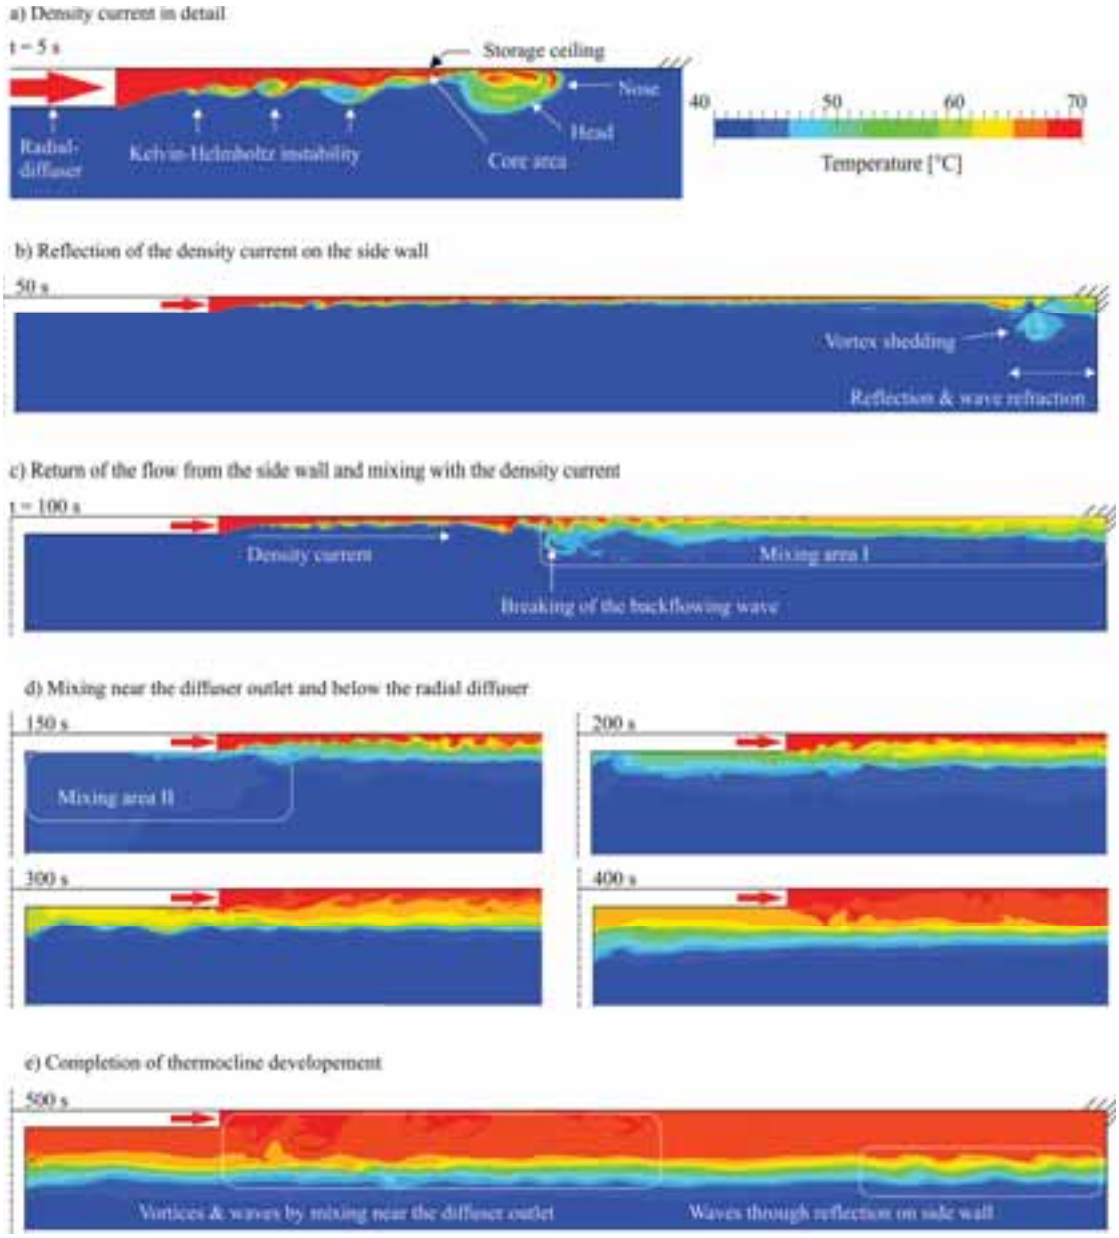

Fig. 9: Temperature field in the cross section area of the cylindrical storage during the development of the thermal stratification

To summarize the results regarding the charging behaviour fig. 7 illustrates the correlation between stratification quality and the Froude number *Fr* used for the radial diffuser design (Findeisen et al., 2017), resp. the storage volume and the height of the diffuser. Due to the high density difference and the moderate loading volume flow a rather conservative design with $Fr = 0.57$ is present in the demonstrator. In store 3, the Froude number is significantly higher at 1.06, but still within the framework of the usual recommendation of $Fr \approx 1$ (Urbaneck, 2012). It can be seen, that the height of the thermocline increases by a factor of about three with a double Froude number. Since in the examples shown the same difference in density exists, here, the height of the thermocline mainly depends on the impulse of the flow.

The diffuser height has a similar tendency to the Froude number on the stratification quality. This correlation is obvious. As previously stated, for the same density differences the impulse of the volume flow rate is decisive and the diffuser height now determines the flow impulse as the outflow velocities are quiet similiar. The LES simulation illustrated this correlation qualitatively (fig. 9): The mixing area I is approximately as high as the gap at the diffuser outlet and the final thermocline has approximately twice the height. The additional mixing occurs in the mixing area II. The differences between the different diffuser variants of store

1 and 2 as well as between the variants of store 3 are also determined by mixing area II (because of vertical speed differences in the near field; see Findeisen et al., 2017).

The compact storage tanks considered in this study have a height to diameter ratio of about one. In larger storage tanks likely more mixing takes place due to the increasing mixing surface on the underside of the jet. On the other hand, in stores with a significantly smaller diameter compared to their height other effects dominate (Lohse, 2012).

The results show for a specific operating point that the stratification quality depends on the store diameter, the Froude number and the diffuser height, which is already contained in the Froude number. In addition to the diffuser height, the Froude number also considers the operating parameters. It is therefore well suited for the dimensioning of radial diffusers. In general, buoyancy forces should outweigh inertia forces and therefore smaller Froude numbers should be preferred. In the present case a more conservative interpretation is recommended as the very low thermocline height of the demonstrator proves.

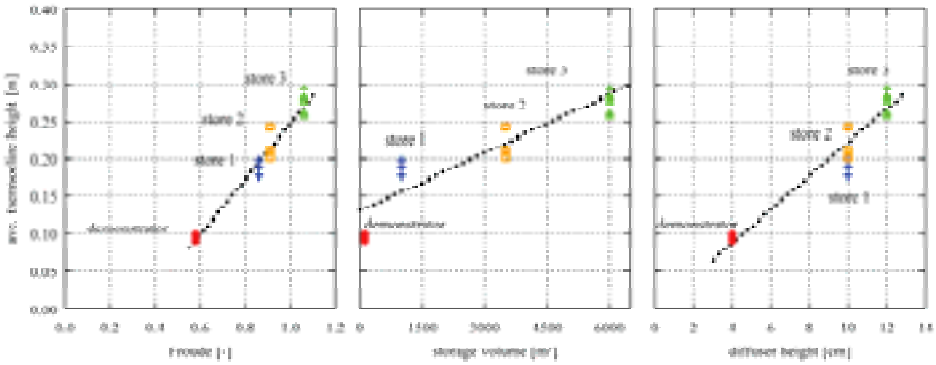

Fig. 9: Results of the average height of the thermocline from all simulated diffuser geometries after 3000 s for different Froude numbers, storage volumes and diffuser heights

5. Conclusion and Outlook

The performance of radial diffusers with different shapes was investigated for a single design point in different hot water storage sizes using CFD. Due to an optimized position of the diffuser in the tank the thermal stratification could be significantly improved. This offers various other advantages and underlines the benefits of a new storage type with a floating ceiling. A new free-form radial diffuser with a flow optimized shape was presented, which enables charging and discharging with temperatures up to 98 °C by reducing the risk of falling below the steam pressure limit. Furthermore, the application of LES identified mixing areas during the beginning of the loading process determining the resulting stratification quality.

Cycling test of liquid sorption thermal energy storage using sodium hydroxide

Benjamin Fumey[1], Robert Weber[1] and Luca Baldini[1]

[1] Empa, Dübendorf (Switzerland)

Abstract

In this paper results of an absorption heat storage cycling test are presented. The specific application is long term heat storage, the test setup is based on a spiral finned tube heat and mass exchanger constructed of stainless steel type 1.4571 and the absorbent working pair is sodium hydroxide and water. A total of 7 cycles are performed at approximately 13.5 hours of absorption and 17 hours of desorption time per cycle. Average concentration of sodium hydroxide in the solution is 48 wt% after desorption and 27 wt% after absorption. Comparison of thermal performance among different cycles is made. No clear tendency of cycling improvement or degradation is found.

Keywords: Absorption heat storage, Long term thermal energy storage, Sodium hydroxide / Water, Cycling test, Spiral finned tube heat and mass exchanger

1. Introduction

Heat storage based on sorption process has the prospective for compact thermal storage without suffering loss during storage time. Much research has been done towards this goal, accompanied by several IEA Technology Collaboration Programs [van Helden et al. 2015]. Sorption heat storage operates as a chemically driven heat pump, storing not heat, but the potential to regain heat at elevated temperatures. Applied sorption materials are generally categorized into adsorbents referring to solid sorbents and absorbents referring to liquid sorbents. Categorization is made from an application perspective whereby the sorbate, frequently taken to be water, adheres to the surface of solids and diffuses into liquids. Theoretical work on absorption materials shows promising potential for heat storage application [Hui, et al. 2011], and is seen to have good potential for building integrated heat storage [N'Tsoukpoe, et al. 2009, Tatsidjodoung, et al. 2013, Zhang, et al. 2014]. Common absorbents considered are the aqueous salts lithium bromide (LiBr) [N'Tsoukpoe et al. 2013, Mortazavi et al. 2015], lithium chloride (LiCl) [Bales et al. 2008], calcium chloride ($CaCl_2$) [Quinnell, et al. 2011, Le Pierrès, et al. 2011] and sodium hydroxide (NaOH) [Weber and Dorer, 2008]. First heat storage prototypes for solar heating have been built based on the conventional falling film tube bundle heat and mass exchanger (HMX) [N'Tsoukpoe et al. 2013, Fumey et al. 2015a]. Nevertheless, various issues related to the required large concentration difference in a single cycle process have led to poor operation results. Challenges include regrouping of droplets due to high viscosity of the absorbent working pair as well as high surface tension and high contact angle. Thus, system performance has generally been unsatisfactory, and it is recognized that new HMX concepts are required [N'Tsoukpoe et al. 2013, Daguenet-Frick, et al. 2017]. In contrast to solar sorption chilling machines [Ibarra-Bahena and Rosenberg, 2014] not cold, but heat is sought and not a full cycle but a time interrupted process is at hand. Absorption heat storage performance is measured in respect to energy density and temperature lift [Fumey et al. 2015b]. Energy density is dependent on the degree of absorbate difference between charged and discharged absorbent working fluid and temperature lift is dependent on the concentration of absorbent in the working fluid. High concentration leads to increased temperature lift. A HMX for absorption heat storage must reach maximum absorbate uptake in a single pass process in order to prevent temperature drop due to concentration reduction through mixing of charged absorbent solution with semi discharged solution. Experiments have shown that substantially more exposure time of absorbent solution to absorbate is required then commonly possible in absorption chiller type HMXs [Fumey et al, 2017]. Alternative HMX designs are suggested by [Michel et al. 2017] and [Fumey et al, 2017].

doi:10.18086/swc.2017.13.05 Available at http://proceedings.ises.org

In this paper the cycling test results of a spiral finned tube HMX design as described in [Fumey et al., 2017] made of stainless steel type 1.4571 and operated with aqueous NaOH are presented and compared in respect to important performance parameters with focus on possible degradation.

2. Setup description

In this absorption process, HMX operation is under exclusion of non-condensing gasses. Fig. 1b shows the finned tube heat exchanger used both as absorber and desorber (A/D) as well as evaporator and condenser (E/C). Dual function is possible due to the time separated processes of evaporation and absorption and the process of desorption and condensation. Both, in absorption and desorption operation, aqueous NaOH is introduced to the top of the A/D spiral fin and flows down, channeled along the fin as illustrated in Fig. 1a. In absorption mode, water follows the same principle on the E/C unit whereby it is evaporated by means of low temperature heat source and in turn absorbed on the aqueous NaOH. The heat of vapor condensation as well as to a smaller part the heat of dilution is released at concentration dependent elevated temperature to the heat transfer fluid (HTF). In desorption mode the revers process is followed; heat from the HTF is released to the absorbent, whereby water is evaporated from the aqueous NaOH solution. The water vapor is in turn condensed on the E/C unit and the heat released to the respective HTF. Depending on the NaOH concentration and the temperature difference between A/D and E/C unit absorption or desorption takes place.

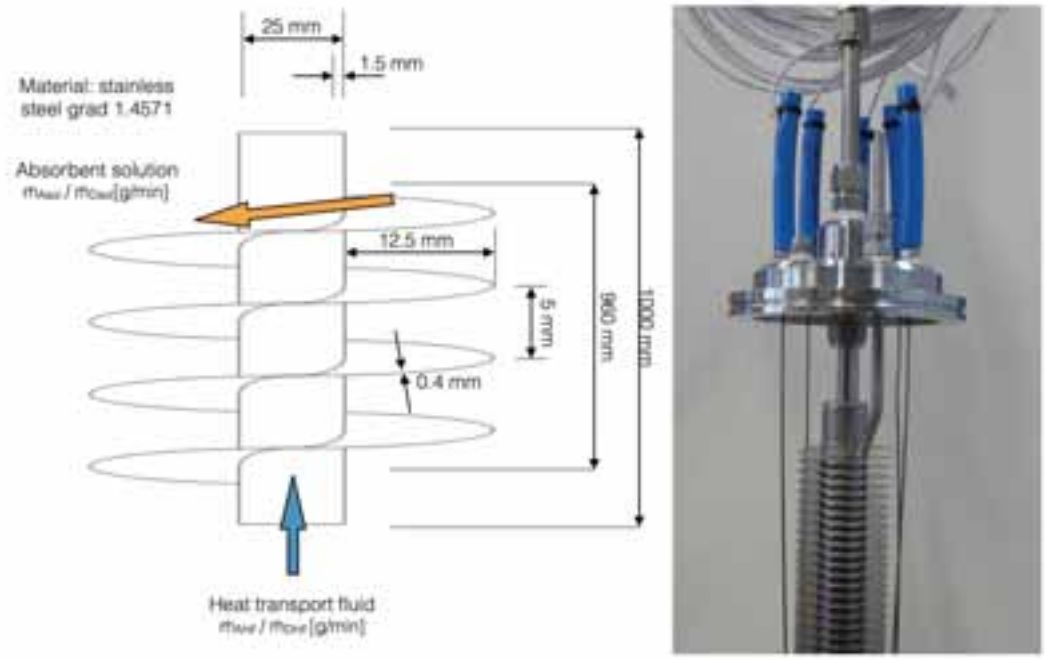

Fig. 1: a) Illustration of the finned tube heat exchanger with absorbent solution flow indicated by the orange arrow and HTF by the blue arrow (left). b) Finned tube heat exchanger showing the sorbent supply tube on the top most fin as well as installed temperature sensors. The HTF flows through the center tube (right).

The benefits of the spiral finned tube heat exchanger are, the long exposure time, large surface area, slow flow of the absorbent and resulting thin film, adjustability of exposure time, film thickness control by absorbent flow regulation, and continuous process both in absorption as well as desorption.

In the lab scale HMX test facility, two spiral finned tubes as A/D and E/C units are installed in two separate chambers respectively as shown in Fig. 2. The two chambers are interconnected in order to enable water vapour exchange and the HMXs are supplied with heat and cold from two thermostat/cryostat baths. These operate as solar heat source and ambient heat sink in desorption also referred to as charging mode as well as low temperature heat source and building heat demand in absorption or discharging mode. Gear pumps circulate the heat transfer fluids, supplied to the bottom of the HMX, in counter flow to the absorbent and absorbate and flow is regulated with buoyancy flow regulators. Both absorbent and absorbate are sourced from plastic canisters at atmospheric pressure. The containers are seen in Fig. 2 at the bottom center. The blue canister holds the absorbent (aqueous NaOH) and the white canister holds the absorbate (water). This is strongly in contrast to the

conventional approach in closed sorption systems where both sorbent and sorbate are stored under low pressure conditions with removal of all non-condensing gasses. Absorbent is dosed to the absorber by a tubing pump seen above the blue canister. Mass flow is monitored by electronic scale placed underneath the absorbent canister. Absorbate is supplied to the E/C chamber from the respective canister by pressure difference between the ambient to the low pressure in the chamber and re-circulated on the HMX using a gear pump. Both absorbent and absorbate are removed from the low pressure HMX chambers by vacuum lock. These consist of a container each connected to the respective chamber via ball valve. The absorber / desorber vacuum lock is indicted in Fig. 2 bottom left. Absorbent and absorbate flows from the HMX into the vacuum lock by gravitational force. Periodically, the interconnecting valves are closed, the lock aired and the working fluids released to plastic container. Prior to opening the valve again, the lock is evacuated. This setup enables periodic sampling without interrupting the continuous operation. Detailed results of initial operation tests are presented in [Fumey et al. 2017].

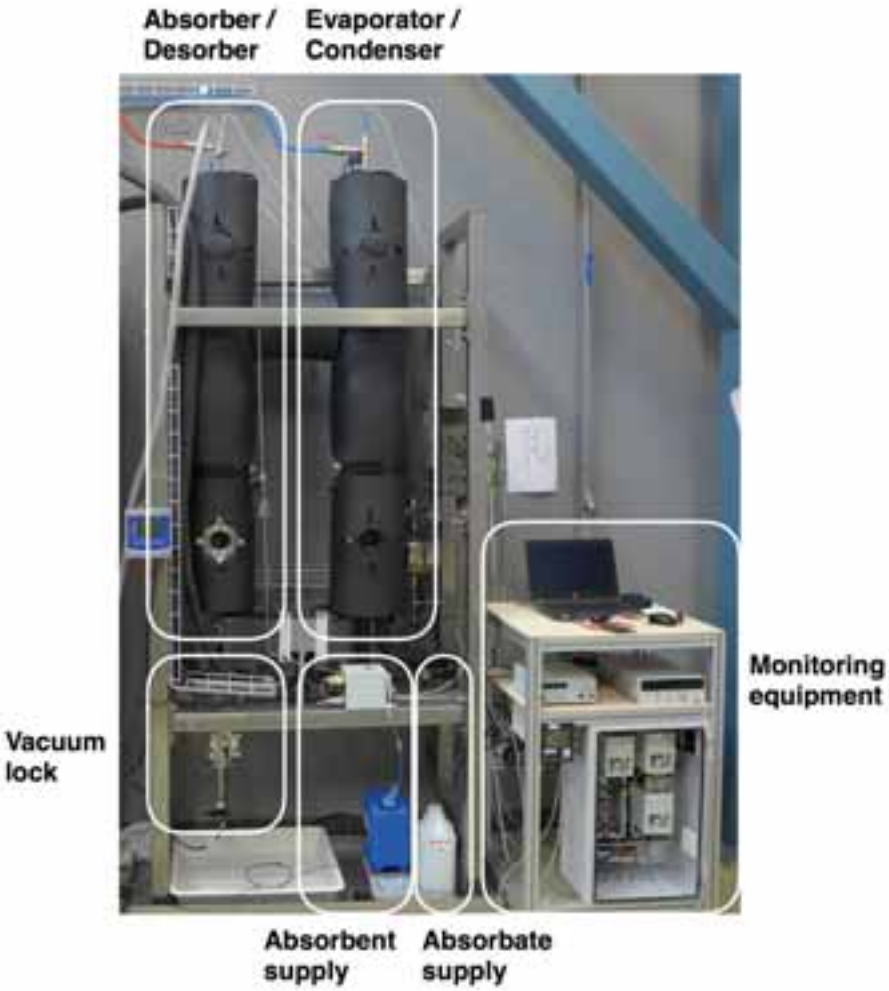

Fig. 2: Test setup including the absorber / desorber composition on the left top, the evaporator / condenser unit on the right top, the absorbent vacuum lock on the left bottom, the absorbent and absorbate supply on the bottom center and the monitoring equipment to the bottom right.

3. Testing procedure

Seven absorption and desorption cycles are undertaken in the described setup and performance is compared in terms of deviation of effective temperature difference from the theoretical temperature difference for a given absorbent concentration. Theoretical values are represented by the equilibrium curve (see Fig. 3-6). This test distinguishes itself from the former tests reported in that both absorbent solution and absorbate are continuously reused. This approach leads to a dependence of absorption performance on the preceding desorption process and

may lead to an accumulation of possible performance depredators. In absorption, the absorbent flow is 6 g/min, the A/D HTF supply temperature is 28 °C at a flow of 200 g/min and the E/C supply temperature is 25°C at a flow of 800 g/min. In desorption the absorbent flow is 8 g/min, the A/D HTF supply temperature is 65 °C at a flow of 800 g/min and the E/C supply temperature is 10 °C at a flow of 1200 g/min. The test duration for a single cycle in absorption is approximately 13.5 hours and the desorption duration is 17 hours due to the greater mass of diluted aqueous NaOH to be transported. One complete absorption and desorption cycle is tested per week resulting in a total test duration of 7 weeks. No absorbent or absorbate is added or removed from the solution during the test series. Both absorbent and absorbate are stored under atmospheric pressure and exposed to air.

4. Results and discussion

Fig. 3 shows the process performance with reference to the ideal equilibrium state of the cycling test with temperature difference between the A/D and E/C unit on the x-axis and the absorbent concentration on the y-axis. Average values of the cycles are shown. The dashed line shows the theoretical equilibrium between the temperature difference and the concentration. In Fig. 3 the red x values show the maximum temperature difference between the absorbent and evaporation temperature during absorption in dependence of the concentration. Due to the varying concentration in the cycling tests, the maximum absorption temperature varies. Performance is measured in dependence of horizontal distance from the equilibrium line. The red + values show the final resulting concentration in the absorption process plotted against the minimum temperature difference between A/D and E/C HMX. As with the x values, performance is measured in dependence of horizontal distance to the equilibrium. Closer fit to the equilibrium line shows good performance in terms of effective mass transfer. The blue o values show the resulting concentration of the desorption cycles. As with the absorption results, close fit to the equilibrium line is desired.

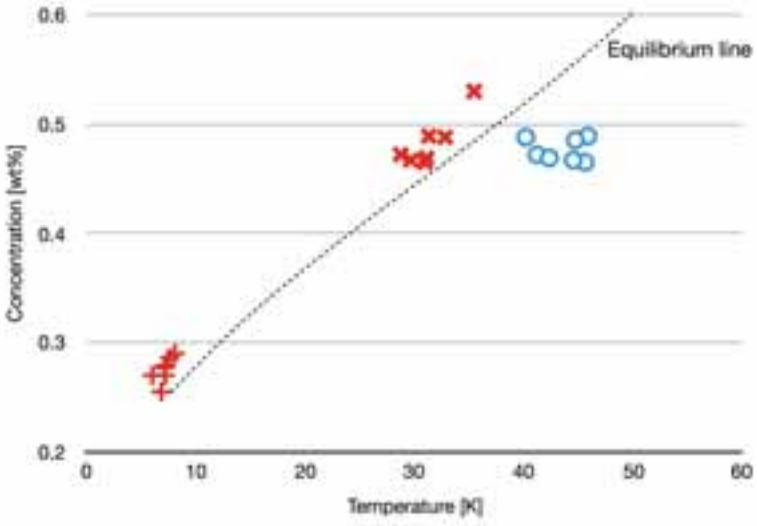

Fig. 3: Overview of resulting concentration/temperature difference pairs recorded during cycle testing in absorption and desorption mode. Red x representing beginning of absorption, red + end of absorption and blue o end of desorption (beginning of desorption is omitted as initial absorbent concentration do not correspond to charging temperatures).

Fig. 4 to 6 show details of the results presented in Fig. 3 for the different operation regimes, beginning and end of absorption as well as end of desorption process, with indication of cycle number for analysis of cycling performance and standard deviation. Fig. 4 shows the maximum temperature increase in respect to concentration in absorption. As expected the temperatures are lower than the equilibrium. Part of this temperature drop is due to water vapor mass diffusion resistance in evaporation, as well as vapor transport from A/D unit to E/C unit and diffusion into the absorbent. It is yet unclear what portion of the total temperature drop is due to this effect.

Test A1 shows a substantially higher temperature gain due to the starting concentration of 53 wt%, temperature increase is directly dependent on absorbent concentration. Nevertheless, it also shoes a large temperature deviation from equilibrium. Interesting is to note that the first 3 cycles have a stronger temperature deviation than the following 4 cycles. Nevertheless, there is no clear tendency observed, highlighting a potential effect of cycling. The least temperature difference is seen at test A5, with tests A6 and A7 showing again an increase. The dashed line is parallel to the equilibrium line with a temperature offset of 4 K representing an average temperature deviation from equilibrium through the set of cycles.

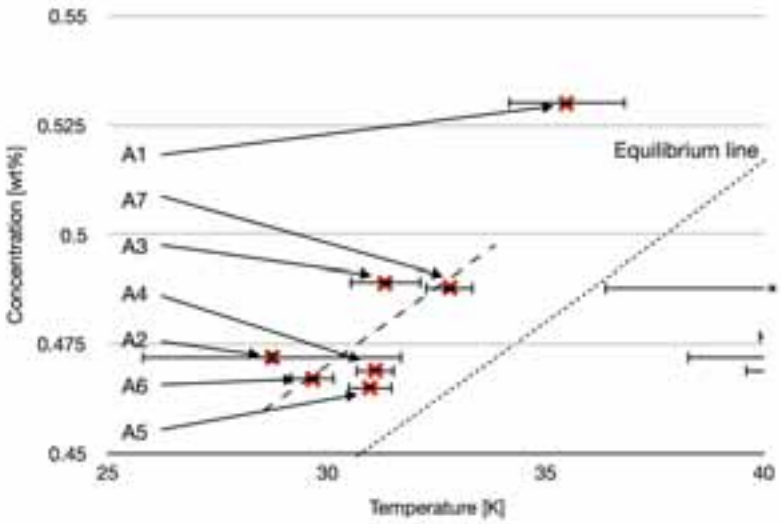

Fig. 4: Focus of Fig. 3 on the maximum temperature increase in respect to the concentration in the absorption process. All values are numbered according to their cycle. The dashed line shows a 4 K offset to the equilibrium line.

Fig. 5 shows the resulting concentration in respect to the minimum temperature difference between the absorber and the evaporator. This is approximately 7 K. As in Fig. 4 there is no trend of degradation or improvement visible across the cycles. Apart from cycle A1 and A6, all results show approximately the same offset to the equilibrium line of approximately 3 K as indicated by the dashed line parallel to the equilibrium line. The concentration difference results from the slightly varying temperature difference between the cycles.

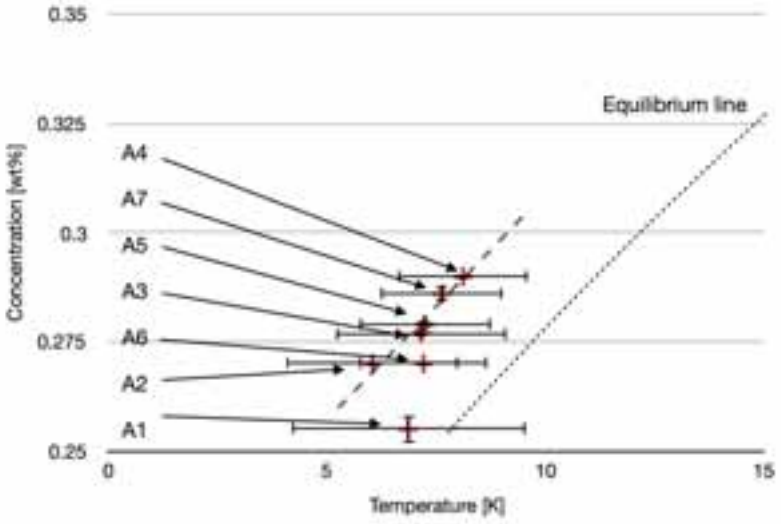

Fig. 5: Focus of Fig. 3 on the minimum concentration reached in absorption modus. All values are numbered according to their cycle. The dashed line shows a 3 K offset to the equilibrium line.

Fig. 6 shows a close up of the resulting concentration in respect to the temperature difference in the desorption process. Compared to the absorption results in figures 4 and 5 there is a greater average deviation from the equilibrium line in the desorption process. It appears that more time is required in order to reach a closer fit to

the equilibrium line. As in absorption, mass transport resistance is three fold; desorption, vapor transport and condensation. Assuming that vapor transport resistance and water phase change on the E/C unit is equal in the absorption as well as the desorption process, it may be concluded that there is a greater mass transport resistance in desorption than in absorption. The dashed line shows an offset of 9 K. As for absorption, there is no clear degradation trend to be recognized in desorption.

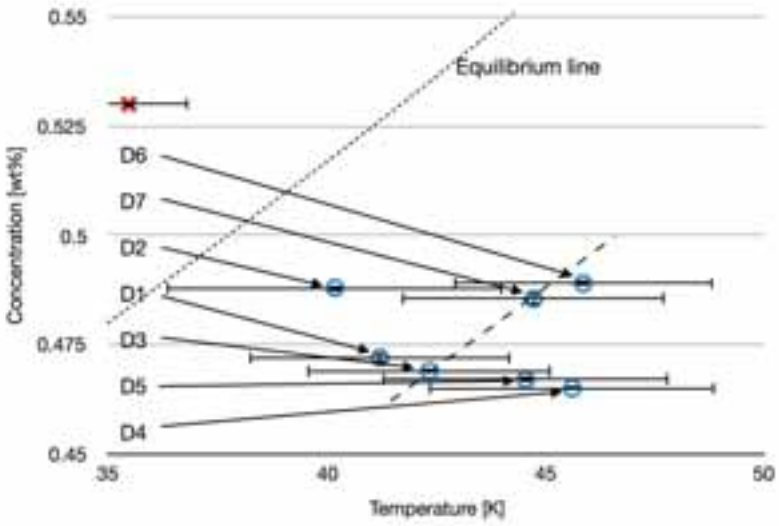

Fig. 6: Focus of Fig. 3 on the maximum concentration reached in desorption modus. All values are numbered according to their cycle. The dashed line shows the 9 K offset to the equilibrium line.

From the illustrated results it is shown that in respect to performance there is no clear trend of degradation or improvement.

It can be seen that even though both absorbent and absorbate are exposed to air in storage, no performance loss is encountered. On a system level this is a very important result, due to the large potential of system simplification and reduction of component costs.

5. Conclusion and outlook

In this paper a cycling test of 7 cycles is presented based on a spiral finned tube heat and mass exchanger for absorption heat storage. Results show good cycling stability without any clear degradation of the process. Storage of both absorbent and absorbate at ambient pressure is seen to be a promising approach for substantial reduction of system complexity and cost. Further work will include measurement over increased number of cycles with chemical analysis of absorbent in between the cycles.

Abstract

This contribution describes a model-based thermal performance test method for outdoor hot water stores for long-term thermal energy storage. For this purpose an existing TRNSYS model for indoor hot water stores is modified. In particular, local variations of the ambient temperature and the influence of solar irradiation are taken into account. A parameter identification process is proposed, which makes it possible to determine the parameters of the model required for the characterization of the thermal performance of an outdoor installed hot water store. The test method has been developed for an outdoor installed hot water store with a volume of 12 m^3, a vacuum thermal insulation and a transparent thermal insulation as well as for an outdoor installed 100 m^3 hot water store with a conventional thermal insulation. The functionality of the test method is confirmed by measured data, plausibility checks of the model parameters and a comparison to theoretical values determined based on material properties. Furthermore, the influences of the minimization algorithm on the results of the parameter identification process are investigated.

Keywords: Hot water store for outdoor installation, thermal performance test method, parameter identification

1. Introduction

Overground hot water stores with volumes in the range of 10 m^3 to 500 m^3 are an attractive technology for efficient and long-term thermal energy storage due to their relatively low surface to volume ratio compared to stores with smaller volumes. Applications of such stores range from SolarActiveHouses (Gerschitzka et al., 2016) to buffer stores in solar district heating systems (Bauer el al., 2010). In the last decade, several demonstration projects with stores in a volume range of 10 m^3 to 500 m^3 were planned, built and monitored within national and international research projects (Bauer et al., 2010, 2016). These stores are often placed overground and outside due to their large size. The resulting dynamic changes in the ambient conditions and novel effects on the heat losses, such as wind and irradiation, compared to a common indoor installation, require a modification and extension of already existing methods for the performance testing of hot water stores. Hence, in this contribution a model-based thermal performance test method for outdoor hot water stores is developed and validated. An existing TRNSYS model for indoor installed hot water stores (Drück, 2006) is modified. In particular, local variations of the ambient temperature and the influence of solar irradiation are taken into account. A parameter identification process is proposed, which makes it possible to determine the parameters of the model required for the characterization of the thermal performance of an outdoor hot water store for long-term thermal energy storage. The new test method was applied to a 12 m^3 hot water store with a vacuum thermal insulation combined with a transparent thermal insulation (TTI) as well as to a 100 m^3 hot water store with a conventional thermal insulation, see figure 1. Both stores were built for demonstration purposes in the context of two German research projects. The stores are equipped with measuring sensors for the determination of the ambient conditions and the store's thermal behaviour. Especially the temperatures inside the storage medium, outside the stores and on the outer surface of the thermal insulations are measured. Furthermore, the wind speed and the solar irradiation are recorded.

Fig. 1: Outdoor installed thermal energy stores with a water volume of 12 m³ (left) and 100 m³ (right)

The store with a volume of 12 m³ was developed as part of the German national research project „StoEx“ (Development of a large-volume, low-cost hot water store with high-efficient thermal insulation for outdoor installation; PTJ grant number: 0325992B). The aim of this project was the development of an advanced hot water store for outdoor installation. A significantly reduced heat loss rate compared to conventionally insulated thermal energy stores was achieved by the use of the high-efficient thermal insulation techniques vacuum thermal insulation and transparent thermal insulation (Gerschitzka et al., 2015a). The store was tested at a novel outdoor test facility especially designed for thermal performance testing of large-scale outdoor installed thermal energy stores (Gerschitzka et al., 2016). The project was carried out by the Research and Testing Centre for Thermal Solar Systems (TZS) of the Institute of Thermodynamics and Thermal Engineering (ITW) of the University of Stuttgart and the company Sirch Tankbau-Tankservice-Speicherbau GmbH from Germany.

The 100 m³ store was developed as part of the German national research project “OBSERW” (Overground stores in segmental construction for district heating systems; grant number: 03ET1230C). The partners of the project are the Professorship of Technical Thermodynamics of the Faculty of Mechanical Engineering of the Chemnitz University of Technology (TUC/TT), the Research and Testing Centre for Thermal Solar Systems (TZS) of the Institute of Thermodynamics and Thermal Engineering (ITW) of the University of Stuttgart and the company farmatic Anlagenbau GmbH from Germany. Within the project a so-called flat bottom hot water store using a thermal insulation based on polyurethane recycling material is developed (Urbaneck and Platzer, 2015). Regarding the store construction, a novel floating ceiling combined with a CFD-optimized charging device is investigated (Findeisen et al., 2016, 2017). Further topics of the research project OBSERW are the laboratory and application scale tests of the sealing material required for the segmental construction (Gerschitzka et al., 2015b).

2. Test method for outdoor hot water stores

The application of well-known test methods for indoor installed hot water stores to outdoor installed stores, e. g. of the test methods according to EN 12977-3 (2012) and EN 12977-4 (2012) is not appropriate since these methods are designed for smaller store volumes up to 5 m³ and for quasi steady state ambient indoor conditions. Additionally, no effects on the heat losses due to the outdoor specific installation are considered such as the decreased heat losses by solar gains. Furthermore, the charging and discharging capacity required to perform the test sequences of these methods is usually not available on-site. Therefore, a modified calculation procedure is developed regarding the determination of heat losses of outdoor installed hot water stores. For this calculation a model based on an extension of the proven TRNSYS Multiport Store-Model by Drück (2006) is used. A novel calculation of the outer surface temperature of the store is considered.

The Multiport Store-Model uses a one dimensional finite difference method to calculate the temperature of the storage medium. The storage medium is discretized along the store height in volume segments characterized by a node representing the temperature of these segments. The temperature of each node is determined by solving the energy balance for all nodes of the store's volume. This is a common approach to model the thermal behaviour of such stores for system simulation studies. A more detailed description of the Multiport Store-Model is given in (Drück, 2006, 2007). The original Multiport Store-Model considers the heat losses of the store medium for each volume segment by a linear approach between the heat flux of the heat losses and the temperature difference between the ambience and the store medium, according to eq. 1. The parameter (UA) represents the heat loss rate. Usually the inner surface temperature of an indoor installed hot water store is assumed to be the storage medium temperature.

$$\dot{Q}_{\mathrm{hl}} = (UA) \cdot (\vartheta_{\mathrm{sto}} - \vartheta_{\mathrm{amb}}) \qquad \text{(eq. 1)}$$

An outdoor installation of a hot water store requires a more detailed approach for the calculation of the heat losses. This is caused by the fact, that the heat flux of the solar irradiation, the convective heat transfer by wind and the heat capacity of the thermal insulation influence the outer surface temperature of the store. Hence, an extension of the Multiport Store-Model is necessary. This extension is done by an afterwards explained novel calculation method using a more detailed calculation of the store's outer surface temperature.

2.1. Calculation of the outer surface temperature

The thermal behaviour of a store's outer surface can be characterized by a multi-node calculation. Each node represents the temperature of a certain area of the outer surface of the store. Eight separate surface temperatures of the store's lateral area in circumferential direction are considered. A vertical temperature distribution within the considered specific surface area is neglected. The outer surface temperatures can be calculated by determining the heat transfer between the outer store surface and the ambience as well as the thermal capacities. The considered heat transport phenomena are the heat transfer by solar and thermal irradiation, a temperature and wind speed dependent convective heat transfer and an internal heat transfer inside the material of the outer surfaces in the circumferential direction.

The model parameters of the surface temperature calculation are the effective heat capacity C_{eff} of the store's thermal insulation, the transmittance-absorptance-product $(\tau_{\mathrm{g}}^{*}\alpha_{\mathrm{a}}^{*})$ and the heat transfer coefficient from the store surface to the ambience h_{ext1} respectively the coefficient of the temperature dependence of heat transfer coefficient h_{ext2}. Furthermore, a wind speed and irradiation dependency of the surface temperature can be included by the parameters h_{w1} and h_{w2}. Concerning the calculation of the incidence angle, depended on solar irradiation, the reflectance of the ambience ρ_{amb}^{*} and the incidence angle modifier K_{b} are of importance. A heat transfer by thermal irradiation between the store's surface and the ambience respectively the sky can be considered by the parameter ϵ^{*}. If there is a transparent thermal insulation on the outer store surface, a heat transfer between different surfaces in circumferential direction can occur. This heat transfer can be considered by the parameter $h_{\mathrm{int,i\rightarrow j}}$ between two neighboring segments.

Assuming only a small change of inner energy compared to the incoming solar irradiation and heat losses of the outer store surface, the energy balance of one surface segment can be approximated according to eq. 3. The subscription is exemplary for a north orientated surface segment. The aim of eq. 3 is to calculate the surface temperature ϑ_{sur} of one segment based on the knowledge of the input values and the temperature of the surface $\vartheta_{\mathrm{sur,old}}$ from the time step before. Considering all individual segment equations, an equation system occurs.

$$\begin{aligned}
\vartheta_{\mathrm{sur,N}} = {} & \vartheta_{\mathrm{sur,old,N}} \\
& + \{\left(\tau_{\mathrm{g}}^{*}\alpha_{\mathrm{a}}^{*}\right)_{\mathrm{N}} \cdot A \cdot (K_{\mathrm{b,N}} \cdot G_{\mathrm{hem,dir,N}} + G_{\mathrm{hem,diff,N}} + 0.5 \cdot \rho_{\mathrm{amb}}^{*} \cdot G_{\mathrm{glob}}) \\
& - A' \cdot h_{\mathrm{ext1,N}} \cdot (\vartheta_{\mathrm{sur,old,N}} - \vartheta_{\mathrm{amb}}) - A' \cdot h_{\mathrm{ext2,N}} \cdot (\vartheta_{\mathrm{sur,old,N}} - \vartheta_{\mathrm{amb}})^{2} \\
& + A'' \cdot h_{\mathrm{int,N\rightarrow NO}} \cdot \left(\vartheta_{\mathrm{sur,old,NO}} - \vartheta_{\mathrm{sur,old,N}}\right) \\
& + A'' \cdot h_{\mathrm{int,N\rightarrow NW}} \cdot (\vartheta_{\mathrm{sur,old,NW}} - \vartheta_{\mathrm{sur,old,N}}) \\
& - A' \cdot h_{\mathrm{w1,N}} \cdot w \cdot G_{\mathrm{hem,N}} - h_{\mathrm{w2,N}} \cdot A' \cdot w \cdot (\vartheta_{\mathrm{sur,old,N}} - \vartheta_{\mathrm{amb}}) \\
& - 0.5 \cdot \epsilon^{*}{}_{\mathrm{N}} \cdot \sigma \cdot A' \cdot [\left({T_{\mathrm{sur,old,N}}}^{4} - {T_{\mathrm{amb}}}^{4}\right) + ({T_{\mathrm{sur,old,N}}}^{4} - {T_{\mathrm{sky}}}^{4})]\} \cdot \Delta t \; / \; C_{\mathrm{eff,N}}
\end{aligned} \qquad \text{(eq. 3)}$$

The incidence angle modifier K_b of the direct irradiation is defined by eq. 4 (Fischer, 2011; Bosanac, 1992). The incident angle Θ between the sun and the normal of the TWD area of each segment is calculated in TRNSYS. The coefficient r_0 is used for the fitting of the incident angle modifier.

$$K_b = 1 - [\tan(\Theta/2)]^{1/r_0} \quad \text{(eq. 4)}$$

The areas A, A' and A'' are multiplied with the corresponding heat transfer coefficients. The sky temperature T_{sky} is calculated according to Swinbank (Fischer, 2006) for the assumption of clear sky. To get a workable number of model coefficients, only the heat transfer coefficient $h_{int,i\rightarrow j}$ is individually determined for all segments. The remaining parameters are equal for all segments. The input values of the surface temperature calculation are the ambient temperature, the global solar irradiation, the diffuse solar irradiation in the horizontal and the wind speed.

In the novel and extended Multiport Store-Model, the calculated local mean surface temperatures are used for the calculation of the heat losses instead of the ambient temperature, according to eq. 5. The mean surface temperature $\bar{\vartheta}_{suf}$ is calculated by the average of all eight individual segment temperatures.

$$\dot{Q}_{hl} = (UA) \cdot (\vartheta_{sto} - \bar{\vartheta}_{suf}) \quad \text{(eq. 5)}$$

In addition to the integration of the surface temperature's calculation into the original Multiport Store-Model (Drück, 2006), two further changes are introduced. On the one hand, the original store model is modified in such a way, that an ambient temperature of the bottom and an ambient temperature of the top can be set as input value. On the other hand, a non-homogeneous temperature distribution in the storage medium is introduced at the initial time step. The possibility of starting the calculation with an inhomogeneous temperature distribution is particularly useful for parameter identification on the basis of in-situ measuring data.

The parameters of the store model, relevant for the thermal behaviour of a long-term thermal energy storage, remain the heat loss rate of the store mantle $(UA)_{man}$, the heat loss rate of the store bottom $(UA)_{bot}$, the heat loss rate of the store top $(UA)_{top}$ and the effective thermal conductivity of the storage medium in a vertical direction k_{eff}. The store model input values are the store's surface temperatures, determined by the novel surface temperature model, and the ambient temperature for the mantle, the bottom and top of the store. It is assumed, that the heat losses of the store don't influence the temperature of the transparent thermal insulation respectively the outer surface temperature of the store.

2.2. Process of parameter identification

The procedure of determining the model parameters of both models, the store and surface temperature model, regarding the thermal behaviour of a long-term thermal energy storage is separated into two individual parameter identification processes. Figure 2 shows the basic approach of such a parameter identification process for a dynamic model (Fischer, 2011). The output values of the model calculation and of the measurement are compared using a target value. Afterwards, an optimization algorithm searches for a minimum of the target value by varying the model parameters.

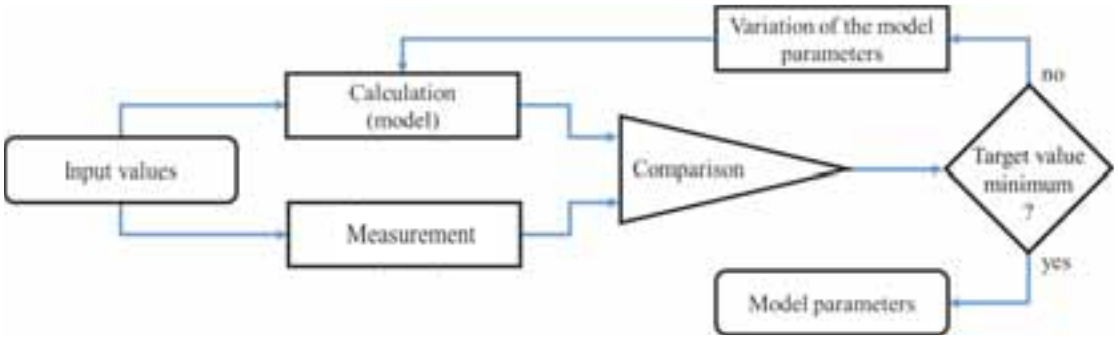

Fig. 2: Schematic process of a parameter identification

In this investigation, several Matlab integrated optimization algorithms are tested. Especially for the dynamic parameter identification of solar collector models in TRNSYS several well working optimization algorithms are known (Bales, 2002; Fischer; 2011, Bosanac, 1992). Because of the similarity to a solar collector, the transparent thermal insulation is also calculated in a time-dependent, dynamic way.

The parameter identification process of the surface temperature model uses the mean quadratic deviation of measured ($\vartheta_{m,j,i}$) and calculated ($\vartheta_{c,j,i}$) surface temperatures as target value. The parameter identification process of the store model uses the mean quadratic deviation of measured ($\vartheta_{m,j,i}$) and calculated ($\vartheta_{c,j,i}$) store medium temperatures as target value. Equation 6 defines the target value with a constant reference temperature ϑ_{ref} of 10 °C. The reference temperature is used to obtain a dimensionless target value. The value N_{MS} is the amount of considered sensors and the value N_{TS} is the amount of measuring time steps during the considered stand-by test.

$$f' = \sqrt{\sum_{i=1}^{N_{TS}} \left(\frac{\sum_{j=1}^{N_{MS}} \left(\vartheta_{m,j,i} - \vartheta_{c,j,i}\right)^2}{N_{MS} \cdot N_{TS} \cdot {\vartheta_{ref}}^2} \right)} \qquad \text{(eq. 6)}$$

This approach for the calculation of the target value is similar to the calculation method in (John, 2002), in which the heat loss rates of a store with a volume of 85 m³ is successfully identified by parameter identification with the Multiport Store-Model.

The charging and discharging characteristics of the Multiport Store-Model with volumes between 5 m³ and 100 m³ are assumed to be equal to stores with volumes lower than 5 m³. This is indicated in (John, 2002), due to a validation of the Multiport Store-Model for a store with a volume of approximately 85 m³. Hence, no modifications in the Multiport Store Model regarding the charging and discharging characteristics are necessary. Model parameters for the charging and discharging characteristics are for example the height of the input and output flow ports, the number of nodes in the store volume and a local turbulent thermal conductivity (Drück, 2007). However, the currently known test methods according to EN 12977-3 (2012) and EN 12977-4 (2012) for the identification of the charging and discharging parameters are again not applicable to stores with volumes greater than 5 m³ for the previously mentioned reasons. The following investigations only consider the thermal behaviour of a long-term thermal energy store respectively a stand-by heat loss test of a store, so these charging and discharging model parameters don't have to be identified.

With the above-described procedure for determining the model parameters three stand-by tests of the store with a volume of 12 m³ and with a vacuum and transparent thermal insulation are exemplary analyzed. These tests include a stand-by test with an inhomogeneous starting temperature distribution in the vertical direction (test 1), a stand-by test with a homogeneous starting temperature distribution (test 2) and a stand-by test with a homogeneous starting temperature distribution and an additional thermal insulation of the bottom of the store (test 3). The mean daily irradiation sum in the horizontal is 5.59 kWh m^{-2} d^{-1} for the duration of 26 days of test 1, 4.54 kWh m^{-2} d^{-1} for the duration of 18 days of test 2 and 2.72 kWh m^{-2} d^{-1} for the duration of 16 days of test 3. The maximum uncertainty of the eleven Pt100 temperature sensors, used for measuring the vertical temperatures in the store, and the eight Pt100 temperature sensors, used for measuring the horizontal surface temperatures of the TTI, is ± 0.35 K. The maximum uncertainty for the pyranometer is ± 1.5 % of the measured value and 0.2 m s^{-1} for the windspeed sensor. A digital data acquisition system measures the measuring values with a time step of 60 s.

3. Results

The following chapter describes a model sensitivity analysis of the surface temperature model and the results of the parameter identification process for measuring data of the three stand-by tests of the thermal energy store with a volume of 12 m³ and with transparent and vacuum thermal insulation.

3.1. Analysis of the model sensitivity

Due to the dynamic parameter identification of the surface temperature model, typical sensitivity analysis methods for the parameters of the model equation cannot be applied. Therefore, an alternative sensitivity analysis method, called morris method (Morris, 1991), is used to identify the main parameters of the models. A

further explanation of the morris method and its extension can be found in (Campolongo et al., 2005; Cropp and Braddock, 2002; Saltelli et al., 2004). The method was successfully implemented in Matlab and tested by means of several test functions compared to literature results. The results of the morris method for the surface temperature model parameter identification show, that the main parameters are $(\tau_g^* \alpha_a^*)$, C_{eff}, h_{ext1}, h_{ext2}, ϵ^*, ρ_{amb}^* and r_0. The parameters h_{w1}, h_{w2} and all individual $h_{\text{int,i}\rightarrow\text{j}}$ seem to be of small importance. This is indicated in figure 3 (left) by a high value of μ'. A high value of σ' indicates a strong dependency on other parameters or a nonlinear model equation. The range in which the parameters are investigated in the morris method is equal to the range of the parameter identification process.

Further investigations also show, that all eight individual $h_{\text{int,i}\rightarrow\text{j}}$ cannot not be neglected completely, but can be assumed to be equal for all segments. This finding was confirmed by means of several individual parameter identification processes with a stepwise decrease of the amount of fitting parameters. Exemplary results of the morris method for a decreased amount of parameters are shown in figure 3 on the right side. Only the parameters $(\tau_g^* \alpha_a^*)$, C_{eff}, h_{ext1} and $h_{\text{int,i}\rightarrow\text{j}}$ are considered. It can be concluded, that due to the parameter reduction the heat losses are characterized completely by h_{ext1}, which is now the most relevant parameter.

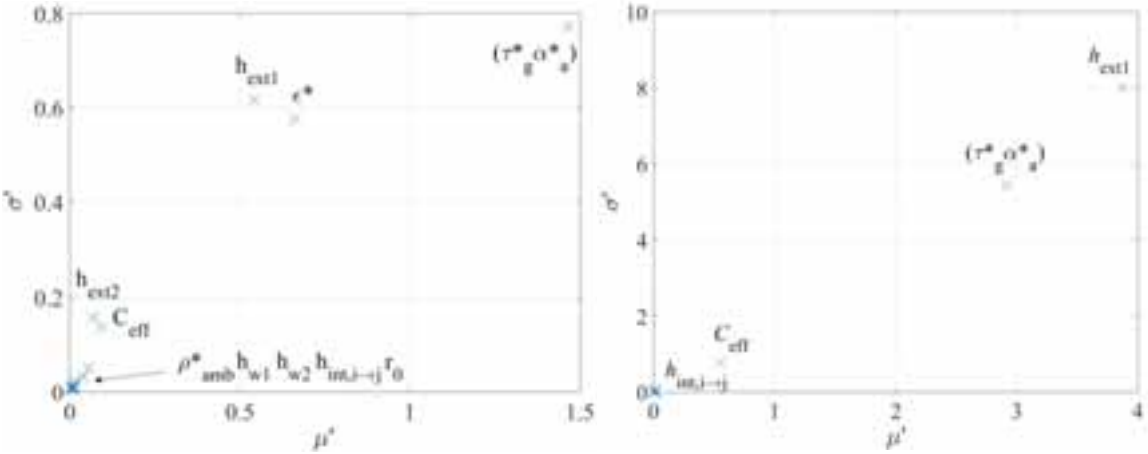

Fig. 3: Results of the morris method ($p' = 50$, $r' = 2000$, stand-by test 1) for the surface model with all (left) and a reduced amount (right) of parameters

Further investigations concerning the parameter identification process of the surface model show, that there is an influence of the solution algorithm on the target value. A comparison of several Matlab integrated minimization algorithms implemented in the parameter identification process was done. Generic algorithms, especially the particle swarm algorithm, and direct search and simulated annealing methods were investigated. However, these algorithms and methods show no or only slight advantages concerning the target value and the simulation time, compared to the standard interior-point algorithm for the parameter identification of the surface model. Hence, the interior-point algorithm was used for all following parameter identifications.

A second sensitivity analysis, based on the fit results of the parameter identification process for each month of one year of measuring data, is determined. Table 1 summarizes the mean parameter values for all fits for one year and the corresponding standard deviations. The parameter $\bar{h}_{\text{int,i}\rightarrow\text{j}}$ represents the average of all individual parameters $h_{\text{int,i}\rightarrow\text{j}}$.

Tab. 1: Selected deviations derived from the cross correlation matrix and mean parameter values of the store model for a monthly parameter identification of one year

	$(\tau^*{}_g \alpha^*{}_a)$ in [-]	C_{eff} in kJ K^{-1}	h_{ext1} in W m^{-2} K^{-1}	h_{ext2} in W m^{-2} K^{-2}	$\bar{h}_{\text{int,i}\rightarrow\text{j}}$ in W m^{-2} K^{-1}	ϵ^* in [-]	ρ_{amb}^* in [-]	r_0 in [-]
mean value	0.60	119.44	3.51	$2.1 \cdot 10^{-2}$	183.37	$4.70 \cdot 10^{-3}$	$2.4 \cdot 10^{-1}$	$3.4 \cdot 10^{-2}$
standard deviation	0.14	25.47	0.54	$1.2 \cdot 10^{-4}$	45.15	$7.79 \cdot 10^{-5}$	$2.4 \cdot 10^{-2}$	$3.0 \cdot 10^{-2}$

It can be concluded, that the standard deviation of most of the parameters is in an acceptable range for the interpretation of the results, expect the parameter r_0. The results of parameter r_0 indicate, that the modelling of the incidence angle modifier strongly depends on the season of the year.

3.2. Results of the parameter identification process

Table 2, table 3 and table 4 show a summary of the parameters determined for the surface temperature model and the store model for all stand-by tests mentioned above by means of parameter identification. The determined overall heat loss rate $(UA)_{\mathrm{ov}}$, which is summed up by $(UA)_{\mathrm{man}}$, $(UA)_{\mathrm{top}}$ and $(UA)_{\mathrm{bot}}$, is 6.410 W K^{-1} for the stand-by test 1, 6.618 W K^{-1} for the stand-by test 2 and 5.038 W K^{-1} for the stand-by test 3. The lower overall heat loss rate of the stand-by test 3 results from the additional thermal insulation at the bottom of the store. The higher value of the effective thermal conductivity k_{eff} compared to the material value of water can be explained due to several stratification devices integrated in the store and the store's lateral walls made of steel, which increase the thermal conductivity in the vertical direction. The quite similar results of the overall heat loss rate and of the store's effective thermal conductivity for all three experiments indicate, that the procedure for modeling dynamic ambient conditions respectively for identifying the model parameters provides reasonable and reproducible results.

Tab. 2: Summary of store model parameters and target values

Test	ϵ^* in [-]	ρ^*_{amb} in [-]	h_{w1} in s m^{-1}	h_{w2} in J m^{-3} K^{-1}	r_0 in [-]	f in [-]
1	0.010	0.231	0.019	1.172	0.028	0.427
2	0.006	0.239	0.018	0.939	0.016	0.369
3	0.004	0.230	0.005	0.492	0.023	0.312

If the averaged sum of the heat loss rate of the mantle and the top for all three experiments is converted to an effective thermal conductivity with the assumption of an one-dimensional heat transfer, a calculated effective thermal conductivity for the vacuum thermal insulation of $13.3 \cdot 10^{-3}$ W m^{-1} K^{-1} is obtained. This value is 11 % higher than the value expected from laboratory measurements of $12.0 \cdot 10^{-3}$ W m^{-1} K^{-1} (Gerschitzka et al., 2016).

The value of the effective heat capacity used in the surface temperature model exceeds the theoretically expected value of a cylindrical metal sheet with same dimension as the store's outer surface steel sheet by 10 %. This indicates, that a part of the pourable filling material of the vacuum thermal insulation also acts as a thermal capacity.

The values of the heat transfer coefficient from the surface to the ambience are within the expected range of free convection at a vertical cylinder. The transmittance-absorptance-product for all stand-by tests falls below the theoretical value of an incidence angle of 90° by 18 %. This can be explained due to the simplified calculation of the incidence angle modifier by only one parameter for all segments. The remaining coefficients of the surface model are within the expected range.

The target value according to eq. 6 multiplied by ϑ_{ref} can be interpreted as mean deviation between the calculated and the measured temperatures of the store and surface temperature model. According to this interpretation, the mean deviation of 0.39 K from the calculated and measured temperatures of the store parameter identification shows very good results and the mean deviation of 3.70 K from the calculated and measured temperatures of the surface parameter identification shows acceptable results.

For an exemplary presentation figure 4 shows the measured and calculated temperatures of the south-orientated surface of the transparent thermal insulation and the hemispherical respectively diffuse solar irradiation for the first three days of the stand-by test 1. Despite some deviation during the time of maximum temperatures, the results of the calculation of the southward-orientated surface temperature fit quite well. It has to be considered, that only the hemispherical und diffuse solar irradiation, the wind speed and the ambient temperature are available as input values. Furthermore, the surface temperature model does not take shadings into account. These occur in the morning and evening of the considered days and are caused by the horizon and neighboring buildings.

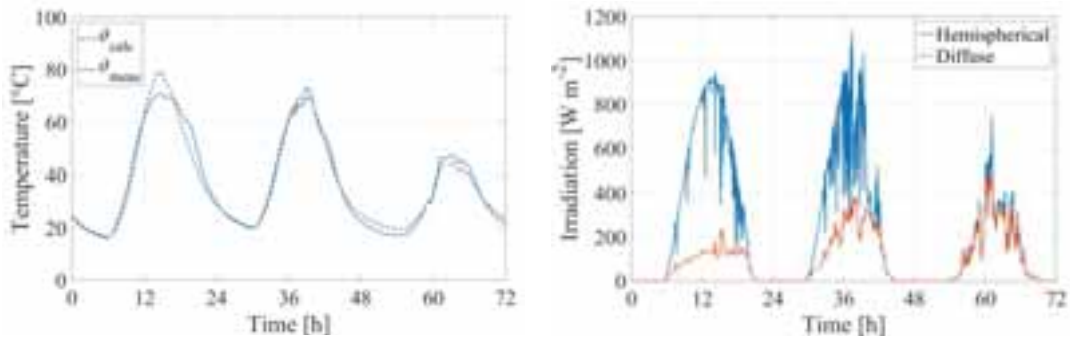

Fig. 4: Measured and calculated temperature of the south orientated surface of the transparent thermal insulation (left) and the south orientated hemispherical respectively diffuse solar irradiation (right)

If the previous calculation method for the heat losses of the store according to equation 1 is used, the determined heat loss rate of the store mantel $(UA)_{\mathrm{man}}$ is on average 30 % lower than the heat loss rate of the store mantle for all three stand-by tests calculated according to equation 5. The reduction of $(UA)_{\mathrm{man}}$ is 38 % for the stand-by test 1, 33 % for the stand-by test 2 and 19 % for the stand-by test 3. These results correspond with the mean daily radiation sum for the three stand-by tests. The heat loss rate decreases, because the positive effect of a lower temperature difference over the vacuum thermal insulation is taken into account for the parameter identification of the heat loss rate. Derived from these results, the importance of the consideration of the surface temperature calculation for the heat loss rate determination can be seen.

4. Conclusions

It can be summarized, that additional effects for the characterization of the heat losses of an outdoor installed hot water store have to be taken into account compared to an indoor installed one. These effects can be described by means of the developed combination of the surface temperature model and the store model. The novel calculation of the outer store surface temperature is applied to separate surface segments of the store's lateral area in circumferential direction. These surface temperatures are used for the calculation of the heat losses of the modified store model derived from the well-known Multiport-Store Model from TRNSYS. An evaluation of both model parameter identification processes using three stand-by tests show reasonable and reproducible results, compared to theoretical, material based values. Based on the identified model parameters of both models, the detailed characterization of the heat losses of outdoor installed hot water stores for long-term

thermal energy storage is possible. A comparison of the identified model parameters using the previous and the novel surface temperature calculation method shows, that the dynamic ambient conditions can have a significant influence on the heat loss rate of a hot water store. A mean change of the mantel heat loss rate of 30 % in the parameter identification process due to the surface temperature calculation cannot be neglected.

Future work will deal with the development of a more detailed node model for the surface temperature calculation, especially to account for a vertical temperature gradient. It is also planned to optimize the surface temperature model for thermal energy stores in outdoor installation with no transparent thermal insulation, especially for the 100 m^3 store of the project OBSERW. For stores of this kind, the influence of the wind speed could be more relevant for the surface temperature calculation than for stores with transparent thermal insulation.

Abstract

This paper deals with the global aging behavior and lifetime assessment of polyethylene liner materials for seasonal heat storages. Hot water aging experiments at elevated temperatures of 95, 105 and 115°C were carried out using specimens with various thicknesses of 100, 500 and 2000 µm. The aging indicator strain-at-break was monitored for up to 1500 days. The experimental hot water data were fitted by potential and Arrhenius equations referring to thickness and temperature dependency. By merging both equations a semi-empirical model was established and used for lifetime estimation of polyethylene liner materials. The low divergence of the lifetime values between experimental and calculated failure data indicates the high accuracy of the thickness/temperature-model. A lifetime value of 18 years was derived for 3 mm thick polyethylene based liner materials for solar district heating systems.

Keywords: Polyethylene liner material, Seasonal heat storage, Thickness/temperature depending model, Lifetime.

1. Introduction

The share of polymeric materials for hot water seasonal heat storages increased steadily due to lower material costs and installation costs compared to stainless steel (Köhl et al., 2012). A better competitiveness especially for big storage volumes greater than 20.000 m³ is given by replacing steel with polymeric liner materials (Heller, 2000). Regarding the material grades, the most common polymeric liner materials are based on special polyethylene grades (PE-RT) or polypropylene random copolymers (PP-R) (Grabmayer, 2014). Improved long-term stability against thermo-oxidation given by stabilization packages is essential to ensure functionality and durability at service temperatures of up to 95°C for more than 20 years (Schramm and Jeruzal, 2006; Paranovska and Pedersen, 2016). While polypropylene materials exhibit a more critical degradation behavior in hot air environment than in hot water, interestingly a reverse phenomenon was reported for polyethylene liner grades (Grabmayer, 2014).

Oven aging tests at elevated temperatures are commonly performed to evaluate the long-term thermo-oxidation behavior of polymeric materials (Gijsman, 1994; Kahlen et al., 2010a; Olivares et al., 2010; Celina, 2013). Enhanced temperatures result in accelerated aging processes with reduced experimental time (Kahlen et al., 2010c, 2010d; Olivares et al., 2010) (Kahlen et al., 2010a; Olivares et al., 2010). Polymer aging is strongly influenced by diffusion limited oxidation (Audouin et al., 1994). Hence, a reduction of the specimen thickness leads to accelerated aging processes (Gugumus, 1996; Grabmayer et al., 2015).

So far, no comprehensive studies on temperature and thickness depending global aging behavior of polyethylene liner materials were published. Hence, it is the main objective of this paper to establish a thickness/temperature model using ultimate failure data. Lifetime assessment under service-relevant loading conditions should be executed for typical liner thicknesses of 2 and 3 mm. This is of utmost importance to clarify the durability of polymeric liner materials and to compare polyolefin liner materials for large solar-thermal district heating systems with seasonal heat storages.

2. Methodological approach

2.1 Materials, aging conditions and characterization methods

A commercial polyethylene high density grade was used. Details as to the molecular structure, morphology and the stabilizers are given in Grabmayer (2014) and Beißmann et al. (2013). The PE grade was extruded to a 2 mm thick sheet by AGRU Kunststofftechnik GmbH. Specimen with various thicknesses of 100 and 500 µm and a length of at least 150 mm were manufactured by using an automated planning technique (Grabmayer et al., 2015). Additionally, ISO 5A specimens with a thickness of 2000 µm were prepared by die-punching.

Due to the more critical aging behavior in water than in air, primarily hot water exposure was performed. The specimens were aged in closed stainless steel vessels with integrated specimen holder at temperatures of 95, 105 and 115°C using a Binder FED53 (Tuttlingen, Germany) heating chamber with forced circulation. Whenever specimens were removed from the vessels, the deionized water was changed. Four specimens were examined per aging interval.

To assess the aging behavior, tensile tests were carried out at ambient conditions using a screw-driven universal testing machine at a deformation rate of 50 mm/min. For various polymeric materials used in solar energy engineering the ultimate mechanical properties strain-at-break or tensile strength are highly sensitive indicators to monitor both, physical and chemical aging phenomena (Wallner et al., 2004; Povacz et al., 2014; Povacz et al., 2016). As aging indicator, strain-at-break was evaluated over the aging period. Ultimate failure was defined when strain-at-break values dropped below the strain-at-yield value ($\varepsilon_b < \varepsilon_y$). The limit value for ε_y was 20% for all investigated specimen thicknesses.

2.2 Modelling the thickness/temperature dependency

A semi-empirical model describing the effect of specimen thickness and exposure temperature on global aging behavior was evolved. Therefore, experimental failure data for specimens of various thicknesses (100, 500 and 2000 µm) at aging temperatures of 95, 105 and 115°C were applied. The thickness and temperature dependency was considered separately and merged. Hülsmann and Wallner (2017) used a similar approach to describe the temperature and thickness dependent water vapor permeation in photovoltaic encapsulation materials.

By using a potential function (eq. 1) the thickness dependency of the failure data was fitted. The effect of temperature on global aging behavior was considered by the well-established Arrhenius model (eq. 2). Both equations give the endurance time ($t_{endurance}$) as a function of thickness (d) or temperature (T) considering material specific constants (A, B, C), the activation energy (E_A) ant the gas constant (R).

$$t_{endurance} = B * d^C \qquad \text{(eq. 1)}$$

$$\ln t_{endurance} = \ln A + \frac{1}{T} * \frac{E_A}{R} \qquad \text{(eq. 2)}$$

The thickness and temperature dependent endurance time is calculated by a two dimensional model (eq. 3). Here, variables with index "0" are experimental values whereby C and E_A are calculated material specific constants from eq. 1 and 2.

$$t_{endurance} = \frac{t_0}{d_0^C} * e^{\frac{E_A}{R}*\left(\frac{1}{T}-\frac{1}{T_0}\right)} * d^C \qquad \text{(eq. 3)}$$

2.3 Lifetime assessment

For lifetime estimation a cumulative damage approach was used, established by Wallner et al. (2016) for black-pigmented PP solar absorber materials. The lifetime assessment approach is based on the simulation of temperature loading profiles for liner materials, the extrapolation of experimental aging data from elevated temperatures to service relevant temperatures and the accumulation of damages at different temperature levels. Temperature loading profiles for seasonal heat storages are dependent on the plant type. As minimum temperature level 50°C was considered for the storage temperature in winter months. Temperature of the storage system increases during warm-weather months and reaches maximum temperature level of 85°C in summer (see Fig. 1). Comparable loading profiles were assumed by Ochs (2008) and deduced for seasonal pit storages in Denmark (Paranovska and Pedersen, 2016).

Experimental aging data obtained at 115, 105 and 95°C were extrapolated to service relevant temperatures (50

to 85°C) using the linear Arrhenius fit approach. Various aging processes and temperature degradation mechanisms as described by Gugumus (1999), Celina et al. (2005), Hoàng and Lowe (2008) and Kahlen et al. (2010c, 2010d) were neglected. According to ISO 13760 a cumulative damage model was used to calculate lifetime values. The theoretical temperature loading profile was transformed to frequency distributions. The lifetime was derived by weighting the frequency distributions with extrapolated endurance times.

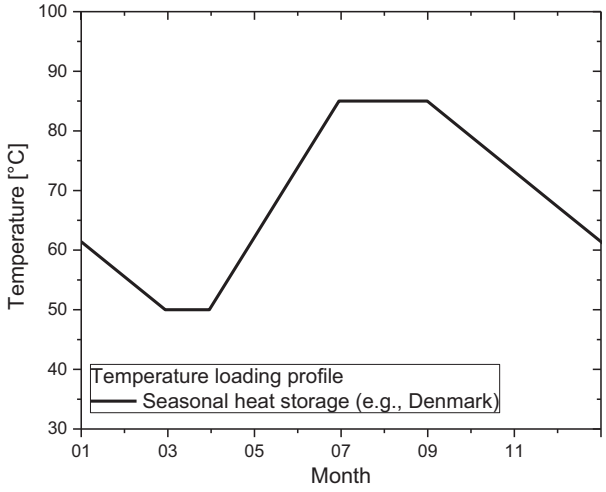

Fig. 1: Assumed temperature loading profile for a seasonal heat storage in Northern hemisphere.

3. Results and discussion

3.1. Hot water aging behavior of the PE liner material

Aging data for up to 900 days in hot air and hot water for micro- and macro-sized specimens are based on previous investigations of Grabmayer et al. (2014). The main result of this study was that the investigated polyethylene liner material revealed a more critical aging behavior in hot water than hot air. Based on these results it was decided to focus on hot water aging. While all specimens were embrittled at 115°C within up to 443 days, no failure for 2000 µm specimens at 95°C were obtained within 1500 days of exposure. These aging experiments are still ongoing.

Figure 2 depicts strain-at-break values of the investigated 100 and 500 µm thick PE liner grade as a function of aging time in hot water at elevated temperatures. Ultimate failure with strain-at-break values below yield point (20%) is indicated with open symbols in the chart. The unaged 100 and 500 µm specimens revealed high ductility with strain-at-break values up to 1400%. Due to different specimen thickness, the unaged 500 µm specimens exhibited slightly lower strain-at-break values. A significant drop in strain-at-break values appeared after initial aging within the first few days. This drop was more pronounced for the 100 µm specimens at all investigated exposure temperatures. This reduction in ultimate strain is presumably related to crystallization effects and higher intersperulitic, internal stresses. In course of aging, strain-at-break values leveled off at about 750 and 1250% for 100 and 500 µm thick specimens, respectively. These plateaus are more pronounced for thicker specimens and lower exposure temperatures. Subsequently, a drop of strain-at-break values was observed resulting in ultimate failure for 115 and 105°C exposure. Interestingly, for 95°C aging experiments a second plateau with strain-at-break values of 25 to 150% was obtained before embrittlement occurred. Ultimate failure first appeared at 115°C after 91 days for 100 µm specimens. Increasing specimen thickness resulted in longer aging times up to 278 and 443 days for 500 and 2000 µm specimens, respectively. Hence, diffusion limited oxidation processes as postulated by Audouin et al. (1994) or Celina (2013) were also ascertained for the investigated PE grade. An less pronounced effect of specimen thickness on endurance times was also described by Grabmayer et al. (2015) for different polypropylene grades. The experimental failure times of the investigated PE liner material of different thicknesses are summarized in Table 1. Up to 1500 days no embrittlement occurred at an exposure temperature of 95°C for 2000 µm specimens. In 115°C hot water a reduction of thickness from 2000 to 100 µm (factor 20) and 500 to 100 µm (factor 5) resulted in a 4.9 and 3.1

times accelerated aging, respectively. Acceleration factors of 5.5 and 2.7 were deduced by exposing to hot water at 105°C. For aging in 95°C hot water an acceleration factor of 3.1 was derived for a thickness reduction from 500 to 100 µm. Compared to data provided by Grabmayer et al. (2015) or Povacz (2014) for polypropylene, for the investigated PE liner material a more pronounced specimen thickness dependency on global aging behavior for similar thickness reduction and exposure temperature was obtained. The acceleraton factors are below 2 for PP specimen with comparable thickness. Based on these results, it was unambiguously confirmed that localized aging effects play a significant role in polyethylene oxidation as pointed out by Audouin et al. (1994) or Celina (2013).

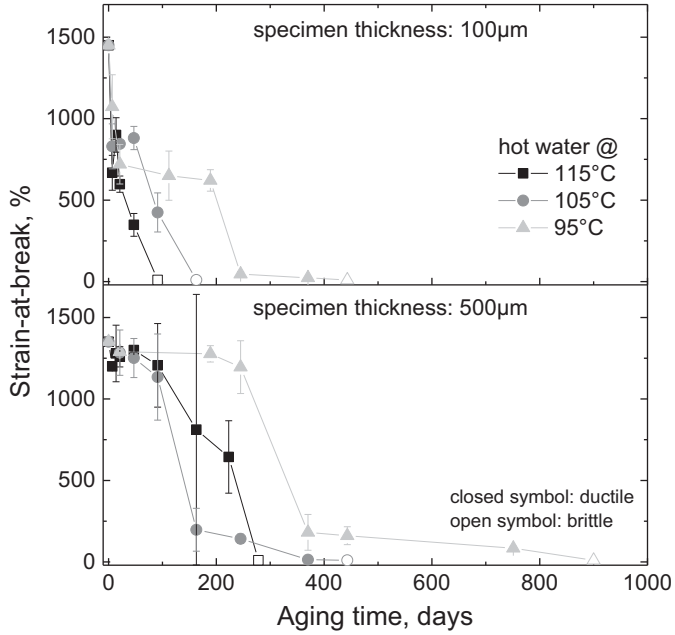

Fig. 2: Strain-at-break of micro-sized PE specimens with a thickness of 100 and 500 µm as a function of aging time exposed in hot water at 115, 105 and 95°C.

Tab. 1: Embrittlement times of PE liner specimens with varying thickness in hot water at 115, 105 and 95°C.

Specimen thickness, µm	Failure time in days in hot water at		
	115°C	105°C	95°C
100	91	163	245
500	278	443	751
2000	443	900	> 1500

3.2. Theoretical model for thickness and temperature dependency

The experimental aging data in hot water at different temperatures and for various PE specimen thicknesses were used to evolve a semi-empirical model. Therefore, the factors specimen thickness and exposure temperature were considered separately and finally merged to a two-dimensional model. Figure 3 depicts the dependency of failure time as a function of specimen thickness in hot water at 115, 105 and 95°C. The fits of the experimental data with potential functions resulted in high coefficients of determination. No embrittlement was observed for 2000 µm specimens in 95°C hot water within 1500 days, so fit parameters gathered from 115 and 105°C aging data were used to implement the model. A significant temperature dependent difference was deduced for the fit parameter B. The material specific constant C was calculated and determined with 0.5522 for the semi-empirical model. For C a temperature induced deviation of <5% was ascertained. Hence, an arithmetic value was deduced and used for the two-dimensional model. The validity and reliability of this parameter will be further improved by continuation of the aging experiments at 95°C.

Experimental aging data and related Arrhenius fittings as a function of temperature are plotted in Fig. 4. Slightly thickness dependent E_A/R-ratios ranging from 7.1 to 10.4 x10^3 K were derived. The E_A/R-ratios were lower for the thinner specimen, which already failed at all investigated temperautres. Due to non-failure of 2000 µm thick

specimens at 95°C within 1500 days, extrapolation was done by only two aging data points resulting in a higher E_A/R value. By using Arrhenius fit parameters gathered from 100 and 500 µm thick specimens an average value of 7.1 x10³ K was used for the two-dimensional model. A specimen thickness dependent E_A/R-ratio can be implemented in the semi-empirical model finishing aging experiments at 95°C. The obtained activation energies are in the range from 59 to 86 kJ/mol. These values are comparable to data given for polyolefins (Kahlen et al., 2010b), but slightly lower than data for specific polyethylene grades (Anderson and Freeman, 1961; Peterson et al., 2001; Gao et al., 2003; Mueller and Jakob, 2003).

As zero or reference values the endurance time at a thickness of 500 µm and a temperature of 105°C were selected. These reference values resulted in best reproduction of experimental values and lowest deviations between theoretical and experimental endurance times. The comparison of the experimental and theoretical values of thick specimens at low temperatures (2000 µm at 105°C and 500 µm at 95°C) revealed a deviation of about 10%, reflecting the uncertainty of the model. Improved accuracy will be achieved by continuation of the experiments at 95°C until ultimate failure of 2000 µm specimens. Figure 5 depicts the calculated endurance times depending on various specimen thicknesses and a wide range of hot water temperature based on equation 3. It can be clearly seen for the plotted range, that the specimen thickness has also a significant impact on the failure times. At 95°C the expected endurance time is compared to 100 µm specimens a factor of 5 and 7 higher for 2 and 3 mm liners, respectively.

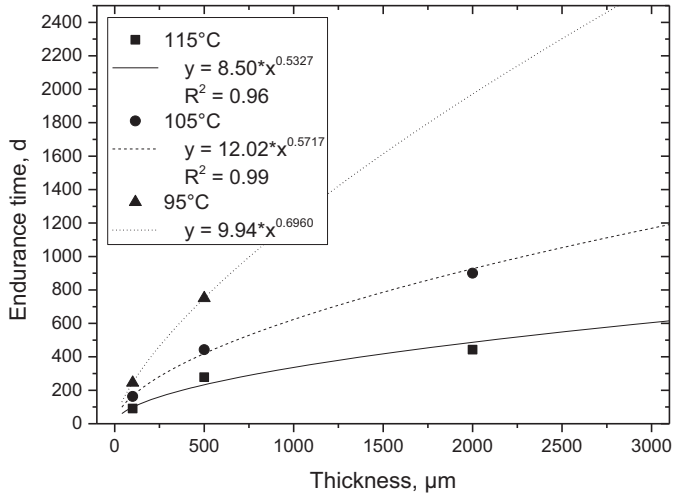

Fig. 3: Experimental endurance time dots and potential fit for aging of PE specimens with varying thickness in hot water at 115, 105 and 95°C.

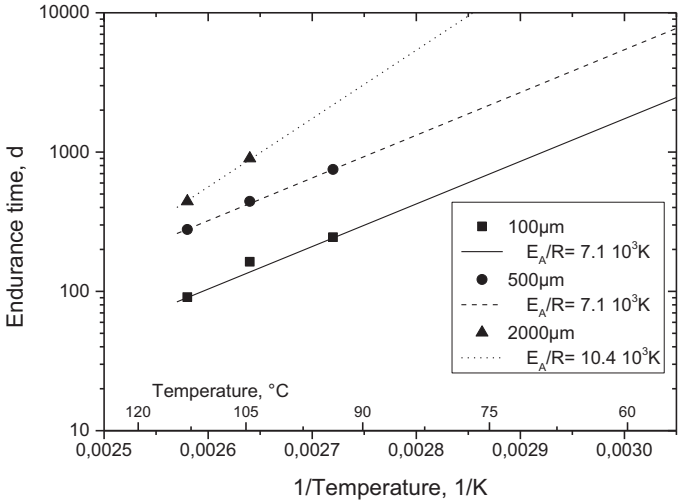

Fig. 4: Experimental endurance time dots and Arrhenius fit for 100, 500 and 2000 µm thick specimens at different temperatures.

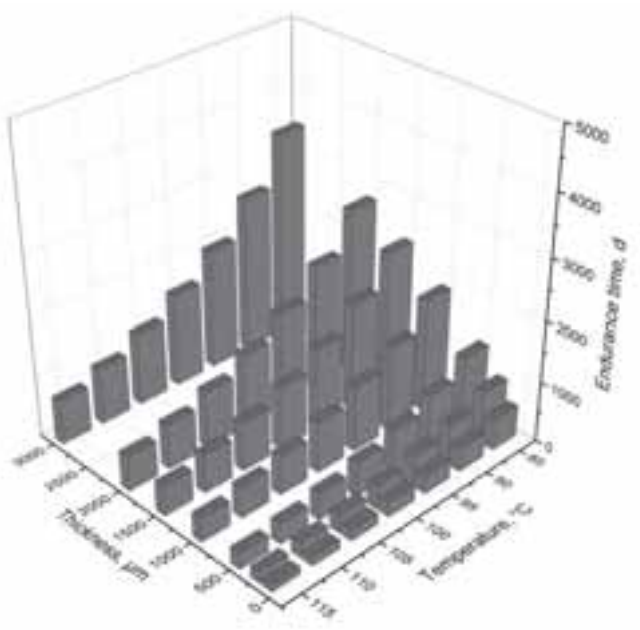

Fig. 5: Calculated endurance times of the investigated polyethylene liner material depending on specimen thickness (100 to 3000 µm) and hot water temperature (85 to 115°C).

3.3 Estimated lifetimes for PE liners

To deduce the lifetime of polyethylene liner materials experimental and theoretical, temperature dependent endurance times were considered. In Fig. 6 the experimental (filled symbols) and theoretical (open symbols) endurance times are displayed for a commercially relevant liner thickness of 2 mm and the reference thickness 500 µm. Additionally, theoretical embrittlement times for a 3 mm thick PE liner are plotted. The closed grey symbol indicates the current maximum exposure time of the non-failed 2000 µm specimens in hot water at 95°C. A good agreement of experimental and theoretical endurance times was obtained with slightly (~10%) overestimated theoretical embrittlement times for the 2 mm thick specimen. By weighting the temperature dependent endurance times with the frequency distribution of the seasonal heat storage lifetime values of 7, 15 and 18 years were obtained for liner thickness of 500, 2000 and 3000 µm. The lifetime values of this study are slightly lower than lifetime estimates published by Paranovska and Pedersen (2016) for polyethylene liners in seasonal storages of Danish solar district heating systems. The deviation of <20% is attributable to different aging and evaluation procedures and other polyethylene material formulations. However, the results of our and the Danish study are in a comparable lifetime range.

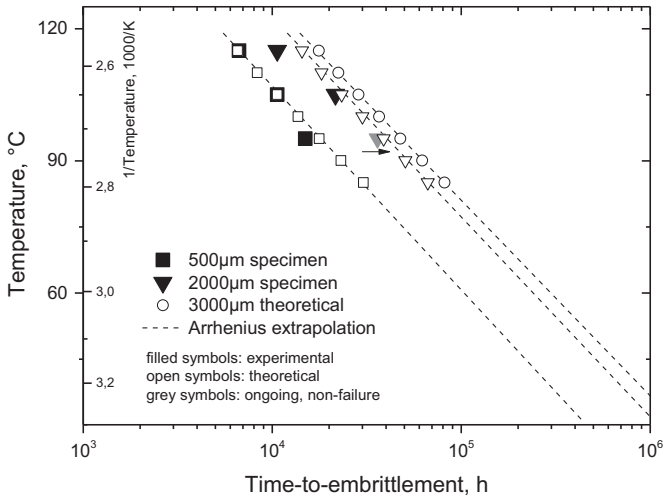

Fig. 6: Experimental and calculated failure times for 500 and 2000 µm thick PE liners.

4. Summary and conclusion

To assess the lifetime of a polyethylene liner material grade, experimental failure data of 100, 500 and 2000 µm thick specimens were gathered at elevated temperatures in hot water. The experimental aging data were used to implement a semi-empirical thickness/temperature-model using a potential and an Arrhenius fit. As a result endurance times for polyethylene liner specimens in a wide range of thickness and temperature (100 to 3000 µm, 85 to 115°C) were derived. Lifetime values were deduced by weighting the endurance times with a temperature loading profile of seasonal heat storages in Danish solar district heating systems.

The polyethylene specimens were exposed to the more critical environment hot water at 95, 105 and 115°C. The strain-at-break values dropped within the first aging interval which was mainly attributed to physical recrystallization mechanisms. After the initial drop a plateau was obtained which was more pronounced at lower exposure temperatures and for thicker specimens. Ultimate failure characterized by full embrittlement was significantly thickness and temperature dependent. A factor of 5 and 3 shorter embrittlement times were discerned by reducing specimen thickness by a factor of 20 and 5 (2000 to 100 µm, 500 to 100 µm), respectively. Similar acceleration factors were obtained for the exposure temperatures of 95 and 105°C. This thickness dependency was fitted with potential functions with a slightly temperature dependent exponent. The effect of temperature was described by an Arrhenius fit. Minor differences in activation energy for hot water exposure at 115 and 105°C were calculated. The implemented two-dimensional model for thickness and temperature dependency was corroborated.

Lifetime values of 15 and 18 years were deduced for PE liners with a thickness of 2 and 3 mm, respectively. Compared to published values for currently used polyethylene liner materials a slightly lower performance was obtained for the investigated polyethylene grade mainly related to differences of the material grade, aging conditions and the failure criterion. Hence, it is concluded that current PE grades reveal sufficient performance for pit storages. However, for insulted tank storages with higher operating temperatures a new class of polymeric liner materials has to be developed. As described in an associated study (Grabmann et al., 2017) polypropylene copolymers are a potential alternative.

Increasing the Photovoltaic Self-Consumption by Integration of an Ice Storage into a Mono-Split-Air Conditioning Unit

Carsten Heinrich[1], Myrea Richter[1], Felix Stelzer[2] and Mathias Safarik[1]

[1] Institute of Air Handling and Refrigeration (ILK Dresden), Dresden (Germany)

[2] Technische Hochschule Nürnberg Georg Simon Ohm, Nuremberg (Germany)

Abstract

Photovoltaic-driven air conditioning systems offer a lot of advantages over solar-thermal driven cooling systems. An open issue is the missing linkage between PV and AC system regarding the different temporal peaks of electricity generation and cooling demand. The paper presents investigation results of an ice storage coupled with a mono-split air-conditioning unit. Resulting average energy efficiency ratios of charging process are between 2.8 and 3.4. Maximum ice fraction was limited due to evaporator – storage geometry to 55 %. Between an ice fraction of 55 down to 5 % a cooling rate of 2 kW was achieved for discharge process.

Keywords: PV-cooling, ice storage

1. Introduction

The number of installed air-conditioning (AC) systems is rapidly increasing worldwide. About 130 million units a year are sold (Holley, 2014). The majority (about 120 million) are lower capacity units. A number of unfavorable effects are associated with the desired gain in comfort: (1) increasing electricity demand and thereby an increasing emission on greenhouse gases (indirect emissions), (2) direct greenhouse gas emissions due to usage of refrigerants with high global warming potential (GWP), (3) distinct peak loads in the grid.

To reduce the impact of solar-driven cooling technologies have been developed and applied in the last ten to fifteen years. In the past the focus was set to solar-thermal systems, due to the use of natural refrigerants (mainly water/lithium bromide) and the cost benefits of thermal collectors. The number of solar-thermal driven cooling systems increased but on low level. Only about 1000 systems are installed worldwide (Mugnier, 2015). A higher dissemination is impeded by high investment costs and complexity of those systems.

On the opposite distinct cost reductions have been achieved in the photovoltaic (PV) sector. Present electricity generation costs of PV-systems turn PV-driven cooling systems into an economic scenario. Investigations within the EvaSolK project revealed lower carbon dioxide abatement costs for PV-driven compression refrigeration systems compared to solar-thermal driven single stage refrigeration systems (Wiemken et al., 2012).

An issue of the majority of existing PV-driven cooling systems is the missing linkage of PV and AC system. Generally the PV-system is operated grid-connected, feeding in electricity during the period of high solar radiation around midday. In residential area AC-systems start operation in the late afternoon when people come home (see Figure 1, left figure). Hence, in countries with a high dissemination of rooftop PV-systems (e.g. Australia (Council, 2016)) the demand peak of AC systems is not noticeable reduced, but during midday an oversupply of electricity is fed in into the grid.

To balance the temporal divergence between electricity generation and cooling demand an integrated energy storage is required. Thermal cold storages offer a number of advantages compared to batteries: Materials are inexpensive and free of risk to the environment. Thermal losses can be regarded as far less relevant if storage is located in the air conditioned room. Using ice storages the required volume can be decreased to suitable sizes. Depending on the concept, maximum cooling capacity provided to the room can be significantly increased in case of parallel operation of storage discharge and outdoor unit.

2. System Concepts and Storage Dimensioning

System Concepts

A standard mono-split AC system consists respectively of an outdoor and an indoor installed unit, linked by a low pressure liquid and low pressure suction gas tube. From refrigeration side the outdoor unit contains compressor, condenser and electric expansion valve and the indoor unit the air-cooling evaporator.

Integration options of an ice storage into mono-split-AC-system can be characterized by

- storage position (outdoor, indoor or inside indoor unit)
- charging by direct evaporation process or via secondary cycle (brine, refrigerant)
- discharging using direct air contact (integration into indoor unit), external melting process (water cycle using the water of the ice storage) or an integrated heat exchanger (using the refrigeration or brine cycle)
- realization of direct cooling mode by usage or by bypassing the storage

Varying the mentioned characteristics lead to a number of cycle options which even increases if valves, bypasses or pumps are taken into account to achieve a more flexible operation.

A number of boundary conditions resulting from market situation and trends, legal regulations and technical standards influences the selection process. Some main aspects are discussed below:

- Required technical solutions are not yet available on the market or in a reasonable cost ranges: Discharge process using the ice storage water by external melting process can be combined with standard air cooler units. But using water in the air cooler is not common in Mono-Split systems so far. Discharge process using the refrigeration cycle requires very low capacity refrigerant pumps with a high pressure rating. There are no standard refrigeration products including such pumps on the market. Pumps from other applications have to be adapted.
- Efficiency requirements arising from legislation and quality labels: The European product regulation requires seasonal cooling efficiency ratios (SEER) calculated according to DIN EN 14825 of > 7 and > 8.5 from 01.01.2019 for air conditioning units with a cooling capacity of less than 12 kW. The German quality label *Blauer Engel* requires an EER Cooling > 4.6. The direct cooling operation will be the minor operation mode of a mono-split-unit with integrated ice storage. Avoiding barriers in the product marketing requires an appropriate cycle design to fulfill these criteria.
- Requirements to refrigerant usage: European F-Gas Regulation requires the usage of refrigerants with a global warming potential < 750 from 01.01.2025 in small scale air-conditioning units. *Blauer Engel* requires the usage of non-halogen refrigerants. Within a progressive intensification of regulations the usage of natural refrigerants gain in importance. Almost all refrigerant with a GWP < 750 that can be applied in split systems are flammable. Therefore the refrigerant charge needs to be limited.

Based on an assessment matrix using the upper characteristics further theoretical and experimental analysis were

focused on a small number of preferred options. Table 1 contains three promising options, including their advantages and drawbacks.

Table 1: Preferred integration options - system description and remarks

system description	remarks
option 1:  - direct charging using an evaporator in the ice storage - discharge using the water of the storage in an hydraulic cycle, indoor unit is replaced to a water based air cooler unit	advantages: - standard products can be applied, no refrigerant pumps required, no development of a specific indoor unit is required - cost efficient solution - simple control - ice melting direction inverse to freezing direction - air cooler surface temperature can be controlled by return flow addition in the water cycle for controlled dehumidification drawbacks: - poor cooling efficiency in direct cooling mode - thermally inertial system, especially not recommendable for heating mode
option 2:  - option 1 is extended by an parallel refrigerant cycle to the indoor unit.	advantages: - direct cooling and heating mode as efficient as in common mono-split systems - extended operation flexibility (e.g. parallel operation of direct cooling and storage discharge is possible) drawbacks: - non-standard indoor unit required - more complex control algorithms required
option 3:  - option 2 is extended by an additional refrigerant pump for discharge process, indoor unit is changed to standard split indoor unit, water cycle is removed	advantages: - standard indoor unit - no water cycle - direct cooling and heating mode as efficient as in common mono-split systems drawbacks: - refrigerant pump availability - discharge process probably less efficient - difficult dehumidification control

Storage Dimensioning

The mono-split unit including an ice storage is connected to a photovoltaic system as well as to the grid, increasing photovoltaic self-consumption and decreasing grid peak loads. The storage should allow equalizing the daily shift between solar irradiation and cooling demand.

A simple algorithm can be applied for storage size estimation

- creation of a building model and definition of surface area and orientation for photovoltaic installation
- definition of a lower radiation limit $E_{PVSurf,low}$, which will account for any cooling generation using electricity from the grid
- daily integration of cooling demand for the condition $E_{PVSurf} < E_{PVSurf,low}$

$$Q_{CD,grid,day,i} = \int_0^{24\text{h}} \dot{Q}_{CD} \quad \text{if } E_{PVSurf} < E_{PVSurf,low} \qquad \text{(eq. 1)}$$

- analysis of the class frequency distribution of $Q_{CD,grid,day,i}$ and selection of a proper storage size

For theoretical investigations a typical single family house according to the German building standard EnEV2016 was selected and modelled (Richter, 2016). The low radiation limit on the southern roof surface area was defined by $E_{PVSurf,low} = 200\ \mathrm{W/m^2}$. Simulation was done for the German site Mannheim.

In different scenarios building heat capacity was used as thermal storage. In case of sufficient solar radiation the building was cooled during absence of inhabitants to 20.0, 22.5 and 25.0 °C, respectively. Figure 2 represent the distribution of daily integrated cooling demand requiring energy from the grid for different scenarios: (1) building is only cooled in case of cooling demand (people are at home), (2 – 4) building is cooled to 25, 22.5 or 20 °C during the day in case of sufficient photovoltaic electricity generation.

Results from Figure 2 are: Cooling demand with electricity consumption from the grid occurs for 131 days a year (case 1). If building is used as thermal storage the number of days is reduced to 126, 125 and 114 (case 2 – 4). Considering only larger cooling demands the number of days decreases. Counting only days with cooling demands $Q_{CD,grid,day} > 5$ kWh (all days below vertical blue lines), the number is reduced to 38, 24, 12 and 3 (case 1 – 4). That means integrating an ice storage with a thermal capacity of 5 kWh in case 1, the number of days with electricity consumption from the grid for cooling generation can be reduced from 131 to 38 days. For the remaining 38 days the cooling demand with electricity consumption from the grid is largely reduced. Using the building as additional thermal storage, the consumption from the grid or the cold storage capacity can be reduced further. But using the building envelope as thermal storage correlates with an increasing total cooling demand, due to additional thermal losses to ambience.

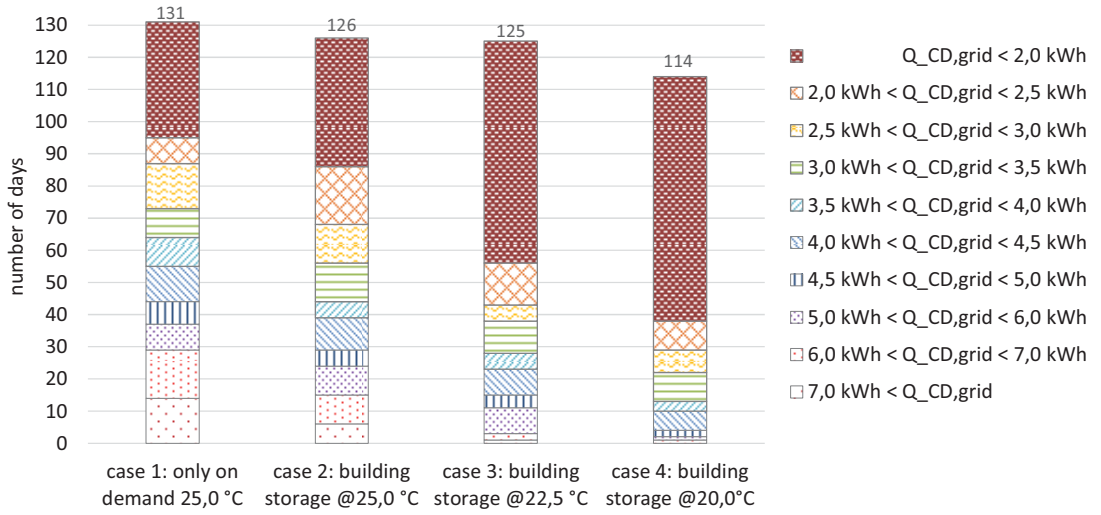

Figure 2: Distribution of daily cooling demand with energy demand from grid

3. Experimental Investigations – Integration Option 1

Motivation and experimental set up

Characteristic data for mono-split-AC-units are limited to air conditioning conditions and are only available as function of room and ambient conditions. Ice growth on evaporator during charging mode and melting during discharging mode represent non-uniform, three dimensional and dynamic processes. Furthermore, mono-split-AC-units include a number of implemented operation and safety algorithms, designed for building cooling (and heating) and dehumidification only. Hence, an evaluation of the operation of a mono-split-AC-unit with integrated ice storage requires experimental analysis.

Experimental investigations focused on

- evaluation of operation control and safety algorithm issues connected with the operation with distinctly lower evaporation pressure and non-corresponding response signals from indoor unit
- operational limits of the outdoor unit in case of distinctly lower evaporation pressures
- cooling capacity and cooling efficiency during charging process for different evaporators, different part

load factors and an increasing state of charge

- evaluation of operation in direct cooling mode (building cooling without changing the ice content within the storage)
- evaluation of influence on cooling characteristics and operational stability in case of partly charge and discharge storage cycles

For the experimental investigations, a test rig was built. The design includes options for extension to investigate a number of further integration options. A simplified piping and installation scheme to investigate option 1 is shown in Figure 3. It includes the outdoor unit (1), ice storage vessel (2), ice storage evaporator (3), hydraulic cycle for discharge mode (4), electrical water heater simulating cooling demand (5), additional manually and electronically controlled expansions valves (6) and an additional unit to directly control the compressor speed in the outdoor unit.

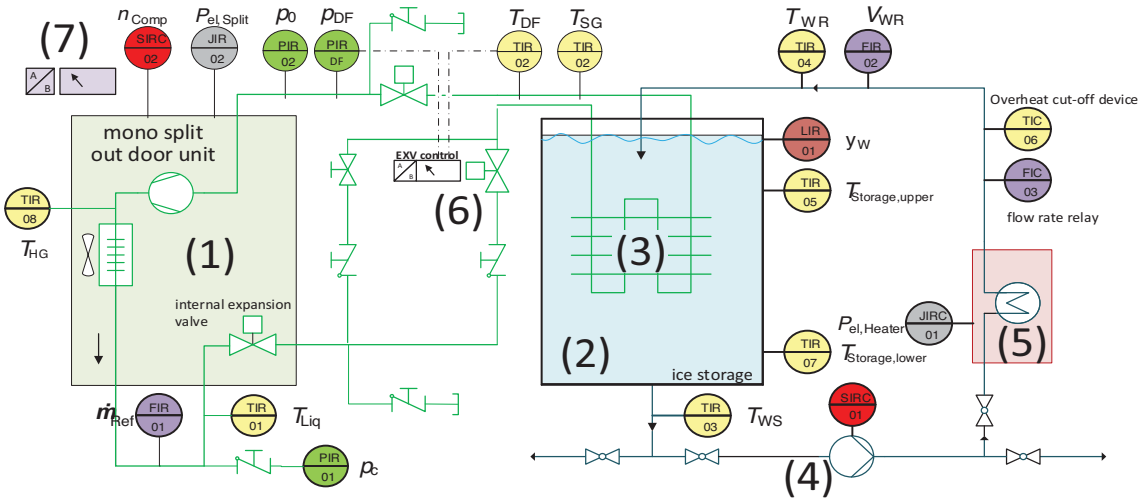

Figure 3: Piping and installation scheme of test rig to investigate the integration option 1 - direct charge process and discharge process applying external melting

Component dimensioning was carried out according to the results of a residential building simulation. A maximum cooling capacity of 2.5 kW is required. An oversized mono-split-outdoor-unit with a rated cooling capacity of 4.0 kW (Fujitsu AOYG 14LMCA) was selected to compensate the required lower evaporation temperature. The installed test rig is shown in Figure 4. Two different evaporator types have been investigated. The selection criteria focused on market availability and price. Table 2 gives relevant geometry parameters..

Table 2: Relevant geometry parameters of evaporators investigated

	tube and fin	finned tube
tube length	2 x 6.2 m, in series	4 x 4.95 m, in parallel
tube outside surface	0.39 m²	0.51 m²
fin water side area	2.32 m²	0.91 m²
total water side area	2.71 m²	1.42 m²
mean fin length	9.8 mm	11.1 mm
refrigerant volume	5.8 l	5.0 l

Refrigerant cycle operation is measured by high pressure liquid medium temperature in front of expansion valve inlet T_{Liq}, suction gas temperature at evaporator outlet T_{SG}, hot gas temperature as tube surface temperature at compressor outlet T_{HG}, condensing pressure p_C in front of expansion valve inlet, evaporation pressure p_0 between evaporator outlet and compressor inlet and refrigerant mass flow rate $\dot{m}_{Ref}$ in front of expansion valve inlet. Furthermore, split-unit power input $P_{el,split}$, which includes power demand for compressor / inverter, electronic

control unit and fan. Compressor speed n_{Comp} and expansion valve opening is taken from split unit service tool, connected to electronic control unit.

Storage and water cycle is measured by upper and lower storage water temperature $T_{Storage,up}$ and $T_{Storage,low}$, return water temperature in front of storage inlet T_{WR}, supply water temperature behind storage outlet T_{WS} , water volume flow rate $\dot{V}_{WR}$ in front of storage inlet and storage liquid level height by an optical system y_W. Additional the power input of electrical heater $P_{el,heater}$ is measured.

If not mentioned differently, all temperatures are measured using PT100 sensor types, directly in the fluid.

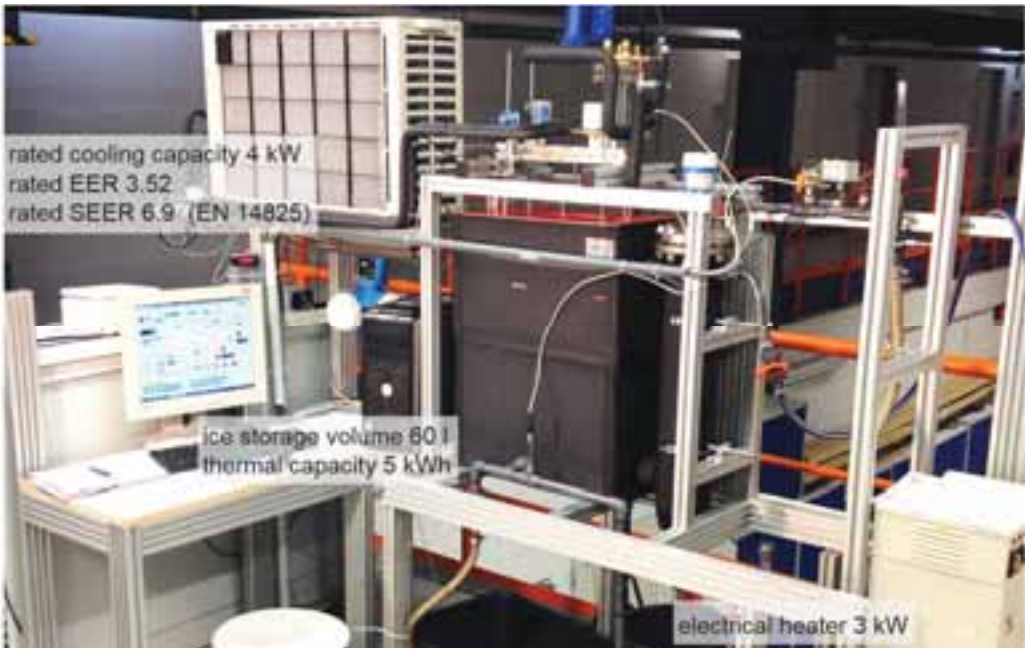

Figure 4: Photo of the test rig

Data post processing

Cooling capacity $\dot{Q}_{\mathrm{Ref,charge}}$ during charging process is calculated under the consumption of subcooled condenser outlet and superheated evaporator refrigerant state. These conditions have been proved for the whole measurement period, except a not fully liquid refrigerant state at condenser outlet for a short period after compressor start:

$$\dot{Q}_{\mathrm{Ref,charge}} = \dot{m}_{\mathrm{Ref}} \cdot \left(h_{\mathrm{gas}}(p_0,\ T_{\mathrm{SG}}) - \ h_{liq}\left(p_{\mathrm{C}}, T_{\mathrm{Liq}}\right)\right) \qquad \text{(eq. 2)}$$

Energy efficiency ratio of charging process EER_{charge} is calculated using cooling capacity and total power consumption of split unit. If convective heat transfer is enforced by pumping the water in the cycle during the sensible cooling phase, the electrical power demand of the pump has to be included.

$$EER_{\mathrm{charge}} = \dot{Q}_{\mathrm{Ref,charge}} \,/\, \left(P_{\mathrm{el,split}} + P_{\mathrm{el,pump}}\right) \qquad \text{(eq. 3)}$$

Ice fraction x_{Ice} of the storage is calculated based on the density difference between liquid and solid phase of water. A reference temperature T_{R} is defined for reference conditions of storage level height $y_{\mathrm{liq,TR}}$ and liquid water density $\varrho_{\mathrm{W,TR}}$.

$$x_{Ice} = \ \left(y/y_{\mathrm{liq,TR}} - 1\right)/\left(1 - \varrho_{\mathrm{W,TR}}/\varrho_{\mathrm{Ice}}\right) \qquad \text{(eq. 4)}$$

Discharge capacity $\dot{Q}_{\mathrm{discharge}}$ is calculated by the enthalpy difference resulting from the temperature difference between storage inlet and outlet. Required mass flow rate is calculated based on the measured volume flow rate in front of the storage inlet $\dot{V}_{WR}$ and the corresponding temperature T_{WR}.

$$\dot{Q}_{\mathrm{discharge}} = \mathrm{V}_{\mathrm{WR}} \cdot \varrho_{\mathrm{W}}(T_{WR}) \cdot \left(h_{\mathrm{W}}(T_{\mathrm{WR}}) - \ h_W(T_{\mathrm{WS}})\right) \qquad \text{(eq. 5)}$$

Overall discharge heat transfer value $G_{\mathrm{discharge}}$ is calculated under the consumption of an ice surface temperature T_{IceSurf} of 0 °C.

$$G_{\mathrm{discharge}} = \dot{Q}_{\mathrm{discharge}} \cdot \ln((T_{\mathrm{WR}} - T_{\mathrm{IceSurf}})/(T_{\mathrm{WS}} - T_{\mathrm{IceSurf}})) \,/(T_{\mathrm{WR}} - T_{\mathrm{WS}}) \qquad \text{(eq. 6)}$$

All media properties for water and the refrigerant R410A are calculated using *CoolProp* (Bell et al., 2014).

Results – Charging Process

The charging process is investigated for both evaporator types varying the outdoor unit part load factor. Initial storage temperature is kept constant at 18 °C. Test rig is located in the main test hall of the institute. Ambient temperature depend on test hall temperature and varied in the measuring period between 20 and 25 °C. The charging process is terminated in case of ice fraction of 80 % or in case a further ice growth could lead to storage damages.

Figure 5 shows the cooling capacity versus ice fraction for both evaporator types and for varying outdoor unit part load factor (plf). Maximum achieved ice fractions are 75 % for the finned tube evaporator and 55 % for the tube and fin evaporator. The cooling capacity decreases with increasing ice fraction and with decreasing outdoor unit part load factor. The decreasing cooling capacity as function of ice fraction is more distinct for the tube and fin evaporator. The cooling capacity decreases from 0 to 50 % ice fraction to about 60 to 65 %. For the finned tube evaporator the cooling capacity decrease for the same ice fraction range to about 80 to 85 %.

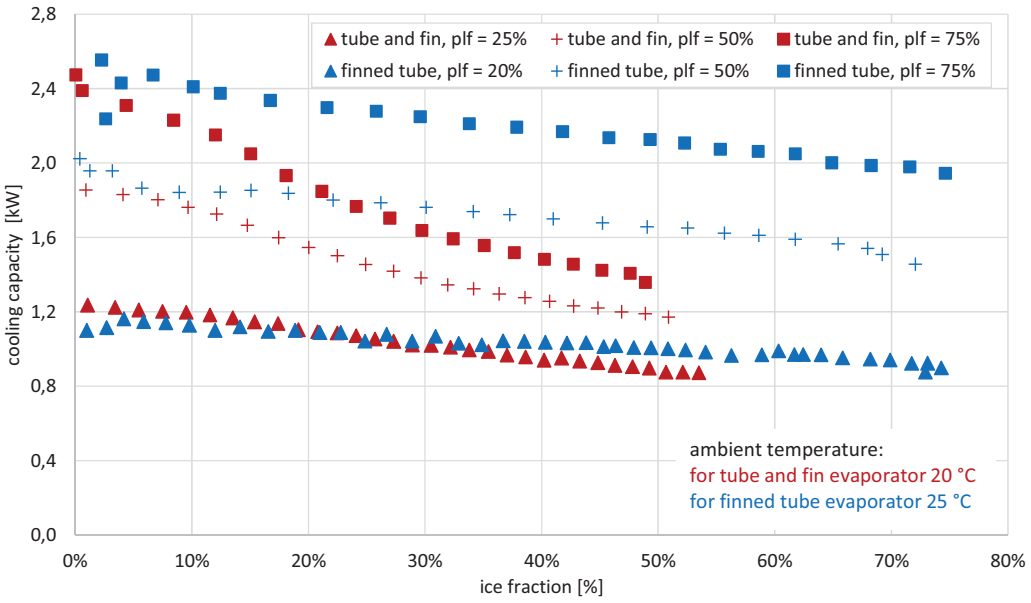

Figure 5: Ice storage charging process - cooling capacity versus ice fraction with variation of outdoor unit part load factor

Figure 6 shows the energy efficiency ratio (EER) of the charging process versus ice fraction for both evaporator types and for varying outdoor unit part load factor. The EER varies between 2 and 4.4. It decreases with increasing part load factor and increasing ice fraction. The EER for the split-unit at a part load factor of 75 %, an ambient temperature of 25 °C and an indoor temperature 25 °C can be estimated using the catalog data (Swegon, 2016) and the info sheet for SEER calculation according to eco design regulation (Fujitsu, 2015) to 6.0.

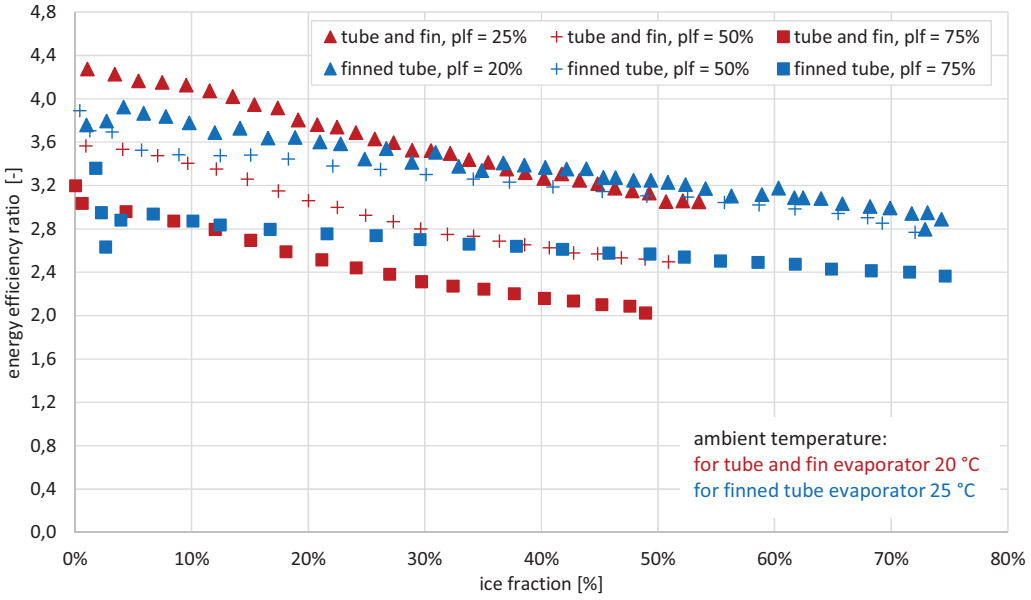

Figure 6: Ice storage charging process - energy efficiency ratio versus ice fraction with variation of outdoor unit part load factor

In Figure 7 charging time and average energy efficiency ratio between a storage temperature of 15 °C and an ice fraction of 50 % are shown as function of outdoor unit part load factor. Charging times for the finned tube evaporator are 40 to 45 minutes lower compared to the fin and tube evaporator for the same part load factors. For part load factors lower than 60 % a strong dependency between charging time and part load factor can be observed. A further increase of the part load factor result in only minor reductions of the charging time.

Average energy efficiency ratios for the defined charging range and ambient temperature of 20 and 25 °C vary between 2.4 and 3.9. Outdoor unit part load factor and average energy efficiency ratio show approximately a linear dependency.

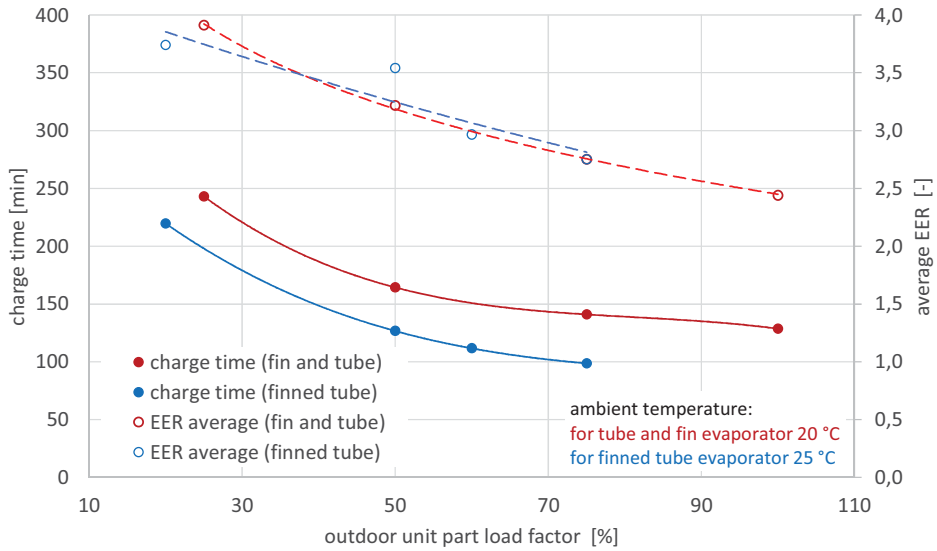

Figure 7: Charge time from 15 °C to 50 % ice fraction and average energy efficiency ratio versus outdoor unit part load factor

Results – Direct Cooling Mode

In direct cooling mode the cooling capacity supplied by the outdoor-unit is directly transferred to the water cycle. Ideally no change of storage state of charge occurs. Cooling capacity is limited by the heat transfer conditions in the storage. Heat transfer is characterized by forced convection due to the storage water flow rate. Evaporation temperature has to be limited to avoid ice growth on the surface. In this case the cooling capacity supplied by the outdoor-unit exceeds the cooling capacity transferred to the water cycle.

Figure 8 shows the maximum cooling capacity and the corresponding energy efficiency ratio depending on the storage volume flow rate for the finned tube evaporator. Maximum cooling capacity increases with increasing water flow rate, due to the improving heat transfer conditions. Energy efficiency ratio decreases with increasing cooling capacity due to the higher part load factor in the outdoor unit.

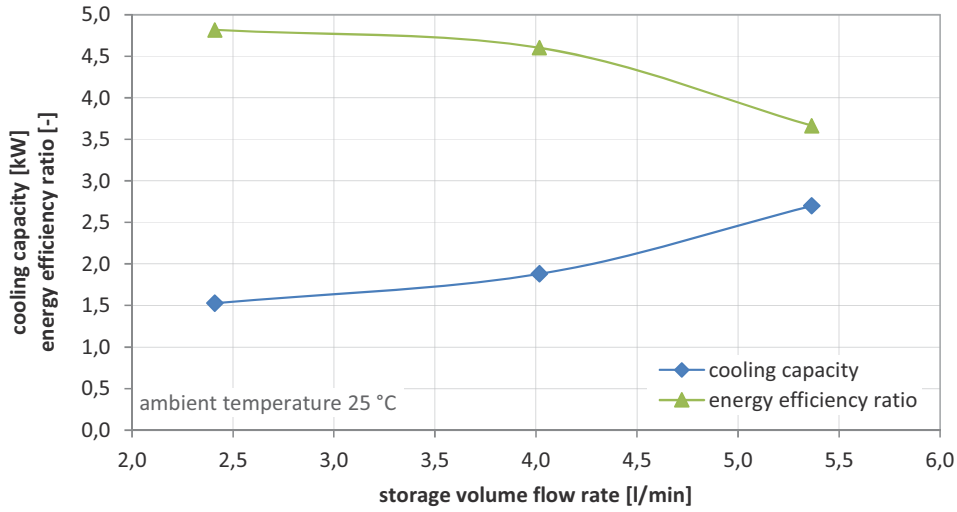

Figure 8: Maximum cooling capacity and energy efficiency ratio versus water volume flow rate for finned tube evaporator

4. Summary and Discussion

Based on daily characteristic of cooling demand and photovoltaic electricity generation in residential buildings the integration of a cold storage into the AC-system can significantly increase photovoltaic self-consumption. Integrating the ice storage into a mono-split-AC-system is a potential option. The system benefits from the high energy efficiency and low investment cost of mono-split-systems. Using an assessment matrix approach the large number of conceivable integration options is reduced to a few technically promising and economically feasible options. Three basic options were presented and discussed. Option 1, charging the storage with an evaporator, discharging the storage with a water cycle using external melting process, was experimentally investigated.

No additional modifications of the outdoor-unit were required. Only a mass flow sensor was implemented between condenser and expansion valve. A successful interaction, an efficient and stable operation of the outdoor unit with the connected storage was achieved after installation of additional refrigeration and electronic components. The required refrigerant charge had increased by about 100 g of R410A. As mono-split-units are designed to operate at evaporation temperatures above 0 °C, some protection functions had to be outwitted.

Charging process at part load factors between 20 and 75 %, ambient temperatures between 20 and 25 °C result in energy efficiency ratios between 2.0 and 4.4. In direct cooling mode in case of maximum achievable cooling capacity at given water flow rate and an ambient temperature of 25 °C energy efficiency ratios between 3.5 and 4.8 were achieved.

The efficiency during charging process is acceptable as in many cases there are not a lot of other applications for self-consumption during the day. For direct cooling mode the required efficiency ratio of 4.6 according to the German quality label *Blauer Engel* (EER = 4.6 at 27 °C room temperature and 35 °C ambient temperature) will be achieved only in low part load ranges.

Based on the obtained results, integration option 1 is a convenient integration option if cooling by storage discharge mode is the predominant operation. If direct cooling becomes more important, integration option 2 becomes more relevant.

5. Outlook

The test rig has been extended to experimentally investigate integration option 2 and 3. Other evaporation types will be included in the investigation. For an economic operation a suitable controller is required including forecast

algorithms taking building behavior, weather and photovoltaic electricity generation into account.

For controller design and optimization a simulation model library have been developed in Modelica. Based on Modelica BuildingSystems models (Nytsch-Geusen et al., 2017) for buildings, weather, radiation processing and photovoltaic generators were created. Based on ThermoFluidILK and using results from experimental investigations a wide range of pure split-unit and split-units with integrated ice storages model have been implemented.

6. Acknowledgment

The investigations were carried out in the SolarSplit project (funding code 0325900A). It is managed by the project management organization Jülich (PTJ) and financially supported by German Federal Minister of Economics and Technology (BMWI) within the 6th Energy Research Program of the German Federal Government.

Abstract

Thermal energy storage systems are necessary to increase the flexibility and the share of renewable energy sources in district heating systems. The use of latent heat storage materials (PCM) can reduce the volume of the storage and at the same time the storage temperature needed for a given heat storage. This work studies since a technical viewpoint the potential application of Thermal Energy Storage using "low cost" emulsion of latent heat storage material in district heating for: central heat storage in Solar District Heating systems (seasonal) and de-centralized heat storage (short-term). Results obtained for the seasonal application showed slight improvement achieved by the latent heat storage system using the selected "low-cost" PCM emulsion. On the other hand, the de-centralized TES unit using the PCM emulsions integrated into the DH grid increased the thermal performance and allowed the connection of additional buildings in a saturated grid.

Keywords: District Heating, thermal energy storage, latent heat, phase change materials emulsion, solar thermal.

1. Introduction

In the European Union (EU), buildings account for 40% of the total energy consumption (European Union, 2010), which suggests a great potential for energy savings. In this regard, the EU Directive on energy efficiency (European Union, 2012) recognizes district heating and cooling networks, as key elements for improving the energy efficiency. Thus, the 4th generation of district heating (DH) systems, i.e. low temperature district heating (LTDH), is being developed in order to accomplish the European goals as well as the target of fossil fuel free by 2050 established by some countries, e.g. Denmark. Lower distribution temperatures and more flexible elements of the network provide heat to low-energy buildings and allow the integration of low-temperature heat sources (Fevrier et al., 2012), as it is the case of solar thermal energy. In northern and central European countries, e.g. Denmark, Germany or Austria, new installations also supply heat for the space heating needs. The approach of central solar heating plants with seasonal storage (CSHPSS) is the storage of solar thermal energy from the period of higher offer (summer) to be consumed in the periods of higher demand (winter). These installations are integrated into district heating systems that supply heat for a large number of dwellings and reach a solar fraction about 50% or higher (Nielsen, 2014).

Thermal energy storage systems (TES) cover a central role in this scenario, increasing the efficiency of the energy systems in which they are integrated and the potential utilization of new renewable energies (RES). Although TES themselves do not save final energy, they are able to "move" heat and cold in space and time, correcting the mismatch between supply and demand allowing: a) energy conservation by exploiting new RES; b) peak shavings both in electric grids and DH grids; c) power conservation by reducing the required power of energy conversion machines; d) reduced GHG emissions (IEA, 2014)

The study of thermal energy storage systems (TES) has been a very intensive branch of research in the last decades. Even though the most commonly used method remains based on sensible heat, the latent heat storages, based on the employment of phase change materials (PCM), are an attractive solution, because they provide higher storage density and smaller temperature difference between the absorbed and the released heat than sensible heat storage. Recently, a new class of latent heat fluids, phase change slurries (PCMs), have been analyzed because of their promising role. The main advantage of PCMs is their applicability either as thermal storage medium and/or heat transfer fluid (HTF). They can be continually pumped in charging/discharging cycle, without the necessity of an additional fluid, reducing the losses and increasing the heat transfer thanks to

doi:10.18086/swc.2017.13.09 Available at http://proceedings.ises.org

the high ratio surface/volume. These slurries are two-phase fluids composed by a PCM dispersed phase in a carrier fluid, usually water. Based on the nature of the dispersed phase, among the PCMs are mentioned the PCM emulsion, ice slurries, microencapsulated PCM slurries (mPCM), clathrate slurries and shape-stabilized PCM slurries (Delgado et al., 2012).

This work studies the potential application of Thermal Energy Storage (TES) using a low-cost emulsion of latent heat storage material (PCM emulsion) in central solar heating plants with seasonal storage (CSHPSS). Furthermore the main outcomes of a second analysis on the application of PCM emulsions into short term de-centralized TES into low temperature district heating (LHTD) networks are presented. The study is made from a technical feasibility viewpoint, analysing the physical advantages and constraints. No economic feasibility analysis is presented due to the lack of appropriate economic information.

2. Thermal energy storage materials: PCM emulsions

The PCM emulsions are mixture of two immiscible fluids whose one forms the continuous phase in which the other part is dispersed in small droplets. They are dispersions with particle size distribution between 1-1000 nm thermodynamically unstable. Usually for energy applications the oil-in-water type, more precisely the paraffin-in-water, is selected because of its suitability given by lower viscosities and higher conductivities than the water-in-oil combination (Edelen, 2012). The properties of a paraffin emulsion depend on many factors like the preparation method, which influences the particle size distribution of the paraffin, and on the surfactants used. The emulsifiers are indispensable components of a PCM emulsion since they provide the kinetical and thermo-mechanical stability between the two phases. The addition of these organic molecules lowers the interfacial tension between the oil and the water and, consequently, lowers the energy required to manufacture the emulsion. Furthermore, the surfactants form a protective layer around the oil droplets preventing coalescence, particles breaking and other instability phenomena like creaming, flocculation and sedimentation. (Shao et al., 2015).

In the current study, two “low cost” paraffinic emulsions were considered. Emulsion 1 is a paraffinic emulsion produced by an oil company, as by-product of the petrochemical industry that has been chosen as test material. This PCM slurry is an anionic emulsion of paraffin with an oleic consistence, with a solid content of about 60% of paraffin, and white color. The thermophysical properties of the selected paraffinic emulsions have been experimentally characterized (Figs. 1-3) applying the methods shown in Table 1, available in the Thermophysical Properties Characterization Lab at the GITSE-I3A facilities in the University of Zaragoza. From the study with the DSC (heating process) and with the T-History (cooling process), the whole phase transition behavior of the Emulsion 1 has been characterized. The phase change occurs in the temperature range of 30 – 50 ºC. Such a wide melting range is due to its by-product nature which enables the cost reduction of the material. However, thermal and rheological properties are not optimal. The enthalpy-temperature curve has been determined (Fig. 1), obtaining a phase change enthalpy value of $h_{sl} \cong 140\ \mathrm{kJ/kg}$. Some hysteresis between the melting and solidification curves was observed, as well as a slight but not significant subcooling. The specific heat curve of the Emulsion 1 as a function of the temperature was also obtained as shown in Fig. 3. Its value outside the change of phase is about 3.2 kJ/(kg K), which is rather poor and lower than the water specific heat. The measured density range of the Emulsion 1 was 0.9372 kg/m^3 at 20 $^{\circ}$C - 0.8704 kg/m^3 at 60 $^{\circ}$C.

Table 1: Properties and equipment used for the characterization of the considered PCM emulsion (Delgado et al., 2015)

Property	Method	Accuracy	Sample size	Equipment
Enthalpy	T-history/DSC	< 10%	≈ 10 g	T-history / DSC 200F3 Maia (Netzsch)
Phase change ΔT	T-history	0.2 K	≈ 10 g	T-history
Specific heat	DSC/T-history	< 1%	≈ 20 mg – 10 g	DSC 200F3 Maia (Netzsch)
Viscosity	Reometer	0.1 nN·m	0.5 cm^3 – 30 cm^3	Reometer AR-G2 TA
Density	Densimeter	< 1%	> 1 cm3	Densimeter DM-40 (Mettler-Toledo)

Subsecuently, a second PCM emulsion, called Emulsion 2, has also been considered in this study for analyzing the applicability of PCM emulsions in Central Solar Heating Plants with Seasonal Storage (CSHPSS. Indeed the advantages obtained with the employment of a PCM usually derive from its utilization as close as possible to the phase transition. For this reason, the study of a second emulsion with a more convenient temperature range of

the phase change has been evaluated to explore the potential utilization of PCM emulsions in this application.

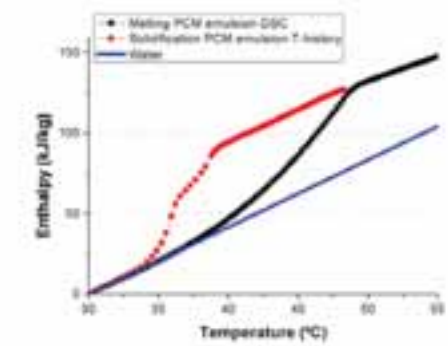

Fig. 1: Enthalpy vs temperature (Emulsion 1)

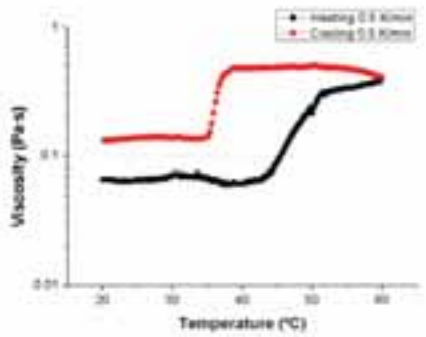

Fig. 2: Viscosity vs. temperature (Emulsion 1)

This Emulsion 2 is a hypothetical material with the same density, thermal conductivity and viscosity values than those experimentally measured for Emulsion 1, but with the curves c_p-T and h-T moved 10 ºC in order to get the phase change in the temperature range of 40 ºC to 60 ºC, as shown in Fig. 3.

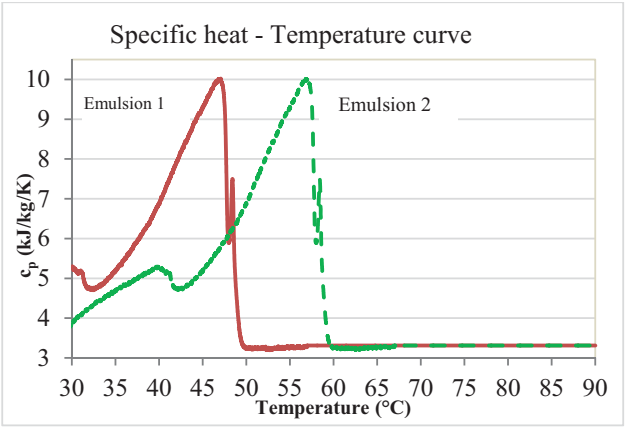

Fig. 3: Specific heat vs temperature curves for the emulsions considered (Emulsion 1 and Emulsion 2).

3. Mathematical model for the evaluation of Central Solar Heating Plants with Seasonal Storage using PCM emulsion as thermal energy storage

The model developed to evaluate the performance of Central Solar Heating Plants with Seasonal Storage (CSHPSS) using PCM emulsion as Thermal Energy Storage (TES) material in the seasonal storage is based on the *simple model* for the predesign of CSHPSS, built on the Engineering Equation Solver (EES, 2016) and developed by Guadalfajara et al. (2015). This model is based on an approximate calculation of the solar collector field production and of the capacity of the seasonal thermal energy storage on a monthly basis and using water as TES working fluid, to match production and demand, as well as to perform easily parametric analysis for the evaluation of CSHPSS. Fig. 4 shows the system scheme and identifies the main energy flows that appear in the system model.

The radiation received, Q_r, over the solar collector is harvested and the production of the solar field, Q_c, is calculated simulating its hourly operation during a representative day of the month. It is considered a complete mixture in the thermal energy storage, i.e. without stratification; so that it keeps uniform the seasonal storage (accumulator) temperature, T_{acu}, along the calculation period, which is a month in the proposed method. With this approach the considered temperature in the tank is lower than the top temperature and higher than the bottom temperature. This approach slightly underestimates the performance of the system, because the estimated temperature of the inlet water of the solar collector is higher than the real value, provoking a reduction of the solar collector efficiency. Nevertheless, the study developed by Braun et al. (1981) revealed that stratification effects have a negligible effect on the performance of CSHPSS. The solar collector performance and the heat losses, Q_l, of the seasonal storage are calculated considering the tank temperature at the beginning of the month.

In a seasonal storage tank, the premise of considering constant the water tank temperature along the month is reasonable due to its high thermal inertia (high volume). A monthly energy balance is used to calculate the temperature in the thermal energy storage at the end of the month. This temperature, water tank temperature at the end of the month, is used to calculate the solar collector performance in the next month.

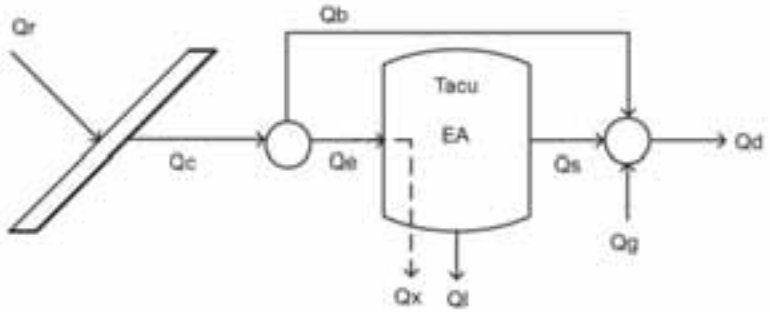

Fig. 4: Energy flow chart of the *simple model* of central solar heating plants with seasonal storage (Guadalfajara et al., 2015)

The monthly operation of the seasonal storage tank has two different operation modes during the year: i) charge and ii) discharge. The charge mode occurs when the production of the solar field, Q_c, is higher than the heat demand, Q_d. Consequently, part of the collected heat is used to attend the immediate demand, Q_b, and the surplus of the collected heat is sent to the seasonal storage for its later consumption, Q_e. In the discharge mode, the heat demand, Q_d, is higher than the production of the solar collector field, Q_c, and the seasonal storage tank is first discharged, Q_s. If it is not sufficient, the auxiliary system, Q_g, provides the required heat to cover the demand. The thermal energy storage operation is constrained by two temperature limits, T_{min} and T_{max}. When the limit of the minimum temperature is reached, the thermal energy storage cannot be discharged anymore and the auxiliary system provides the required heat, Q_g, to fulfill the demand. The thermal energy storage cannot be either charged over the maximum temperature. When it achieves this maximum temperature limit, part of the heat production is rejected, Q_x, to avoid overheating and equipment damage. As the thermal energy storage is warm, the heat losses to the environment, Q_l, are also calculated. The thermal energy accumulated in the storage tank is denoted by the variable EA, and its maximum value EA_{max} depends on the temperature limits. A complete description of this model as well as its validation can be found in Guadalfajara et al. (2015) and Guadalfajara (2016). Note, that this model is suitable for studying the employment of water as storage medium. Although the overall framework of the model has been maintained, several modifications have been required for testing the performance of a different material and especially when considering a PCM emulsion (Rinaldi, 2016).

Thus, replacing the current storage material (water) with the investigated PCM emulsions requires using their properties, obtained from the thermo-physical characterization of the PCM emulsions (Delgado et al., 2015), in the equations related to the storage and to the secondary circuit. While the density of the emulsions, $\rho_{em}(30°C)$ = 921.5 kg/m^3, and their conductivity, λ_{em} = 0.4 W/m/K, were assumed constant in all the analyzed cases, the viscosity depends on the shear stress. However, to minimize the pressure losses, the working fluid conditions have been created in order to attain the lowest viscosities of the curve (~0.05 Pa·s; see Fig. 2). Moreover, when a PCM emulsion is used as storage material, the latent heat of the phase transition is exploited for storing or discharging thermal energy, and it has been necessary to consider the enthalpy-temperature curves measured with the DSC and T-History (Fig. 1).

Additionally, a second modification was implemented. In the model developed by Guadalfajara et al. (2015) it was considered that the fluid circulating through the solar collector transfers the collected heat to the water of the seasonal storage through a heat exchanger with effectiveness, E_{ff} = 0.9. This value is used to calculate the heat exchanger inlet and outlet temperatures. Substituting the heat storage medium with a PCM emulsion, a heat transfer study was required due to the significant different properties of the secondary fluid affecting the efficiency of the process. Consequently, a specific flat-plate heat exchanger was modeled. For a detailed explanation see Rinaldi (2016).

3.1. Base case

The considered base case taken as a reference for the analysis presented in this paper is a CSHPSS, in which a water tank is a seasonal thermal energy storage system (sensible heat), located in Zaragoza, Spain (latitude 41.6º North) supplying heat for space heating and domestic hot water to a community of 1000 dwellings of 100 m^2 each. The input data required few public available data (Guadalfajara et al., 2015): annual demand of domestic hot water, Q_{DHW}, and space heating, Q_{SH}; latitude of the location of the plant; monthly average of daily global radiation on a horizontal surface, H (monthly data); monthly average of daily medium, minimum and maximum ambient temperatures, Ta_{ave}, Ta_{min} and Ta_{max} (monthly data); cold water temperature from the net, T_{net} (monthly data); ground temperature, T_{ter}; and ground reflectance, ρ_g.

The design data for the base case, which were selected based on manufacturers' catalogues, existing plants and bibliographic information, are presented in Table 2.

Table 2: Design parameters for the base case with water as storage material (Guadalfajara et al., 2015; Rinaldi, 2016).

	Parameter	Value		Parameter	Value
Solar Collector Field	RAD: ratio collector area / demand	0.6 m^2/(MWh/yr)	Seasonal Storage	RVA: ratio volume / area	6 m^3/m^2
	A: area of solar collectors	3210 m^2		V: volume of seasonal storage	19,260 m^3
	η_0: optical efficiency	0.816		T_{min}: minimum storage temperature	30ºC
	k_1: 1st order heat loss coefficient	2.235 W/(m^2·K)		T_{max}: maximum storage temperature	90ºC
	k_2: 2nd order heat loss coefficient	0.0135 W/(m^2·K^2)		RHD: ratio height / diameter	0.6 m/m
	β: tilt	45º		U_{acu}: heat transfer coefficient	0.12 W/(m^2·K)
	γ: orientation	0º		A_{acu}: heat transfer area	4101 m^2
	m_s: solar field flow rate	20 kg/(h·m^2)		$\rho \cdot c_p$: heat capacity	4.18 MJ/(m^3·K)
				EA_{max}: storage capacity	1342 MWh
Flat Plate Heat Exchanger	E_{ff}: heat exchanger effectiveness	0.90		Φ: corrugation factor	1.22
	A_{ht}: total heat exchange area	73.78 m^2		N_{pl}: number of plates	42
Annual Heating Demand	Q_{SH}: annual space heating demand	4060 MWh/year	District Heating	T_{sup}: supply temperature	50ºC
	Q_{DHW}: annual DHW demand	1290 MWh/year		T_{ret}: return temperature	30ºC
	Q_d: annual demand	5350 MWh/year		T_{DHW}: DHW temperature	50ºC

Primary design variables considered in the model are: solar collector's area, A (or RAD, which is the ratio of the area of the solar field, m^2, divided by the annual demand in MWh/year), and the volume of the seasonal storage tank, V (or RVA, which is the ratio of the volume of the seasonal storage tank, m^3, divided by the area of the solar field in m^2). The RAD and RVA values for the base case were selected to obtain a significant solar fraction, higher than 50%, avoiding stagnation and heat rejection during the summer period.

Secondary design variables are: the efficiency curve parameters (η_0, k_1, k_2) taken from a manufacturer's catalog (Arcon, 2013) of large solar collectors employed in CSHPSS; tilt, β, and orientation, γ, of the solar collectors, which values were defined considering the geographical coordinates of the plant location; the specific mass flow rate of the working fluid circulating through the solar collectors, m_s, based on the low-flow model (Peuser at al., 2010), characterized by a nominal flow rate of 12-20 l/(h·m^2), and suitable for larger solar thermal installations, since it favors a higher temperature spread between outlet and inlet in the solar collector and pumping savings in the solar field; the temperature of the water supplied to the district heating network, T_{sup} and the temperature of the water returning from the district heating network, T_{ret}, which values were selected considering a high efficiency district heating network (Nielsen, 2014); the minimum and maximum temperatures allowed in the storage tank, T_{min} and T_{max}, and its global heat transfer coefficient for the calculation of the heat losses, U_{acu}. The seasonal storage has been modeled considering a global heat transfer coefficient value of 0.12 W/(m^2·K), in agreement with the specialized literature (Raab et al., 2003; Raab et al. 2005). The seasonal storage is assumed as an underground cylindrical tank with a shape ratio RHD = 0.6 (height divided by diameter). Once the volume is known, the other dimensions can be calculated. The flat plate heat exchanger, consisting of N_{pl} = 42 thin corrugated plates, was modeled following technical specification of manufacturers (ALFA LAVAL, 2015; SWEP, 2015) and recommendations of specialized bibliography (Marin and Guillen, 2013). It has been sized considering the maximum energy flow which has to be handled (in the considered base case location the maximum solar heat production occurred in July 1st at 13 hours), the corresponding inlet and outlet temperatures, the same water mass flow rate in both sides, an effectiveness E_{ff} = 0.90, and a corrugation factor Φ with a typical value of Φ = 1.22.

(i) Comparison of CSHPSS base case behavior: water vs. PCM emulsions

Once the model of the flat plate heat exchanger was implemented in the *simple model*, it was possible to analyze the heat transfer phenomenon when operating with PCM emulsions. Table 3 shows the comparison of the plate heat exchanger working with water in both sides (water-water) or with the investigated PCM emulsions in the secondary side (water-emulsion)

Table 3. Heat transfer study results and comparison of plate heat exchanger performance: water-water vs. water-emulsions.

$\dot{m}_{sto}$= 20.5 kg/s	Water	Emulsion 1	Emulsion 2
v_{sto} (m/s)	0.5362	0.5793	0.5793
Re_{sto}	2633	42.01	42.01
Pr_{sto}	5.53	551.6	551.6
α_{sto} (W/(m^{2}K))	14047	2890	2939
U (W/(m²K))	6346	2313	2344
E_{ff}	0.9067	0.7382	0.7505
Δp_{distr} (Pa)	131317	403012	403012

The results indicate a relevant decrement in the heat exchanger effectiveness when working with the PCM emulsions, caused by the drop of the Reynolds number and, consequently, of the global heat transfer coefficient.

This phenomenon is due to the high viscosity (0.05 Pa·s) of the investigated material compared to the water. The significant rise of the Prandtl number highlights that the momentum diffusivity dominates the heat transfer in the PCM emulsions, while the pure conduction diffusivity in the fluid is low. Choi et al. (1994) reported that the local convective heat transfer coefficient varies slightly in forced convection heat transfer with phase-change-material slurries. However, the lack of experimental study and literature about test of PCM emulsions in plate heat exchangers does not permit to consider this factor. Consequently, the heat convective coefficient of the emulsion and the overall heat transfer performance of the plate heat exchanger experience a significant reduction. This phenomenon affects the operation of the global CSHPSS plant since the solar collected heat is not well discharged and utilized. Another important aspect, related to the utilization of the PCM emulsion in the secondary circuit, is the pressure losses. Just analyzing the distributed pressure drop (Δp_{distr}) that occurs in the heat exchanger, they result almost four times higher than those generated by the water circulation in the same circumstances. The high viscosity of the studied PCM emulsion arises to be one of the critical factors on which it is necessary to work for achieving a satisfactory behavior.

Table 4. TES comparison: water vs. PCM emulsions (Annual results. Base case, T_{max}= 90°C, V= 19260 m^3, A= 3210 m^2).

	Water	Emulsion 1	Emulsion 2	*Annual energy flows*	Water	Emulsion 1	Emulsion 2
PHE E_{ff}	0.9067	0.7504	0.7641	Q_x (MWh/y)	0	0	0
$EA_{max,calc}$ (MWh)	1153	1167	1180	Q_l (MWh/y)	148.8	140.2	138.5
Solar fration and efficiencies				Q_{aux} (MWh/y)	2359	2368	2342
SF	0.5591	0.5574	0.5622	Q_c (MWh/y)	3140	3122	3146
η_{coll}	0.5706	0.5673	0.5717	Q_e (MWh/y)	1244	1252	1263
η_{sto}	0.8803	0.8880	0.8904	Q_s (MWh/y)	1095	1111	1125
η_{sys}	0.5435	0.5419	0.5466	Q_b (MWh/y)	1896	1870	1883

Table 4 illustrates the results obtained from the annual calculation of the CSHPSS. As can be observed, in these circumstances the substitution of the water with the PCM slurry in the storage does not represent any significant benefit. The storage temperature along the year with both water and emulsion does not reach the maximum fixed constrain (T_{max}= 90°C) and it remains below 82°C in all the cases, for water and for both PCM emulsions. In terms of solar fraction, SF, and global efficiencies, Emulsion 2 presents a slightly improved performance while Emulsion 1 is even slightly worse than water. Even though the solar heat transferred to the secondary circuit Q_c diminishes in the case of Emulsion 1 compared to the case of water-water, surprisingly the calculated energy accumulated in the storage ($EA_{max,calc}$) is higher. This was mainly due to two factors: the decrease of the heat losses in the storage (Q_l), due to the lower temperatures in the seasonal storage tank when using PCM

emulsions as TES, and the change in the collector efficiency curve along the year (Rinaldi, 2016). Although the yearly solar collector field efficiency (η_{coll}) is reduced and, consequently, the yearly solar heat collected (Q_c), the solar field presents a greater performance in the summer months, when a significant share of energy is stored, due to the lower temperature in the seasonal storage when operating with PCM emulsions. The critical feature that was recognized in the utilization of the PCM emulsion in this particular case is the large operating temperature range. Indeed, the advantages obtained with the employment of a PCM usually derive from the utilization of the material always close to the phase transition. The chart of the cp_{em} of the PCM emulsions as the function of temperature (Fig. 3) shows that the cp_{em} outside the change of phase is about 3.2 kJ/(kg K), which is a rather poor value and lower than the water specific heat. Accordingly, the benefits linked to handling PCM materials are limited by the running conditions of this application since it has to operate mostly out of the melting-solidification stages.

(ii) Sensitivity analysis of CSHPSS operation with PCM emulsions

From the first two steps of the calculation procedure, the results highlight that two are the main obstacles which make difficult the exploitation of the real PCM emulsion as seasonal storage material: a) the high viscosity and b) the incompatibility between the phase change temperature and the operating conditions of the storage. Thus, a sensitive analysis was performed based on the base case design, decreasing only the seasonal storage upper limit (T_{max}) and varying this parameter from T_{max}= 80°C until the minimum allowed temperature, T_{max}= 60°C, for discharging heat to the DH grid.

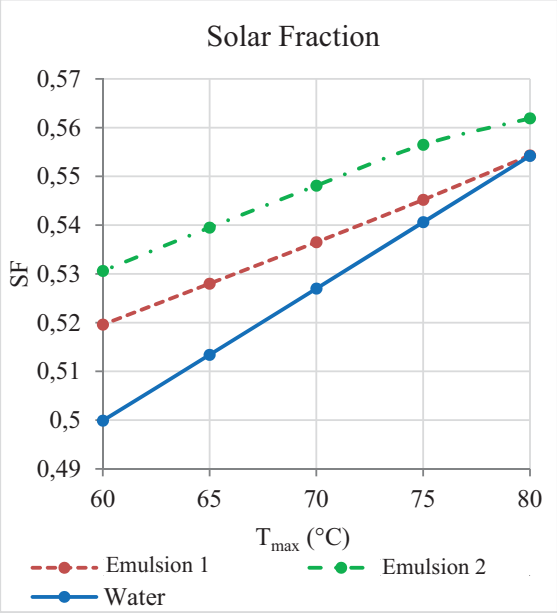

Fig. 5. Base case: Solar fraction (SF) versus T_{max} of TES.

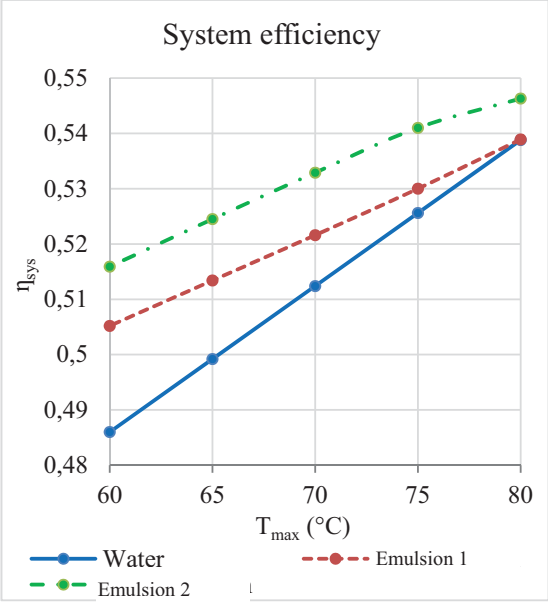

Fig. 6. Base case: System efficiency, η_{sys}, versus T_{max} of TES.

As shown in Figs. 5 and 6, the benefit coupled with the replacement of water with the studied emulsions grows moving T_{max} towards values closer to the phase transition. This benefit is particularly interesting in the case of Emulsion 2, in which enables to achieve a 6% higher of solar fraction with respect to the water as TES material thanks to the increased efficiency of the system. The growing heat capacity of the PCM emulsions working closer to the phase transition permits to accumulate more thermal energy in the same volume (see Table 5). Nevertheless, from results shown in Table 5 it is possible to note that when the maximum allowed temperature in the seasonal storage is T_{max}= 60°C, some solar heat is rejected. However, this phenomenon is significantly lower when PCM emulsions are employed and particularly operating with Emulsion 2, generates a reduction of about 40% in heat rejection compared with the water case. In order to avoid heat rejection when working with the Emulsion 2 and T_{max}= 60°C, the volume of the seasonal storage tank should be increased about 8540 m^3, requiring a seasonal storage tank of 27,800 m^3 (Rinaldi, 2016). However, in this later case 305 MWh/y would be still rejected if the seasonal storage tank were operating with water. An additional volume of about 8740 m^3, reaching a tank volume larger than 36,500 m^3, would be required in order to avoid heat rejection when water is used as storage medium and T_{max}= 60°C. In these conditions, the volume of the seasonal storage with Emulsion

2 would be about 25% smaller than when operating with water. Additionally, note in Table 5 that the heat transfer in the flat plate heat exchanger operating with PCM emulsions, being worse than operating with water (Table 3), increases due to the higher specific heat values, since the operation temperature range is more favorable and closer to the phase change.

Table 5. TES comparison: water vs. PCM emulsions when T_{max}= 60°C (Annual results, Zaragoza, V= 19260 m^3, A= 3210 m^2).

	Water	Emulsion 1	Emulsion 2	*Annual energy flows*	Water	Emulsion 1	Emulsion 2
PHE Eff	0.9067	0.7907	0.8073	Q_x (MWh/y)	567.9	421.5	343.2
$EA_{max,calc}$ (MWh)	668	815.4	884	Q_l (MWh/y)	120	118	121.4
Solar fration and efficiencies				Q_{aux} (MWh/y)	2676	2570	2511
SF	0.4999	0.5196	0.5306	Q_c (MWh/y)	3362	3319	3303
η_{coll}	0.6110	0.6032	0.6003	Q_e (MWh/y)	1318	1315	1307
η_{sto}	0.9089	0.9103	0.9071	Q_s (MWh/y)	629.9	776	842.3
η_{sys}	0.4860	0.5052	0.5159	Q_b (MWh/y)	2044	2004	1996

3.2. Geographic analysis of CSHPSS operation with PCM emulsions

Since the CSHPSS performance is strongly related to the climate conditions as well as to the heat demand characteristics, the assessment of a plant situated in a different European climatic zone, as it is the case of Oslo (Norway), was also analyzed. The location of the CSHPSS highly influences the design process and parameters of the whole system. Considering a colder area than the south of Europe, the heat demand rises because of the higher space heating requirements, caused by the more severe winters, as well as its distribution (SH demand) along the year. Moreover, the solar radiation decreases and consequently, the solar energy production per area of solar collector falls down making necessary the installation of a larger solar field surface per MWh of heat demanded (i.e. increase of RAD). Furthermore, the lower average environmental temperature along the year reduces the collector efficiency because of the higher heat losses with the surroundings. In regard to the seasonal storage, colder climates need relative smaller storage per unit area of solar collector (i.e. smaller RVA ratio). Warmer locations, present higher accumulation requirements per area of solar collector because of the shorter heating period and of the larger solar energy yielded in summer (Guadalfajara, 2016). Thus, the CSHPSS placed in Oslo (latitude 59.93º North), sized according to the criteria previously adopted for the plant in Zaragoza (1000 dwellings of 100 m^2 each, T_{max}= 90°C, SF~0.5, no heat rejection), owns the specific design parameters listed in Table 6. The rest of the parameters are the same shown in Table 2.

Table 6: Design parameters for the CSHPSS in Oslo with water as seasonal TES material (1000 dwellings of 100 m^2 each, T_{max}= 90°C, SF~0.5, no heat rejection) (Rinaldi, 2016).

CSHPSS Oslo **(latitude 59.93º North)**							
Solar collector field		*Seasonal storage*		*Flat plate heat exchanger*		*Annual heating demand*	
RAD	1.39 m^2/MWh	RVA	1.75 m^3/m^2	E_{ff}	0.9	Q_{SH}	6427 MWh/y
A	11,383 m^2	V	19,920 m^3	A_{ht}	342.47 m^2	Q_{DHW}	1769 MWh/y
β	60°	A_{acu}	4196 m^2	N_{pl}	116	Q_d	8197 MWh/y
γ	0°	Ea_{max}	1389 MWh				

The heat transfer problems occurring when operating with PCM emulsion in the seasonal TES already explained in subsection 3.1 were also observed in this case. Indeed, the change of the equipment dimensions does not vary the worsening heat transfer performance utilizing the PCM emulsions instead of water. As already noticed, the heat exchanger effectiveness working with the Emulsion 2 appears improved respect to the Emulsion 1 because of its higher average specific heat in the working temperature range (Rinaldi, 2016). A comparison of the behavior of the CSHPSS located in Oslo operating with different seasonal storage materials (water and PCM emulsions) are shown in Table 7. As occurred in the base case analysis, the Emulsion 1 does not provide any enhancement of the overall system efficiencies. Additionally, the seasonal storage with this PCM emulsion as storage material has a lower heat storage capacity than with water. Consequently, the main benefit linked to the employment of a PCM is lost as well as the possibility of the application of this solution in the studied conditions (large temperature range). In contrast, interesting outcomes have arisen from the CSHPSS calculations using the Emulsion 2. From a first look to Table 7, there is a slight increase of the overall plant performance as well as of the component performances coupled with the higher maximum storage capacity of

the seasonal TES (EA_{max}). Thus, it is observed an appreciable rise of the solar production Q_c (+74 MWh/y) and the decrease of the tank losses Q_l (-6.4 MWh), obtaining as a consequence some heat rejection (Q_x= 28.2 MWh).

Table 7. TES comparison: water vs. PCM emulsions (Annual results. Oslo, T_{max}= 90°C, V= 19,920 m^3, A= 11,383 m^2).

	Water	Emulsion 1	Emulsion 2	*Annual energy flows*	Water	Emulsion 1	Emulsion 2
PHE E_{ff}	0.8951	0.7525	0.7600	Q_x (MWh/y)	0	0	28.2
$EA_{max,calc}$ (MWh)	1372	1350	1419	Q_l (MWh/y)	194.1	187.8	187.7
Solar fration and efficiencies				Q_{aux} (MWh/y)	4129	4148	4077
SF	0.4958	0.4935	0.5021	Q_c (MWh/y)	4254	4282	4328
η_{coll}	0.3755	0.3780	0.3820	Q_e (MWh/y)	1468	1495	1538
η_{sto}	0.8678	0.8744	0.8779	Q_s (MWh/y)	1274	1255	1322
η_{sys}	0.3584	0.3567	0.3630	Q_b (MWh/y)	2786	2787	2790

The explanation to these effects can be found evaluating the seasonal storage temperature (T_{acu}) along the year (Fig. 7). Indeed, the higher specific heat of the PCM emulsion during the phase change generates lower storage temperatures. This fact reduces the heat losses of the tank, which are larger in a cold climate. Furthermore, since the storage temperature affects the solar field efficiency, its decrement leads to higher collector performances despite the worse solar heat transfer through the PHE, thanks to the lower temperature of the working fluid when the PCM emulsion is used. The most profitable solution in order to avoid the heat rejection is the reduction of the solar field area. Since the collector production is more effective, a smaller surface area of solar collectors can be installed for generating the same amount of solar heat avoiding heat rejection. The value obtained was 11,040 m^2, which is 335 m^2 smaller than the required for satisfying the heat demand employing water in the Seasonal TES. Despite the smaller solar field, the whole plant operation with the Emulsion 2 is even slightly more efficient than operating with water, reaching very similar values to those shown in Table 7.

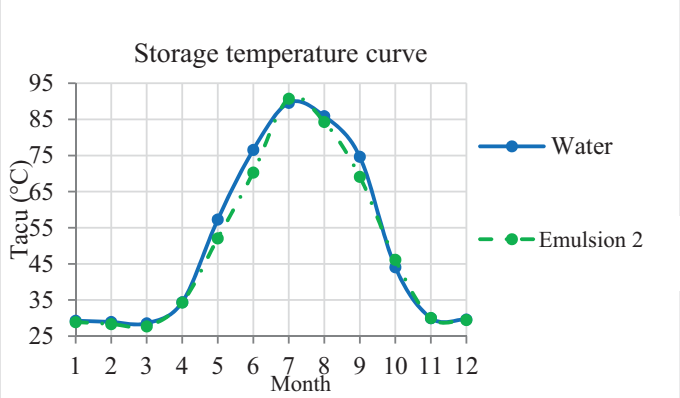

Fig. 7. Monthly temperatures of the water and Emulsion 2 in the seasonal TES

From the conclusions achieved studying the base case, working with temperatures closer to the phase transition of the emulsion would allow to accomplish more relevant advantages. Consequently, a sensitivity analysis lowering T_{max} of the Oslo seasonal TES has been carried out in order to create a more favorable state for the PCM emulsion operation.

As shown in Figs. 8 and 9, and similarly to the base case, the performance of the yearly plant operation continually gets worse with the decrease of the seasonal TES maximum temperature, T_{max}. Indeed, the volume of the seasonal TES is kept unchanged (V= 19,920 m^3). It has been sized to be appropriate for reaching T_{max} = 90 ºC. Thus, when limiting T_{max} to a lower value, the seasonal TES is not able of storing all the collected solar energy and there is heat rejection, reducing the solar fraction and the system efficiency. However, Figs. 8 and 9 show that this decay is smaller for the PCM emulsions, particularly for the Emulsion 2. Note that the lower is T_{max}, the better is the paraffinic emulsions performance and, consequently, the lower is the reduction of SF and η_{sys} compared to the water case. Further, note that the whole SF and η_{sys} variations along the sensitivity study are less significant in the Oslo case in comparison with the sensitivity analysis of the base case (Figs. 5 and 6). These observations show that in cold climate the variation of T_{max} has a less important impact on the overall

efficiencies, due to the improvement of the solar collector efficiency when lowering the seasonal TES temperature, which provokes an increased solar production. The reduction of the storage temperature can be performed substituting the water with the PCM emulsion or by lowering $T_{max.}$

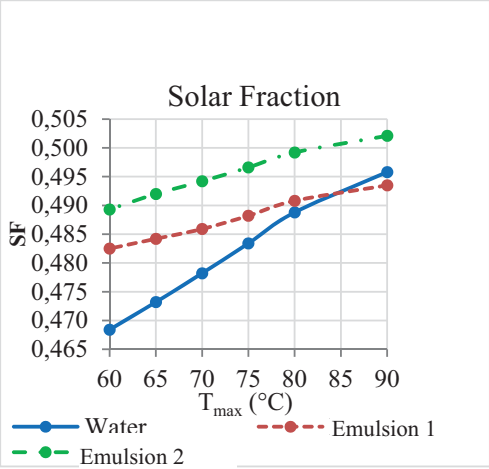

Fig. 8. Oslo case: Solar fraction (SF) versus Tmax of TES.

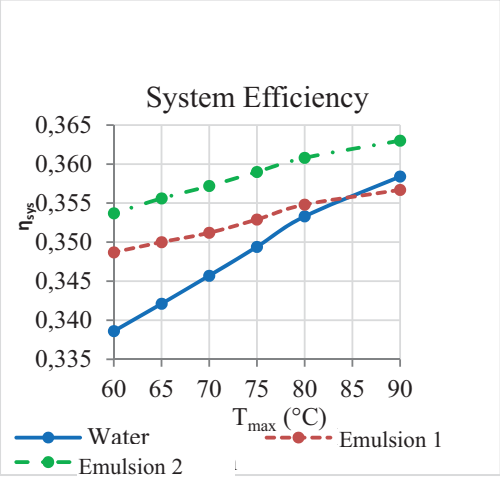

Fig. 9. Oslo case: System efficiency, Πsys, versus Tmax of TES.

In the Oslo case, the required collectors surface area, for a seasonal TES using Emulsion 2 as storage material with T_{max}= 60°C, avoiding heat rejection (Q_x= 0 MWh/y), and maintaining unchanged the volume of the seasonal TES (V = 19,920 m^3), is A = 7270 m^2. This represents a reduction of the solar collector area of about 36%, in comparison with the design value at T_{max} = 90°C (Table 6). As a consequence, the obtained solar fraction is obviously lower, SF = 0.4192, when T_{max}= 60°C. If the storage material employed in these operating conditions and with these last design values were water instead of Emulsion 2, there would be a significant heat rejection (Q_x = 192.8 MWh/y) requiring a seasonal TES 28% larger, i.e. with a volume of 25,450 m^3. These results show that significant reductions in seasonal TES volume could be achieved when using PCM emulsions with appropriate properties. The narrower is the temperature range of the seasonal TES the better is the behavior of the PCM emulsion thanks to the longer period working at the phase transition.

4. Integration of de-centralized TES with PCM emulsion into LTDH

This section presents the results of a research carried out on the improvement that a utility of Low Temperature District Heating (LTDH) can undergo when a tank of thermal energy storage is integrated into its network. The performance of two different cases, with water and with a PCM emulsion, have been analyzed and compared within a set of 40 residential buildings consisting of twenty-five apartments each, i.e. 500 dwellings, located in Zaragoza (Spain). A detailed heat transfer model of the storage tank was established to determine the actual behavior of a system TES-DH in de-centralized storage application. The chosen configuration is a typical cylindrical tank with internal coils through which the DH water flows to carry out the charge and discharge processes. The outcomes show the benefit of the operation with either water or PCM emulsion as storage materials, with a noticeable advantage for the PCM emulsion. See Rinaldi (2016) for further details of the model and the analysis.

The results obtained show that a de-centralized TES unit integrated into the DH grid is able to curtail the peak demand and, consequently, to reduce the mass flow that the network has to handle. This solution allows the connection of additional buildings in a saturated grid.

Concerning the additional new area that could be connected to the district heating (DH) network thanks to the de-centralized TES unit, it has been possible to maintain a regular nominal power supplied by the DH without raising the production during the peak hours. Furthermore, this solution permits to move the heat production to the night where the electricity costs and requirements are lower. Additionally to the potential economic benefits, the installation of de-centralized storages allows to the power unit to operate more regularly and provide the peak energy that otherwise should be supplied by auxiliary units (e.g. boilers).

In respect to the PCM emulsions as storage medium, it has been shown that their use provides remarkable

benefits in relation to the conventional use of water. These positive effects are due to the favorable working conditions due to the phase change of the PCM. According to the priority of the system design and to the main objective pursued, the particular advantages are: 1) Accumulation of a greater amount of thermal energy than water in the same configuration of the system, generating a smoother operation with less abrupt changes in the mass flow circulating in different hours. Thus, higher TES temperature during the discharge hours guarantees an easier control of mass flows variation. Additionally, the flat-plate heat exchanger in the customers substation works better thanks to the greater temperature at the heat exchanger inlet, $T_{HE,in,}$ also when part of the heat is delivered by the TES. 2) Reduction of the storage volume and, consequently, of the investment costs in order to achieve the same system operation than that attained using water. 3) Reduction of the nominal monthly DH power and, therefore, the additional mass flow rate that the existing DH pipes have to handle with the connection of the new area. Fig. 10 shows an example of the results obtained (Rinaldi, 2016).

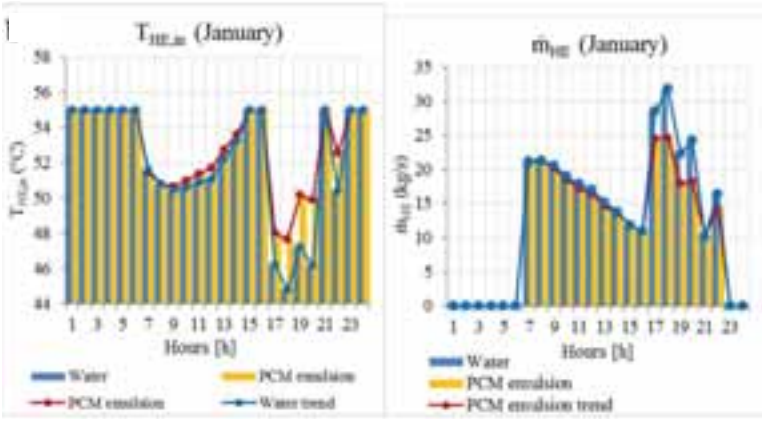

Fig. 10 Example of the results obtained in the case of Vsto,eff=180 m^3 in Zaragoza (Spain)

5. Conclusions

The potential application of Thermal Energy Storage using a low-cost emulsion of latent heat storage material (PCM emulsion) in two different District Heating applications has been studied from a technical viewpoint. It has not been presented an economic analysis due to the lack of appropriate economic information.

The analysis of the behavior of CSHPSS operating with two different PCM emulsions has been performed for several scenarios in different climates (Zaragoza, Spain and Oslo, Norway). The study revealed that the wide temperature working range of this application makes non-optimal the operation with the analyzed PCM emulsions, particularly with Emulsion 1. The operation of the CSHPSS operating with the improved Emulsion 2 has shown some advantages. The temperature stabilization produced by the phase change, especially along the charging process, improved the solar field production and, consequently, the overall system performance and the solar fraction, as well as the storage efficiency. Thus, the material properties enhancements that are necessary to seek for the application of PCM emulsions in CSHPSS are: i) higher density; ii) lower viscosity; and iii) more suitable h-T and c_p-T curves: all the phase transition temperature range has to be included in the working interval of the STES, higher c_p values outside solidification-melting window, higher c_p peak, reduced phase transition range for a more relevant temperature stabilization.

The connection of de-centralized TES units has demonstrated to be a valuable solution for the peak shaving of the thermal demand and for the decrement in the DH mass flow permitting additional connections. The usage of the analysed PCM emulsion improved the overall system operation thanks to the temperature stabilization generated by the change of phase, and to the greater thermal storage capacity of the TES. The hydraulic transients resulted less abrupt and the mass flow changes smoother. This suggested an easier regulation of the DH-TES connection and more regular working conditions, allowing higher efficiencies of the components.

Abstract

The overall experimental thermal performance for complete charging and discharging cycles of a 40 L Sunflower Oil storage tank is presented. Results of two complete charging and discharging cycles are presented. The oil is heated electrically using a copper spiral coil in thermal contact with electrical heaters. A spiral copper coil immersed in a water bath discharges the stored thermal energy. The first complete cycle charges at a low flow-rate of 0.6 L/min and discharges at a high flow-rate of 1.7 L/min. The second cycle charges at a high flow-rate of 1.8 L/min and discharges at a high flow-rate of 1.7 L/min. The charging energy and exergy rates for the first cycle are higher than that of the second cycle, however, the discharging energy and exergy rates are higher for the second cycle. Total stored energy and exergy values for the charging period are higher for the first cycle as compared to the second cycle. The stored energy and exergy are discharged more efficiently in the second cycle. The overall energetic and exergetic efficiencies of the second cycle are higher than those of the first cycle suggesting that a high charging and discharging flow-rate is essential to increase the overall efficiency of the system.

Keywords:Charging; Discharging; Energy; Exergy; Oil Storage Tank

1. Introduction

Two widely adopted thermal energy storage (TES) systems for domestic applications are sensible heat TES (SHTES) and latent heat TES (LHTES) (Dincer and Rosen, 2002). These systems are essential to cater for the mismatch between energy supply and demand especially when intermittent energy resources like solar energy are involved. LHTES has advantages of a high energy storage density and controlled charging and discharging temperatures but it suffers from some disadvantages such as high cost, low thermal conductivity and supercooling in some phase change materials (PCMs), only to mention a few. When issues of cost outweigh the issues of energy storage density and temperature controlled applications, SHTES seems to be the most viable option. Water is the mostly used SHTES for low temperature applications, however, its use is limited to applications below its boiling point so it cannot be used for medium to high temperature applications without pressuring the storage vessel. Thermal oils have been used in recent years for domestic and industrial applications (Mussard and Nydal, 2013; Mussard et al., 2013; Mawire et al. 2009, Bruch et al., 2014; Bruch et al., 2017) . The advantages of these oils are that they can be used for higher temperatures and they exhibit better thermal stratification as compared to water.

Previous studies (Mawire et al., 2014; Mawire, 2016) have focused on the use of Sunflower Oil as a TES medium since it is cheap, it is readily available locally in most countries in the world, it is food grade and environmentally friendly and it has comparable characteristics to commercially available thermal oils. In previous studies smaller storage tanks were used to characterize the performance of Sunflower Oil using separate charging, discharging and heat retention cycles. Energy, exergy and thermal stratification related quantities were evaluated in these separate cycles and the overall thermal performance for a complete charging and discharging cycle was not evaluated which is necessary for a complete understanding of the end user application. Besides this, the previously reported storage tanks were smaller for any real sustainable practical purpose and some initial storage charging conditions were not similar within experimental error limits.

In a bid to understand the overall thermal performance of a domestic oil storage tank during complete charging and discharging cycles, an experimental setup is presented in this paper under two cases and different TES

doi:10.18086/swc.2017.13.10 Available at http://proceedings.ises.org

parameters are evaluated. The aim is to evaluate the energetic and exergetic performance of the TES system for the two complete charging and discharging cycles. The first complete cycle charges the storage tank at a low flow-rate of 0.6 L/min and discharges it at a high flow-rate of 1.7 L/min. In the second complete cycle, the storage tank charges at a high flow-rate of 1.8 L/min and discharges it at a high flow-rate of 1.7 L/min.

2. Experimental setup and procedure

The experimental setup and procedure for the charging and discharging experiments is shown in Fig. 1 and the main components of the experimental setup are shown in the photograph of Fig. 2. The insulated storage tank (i) is 40 litres and it contains Sunflower Oil. During charging with the electric heater in thermal contact with an oil circulating copper coil, valves (1) and (2) are opened while valves (3), (4), (5), (6) are closed. During discharging, valves (4), and (5) are opened while valves (1), (2), (3) and (6) are closed. The HTF flow rate is controlled by adjusting the frequency of the circulating pump (c) via the VLT microdrive (b). The maximum temperature of the electric heating unit (d) is adjusted by the temperature controller module (e). The flow of the HTF is from the top of the tank to the bottom during both charging and discharging cycles and this is measured with a positive displacement flow meter (f). 5 radial K thermocouples measure the temperature distribution at five different axial positions. Thermocouples T11-T15 measure the temperatures at the top of the storage tank such that an average temperature at the top of the storage is determined. Other average temperatures for levels 2-5 are determined in a similar manner.

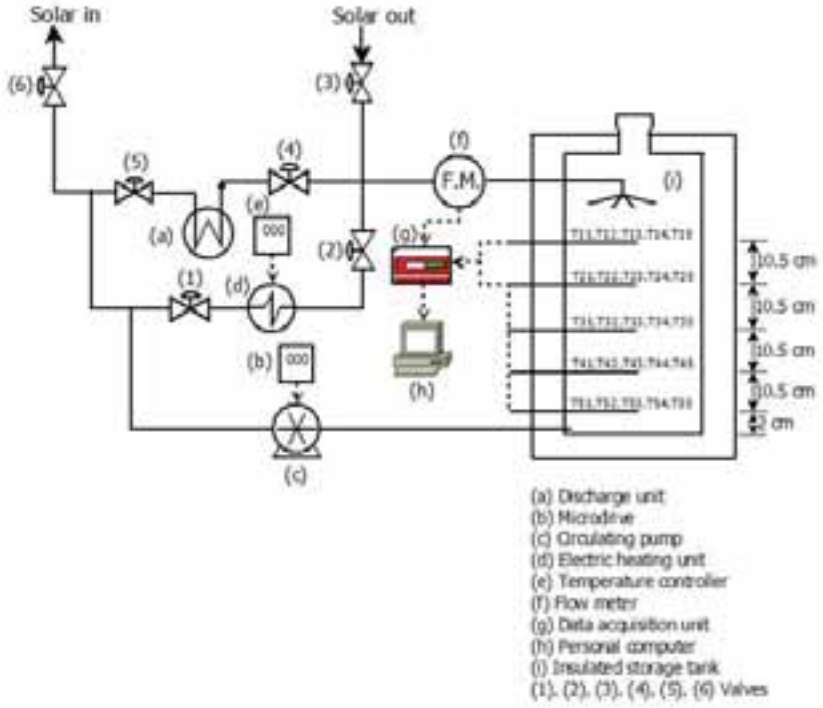

Figure 1: Experimental setup

Firstly it was ensured that the average temperature of the storage tank was around 40 ^{o}C by slightly charging it if it was below this temperature, or discharging it if it was above this temperature. Charging was performed by opening valves (1) and (2) in Fig. 1, while the other valves were left closed. For discharging, valves (5) and (4) were opened while the other valves were closed. During each charging cycle, the temperature controller for the electrical heater was set to 250 ^{o}C and the flow-rate was set to a desired value by adjusting the frequency of the microdrive. Charging was continued until the top of the storage tank attained an average temperature of just above 190 ^{o}C. After this, discharging was immediately done by opening valves (5) and (4) and the discharging cycle was stopped when the temperature of the water bath (which contained 3 liters of waters) fell to just below 100 ^{o}C.

Figure 2: Photograph of experimental setup showing the main components. (1) Insulated storage tank (2) Electrical heater with copper spiral coil (3) Control valves (4) PID temperature controller (5) Discharging coil (6) Datalogger

3. Thermal performance parameters

The charging energy rate depends on the inlet and outlet charging temperatures of the storage tank and is expressed as

$$\dot{E}_{ch} = \rho_{av} c_{av} \dot{v}_{ch} (T_{chin} - T_{chout}) \quad (1)$$

where ρ_{av} is the temperature dependent average density of the oil at the start and end of charging, c_{av} is the temperature dependent average density of the oil at the start and end of charging, $\dot{v}_{ch}$ is the volumetric charging flow-rate, T_{chin} is the inlet charging temperature at the top of the storage tank and T_{chout} is the outlet charging temperature at the bottom of the storage tank. The total energy stored in stored tank can be estimated by integrating Eq. (1) from the start of charging to the end of charging for each small temperature measurement interval and this can be expressed as (Alam; 2015; Jegadheeswaran et al., 2010)

$$E_{ST} = \int_{t_{ini}}^{t_f} \rho_{av} c_{av} \dot{v}_{ch} (T_{chin} - T_{chout}) dt \quad (2)$$

and the charging exergy rate is given as (Jegadheeswaran et al., 2010)

$$\dot{E}_{xch} = \rho_{av} c_{av} \dot{v}_{ch} \left[(T_{chin} - T_{chout}) - \left(T_{amb} \ln \frac{T_{chin}}{T_{chout}} \right) \right] \quad (3)$$

where T_{amb} is the ambient temperature. The total charging exergy is also evaluated by integrating Eq. (3) and it is expressed as

$$E_{XCHT} = \int_{t_{ini}}^{t_f} \rho_{av} c_{av} \dot{v}_{ch} \left[(T_{chin} - T_{chout}) - \left(T_{amb} \ln \frac{T_{chin}}{T_{chout}} \right) \right] dt. \quad (4)$$

The discharging energy rate can be expressed as

$$\dot{E}_{dis} = \rho_{av} c_{av} \dot{v}_{dis} (T_{disin} - T_{disout}) \quad (5)$$

where $\dot{v}_{dis}$ is the discharging volumetric flow-rate, T_{disin} is the discharging inlet temperature from the storage tank to the discharging coil and T_{disout} is the discharging outlet temperature from the discharging coil to the storage tank. The total energy discharged from the stored tank can be estimated by integrating Eq. (5) from the start of discharging to the end of discharging for each small temperature measurement interval and this can be expressed as (Alam, 2015, Jegadheeswaran et al., 2010)

$$E_{DIST} = \int_{t_{ini}}^{t_f} \rho_{av} c_{av} \dot{v}_{dis} (T_{disin} - T_{disout}) dt. \quad (6)$$

The discharging exergy rate is expressed as (Alam; 2015; Jegadheeswaran et al., 2010)

$$\dot{E}_{xdis} = \rho_{av} c_{av} \dot{v}_{dis} \left[(T_{disin} - T_{disout}) - \left(T_{amb} \ln \frac{T_{disin}}{T_{disout}} \right) \right]. \quad (7)$$

The total exergy discharged is obtained by integrating Eq. (7) and this is expressed as

$$E_{XDIST} = \int_{t_{ini}}^{t_f} \rho_{av} c_{av} \dot{v}_{dis} \left[(T_{disin} - T_{disout}) - \left(T_{amb} \ln \frac{T_{disin}}{T_{disout}} \right) \right] dt \quad . \tag{8}$$

The overall energy efficiency can be expressed by the ratio of the total energy discharged to the total energy stored and this is expressed as (Alam, 2015; Jegadheeswaran et al., 2010)

$$\eta_e = \frac{E_{DIST}}{E_{ST}}. \tag{9}$$

The overall exergy efficiency can also be expressed as the ratio of the total exergy discharged to the total charging exergy and this is given as

$$\eta_{ex} = \frac{E_{XDIST}}{E_{XCHT}}. \tag{10}$$

The exergy factor (Mawire and Taole, 2014) can be expressed as the ratio of the exergy charging/discharging rate to the ratio of the energy charging/discharging rate and it is given as

$$E_{XF} = \frac{\dot{E}_{xch}}{\dot{E}_{ch}} \quad \text{or} \quad E_{XF} = \frac{\dot{E}_{xdis}}{\dot{E}_{dis}}. \tag{11}$$

The variation of the density and the specific heat capacity with temperature is given as (Mawire, 2016; Mawire et al., 2014)

$$\rho_s = 930.62 - 0.65T \tag{12}$$

and

$$c_s = 2115.0 + 3.13T. \tag{13}$$

4. Results and discussion

Fig. 3 shows two experimental charging plots using the same flow-rate of 0.6 L/min with almost the same initial conditions to test the repeatability of the experimental results. The plots for the two tests are almost identical for the charging temperatures at the top and the bottom of the tank (T_{chin} and T_{chout}), for the top level of the storage tank (T_1) and for the middle of the storage tank (T_3). Small deviations between the two tests are due slightly different initial conditions and the measurement errors due to the accuracies of the thermocouples used in the measurements. It can thus be concluded that the experimental results are reproducible and reliable within the experimental error limits.

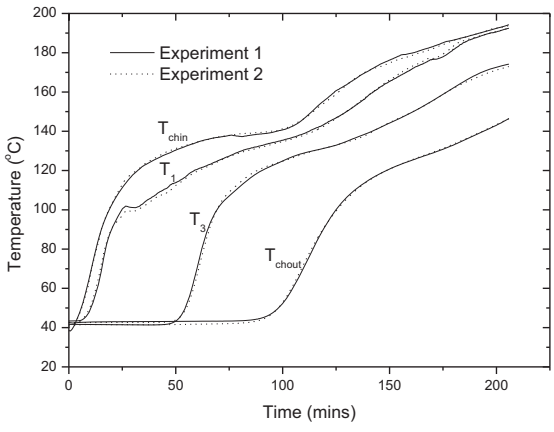

Figure 3: Repeatability charging experiments with a flow-rate of 0.6 L/min.

Fig. 4 shows the temperature profiles along the height of the storage tank for the two complete charging and discharging cycles. For case 1, the temperature profiles show evident layering of the storage tank levels due to the lower charging flow-rate which promotes a larger degree of thermal stratification. The higher flow-rate shows lower temperature differences between adjacent levels due to the larger flow-rate which promotes a higher degree of heat transfer during charging and thus a loss of thermal stratification. Case 2 is charged for a

longer period because of the higher flow-rate that causes the upper limit charging temperature of about 190 °C at the top of the storage to be achieved later. The temperature variations for case 1 during charging show a characteristic flattening of the profiles particularly at the top possibly due to heat losses and radial thermal conductivity, thus slowing down the rate of axial heat transfer. Discharging temperature profiles are almost identical for both cases although case 1 has a more thermally stratified distribution at the onset of discharging. Slightly higher TES temperatures are obtained at the end of discharging for case 1 as compared case 2 possibly due to the more thermally stratified distribution

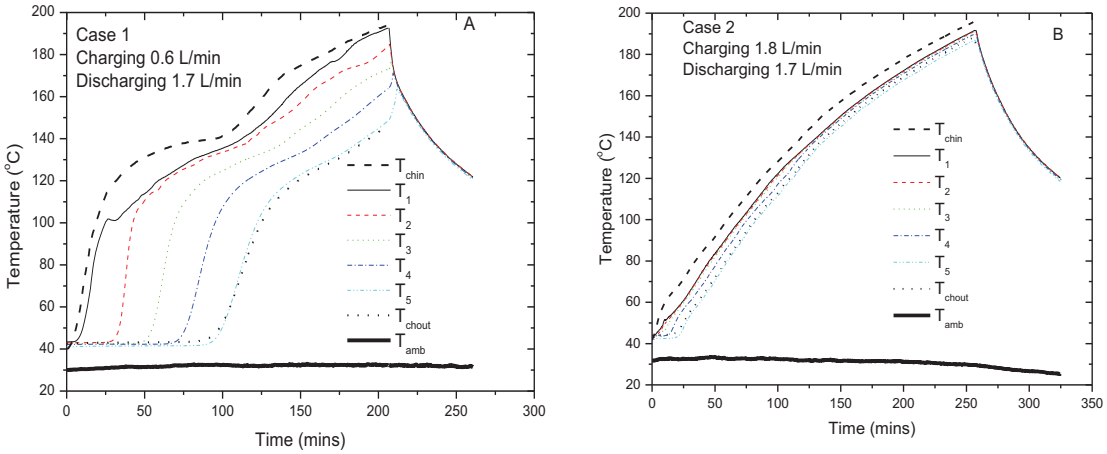

Figure 4: Temperature profiles along the height of the storage tank for experimental charging and discharging cycles case 1 (A) and case 2(B).

Table 1: Thermal performance parameters for the two cases

Parameter	**Case 1**	**Case 2**
Charging flow-rate (L/min)	0.6	1.8
Initial average storage temperature, T_{iniav} (°C)	42.4	43.1
T_{1av} at the end of charging (°C)	193.0	191.5
Average charging ambient temperature, $T_{ambchav}$	31.9	31.8
Average discharging ambient temperature, $T_{ambdisav}$	32.0	27.2
Charging time (mins)	206	258
Discharging time (mins)	54	60
Total energy stored, E_{ST} (MJ)	17.28	12.69
Total exergy stored, E_{CHXT} (MJ)	3.41	2.67
Discharging flow-rate(L/min)	1.7	1.7
Maximum charging energy rate (W)	2920	560
Maximum charging exergy rate (W)	490	180
Maximum charging exergy factor (-)	0.31	0.35
Maximum discharging energy rate (W)	3000	3800
Maximum discharging exergy rate (W)	550	950
Maximum discharging exergy factor (-)	0.18	0.25
Total energy discharged , E_{DIST}(MJ)	3.70	4.69
Total exergy discharged, E_{XDIST} (MJ)	0.88	1.25
Overall energy efficiency, η_e(-)	0.21	0.37
Overall exergy efficiency, η_{ex}(-)	0.26	0.47

Table 1 shows the thermal performance parameters for the two cases The total energy and exergy values stored during the charging period for case 1 are higher as compared to case 2 due to the larger degree of thermal stratification in case 1. It is clear that the higher charging flow-rate results in low values of the total energy and exergy stored due to a loss in thermal stratification. Due to a smaller temperature difference between the top and the bottom of the storage tank for the higher charging flow-rate, the maximum charging energy and exergy rates for case 2 are lower as compared to case 1. Even though, the energy and exergy rates for case 1 are

higher than that of case 2, the maximum exergy factor for case 2 is larger than that of case 1 due the higher average thermal energy storage temperatures for case 2. This suggests that more quality energy stored is at a higher flow-rate due the increase in the heat transfer rate. For the discharging period, case 2 with the higher temperatures induced by the higher charging flow-rate shows higher values of the total discharged energy and exergy. The overall energy and exergy efficiencies for case 2 are higher as compared to case 1, suggesting that the storage tank should be charged with a high flow-rate which increases the rate of heat transfer thus enabling high TES temperatures to be obtained. These higher temperatures ensure that the energy and exergy is discharged more efficiently with a high discharging flow-rate. Charging with a high flow-rate, however, comes at an expense of increasing the charging time with the currently imposed charging conditions. The overall energy efficiencies increase from 0.21 to 0.37 for case 1 to case 2 and the corresponding exergy efficiencies increase from 0.26 and 0.47 respectively. The exergy efficiencies are seen to be higher than the energy efficiencies which also agrees with previous simulated studies (Mawire et al., 2010) done on an oil/packed bed TES system. Although thermal stratification is important in storing maximum energy and exergy, it seems to be outweighed by the maximum temperature (due to high rate of heat transfer) that can be achieved which improves the overall storage efficiency.

5. Conclusion

An experimental study on the overall experimental thermal performance for two complete charging and discharging cycles of a 40 L Sunflower Oil storage tank has been presented. The oil was heated electrically using a copper spiral coil in thermal contact with electrical heaters. A spiral copper coil immersed in a water bath discharged the stored thermal energy. The first complete cycle charged at a low flow-rate of 0.6 L/min and discharged at a high flow-rate of 1.7 L/min. The second cycle charged at a high flow-rate of 1.8 L/min and discharged at a high flow-rate of 1.7 L/min. The charging energy and exergy rates for the first cycle were higher than that of the second cycle due to the larger degree of thermal stratification induced by the lower flow-rate. The discharging energy and exergy rates were higher for the second cycle due to the higher heat transfer rates which resulted in higher storage tank temperatures. Total stored energy and exergy values for the charging period were higher for the first cycle as compared to the second cycle due to the higher degree of thermal stratification in the first cycle. The stored energy and exergy was discharged more efficiently in the second cycle. The overall energetic and exergetic efficiencies of the second cycle were higher than those of the first cycle suggesting that a high charging and discharging flow-rate is essential to increase the overall efficiency of the system. Although thermal stratification was important in storing maximum energy and exergy, it seemed to be outweighed by the maximum temperature (due to high rate of heat transfer) that could be achieved which improved the overall storage efficiency..

Abstract

Thermal energy stores can significantly improve the efficiency and environment-friendliness of the heat supply. Therefore, a high demand for cost-effective storage systems with low energy losses exists. This contribution deals with thermal energy stores for heat supply systems and presents a new aboveground store in segmental construction that allows temperatures up to 98 °C. The construction of a demonstrator is part of the OBSERW project, where researchers show the advantages of this technology, particularly regarding thermal insulation and storage efficiency.

Keywords: district heating, floating ceiling, heat supply, hot water, segmental construction, solar heating, thermal energy storage, thermal stratification

1. Introduction

Thermal energy stores can make heat surpluses available to the consumer if necessary. A thermal stratification inside the storage tank is achieved by separating water with different temperatures through buoyancy. In a storage tank operating according to the displacement principle, a water exchange takes place by direct charging and discharging.

Significant potential for optimization can be identified by comparing currently available storage technologies, in particular pressure vessels and flat-bottom tanks as illustrated in fig. 1 and 2. Pressure vessels (b) allow higher storage densities as well as higher temperature differences but often have low storage volumes, higher heat losses and higher investment costs. However, flat-bottom tanks (a) combine large volumes with relatively low costs. A drawback is that a second zone, respectively a higher fill level is required to apply a hydrostatic load. Furthermore, for safe operation low-pressure steam or an inert gas in the attic is mandatory. This leads to higher heat losses, unfavorable thermal stratification and operation conditions plus unused storage volume. A new storage tank design eliminates these disadvantages and offers numerous benefits. A demonstrator was already built in cooperation with industrial partners as part of the OBSERW project (see also Urbaneck et al., 2017), which will be presented here.

2. New Storage Tank Design with a Floating Ceiling

In contrast to welded flat-bottom tanks, respectively pressure vessels a storage tank design with bolted and sealed segments has already proven to be advantageous for large cold water storages (Urbaneck, 2012) for the following reasons:

- use of storage tanks at ambient pressure for cost reasons compared to pressure vessels (use of thin-walled metal sheets, minimization of material),
- thereby avoiding classification in pressure vessels (avoidance of cyclical checks, etc.), storage tanks are considered as a building with simple permission,
- elimination of excavation in comparison to underground reservoirs (strong cost reduction),
- significant reduction of problems with regard to the accumulation of moisture in the thermal insulation (reduction of the thermal resistance of the thermal insulation, impairment of the long-term durability),
- easy geometric design with sufficient storage tank height (essential prerequisite for operation with thermal stratification),
- more efficient construction technology and logistics and therefore faster production,
- unproblematic use in many places (e.g. no geological requirements).

In principle, this storage tank design is also of interest for hot water storage tanks. However, this technology cannot be transferred to high operating temperatures (up to 98 °C) or use in local and district heating systems without further research and development work. Thus, several adaptions of the design are necessary.

The main novelty of the new construction is an indoor protected floating ceiling with the upper loading device (e. g. a radial diffuser) attached directly to it, as shown in fig. 3. A flexible connection allows the free movement of the floating ceiling between a top and bottom dead center. During charging of the tank a gravity current occurs directly at the ceiling, which is an essential prerequisite for a good thermal stratification (Findeisen et al., 2017a). When discharging, hot water is sucked straight along the ceiling, which allows the full use of the warm zone. The aim is to operate the storage tank with a maximum temperature of 98 °C. The elimination of a hydrostatic pressure relief means that there is a risk of falling below the steam pressure limit. This has to be avoided, as it could lead to cavitation or other transient effects during discharging. A free-form radial diffuser lowers the local pressure drop due to its flow-optimized shape and thus improves operation safety as recently shown by Findeisen et al. (2017b, c). A flexible sealing and the pressure compensation pipe ensure volume and pressure compensation in both storage tank and attic. This allows the storage in combination with a pressure-increase or pressure-reduction installation, to provide functions such as pressure maintenance as integration into heat supply networks (Urbaneck and Platzer, 2015). The pressure compensation pipe is also used for independent ventilation (e.g. during commissioning) and secures the storage tank against overpressure and underpressure. This may also occur, e.g., when the appliance is not in use and the water level falls while the floating ceiling rests on the support (bottom dead center). The floating ceiling and the flexible sealing avoid a gas input into the storage water and thus help to avoid corrosion in the system. Furthermore, flexible sealing lips are located at the edge of the ceiling to suppress free convection between the ceiling and the storage tank wall. As a result, heat losses are reduced and the flexible sealing is less thermally stressed. For the construction of the ceiling, bolted and sealed segments are provided which can be easily filled with a blow-in thermal insulation material. The use of plates is also conceivable. Compared to other constructions, the thermal insulation is located directly on the hot zone, which is topologically the best solution. The storage roof protects the thermal insulation from weather influences. Since the attic can be equipped with ventilation, drying is possible if humidification occurs (e.g. temperature falls below dew point in winter).

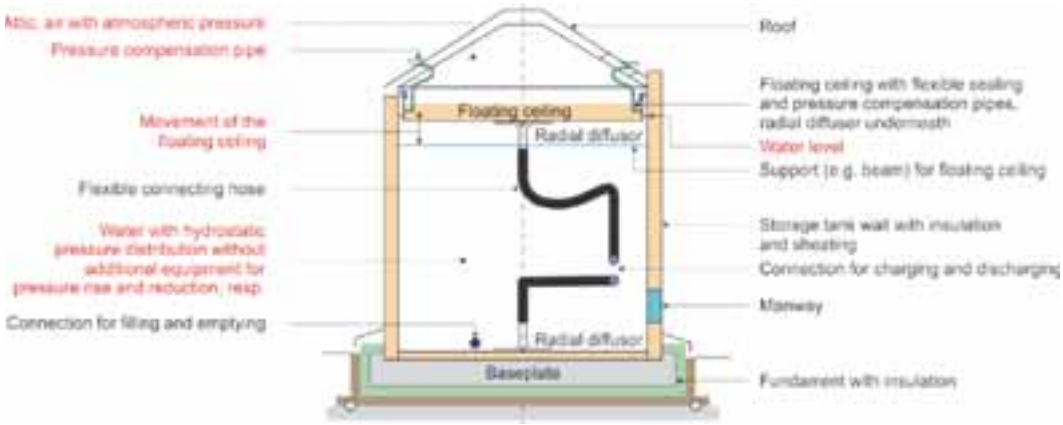

Fig. 3: Aboveground thermal energy store with floating ceiling and directly mounted radial diffuser, Urbaneck et al. (2016a)

3. Concept and Project Organization

The aim of the project is the development of a storage tank in segmental construction as proposed in fig. 3 with a volume from 500 to 8000 m³ that should be suitable for the following applications:

- district heating networks with central heating power plants and combined heat and power generation, used in the grid area (typically for short-term storage),
- local heating networks with decentralized combined heat and power plants (typically for short-term storage),
- large solar heating systems (short- and longterm storage),
- systems with industrial waste heat.

For a tank design which meets these goals several sub-problems must be solved. First, temperature- and water vapour diffusion-resistant roof and wall structures must be designed, with a special focus on the seal between the floating ceiling and the tank wall. In addition, improvements to the thermal insulation design must be undertaken, including the use of innovative substances and the elimination of thermal bridges. Advances in charging and discharging design are required. Finally, methods for better integration into existing networks, and reduced cost, on-site manufacturing procedures should be developed.

The consortium carrying out this project consists of the following partners:

- Chemnitz University of Technology, Professorship Technical Thermodynamics (TUC/TT): accompanying research and coordination of the collaborative project;
- University of Stuttgart, Institute of Thermodynamics and Thermal Engineering, Research and Testing Centre for Thermal Solar Systems (ITW/TZS): accompanying research;
- Farmatic Tank Systems (FTS), Nortorf (Germany): practical oriented development and demonstration.

Fig. 4 shows the procedure to solve the named subproblems. After defining requirements and three typical storage tank sizes, in a first stage fundamental investigations of the materials were carried out by Lang et al. (2016) and Gerschitzka et al. (2016). Furthermore, Urbaneck et al. (2016b) and Findeisen et al. (2017) verified the benefits regarding storage tank design and loading behavior. In a second and ongoing stage, practical tests on a special test rig in the laboratory (fig. 5) help to understand the characteristics of multilayered wall structures in detail. In the third stage, theoretical and practical results are transferred to the demonstrator. Here, many different tests are in progress to secure the technical feasibility and to prove the substantial benefits compared to other storage tank technologies. For this purpose, accompanying measures are provided.

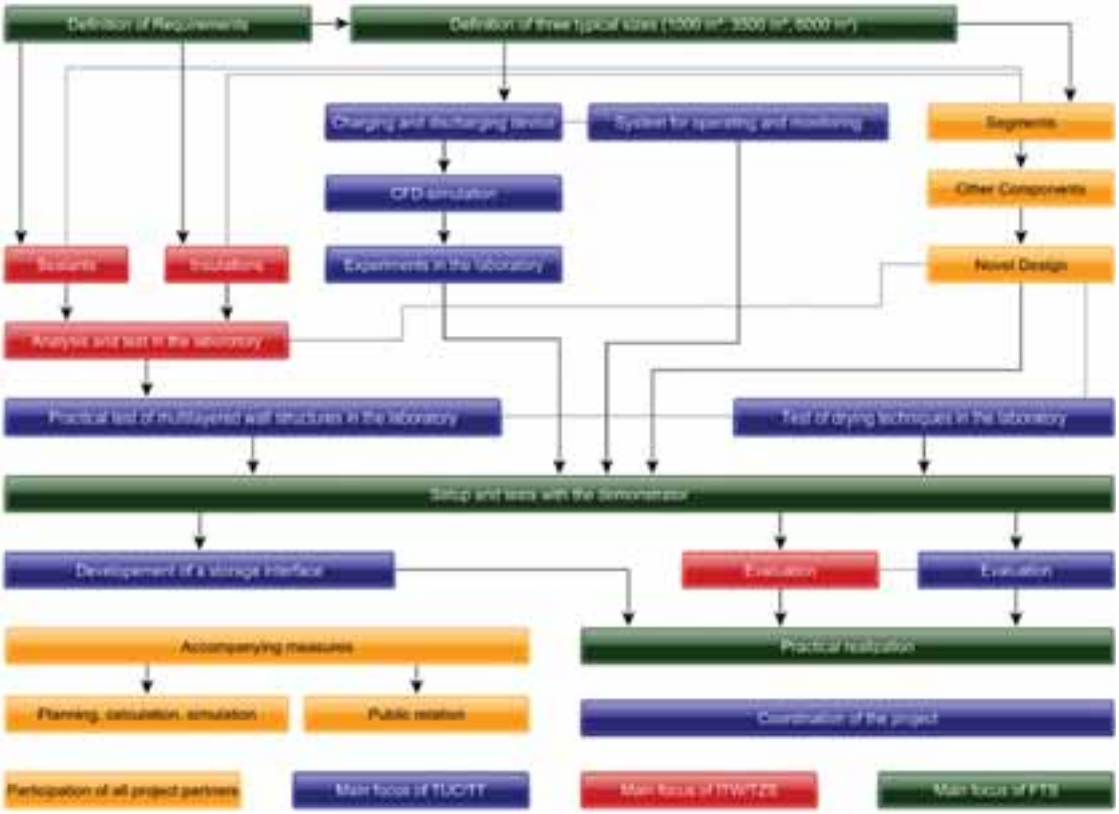

Fig. 4: Overview of the division of work and the procedure in the project, Urbaneck et al. 2016b

Figure 5: Test rig for practical testing of multi-layered wall structures in Chemnitz, enamelled and sealed wall segment (left), pivoting wall cut-out with thermal insulation and cladding panel in the vertical position during the test (right)

Fig. 6 to 8 shows the segmental wall construction, the thermal insulation of the floating device as well as the charging devices in an early state of construction. Fig. 9 presents the final construction of the demonstrator.

After filling the tank and performing first charging tests with hot water, it appears that

- the sealed wall construction is watertight (leakage tests successful),
- the floating ceiling and the flexible sealing work as expected and
- a high stratification quality can be achieved (hot water tests successful).

4. Conclusion and Outlook

A project for the development of a novel thermal energy storage tank type with a floating ceiling was presented. The design has multiple advantages. Besides a very efficient thermal insulation at the top of the tank it ensures protection of the thermal insulation by avoiding practical problems like moisture penetration. The simple design provides significant benefits compared to other storage types. However, because of the thin-walled construction and the project objectives, the wall structure as well as installations and peripherals need further research and development. The direct integration of solar thermal systems is intended. By now, the construction process is finished. First tests showed, that the design is suitable to operate as an aboveground hot water store in segmental construction for solar and district heating systems. Ongoing work is focused on tests regarding stratification quality and external heat losses.

Abstract

The reversible reaction of metal oxides with CO_2 forming metal carbonates with concomitant release of energy is considered as a promising concept for thermochemical energy storage. One major advantage of thermochemical energy storage materials is the possibility of a lossless mid-term and long-term storage of waste heat. Metal carbonates provide high-energy densities and were so far investigated for their application in high-temperature processes. Inspired by the carbonatization of (main group II) metal oxides in nature during mineralization and CO_2 fixation in the presence of moisture under elevated pressures, the Me (II) oxides (Me = Mg, Ca, Sr, Ba) were investigated with respect to their reactivities with CO_2 at pressures up to 55 bar and ambient temperature. Whereas for MgO none of the applied conditions yielded any formation of a carbonate phase, the other oxides revealed appropriate reactivities by forming corresponding carbonates under considerably mild reaction conditions.

Keywords: main group II oxides, main group II carbonates, low-temperature carbonatization, in-situ powder X-Ray diffraction, thermochemical energy storage

1. Introduction

Reliable energy supply has become a fundamental in today's society. Although notable efforts were made within the last decade to decrease the ecological footprint of the global energy supply by supporting sustainable energy sources, fossil raw materials are still the fundamental resource for energy production. (Shine, 2005) Aiming for an increased awareness of sustainable energy management the International Energy Agency (IEA) reported in 2011, that the global energy loss in form of waste heat during electricity generation accounts for approximately 66 %. (IEA, 2011) This stimulated equally politics and science to focus on a reduction and recycling of waste heat to contribute to a more efficient energy management. (IEA, 2014; Arce et al., 2011)

A major challenge for waste heat management is the temporal mismatch between heat production and consumption. (Solé et al., 2012) Therefore, a feasible approach towards a more efficient energy balance could be the storage of so far unused waste heat, allowing for a decoupling of production and consumption in space and

doi:10.18086/swc.2017.14.01 Available at http://proceedings.ises.org

time. (Zhang et al., 2016) The concept of thermal energy storage enables the transfer of excess energy to a suitable storage medium, thus preserving the stored energy for the case of a sudden demand. (Bauer et al., 2012; Abedin, 2011) Several methods categorized according to the used storage medium, are known for this purpose. Whereas sensible (Dinker et al., 2015) and latent heat storage (Zalba et al., 2003) transferring the heat to a liquid or solid storage medium, respectively to a phase-change material are mainly suitable for low- to medium-temperature storage, thermochemical energy storage (TCES) offers a much larger temperature compatibility, being tunable by the applied storage reaction. (Abedin, 2011; Cot-Gores et al., 2012) By charging the storage material (*A*, Eq.1) with the waste heat its dissociation is forced, liberating a reactive gas (*B*, Eq.1) as H_2O, CO_2, O_2, NH_3, … Once the formed decomposition product (*C*, Eq. 1) is contacted with the reactive gas under suitable reaction conditions, the back-reaction takes place, discharging the stored energy. A general equation for a thermochemical energy storage reaction is given in Eq.1.

$$A + \Delta H \leftrightharpoons B + C \tag{1}$$

Compared to sensible and latent heat storage, thermochemical storage offers - besides the broad applicable temperature range (between room-temperature and 1200 °C in *e.g.* concentrating solar power plants (Prieto et al., 2016)) - notably higher energy densities, decreasing amounts of necessary material. Moreover, it avoids insulation of the material once charged, as until contacted with the reactant no discharging will occur. The possibility of lossless storage lends TCES-materials for mid-term to long-term storage applications, (Xu, 2014) where *e.g.* waste heat is continuously stored but liberated periodically to fit heat-demands going beyond the daily process routine. For such applications a storage at preferably room-temperature would be desirable, followed by a discharging of the material at low-temperatures avoiding a preheating of the material.

A class of TCES-materials featuring relatively high energy contents are metal carbonates, (Kyaw et al., 1996; Yamauchi et al., 2007) commonly investigated for application at elevated temperatures in combination with *e.g.* concentrating solar power plants. (Reich, 2014; Rhodes et al., 2015) Recently we could demonstrate, that various metal oxides (obtained from decomposition of the corresponding carbonates) undergo carbonatization already at moderate temperatures in the presence of moisture and by increasing the partial pressure of CO_2 to 55 bar. (Müller et al., 2017a)

Main-group II metal oxides were so far mainly known as TCES-materials with respect of being considered for hydrate reactions. In order to broaden the scope of applicability, the process of CO_2 sequestration in rock mineralization (Fagerlund et al., 2012; Sissmann et al., 2014; Yamauchi et al., 2007; Morales-Flórez et al., 2015) inspired this endeavour reported here. Carbonatization reactivity at low-temperatures and elevated CO_2 pressures were studied aiming for novel low-temperature carbonate TCES-materials for mid- and long-term storage.

2. Results and Discussion

2.1 Carbonatization of MgO

Among the different main-group II metal oxides in particular MgO appears to be perfectly suitable for an application in thermochemical energy storage due to its availability as industrial raw material. It is known from earlier studies on the hydration behavior of MgO, which also have been aiming for a TCES-process, that the calcination conditions determine the reactivity of the material. Previous work on $Mg(OH)_2$-calcination resulted in calcination conditions providing a notably reactive material (Müller et al., 2017b), which was also used in the current low-temperature carbonatization study.

Successful carbonatization of MgO was already reported for reactions at temperatures around 575 °C (Fagerlund et al., 2012). Nevertheless, at ambient temperatures under the applied conditions varying from 8 bar wet CO_2 in the *in-situ* P-XRD setup (see experimental) to 55 bar wet CO_2 in the autoclave, in none of the experiments terminated after 2 h any detectable trace of $MgCO_3$ has been found. The same negative result accounts for experiments at temperatures up to 60 °C in the autoclave. The most likely explanation for the absence of any reactivity is the relatively high energetic barrier of the CO_2-absorption, which cannot be overcome by simply

increasing the CO_2-pressure. In order to investigate even higher CO_2-pressures under supercritical conditions, MgO was exposed to H_2O and kept for 4 h in a supercritical CO_2-reactor at 150 °C, 150 bar. In this case a complete conversion to $Mg(OH)_2$ can be observed, but still no reaction with CO_2 and hence no carbonate formation occurs.

A notable kinetic hindrance was already reported in literature (Hu et al., 2011) not only for the CO_2-absorption on the MgO surface, but also for the H_2O dissociation on a MgO surface forming $Mg(OH)_2$. To exclude, that the carbonatization of MgO is hampered by a required intermediate formation of $Mg(OH)_2$, all experiments were repeated using $Mg(OH)_2$ as a precursor material. Nevertheless, even the choice of reactant material reveals to be not critical for the observed absence of any significant carbonatization.

Most recently it was shown, that the energetic barrier of the H_2O-dissociation on the MgO surface could be notably decreased by the dotation of the MgO lattice with a degree of dotation by up to 10 % of Ca^{2+}-ions (Müller et al., 2017c). In order to derive, whether a similar effect could also be observed in the case of the carbonatization, samples of $Mg_{1-x}Ca_xO$ with Ca-contents x = 0-1 were moistened and kept for 2 h at 55 bar in the autoclave. The phase composition of the different samples after 2 h reaction time is shown in Figure 1.

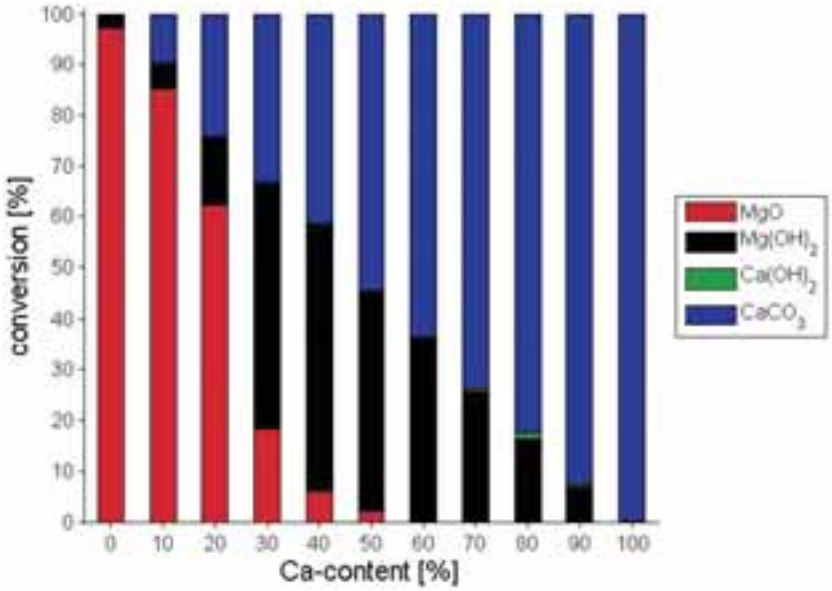

Fig. 1: Phase composition after 2 h reaction time of the $Mg_{1-x}Ca_xO$ samples in the presence of moisture at 55 bar CO_2

Phase analyses as carried out by means of X-ray powder diffraction gave evidence for significant conversion to carbonate for the Ca^{2+}-doped MgO materials, with a selective carbonate formation on the Ca^{2+}-components. Starting from the sample with 10 % Ca^{2+}-dotation, the complete amount of Ca^{2+}-dopant was carbonated, whereas the MgO component remained unchanged, or was partially hydrated forming $Mg(OH)_2$. The same result was obtained, when the mixed hydroxides $Mg_{1-x}Ca_x(OH)_2$ were used as starting material for carbonatization (see figure 2).*

* The phase composition of a comparable experiment regarding the reactivity of both the mixed oxides $Mg_{1-x}Ca_xO$ and hydroxides $Mg_{1-x}Ca_x(OH)_2$ in the absence of moisture are shown in Figure S1 and S2.

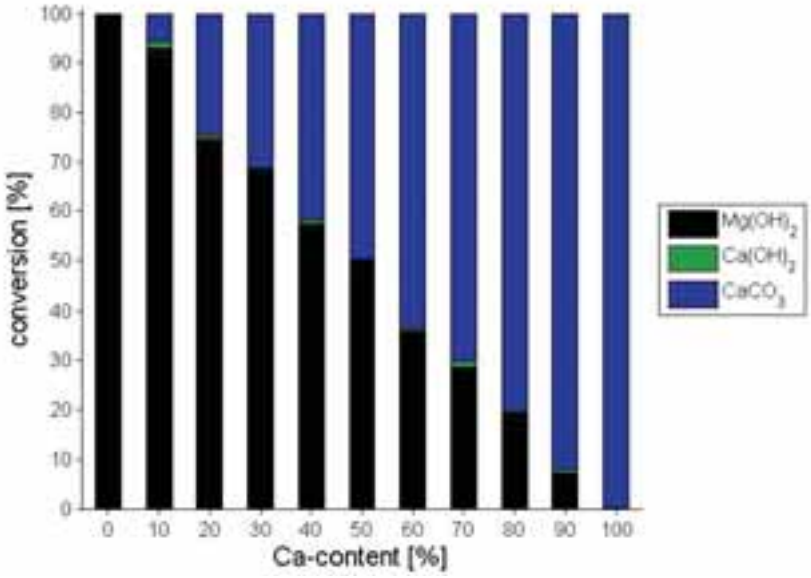

Fig. 2: Phase composition after 2 h reaction time of the $Mg_{1-x}Ca_x(OH)_2$ samples in the presence of moisture at 55 bar CO_2

This allows for the conclusion, that although a Ca^{2+}-dotation can effectively promote the H_2O dissociation, no similar catalytic effect is found in the case of the CO_2-absorption.

2.2 Carbonatization of CaO

Based on the promising carbonatization results of the Ca^{2+}-doped MgO samples, and demonstrating the favorable transformation of the CaO components to the corresponding carbonate within 2 h at 55 bar and room-temperature, as a result both the time dependency of the reaction and the influence of the moisture concentration has been investigated.†

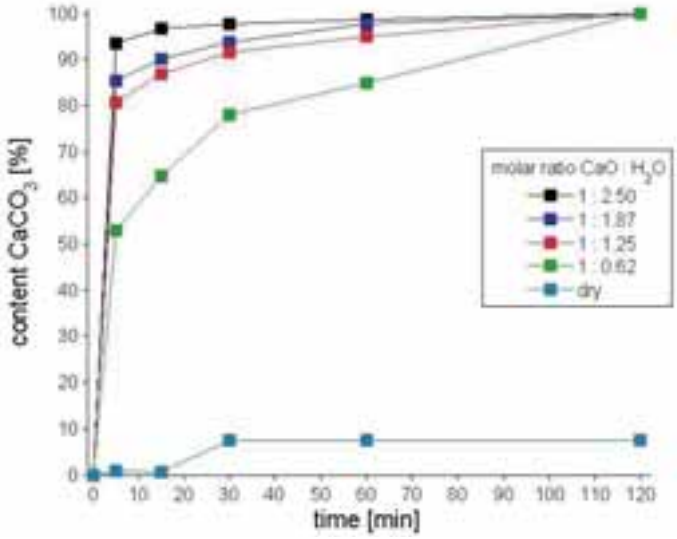

Fig. 3: Time- and moisture dependent carbonatization of CaO at 55 bar CO_2

Figure 3 shows the time dependent increase of the $CaCO_3$-concetration for 5 different moisture concentrations, ranging between 0 and 2.5 molar equivalents of H_2O per equivalent CaO. Without additional moisture, the initial

† Prior experiments on CaO-carbonatization in the P-XRD at 8 bar of wet CO_2 resulted only incomplete conversion to 34 % $CaCO_3$ after 120 minutes. (Müller et al., 2017a)

CaO is converted to 9 % into $CaCO_3$, keeping this phase composition constant over the observed time. Already after 5 minutes, more than 50 % of CaO are carbonated for the various amounts of added H_2O. In the case of 2.5 equivalents of H_2O even 94 % $CaCO_3$ had formed. The CaO phase was completely carbonated after 120 minutes for all investigated variations of H_2O contents. As even in the case of molar deficits of H_2O the complete carbonatization of CaO to $CaCO_3$ takes place, it indicates that H_2O appears to have only a catalytic role in the process, otherwise no quantitative $CaCO_3$ formation would have been possible. According to the SEM-images shown in figure S3 an increasing amount of H_2O present during the carbonatization promotes the observable fragmentation of the particles, facilitating easier access of reactive gas CO_2 to the remaining CaO.

Once a fully reversible reaction, which is potentially suitable for a TCES-process, has been identified another intriguing aspect is the cycle stability of the process. To assess the reproducibility of the quantitative CaO-carbonatization, the same sample of $CaCO_3$ was calcined at 900 °C for 1 h and re-carbonated in the autoclave at 55 bar in the presence of 0.62 equivalents H_2O for 120 minutes in 7 subsequent cycles. The phase composition of a representative sample after each cycle is shown in Figure 4.

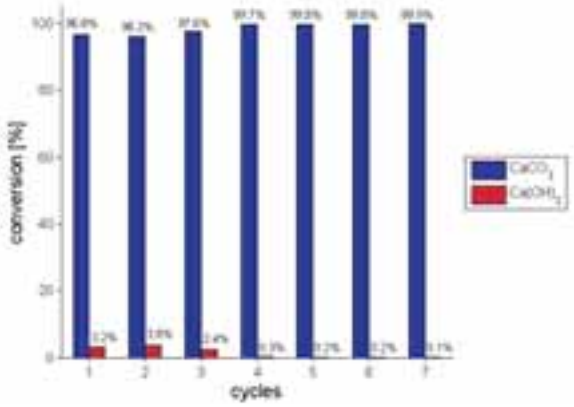

Fig. 4: Phase composition during cycle-stability test of $CaCO_3$ / CaO

For all 7 cycles after 120 minutes the carbonatization was found nearly quantitative, only in the first 3 cycles a small residue of <4 % $Ca(OH)_2$ could be observed. The reduction of the residual CaO is attributed to an increasing degree of particle fragmentation with the number of cycles, which in turn decreases the diffusion pathways for any volatile component. In the SEM-images in Figure 5, a fragmentation of the particles on repeated carbonatization / calcination process could be observed. In Figure 5a – showing CaO after the first calcination – a rather uniform particle size distribution is found. With increasing number of cycles also a fraction of smaller particles is observed, which results from the mechanical stress originating from the volume work accompanying the transformation from CaO to $CaCO_3$.

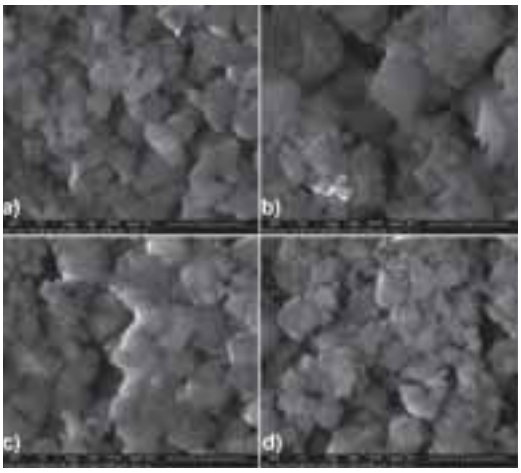

Fig. 5: SEM images of various stages of the cycle stability test a) CaO after first decomposition of $CaCO_3$ b) $CaCO_3$ after 1 cycle c) $CaCO_3$ after 4 cycles d) $CaCO_3$ after 7 cycles. Image size 9 x 9 µm

As the reaction $CaCO_3 \leftrightarrow CaO + CO_2$ revealed an attractive reactivity and cycle stability, subsequent investigations will focus on determination of the thermochemical parameters and energy density under the applied low-temperature carbonatization conditions.

2.3 Carbonatization of SrO

A direct comparison of the carbonatization behavior of MgO and CaO suggests an increased CO_2-affinity moving towards the heavier alkaline earth cations, correlating with the increased ionic radii. Attempted carbonation of SrO in the absence of H_2O failed both under 8 bar and 55 bar of CO_2, which could be anticipated based on the prior experience. In contrast, P-XRD patterns of the sample in the presence of moisture under 8 bar CO_2 reveal an interesting behavior as shown in Figure 6.

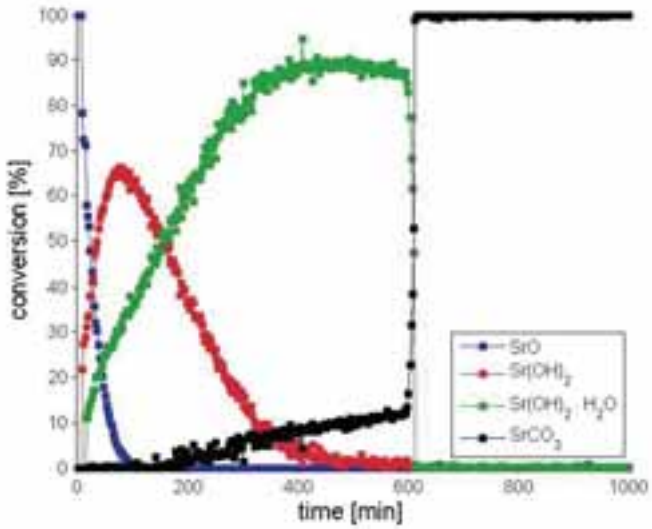

Fig. 6: Time-dependent phase composition of SrO during carbonatization in the presence of moisture at 8 bar CO_2

SrO is very hygroscopic, transforming immediately in the presence of H_2O to crystalline $Sr(OH)_2$ (red symbols). It directly hydrates yielding the monohydrate phase $Sr(OH)_2 \cdot H_2O$ (green symbols). This hydration process occurs simultaneously, and after 500 minutes the intermediate $Sr(OH)_2$ completely converted to $Sr(OH)_2 \cdot H_2O$. In parallel to this process after approximately 180 minutes the carbonatization starts at a nearly exact 1:1 ratio of $Sr(OH)_2$ to $Sr(OH)_2 \cdot H_2O$. The XRD pattern provides evidence for the formation of $SrCO_3$ as new phase (black symbols). Within the next 400 minutes the $SrCO_3$ phase augments slightly up to about 12 %, when suddenly the carbonatization gets significantly accelerated and the conversion is completed within a short time interval (*i.e.* 15 minutes). This spontaneous acceleration of the carbonatization rate was found to be reproducible on repeated experiments.

Apart of this unexpected carbonatization behavior, SrO behaves also different with respect to the role of H_2O in the process. Whereas in the case of CaO H_2O seems to have only a catalytic impact – under-stoichiometric H_2O amounts still allow for quantitative carbonatization of CaO, – in the case of SrO the intermediate $Sr(OH)_2 \cdot H_2O$ is the apparently critical reactive species. Once enough $Sr(OH)_2 \cdot H_2O$ had formed, the carbonatization starts from the surface of the particles, most likely forming a thin layer of $SrCO_3$ on the particle surface. As this $SrCO_3$ layer is denser than the original hydroxide phase, it acts as a barrier for diffusion of water and CO_2 into the inner bulk of the particles. A likely explanation for the observed sudden acceleration of the carbonatization rate is the formation of micro-cracks, mechanical changes including fragmentation of the particles as caused by the volume work and strain occurring at the interface between the hydrous phase and the carbonate.‡ Table S1 provides the corresponding crystallographic cell-parameters for SrO, $Sr(OH)_2$, $Sr(OH)_2 \cdot H_2O$ and $SrCO_3$. This interpretation is supported by SEM-images of SrO material before and after carbonatization (figure 7), as the images reveal a

‡ The carbonation of $Sr(OH)_2 \cdot H_2O$ to $SrCO_3$ goes along with an expansion of the cell about 68 %.

notable particle fragmentation during the carbonatization process.

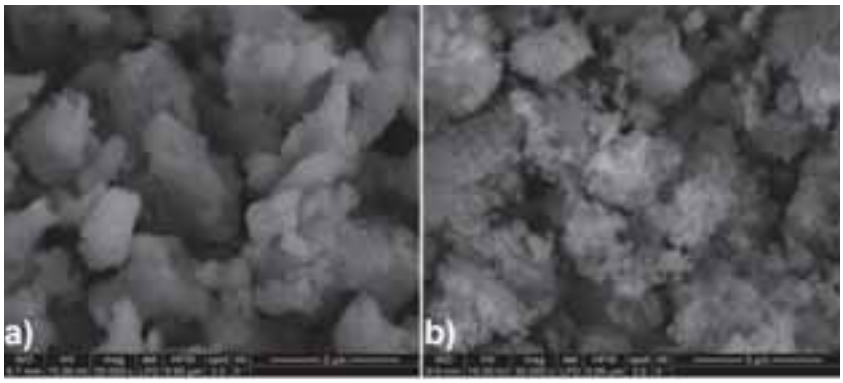

Fig. 7: SEM-images of a) SrO before carbonatization and b) $SrCO_3$ after carbonatization. Image size 9 x 9 µm

The same carbonatization experiment was repeated under 8 bar of wet CO_2, using a mixture of $Sr(OH)_2 \cdot 8H_2O$ (50 %) and $Sr(OH)_2 \cdot H_2O$ (50 %) as starting material in order to derive, whether a higher hydrate coordination around the Sr^{2+}-cation would significantly enhance the progress of the carbonatization process.

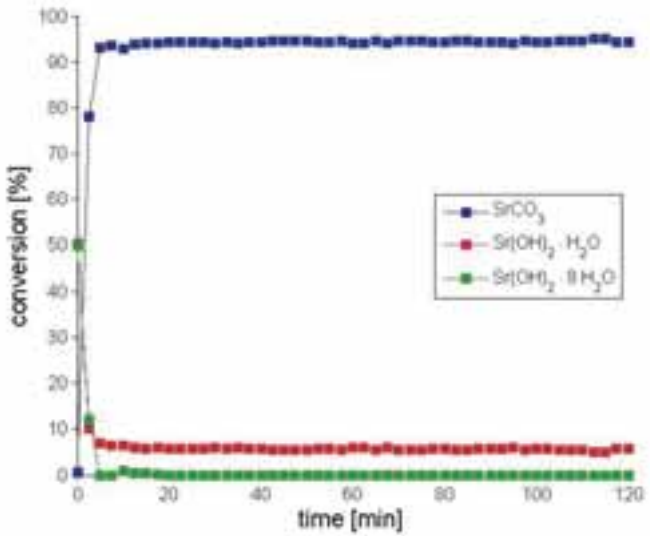

Fig. 8: Time-dependent phase composition of a mixture of $Sr(OH)_2 \cdot 8H_2O$ (50 %) and $Sr(OH)_2 \cdot H_2O$ (50 %) during carbonatization in the presence of moisture at 8 bar CO_2

Figure 8 reveals, that within 6 minutes the complete amount of $Sr(OH)_2 \cdot 8H_2O$ and 82 % of the $Sr(OH)_2 \cdot H_2O$ phase were converted into $SrCO_3$. The residual $Sr(OH)_2 \cdot H_2O$ was found inert towards further carbonatization within the next 120 minutes. This different carbonatization behavior allows for the conclusion, that carbonatization is favored by the higher hydrate coordination of Sr^{2+}.

2.4 Carbonatization of BaO

Based on the chemical similarity between Sr^{2+} and Ba^{2+} and the fact, that both form hydrated hydroxides, the behavior of BaO reacting with wet CO_2 was expected to be similar to that observed for SrO.

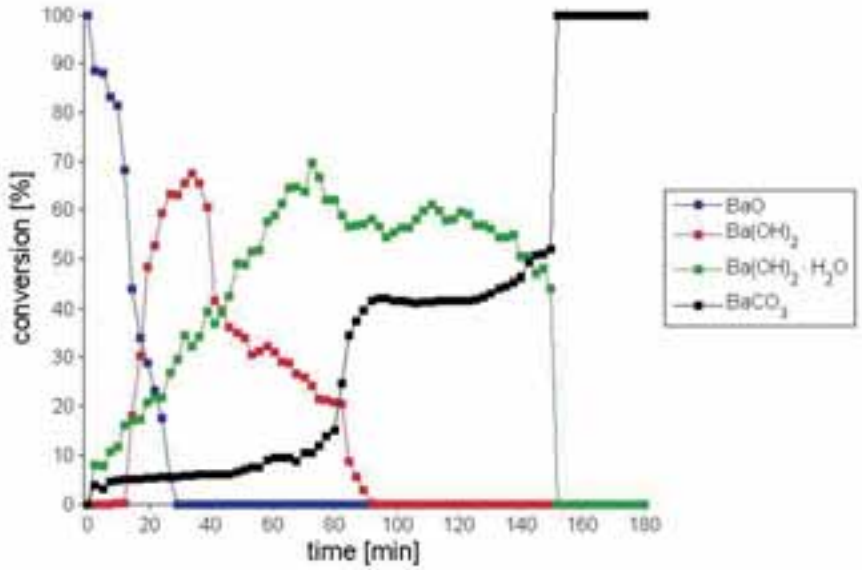

Fig. 9: Time-dependent phase composition of BaO during carbonatization in the presence of moisture under CO_2 atmosphere

Whereas in the case of SrO the carbonate formation initiated after formation of a 1:1 mixture between hydroxide and hydroxide monohydrate, in the case of BaO already after 2 minutes a small amount of the $BaCO_3$-phase is found. This may be attributed to a higher CO_2-affinity of Ba^{2+}, but also to the much faster conversion of BaO into the hydroxide and hydroxide monohydrate. In fact, the conversion of $Ba(OH)_2$ to $Ba(OH)_2{\cdot}H_2O$ is under the applied conditions so fast, that for the first 15 minutes only the $Ba(OH)_2{\cdot}H_2O$ – originating from the immediate hydration of the former $Ba(OH)_2$ – is observed. After that time also the $Ba(OH)_2$ phase increases, converting to the $Ba(OH)_2{\cdot}H_2O$ within 90 minutes. The carbonatization seems in the case of Ba^{2+} not as strictly related to the hydroxide monohydrate as in the case of Sr^{2+}. In fact, after the initial formation of around 5 % $BaCO_3$, the carbonate formation occurs via a two-step process with an intermediate plateau-phase: After 75 minutes the carbonatization rate increases, decelerating again once 42 % of $BaCO_3$ were formed. After 50 minutes of a nearly constant $BaCO_3$ content, only slightly increasing towards the end to 52 % $BaCO_3$, within 2 minutes a spontaneous completion yielding 100 % of $BaCO_3$ occurs. Based on the present data no final explanation of this in the series so far unique carbonatization process is possible.[§]

Also for Ba^{2+} a mixed sample of $Ba(OH)_2{\cdot}8H_2O$ (50 %) and $Ba(OH)_2{\cdot}H_2O$ (50 %) was compared regarding their carbonatization behavior (Figure 10).

[§] Table S2 provides the corresponding crystallographic cell-parameters for BaO, $Ba(OH)_2$, $Ba(OH)_2{\cdot}H_2O$ and $BaCO_3$.

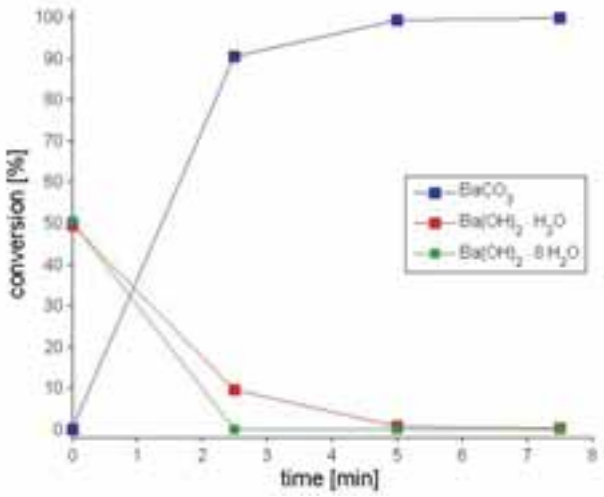

Fig.10: Time-dependent phase composition of a mixture of $Ba(OH)_2 \cdot 8H_2O$ (50 %) and $Ba(OH)_2 \cdot H_2O$ (50 %) during carbonatization in the presence of moisture at 8 bar CO_2

In the case of Ba^{2+} the carbonatization of both hydroxides is completed already within 5 minutes. Nevertheless, also in this case a slightly higher reactivity for the $Ba(OH)_2 \cdot 8H_2O$ is found, as after 2.5 minutes the complete octahydrate phase was carbonated, whereas still 12 % of $Ba(OH)_2 \cdot H_2O$ were present.

3. Conclusion

In the present study main group II oxides were investigated for their reactivity towards CO_2 in the presence of moisture at ambient temperature and elevated pressures up to 55 bar of CO_2. The aim of this approach was the investigation of a carbonatization process for main group II oxides regarding their application as long-term thermochemical storage materials with discharging of the stored energy near to ambient temperature.

From the investigated series of MgO, CaO, SrO and BaO, all oxides apart from MgO were found to carbonate under the applied conditions at the given time scales. The best performance was observed for CaO, transforming quantitatively to the corresponding carbonate in the presence of moisture at 55 bar CO_2 within 120 minutes. Repeated calcination / carbonatization of the material under the same conditions revealed a very appealing cycle stability of the process, although a concomitant particle fragmentation was observed, which can be attributed to the volume work involved into the reaction. In case of SrO the hydrate coordination sphere around the Sr^{2+} seems to have a notable impact on the calcination behavior. Treated with 8 bar wet CO_2, SrO was hydrated immediately to $Sr(OH)_2$ in a first step and consequently to $Sr(OH)_2 \cdot H_2O$, which was then the active phase reacting with CO_2 to form $SrCO_3$. An initial slow conversion rate observed for the carbonatization was suddenly accelerated and is assigned to particle changes, most likely due to the formation of micro-cracks and fragmentation. Additional experiments using $Sr(OH)_2 \cdot H_2O$ and $Sr(OH)_2 \cdot 8H_2O$ in carbonatization further supported the postulated importance of the hydrate coordination sphere around the cation, as in contrast to the monohydrate the octahydrate was quantitatively carbonated within 6 minutes. In the case of BaO a much higher carbonatization reactivity than for SrO, reaching complete conversion after 150 minutes, was found. Although, the reaction involves the intermediate formation of $Ba(OH)_2$ and $Ba(OH)_2 \cdot H_2O$, the carbonatization mechanism seems different, as a two-step carbonatization with an intermediate plateau was observed. Also in the case of Ba^{2+} the hydrate coordination sphere around the cation promotes the carbonatization.

Based on the present work regarding a general feasibility of an ambient-temperature carbonatization for main group II oxides, within a next step the thermochemical data and energy densities for the materials under the selected process parameters will be established. A further in-depth investigation of the impact of H_2O on a molecular level during the carbonatization process, as well as on the detailed carbonatization mechanisms for SrO and BaO is currently ongoing.

4. Experimental

4.1 Material

MgO (calcined from $Mg(OH)_2$,), CaO (calcined from commercially available $Ca(OH)_2$) and the mixed $Mg_{1-x}Ca_xO$ were prepared by thermal decomposition of the commercially available (or in the case of $Mg_{1-x}Ca_x(OH)_2$ freshly precipitated) hydroxides. All other materials were commercially obtained and used as supplied.

4.2 X-Ray Powder Diffraction

The powder X-ray diffraction measurements were carried out on a PANalytical X'Pert Pro diffractometer in Bragg-Brentano geometry using Cu $K_{\alpha1,2}$ radiation and an X'Celerator linear detector with a Ni-filter. For *in-situ* monitoring of experiments an Anton Paar XRK 900 reaction chamber was used. The sample was mounted on a hollow ceramic powder sample holder, allowing for complete perfusion of the sample with the reactive gas. The sample temperature is controlled directly via a NiCr-NiAl thermocouple and direct environmental heating. The diffractograms were evaluated using the PANalytical program suite HighScorePlus v4.6a. (Degen et al., 2014) A background correction and a $K_{\alpha2}$ strip were performed. Phase assignment is based on the ICDD-PDF4+ database ((http://www.icdd.com), the exact phase composition, shown in the conversion plots, was obtained via Rietveld-refinement incorporated in the program suite HighScorePlus v4.6a. (Degen et al., 2014) All phase quantifications based on P-XRD are accurate within ±5 %. For the carbonization experiments the pressure in the sample chamber was adjusted to 8 bar, maintaining a constant flow through the chamber of 0.4 L CO_2 min^{-1}. To investigate the carbonation in the presence of moisture, the CO_2 was passed through an external moisturiser. The CO_2 was bubbled through a 20 cm high water tank followed by a droplet-separator before contacting the sample in the reaction chamber. At the entrance of the reaction chamber the gas had a dew-point temperature of 23.2 °C with a constant sample temperature of 25 °C.

4.3 Carbonation in the reactor

For the carbonation of the metal oxides at higher CO_2 pressure a stainless-steel autoclave with a volume of 0.19 L was used. A small amount of the metal oxides (around 250 mg) was placed in a glass-vial with perforated cap to avoid cross-contamination during pressure release and moistened with 200 µL H_2O. The reactor was pressurized with CO_2 at 55 bar unless otherwise stated, controlling the internal pressure with the integrated manometer of the reactor. The carbonation process was stopped after the specified reaction time by releasing the CO_2.

4.4 Scanning Electron Microscopy

SEM images were recorded on gold coated samples with a Quanta 200 SEM instrument from FEI under low-vacuum at a water vapor pressure of 80 Pa to prevent electrostatic charging.

Abstract

Metal oxides providing various, reversibly accessible oxidation states are in the focus as auspicious materials for high-temperature thermochemical energy storage (TCES) materials. Among all principally suitable metal oxides due to equilibrium temperature and, in particular, reaction rate and reversibility, only the couple Co_3O_4 / CoO and to a smaller extend Mn_2O_3 / Mn_3O_4 are considered as suitable candidates. Based on recent studies on isothermal TCES-cycles, the impact of temperature and increased O_2-pressure on the reaction rate was investigated by varying the O_2-partial pressure in the low-temperature oxidation of the reduced oxide. Whereas Mn_3O_4 was found to react too slow for a process at lower temperatures, CoO was found suitable. For an increase of the O_2 pressure to 6 bar between 500 – 550 °C an attractive oxidation behavior was observed. At 900 °C Co_3O_4 / CoO could be cycled within 4.5 minutes between both oxidation states by changing the atmosphere from N_2 to O_2 and vice versa.

Keywords: cobalt oxide, manganese oxide, non-ambient pressure, in-situ powder X-Ray diffraction, thermochemical energy storage

1. Introduction

The different technologies suitable for thermal energy storage are defined according to the storage process as sensible (Dinker et al., 2015), latent (Zalba et al., 2003) and thermochemical heat storage (Abedin, 2011; Cot-Gores et al., 2012). The latter provides the highest storage densities and has the potential for loss-less storage, once the material was charged. The necessary smaller amounts of material – related to the higher storage densities compared to other techniques, – as well as the enormous applicational flexibility due to the large temperature range being tolerated, are additional advantages of this technique. (Yan, 2015)

The loss-less storage ability of thermochemical energy storage materials (TCES-materials) is an intrinsic feature, as no discharging of the storage occurs in the absence of the reactive gas. The broad operational temperature

doi:10.18086/swc.2017.14.02 Available at http://proceedings.ises.org

profile of TCES-materials is given by the equilibrium temperatures of the applied substance classes. By ranking the materials following to the involved reactive gases such as H_2O, NH_3, H_2, CO_2 or O_2, the field of application for TCES-materials ranges from low-temperature storage with temperatures below 100 °C (van Essen et al., 2009; Knoll et al., 2017) (mostly hydrated salts for *e.g.* civil engineering applications as in an energy self-sufficient building) to medium-temperature storage using ammoniates or hydrides and to temperatures between 800-1200 °C (T. Yan, 2015), using carbonates or oxides in combination with *e.g.* concentrating solar power plants. (Pardo et al., 2014)

Oxides suitable for TCES require several stable oxidation states of the metal, reversibly accessible via redox-reactions. During the charging of the storage material the metal is reduced, while discharging in the presence of O_2 leads to a restorage of the (initial) higher oxidation state (see equation 1).

$$M_xO_{y+n} + \Delta H \leftrightarrow M_xO_y + \frac{n}{2} O_2 \quad (1)$$

Although, metal oxides are investigated with respect to their thermochemical properties since the 80's, only a few suitable oxides are known due to the necessary reversibility of the redox-process. Candidate materials promising for application are the couple Co_3O_4 / CoO, as well as Mn_2O_3 / Mn_3O_4 considering reversibility, toxicity issues, temperature range and reaction time. A variety of studies was reported in particular for the cobalt system, covering cycle stability tests (Agrafiotis et al., 2014), composite materials, (Agrafiotis et al., 2016a), (Agrafiotis et al., 2015a; 2015b; Karagiannakis et al., 2016) materials optimization via spinel-phases (Babiniec et al., 2015; Block et al., 2014; LiuPrewitt, 1990), mechanical stress (Karagiannakis et al., 2016), etc. Although, Mn_2O_3 is also widely known for TCES purposes, (Carrillo, A. J. et al., 2014) due to the slower reaction kinetics, (Alonso et al., 2013; Chen et al., 2013) as well as the minor performance compared to the cobalt-system. Most efforts focussed on the dotation of Mn_2O_3 with iron (Carrillo, A. J. et al., 2015;Wokon et al., 2017), forming perovskites, or the combination with Co_3O_4 for a combined system. (Agrafiotis et al., 2016b)

Theoretically suitable metal oxides such as ZnO, (Palumbo, 2001) Fe_2O_3 or V_2O_5 feature equilibrium temperatures well above 1500 °C (Pardo et al., 2014), hampering both their routine investigation for storage processes, and their combination with conventional concentrating solar power plants. In order to expand the portfolio of redox-TCES materials, experimental approaches combining TCES with syngas production (Muthusamy et al., 2014), or the application of peroxide / oxide reactions (Carrillo, A. J. et al., 2016) were reported for energy storage in literature.

Apart from their potential of bridging non-operational times in concentrating power plants, the interest in oxidic TCES-materials relates mainly to their high storage density. Recently we could demonstrate (Müller et al., 2017), that between 830 - 930 °C a regime of coexistence between CoO and Co_3O_4, depending on the O_2-concentration, allows for isothermal TCES-cycles. Moreover, both CoO and Mn_3O_4 start oxidation under O_2-atmosphere already below 500 °C. Materials of high storage densities would be highly appreciated for applications around these temperatures. To enhance the reaction rate and obtain a material, which would combine fast reaction rates with high energy densities and a broad perspective of applicability, in the present study the impact of temperature on the isothermal redox-cycle, and the effect of an increased oxygen partial pressure on the oxidation rate was investigated by an *in-situ* powder diffraction (P-XRD) study.

2. Experimental

2.1 Material

Cobalt(II,III) oxide (99.995%), cobalt(II) oxide (99.99%), manganese(IV) oxide (99.99%) and manganese(II, III) oxide (97%) were obtained from Sigma-Aldrich and used as supplied.

2.2 X-Ray Powder Diffraction

The powder X-ray diffraction measurements were carried out on a PANalytical X'Pert Pro diffractometer in Bragg-Brentano geometry using Cu $K_{\alpha1,2}$ radiation and an X'Celerator linear detector with a Ni-filter. For *in-situ*

experiments at elevated pressures an Anton Paar XRK 900 reaction chamber, operable between ambient pressure and 12 bar was used. The sample was mounted on a hollow ceramic powder sample holder, allowing for complete perfusion of the sample with the reactive gas. The sample temperature is controlled directly via a NiCr-NiAl thermocouple and direct environmental heating. For the *in-situ* experiments at ambient pressure an Anton Paar HTK 1200N sample chamber was used. The sample temperature is controlled via a Pt 10 % RhPt thermocouple and direct environmental heating. The diffractograms were evaluated using the PANalytical program suite HighScorePlus v4.6a. (Degen et al., 2014) A background correction and a $K_{\alpha 2}$ strip were performed. Phase assignment is based on the ICDD-PDF4+ database ((http://www.icdd.com), the exact phase composition, shown in the conversion plots, was obtained via Rietveld-refinement incorporated in the program suite HighScorePlus v4.6a. (Degen et al., 2014) All quantifications based on P-XRD are accurate within of ±5 %.

2.3 Thermal Analysis

For thermal analysis of the redox-reactions a Netzsch TGA/DSC 449 C Jupiter ® equipped with a water vapour furnace including an air-cooled double jacket was used. The oven operates between 25 °C and 1250 °C, regulated by an S-type thermocouple. Oxygen and nitrogen gases were 99.999 % and obtained from Messer. For all measurements under air a mixture of 21 % O_2 and 79 % N_2 was applied. The gas flow was set to 25 ml min^{-1}, controlled and mixed with Vögtlin Instruments "red-y" mass flow controllers. A sample mass of 20 mg in an open Al_2O_3 crucible was used for all experiments with heating and cooling rates of 10 °C min^{-1}. The DSC was calibrated according to the procedure suggested by Netzsch, using the In, Sn, Bi, Zn, Al and Ag standards provided by the manufacturer.

2.4 Scanning Electron Microscopy

SEM images were recorded on gold coated samples with a Quanta 200 SEM instrument from FEI under low-vacuum at a water vapor pressure of 80 Pa to prevent electrostatic charging.

3. Results and Discussion

3.1 Isothermal oxidation of CoO triggered by variation of the reactive gas

Based on the previously identified window of coexistence between CoO and Co_3O_4, selected temperatures between 880 °C and 920 °C were chosen to determine the reaction rate by isothermal thermogravimetry / differential scanning calorimetry (TG / DSC). The isothermal reduction of Co_3O_4 under N_2 with subsequent oxidation by changing the atmosphere to O_2[*] was investigated at five temperature levels for each two cycles (figure 1).

[*] The redox-reaction of Co_3O_4 under gas-change conditions was confirmed to be highly comparable for 20 consecutive cycles (figure S1).

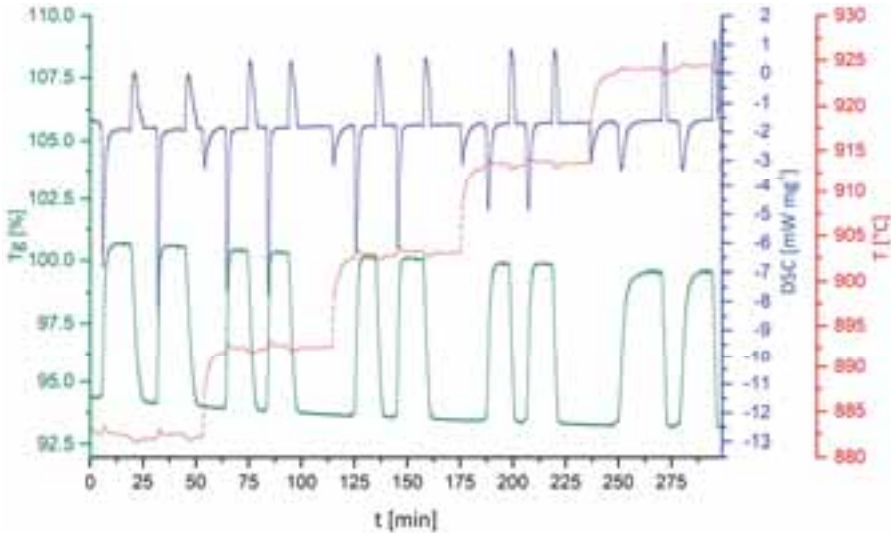

Fig. 1: TG / DSC of isothermal redox-cycles of Co_3O_4, triggered by variation of the atmosphere at 880, 890, 900, 910 and 920 °C. Reduction occurs under N_2-atmosphere, oxidation under O_2-atmosphere.

The averaged reaction times for reduction and oxidation, obtained from figure 1, are given in table 1.

Tab. 1: Average reaction times for isothermal reduction of Co_3O_4 (under N_2) and oxidation of CoO (under O_2), calculated from the differential scanning calorimetry data

	880 °C	**890 °C**	**900 °C**	**910 °C**	**920 °C**
Oxidation [min]	3.92 ± 0.40	3.35 ± 0.03	4.54 ± 0.11	4.95 ± 0.03	6.91 ± 0.28
Reduction [min]	7.07 ± 0.15	5.58 ± 0.05	4.62 ± 0.08	3.96 ± 0.08	3.41 ± 0.19

Except the spike for the oxidation time at 890 °C, an apparent linear correlation between reaction time and temperature is obtained. The oxidation time doubles with increased isothermal temperature almost nearly over the whole investigated temperature range, whereas the reduction time is exactly halved. Based on the herein obtained results the most suitable temperature for such an isothermal TCES-process is identified with 900 °C, where oxidation and reduction of the material are taking equal times.

The presented isothermal redox-cycling between 880 - 920 °C with the optimum at 900 °C represents a notable improvement regarding the earlier investigations, where oxidation was accomplished within 10.4 minutes at 848 °C and the complete reduction accounted for 23 minutes. (Müller et al., 2017)

3.2 Isothermal oxidation of CoO

The second objective of the current study on isothermal redox-reactions for thermochemical energy storage was the combination of low-temperature oxidation of CoO at around 500 °C under increased O_2-pressure. The isothermal oxidation under varied oxygen contents at ambient pressure was selected as a starting point. In order to compare the reactivity towards O_2 in the desired temperature regime, samples of CoO were oxidized at 500, 520 and 550 °C using an atmosphere with 21 % O_2 (synthetic air) and 100 % O_2.

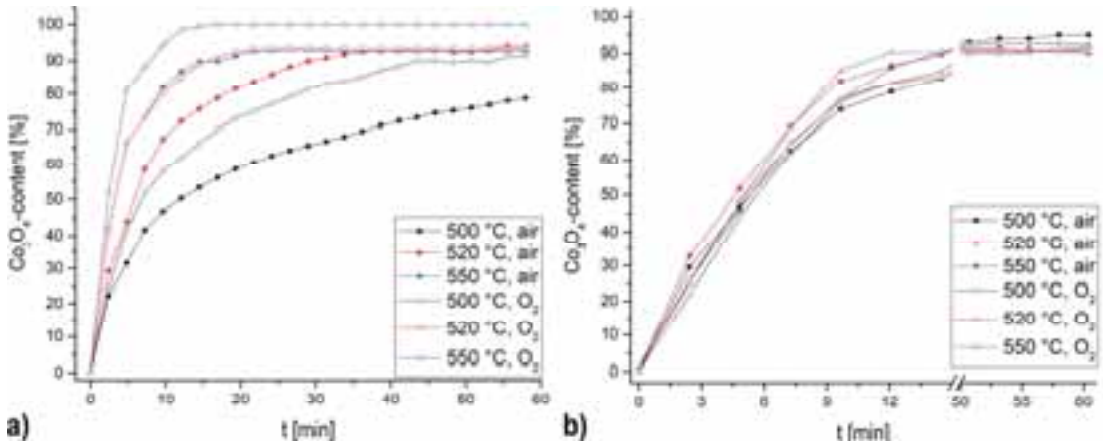

Fig. 2: Oxidation rate of CoO at several temperatures and O_2-concentrations for a) a CoO-sample obtained from thermal decomposition of Co_3O_4 under N_2 b) a commercial CoO sample

A concentrating plot of the different oxidation rates for CoO – obtained from Co_3O_4 by thermal reduction of the material under N_2 at 890 °C for 5 minutes – is shown in figure 2a. Especially for the series at 500 °C a notable difference in oxidation rate between the measurement under air and O_2 is found. The impact of the O_2 concentration with increasing temperature is superimposed by the thermal contribution, leading to a nearly identical oxidation rate observed in the experiments at 520 °C under O_2 and 550 °C under air.

In principle both a Co_3O_4 initially reduced to CoO and a CoO prepared on an industrial scale should be feasible for a Co-based TCES process. For comparison, the same series of oxidation experiments was repeated using a commercial sample of CoO (figure 2b). Interestingly, a completely different picture is observed in this case. The chemically identical sample provides much faster oxidation rates with conversions above 80 % under all applied conditions within the first 15 minutes. The reason for this behavior was found in the SEM-images of both precursors, showing for the Co_3O_4 (figure 3a) large sintered agglomerates, whereas the CoO (figure 3b) consisted of small, isolated particles. The different O_2-concentrations, as well as the various temperatures, have no impact on the initial particle morphology (see figure S2).

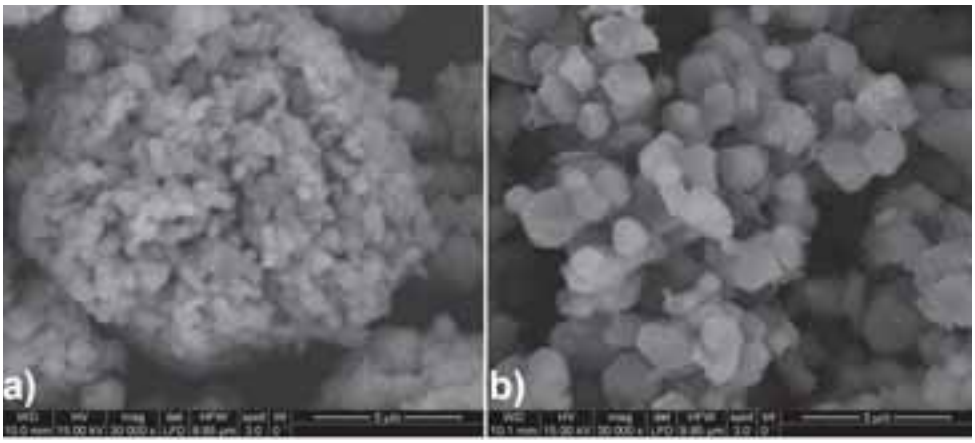

Fig. 3: SEM-images of a) commercial Co_3O_4 b) commercial CoO. Image size 9 x 9 µm

3.3 Isothermal oxidation of CoO under elevated O_2 pressure

In order to facilitate investigations on the impact of an increased oxygen pressure, which is higher than the atmospheric one, Co_3O_4 that has been *in-situ* reduced under N_2 was used for the experimental approach. Although, the commercial CoO sample would provide faster reaction rates, no reliable results would have been obtained even with a high-end laboratory P-XRD setup.†

The oxidation rates for the experiments under ambient pressure, 3 bar and 6 bar O_2‡ are shown in figure 4, which reveals a rate-enhancing effect of the increased O_2 pressure for all three temperature levels. Obviously, the largest influence on the oxidation is observed for 500 °C (figure 4a). By applying 3 bar O_2 the conversion within the first 15 minutes is enhanced about 20 %. 6 bar O_2 result in a quantitative Co_3O_4 formation after 30 minutes, the reaction rate being only slightly faster than for 3 bar.

In case of the series at 520 °C, O_2 oxidation under ambient pressure and 3 bar O_2 reveal only slight differences in the reaction rate. At 6 bar O_2 an increased oxidation within the first 6 minutes leads to quantitative Co_3O_4 formation after 15 minutes. Finally, at 550 °C the temperature increase predominates over the increased pressure, as both 3 bar and 6 bar O_2 yield a complete oxidation - 3 bar after 12 minutes, 6 bar after 8 minutes.

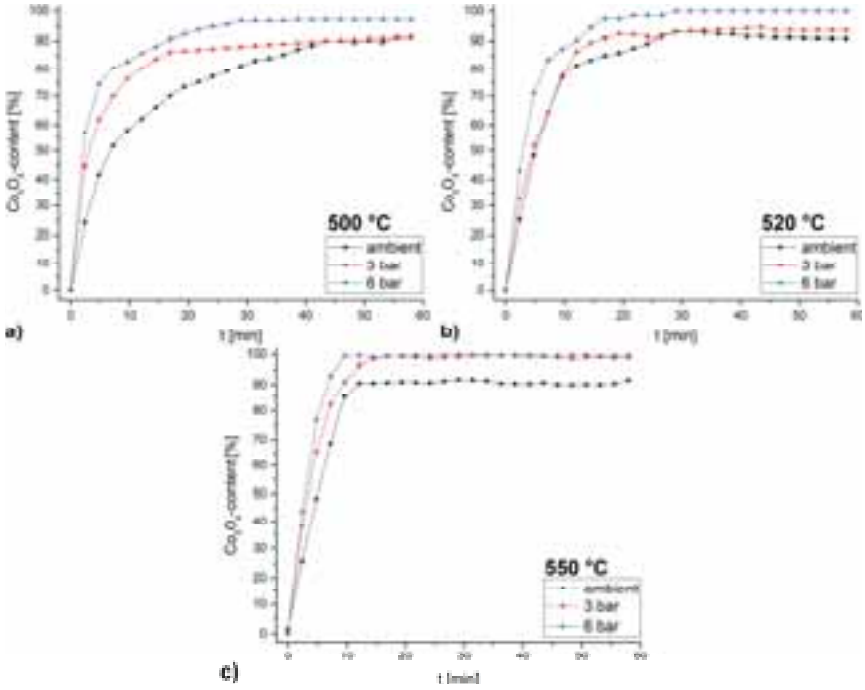

Fig. 4: Oxidation rate of CoO at different pressures and temperatures at a) 500 °C b) 520 °C c) 550 °C

Based on these results a lower oxidation temperature for CoO in a TCES-process seems feasible, increasing the reaction rate by moderately enhanced pressure. For technological processes elevated pressure is always correlated with much higher expenditures regarding the process design. Using only 6 bar O_2 – for all three temperatures yielding a notable enhancement of the conversion rate – may be still worth the efforts aiming for an oxide-based

† This limitation – also slightly affecting the accuracy of the phase-determination for the high Co_3O_4-contents – is attributed to the overlap of significant peaks in the diffractograms of the two Co-phases, as well as the high fluorescence of the Co-containing samples in combination with the available Cu K_α-radiation (see figure S3). To ensure the data quality, a minimum measurement time of 2 minutes per diffractogram was necessary.

‡ Although, the used Anton Paar XRK 900 would tolerate pressures up to 12 bar, applying a higher pressure than 6 bar O_2 extends due to radiation absorption and the fluorescence background the measurement time notably, so within one diffractogram the transformation from CoO to Co_3O_4 is completed. For similar measurements under higher pressures a different X-Ray source or a synchrotron would be needed.

medium-temperature TCES-process.

The only drawback of the increased pressure is the promoted sintering of the material, which is already evidenced in the SEM-images of the Co_3O_4 samples, oxidized at 550 °C and various pressures (see figure 5). Nevertheless, this changed particle morphology so far was not found to decrease the reactivity of the material on repeated cycling.

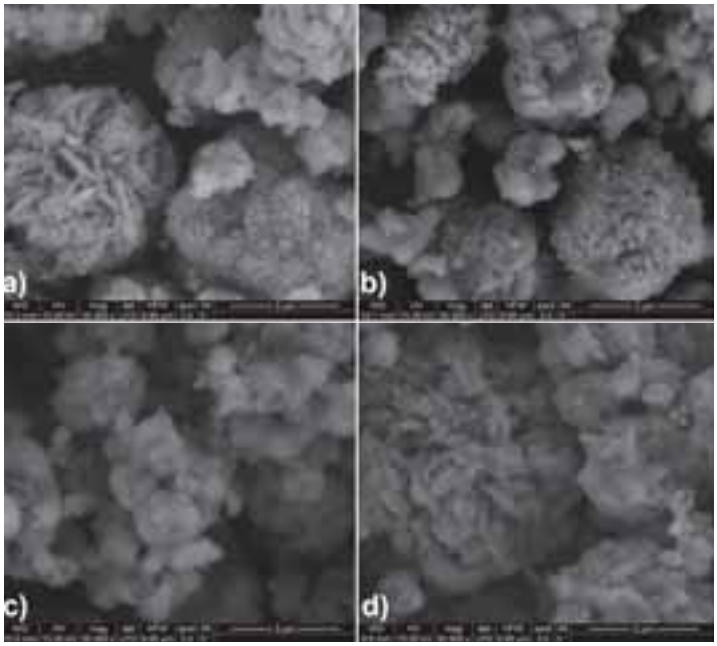

Fig. 5: Particle morphology of Co_3O_4 after oxidation at 550 °C and varied O_2 pressures a) Co_3O_4 starting material b) ambient pressure c) 3 bar O_2 d) 6 bar O_2. Image size 9 x 9 µm

3.4 Isothermal oxidation of Mn_3O_4

Similar to the study on the isothermal oxidation of CoO, a series was carried out also on Mn_3O_4 which was oxidized at different temperatures (470 °C, 500 °C, 520 °C, 550 °C) and ambient pressure under synthetic air and pure oxygen (figure 6).

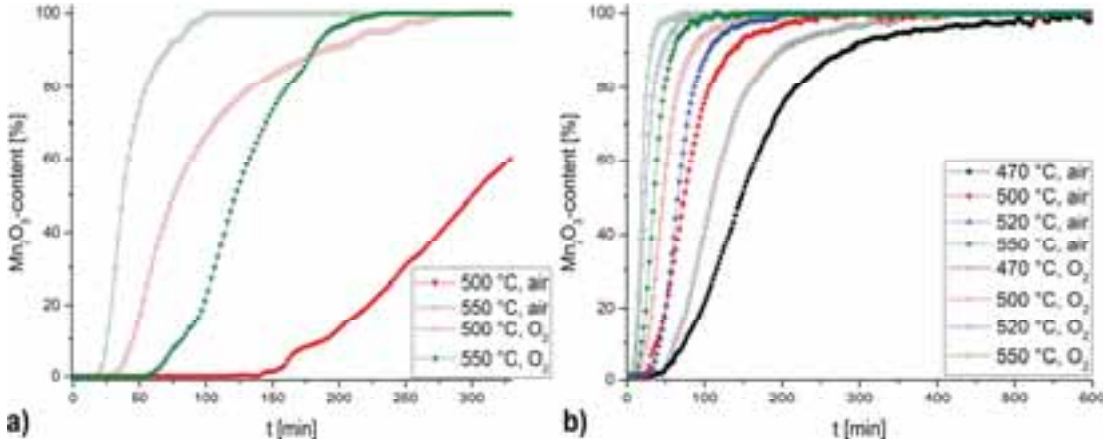

Fig. 6: Oxidation rate of Mn_3O_4 at various temperatures and O_2-concentrations for a) a Mn_3O_4-sample obtained from thermal decomposition of MnO_2 under N_2 b) a commercial Mn_3O_4 sample

Similar to the Co-system also for Mn_3O_4 a notable difference between the *in-situ* reduced sample under N_2 (figure 6a) and the commercially obtained Mn_3O_4 (figure 6b) was found. For the freshly reduced Mn_3O_4 at 500 °C under

air within 330 minutes only 62 % of Mn_2O_3 are formed, whereas O_2 enables complete conversion to Mn_2O_3. Still a notable difference is observed at 550 °C, where both air and O_2 result in complete re-oxidation.

In the case of the commercial Mn_3O_4 a clear trend towards faster oxidation rates, both with increased temperature and O_2-content is found. Similar to CoO also for Mn_3O_4 temperature increases the oxidation rate more efficiently than a higher O_2 concentration. Comparable oxidation rates in this case are found at 550 °C under air and 520 °C under O_2.

4. Conclusion

In the present study the redox-couple Co_3O_4 / CoO was investigated with respect to an isothermal redox-cycle, triggered by changing the atmosphere from N_2 to O_2 between 880 – 920 °C. A reasonably linear correlation was found between the reduction / oxidation times and the applied temperature. Within the investigated temperature range the best conditions for an isothermal redox-cycle were found at 900 °C, as both reduction and oxidation take place quantitatively within 4.5 minutes. This represents an improvement of the so far reported results on isothermal cycling.

Based on former results an isothermal low-temperature oxidation of CoO between 500-550 °C under increased O_2-pressure was attempted, allowing for the application (only discharging) of a TCES-material featuring a high energy density at medium-temperatures. Increasing the O_2-pressure during oxidation from ambient conditions to 6 bar resulted in an attractive increase of reaction rate, discharging the CoO (oxidation to Co_3O_4) quantitatively at 500 °C within 24 minutes, at 550 °C within 8 minutes.

Elevated pressures during the oxidation process allow for a shift of the discharging reaction towards lower temperatures. This enables the application of the *per se* attractive high energy density of metal-oxide redox-reactions at temperatures, where they so far could not be operated, as the oxidation (discharging) required higher temperatures. This could be attractive for complementing an existing process with thermochemical energy storage, when pressurized air / oxygen is already available, or when a storage material with high energy density and a fast reaction rate is required at lower temperatures.

Mn_3O_4 was found to be too slow in its oxidation under all investigated conditions to be competitive in comparison to CoO.

Thermo-physical properties of NaCl – Na_2CO_3 – NaOH as a high-temperature sensible heat storage medium

Gowtham Mohan, Mahesh Venkataraman and Joe Coventry

Research school of engineering, Australian National University, Canberra (Australia)

Abstract

A novel ternary salt mixture composed of sodium chloride, sodium carbonate and sodium hydroxide (Na-Cl-CO_3-OH) was developed for high-temperature sensible thermal energy storage (HTSTES) application. The melting point and the heat capacity of the Na-Cl-CO_3-OH mixture was measured using a differential scanning calorimeter. The final melting temperature of the blend was estimated as 347.3°C. The average heat capacity of the blend was calculated as 1.50 J g^{-1} K^{-1} by following the ASTM standard E1269. The mass loss of the molten salt mixture was studied up to 1000°C using a thermogravimetric analyser in three different atmospheres, and the salt was found to be stable over 700°C. In terms of cost, Na-Cl-CO_3-OH mixture costs approximately 4.5 USD/kWh, around 60% less than the commercial "solar salt" nitrate salt mixture.

Keywords: Molten salt, sensible energy storage, thermophysical properties, mixed-anion.

1. Introduction

Thermal energy storage (TES) plays a vital role in the effective and efficient use of concentrated solar power (CSP) to provide steady output and meet intermittent electricity demands. The storage media is the most important component in any thermal energy storage (TES) system (Kuravi et al., 2013). Molten salts are extensively used thermal storage media and heat transfer fluid (HTF) in CSP plants due to their favourable thermo-physical properties. Current state-of-the-art CSP plants utilise "solar salt" (60 wt. % $NaNO_3$ – 40 wt. % KNO_3) and HITEC salt (53 wt. % KNO_3 – 40 wt. % $NaNO_2$ – 7 wt. % $NaNO_3$) for TES due to their acceptably low melting point and reasonable heat capacity (Ushak et al., 2015). Several recent CSP research programs have focused on developing high-temperature, and high-efficiency CSP plants incorporating advanced power cycles such as the supercritical Rankine, supercritical CO_2, and air-Brayton cycles. Selection of the HTF and TES media plays a crucial role in developing a modern CSP plant. The current generation molten salts (solar salt and HITEC) decompose around 600°C, which is insufficient for high-temperature power cycles (Gil et al., 2010; Kenisarin, 2010; Medrano et al., 2010), although a slight extension in the operating temperature is possible with meticulous atmospheric control (Olivares, 2012). Thus, development of new high-temperature molten salts with high thermal stability, specific heat capacity, reasonable melting point, and low cost is vital to support advanced power cycles. For the operating temperature range between 500°C and 700°C, mixtures of carbonates, chlorides, fluorides and hydroxides can potentially be exploited for high temperature sensible thermal energy storage (HTSTES). Several researchers attempted to develop HTSTES molten salt mixtures with carbonates (Olivares et al., 2012; Wu et al., 2011), chlorides (Wei et al., 2015), fluorides (Forsberg et al., 2007), and also mixed anions (Wang et al., 2015). Most of these mixtures had one or all of the following issues: (i) high melting point, (ii) low heat capacities, and (iii) an expensive salt component.

In this research work, a ternary salt mixture with a mixed anion configuration, and sodium (Na) cation (NaCl – Na_2CO_3 – NaOH), was developed based on the FactSage prediction reported by Gomez (Gomez, 2011) for latent heat storage. To the best of the authors' knowledge, this mixture has not been investigated as a sensible heat storage media. In this research work, we assume the thermal storage system is in the 'two-tank' configuration, as shown schematically in Figure 1. Note, Figure 1 includes a heat exchanger between the storage tank and the receiver, which allows for a separate heat transfer fluid (HTF) in the receiver (such as sodium). This particular mixture is interesting for HTSTES because of three important factors: firstly, low predicted melting point with inexpensive materials; secondly, the use of sodium (Na^+) as the cation for all three salts, which allows compatibility with an elemental sodium HTF for direct-contact heat exchange (Venkataraman, 2017); and finally, presence of large proportion of NaOH augments the specific heat capacity of the molten salt mixture. The key thermo-physical properties, such as, melting point, heat capacity, and thermal stability of this

doi:10.18086/swc.2017.14.03 Available at http://proceedings.ises.org

ternary mixture were experimentally determined, and its commercial suitability for HTSTES application has been assessed.

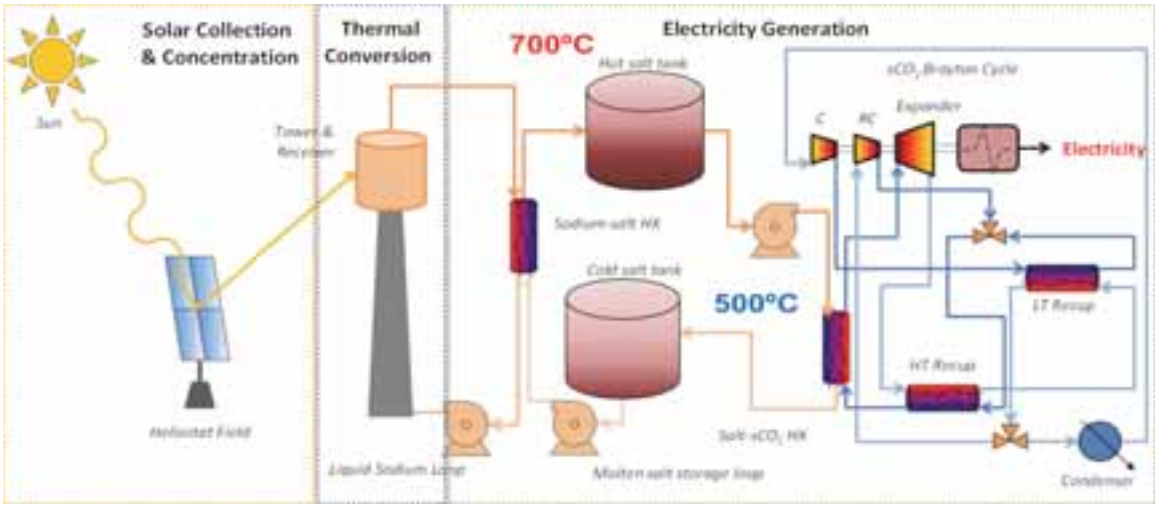

Fig. 1: Schematic diagram of proposed next-gen two-tank CSP power plant

2. Experimental procedure

A ternary mixture of NaCl – Na_2CO_3 – NaOH (Na-Cl-CO_3-OH) (mass ratio- 24.68:15.67:59.65) was synthesised. The three salts — NaCl (>99% purity, ACS grade), Na_2CO_3 (>99.5% purity, ACS grade), and NaOH (>98% purity) — were procured from Alfa Aesar and stored under nitrogen flow to avoid moisture absorption. The salt components were weighed in proportion to the FactSage prediction, then blended by hand-grinding inside a glove box using a mortar and pestle for 30 min.

The ground mixture was used directly in a Netzsch Pegasus DSC 404 to determine the melting point and heat capacity. Graphite crucibles with lids were utilised for the DSC experiments to attain faster heat transfer into the salt mixtures. The melting point and heat capacity measurements were conducted using SiC and Pt-Rd furnaces respectively at a heating/cooling rate of 10 °C/min and 20 °C/min respectively with 50 ml/min of nitrogen purge. The heat capacity of the sample was determined by following ASTM standard E1269 with a sapphire disk as the reference.

The mass loss of the salt mixture was tested using a Q600 SDT TG/DSC (TA instruments). Experiments were conducted from room temperature to 1000°C at a heating rate of 10°C/min in three different atmospheres (nitrogen, argon and air), at a flow rate of 50 mL/min. Each sample of about 5-10 mg was placed into an 85 μL alumina crucible and covered with a perforated lid.

3. Results and discussions

3.1. Determination of melting point

The melting point of the Na-Cl-CO_3-OH mixture was predicted as 320°C by FactSage. Fig. 1(a) shows the DSC curve with onset and peak melting temperatures, and multiple endothermic peaks suggesting that the mixture is off-eutectic. It is evident from Fig. 2 that complete melting of the ternary mixture takes place around 347.3°C. The freezing of the salt mixture begins at 325°C, and this difference between the melting and freezing temperatures is due to sub cooling. Four continuous heating and cooling cycles were run for each sample. The fusion between the salts in the mixture was achieved during the first heating cycle, and the melting point determined from the three subsequent cycles.

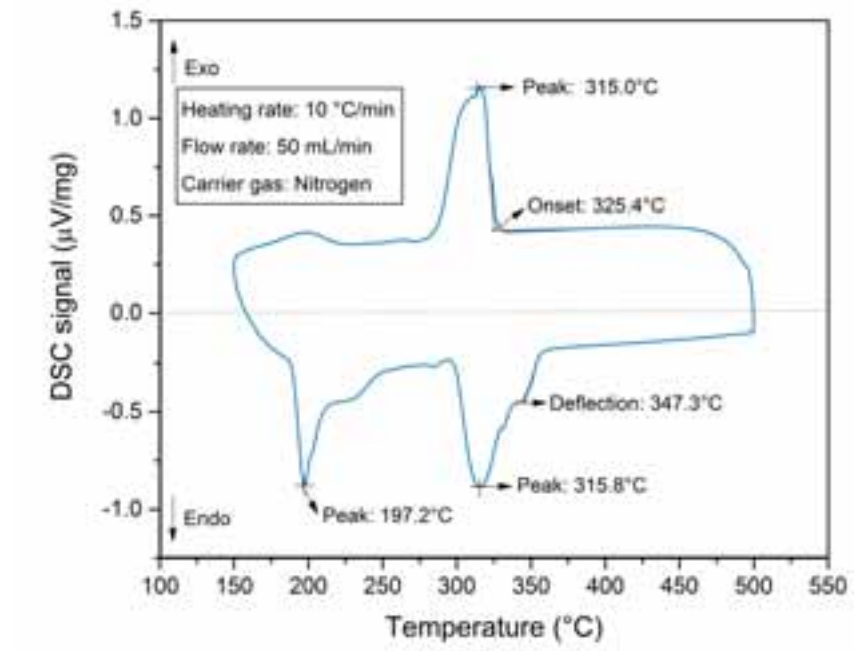

Fig. 2: Melting point analysis of Na-Cl-CO_3-OH mixture in a nitrogen atmosphere

3.2. Heat capacity measurement

The experimental measurement of specific heat capacity, c_p in the DSC followed the ASTM E1269 standard with a sapphire disk as the reference. The specific heat capacity measurement method was validated by correlating the heat capacity values obtained for a unary salt (NaCl) with the theoretical values (Chase-Jr, 1998) in the temperature range 400 – 600°C. The maximum variation between the experimental and theoretical values was less than ±2%, as presented in Fig. 3. The heat capacity of the mixed anion ternary was measured above the liquidus temperature between 450 and 600°C as shown in Fig. 4. The experiments were conducted in a nitrogen atmosphere at 50 mL/min, and measured over 10 heating-cooling cycles. The average heat capacity of the mixture is 1.508±0.005 J g^{-1} K^{-1}, which is similar to the commercial 'solar salt' mixture. Values for average specific heat capacity is first averaged across all 10 cycles, and then averaged across the measurement temperature range. The error value (±0.005) is the standard deviation from the mean of the temperature averaged values across the 10 heat capacity measurements. The liquid heat capacity values (J g^{-1} K^{-1}) of Na-Cl-CO_3-OH are fitted into a polynomial function for convenience of use. Polynomial regression is used to fit curves to the c_p data with good agreement, and therefore, within the nominated temperature ranges, specific heat capacity can be taken as follows:

$$c_p = aT^3 + bT^2 + cT + d \quad (1)$$

where temperature T is the salt temperature in °C and the coefficients are given in Table 1. The R^2 value from the regression analysis is also given.

Tab. 1: Polynomial coefficients for the heat capacity

Mixture	Validity	a	b	c	d	R^2
NaCl – Na_2CO_3 – NaOH	455 – 600	$-3E^{-7}$	0.000516	0.281139	52.45630	0.972

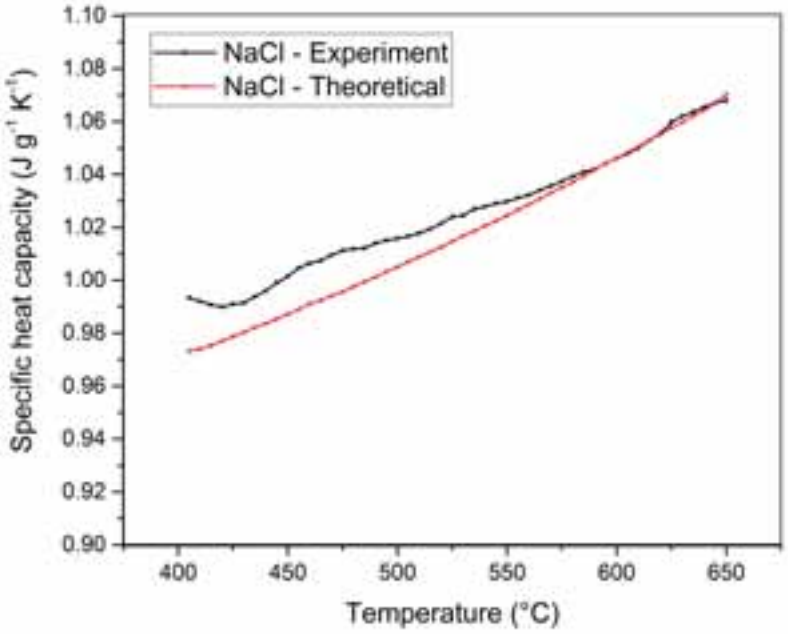

Fig. 3: Validation of heat capacity measurement with NaCl

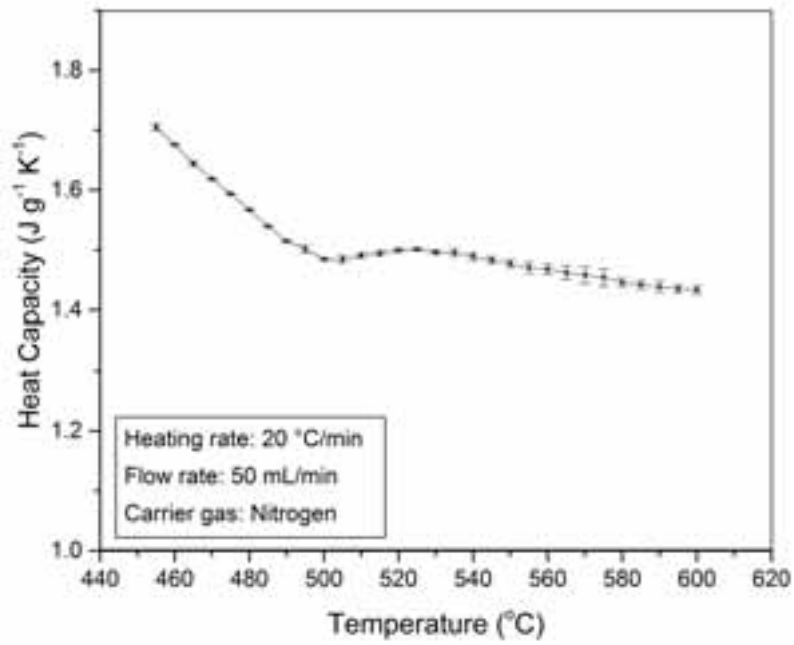

Fig. 4: Heat capacity measurement of Na-Cl-CO_3-OH mixture in a nitrogen atmosphere

3.3. Mass loss testing of the ternary mixture

Both thermal stability and mass loss due to vaporisation of the molten salt are important considerations for solar thermal application. Here we distinguish between the physical decomposition of the salt (thermal stability) and mass loss due to vaporisation caused by high vapour pressure. The mass loss of the salt mixture was measured in three different atmospheres with a flow rate of 50 mL/min using the DSC-TGA equipment. The experiments were conducted up to 1000°C from room temperature as shown in Fig. 3. An initial mass loss is observed due to evaporation of absorbed moisture during sample loading process. The tested salt mixture showed excellent stability over 700°C in inert atmospheres. In the presence of air, the ternary mixture reacts and increases in mass as shown in Fig. 5. This may be due to the interaction between NaOH and CO_2, leading to the formation of Na_2CO_3 (Zeman, 2007). Fig. 6 shows that pure liquid NaOH reacts with air at higher temperatures, causing a

change in mass, which reaffirms the previous statement. It is evident from the tests, that the Na-Cl-CO_3-OH mixture shows promising thermal stability as a HTSTES media for modern high-temperature CSP plants.

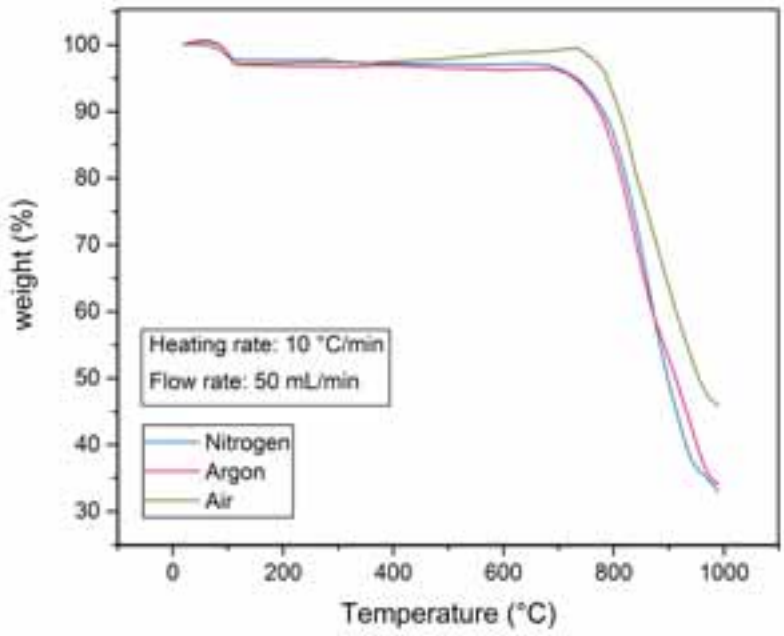

Fig. 5: Thermal stability of ternary mixture in three atmospheres

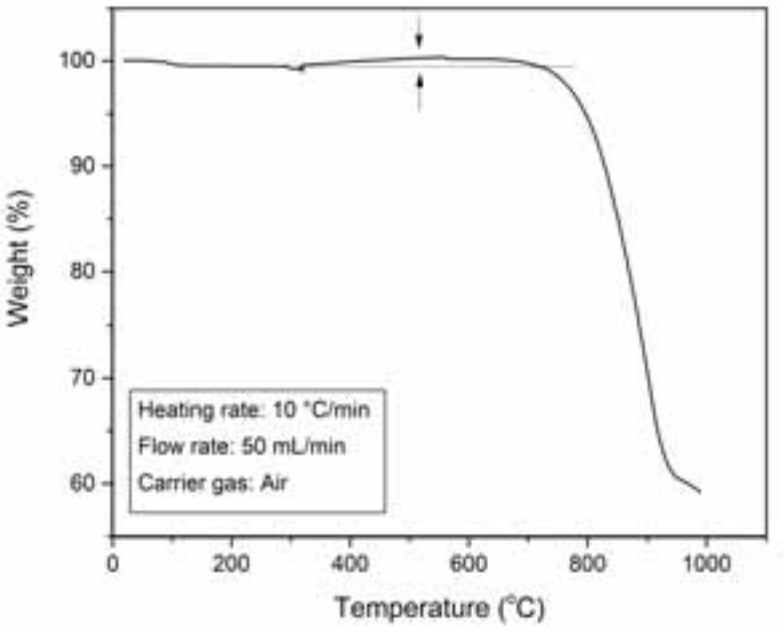

Fig. 6: Thermal stability of NaOH in air

3.3. Economic analysis

The cost of the storage media is one of the important parameter in the selection process. The costs of individual salt components considered in the study, as well as the reference case 'solar salt', are shown in Table 2. All the values shown in the table are adjusted to December 2016 currency using the PPI (producer price index) commodity data for industrial chemicals provided by Bureau of Labor Statistics (BLS) (BLS, 2016). The cost of each salt mixtures was calculated in terms of USD/tonne and USD/kWh, assuming operating temperature range between 500°C and 700°C. Prices were obtained from industrial suppliers. The total cost of the salt mixture was 390 USD/tonne and 4.5 USD/kWh, which is approximately 60% cheaper than the 'solar salt'.

Tab. 2: Cost of individual salts, as in Dec 2016. PPI: average Purchaser Price Index provided by (BLS, 2016)

Material	Cost (USD/tonne)	Source
NaCl	49	52 USD/tonne in Mar'16 (Industrial minerals, 2016). PPI = -6%
Na_2CO_3	324	320 USD/tonne in Sep'15 (Industrial minerals, 2016). PPI = 1%
NaOH	550	550 USD/tonne in Dec'16 (Alibaba, 2016)
Solar Salt	950	950 USD/tonne in Dec'16 (SQM, 2016)

4. Conclusion

The current state-of-the-art storage media decomposes around 600°C, and there is therefore a need for new storage media with thermal stability over 700°C to support modern high-efficiency CSP plants. In this research work, a new ternary mixture was developed and its thermo-physical properties evaluated for HTSTES applications. The molten salt mixture displayed acceptable melting point (<350°C), good heat capacity (1.50 $J\ g^{-1}\ K^{-1}$) and excellent thermal stability (>700°C). Most importantly, the ternary mixture was more economical (4.5 USD/kWh) that the nitrate 'solar salt' blend used in many current CSP plants. The experimental results indicate that Na-Cl-CO_3-OH mixture is a promising candidate for future HTSTES applications. The corrosion behaviour of containment materials and interacting surfaces is an important issue which needs to be addressed, before this mixed anion salt mixture can be recommended for use in high-temperature CSP systems.

Abstract

High energy densities are one key-feature of thermochemical energy storage materials. Among the substance classes featuring the highest energy densities are oxides and carbonates, having both operational temperature profiles between 800 °C - 1200 °C. Comparable high energy contents are provided by the reaction between ammonia and (transition) metal salts, operable in a medium-temperature range between 150 °C - 450 °C. Due to the toxicity of ammonia a closed cycle preventing the release of ammonia to the surrounding environment would be necessary.

Herein, $CuSO_4$ and $CuCl_2$ are investigated in a laboratory scale reactor for their application in thermochemical energy storage with ammonia as reactive gas. In the current setup after 80 seconds peak temperatures of 312 °C and 238 °C respectively were measured. To circumvent the notable volume expansion during the reaction with ammonia, both copper salts were loaded on zeolite 13X, yielding matrix-supported composite materials. Operation of those materials in the laboratory scale reactor under ammonia revealed, that the rapid temperature increase and the high peak temperatures could be retained, simultaneously simplifying the handling of the materials.

Keywords: copper salts, copper ammoniates, laboratory scale reactor, thermochemical energy storage

1. Introduction

Increased awareness of a necessary reduction of greenhouse gasses in relation to energy production stimulated an ongoing reorientation of the energy market. (IEA, 2014, Paris agreement, 2015) Environmentally benign energy production with increasing percentages of renewable energy, a sustainable energy management and a responsible use of the produced energy led to a multiplicity of innovative approaches, complying the climate targets. (Keith Shine, 2005) Related to this development are also the increase of energy efficiency, especially in context of electricity production, as according to the IEA about 2/3 of the therefore used energy are lost in form of waste heat. (IEA, 2011)

Optimizing the waste heat management encouraged research to develop recycling methods for so far lost waste heat. (Bauer et al., 2012; Hasnain, 1998) One auspicious approach due to its broad application profile is the thermal storage of waste heat by sensible, (Zhang et al., 2016) latent (Zalba et al., 2003) or thermochemical energy storage materials. (Abedin; A.H. 2011; Cot-Gores et al.; 2012, T. Yan, 2015) Thermochemical energy storage (TCES) takes a very prominent position amongst these approaches, as highest storage densities, loss-less storage, a broad

doi:10.18086/swc.2017.14.04 Available at http://proceedings.ises.org

operational temperature profile and fast reaction times allow for a flexible application in domestic and industrial environments, compatible with waste heat temperatures between 30 °C and above 1200 °C.(T. Yan, 2015)

Depending on the available waste heat source, the suitable materials may be selected from an ample catalogue of principally suitable reactions, ranked according to their storage density and application temperature.(Deutsch et al., 2016) On the lower end of the temperature spectrum are located salt hydrates for *e.g.* application in energy efficient housing projects,(van Essen et al., 2009) whereas the high temperature end around 800 °C - 1200 °C is covered by carbonates and oxides, complementing *e.g.* concentrating solar power plants (CSP) during non-operational times. (Pardo et al., 2014) For the medium temperature region between 150 °C - 450 °C so far mainly hydroxide / oxide reactions (Criado et al., 2014) or metal hydrides were considered. (T. Yan, 2015)

A so far widely neglected class of TCES-materials operating in this temperature range are (transition) metal salt ammoniates, featuring notably high storage densities, comparable to redox-active metal oxides. Although, first reports on reactions of NH_3 with salts for energy storage purposes date back to the 80's, (Dunlap, 1982) until today only a handful of publications dealing with the reaction between $CoCl_2$, (AidounTernan, 2001; Trudel et al., 1999) $MnCl_2$ (Jiang et al., 2016) or $ZnCl_2$ and NH_3 (Dunlap, 1982) is known. Concepts for NH_3 in energy storage technology relate mainly on the NH_3 formation / splitting in combination with solar power. (Dunn et al., 2012; Lavine et al., 2016; Lepinasse-Spinner, 1994; Lovegrove et al., 1999; 2004)

One major obstacle of NH_3 is its inherent toxicity. Therefore, to enable thermochemical energy storage based on NH_3-metal salt reactions, a closed reactor design, avoiding any release of NH_3, would be necessary. For this purpose, in the present work a feasibility study of a NH_3-based storage reaction, using $CuSO_4$ / $CuCl_2$ loaded on zeolite 13X in a hermetically closed laboratory scale reactor, is presented.

2. Experimental

2.1 Material

$CuSO_4$ was obtained by drying $CuSO_4 \cdot 5H_2O$ for 3 h at 400 °C in an electric furnace. All other materials were commercially obtained and used as supplied.

The copper-loaded zeolites **13X-SO_4** and **13X-Cl** were prepared by soaking zeolite 13X for 30 minutes in a saturated solution of $CuSO_4 \cdot 5H_2O$ or $CuCl_2 \cdot 2H_2O$. The zeolite was rinsed with water and dried for 2 h at 150 °C under vacuum, before the soaking procedure was repeated. After rinsing with water, the loaded zeolite was dried for 2 h at 400 °C and stored after cooling in a desiccator. The Cu-loading was determined gravimetrically and by X-Ray fluorescence spectroscopy with 0.16 g $CuSO_4$, and 0.09 g $CuCl_2$ per gram of zeolite.

For preparation of the partially reduced copper-loaded zeolites, dried samples of **13X-SO_4** and **13X-Cl** were soaked for 15 minutes in a 10 % aqueous solution of $N_2H_4 \cdot H_2O$. Due to the exothermic reaction no additional heating was necessary to keep the reaction constantly at 65 °C.

2.2 Thermal Analysis

For thermal analysis a Netzsch TGA/DSC 449 C Jupiter ® equipped with a water vapour furnace including an air-cooled double jacket was used. The oven operates between 25 °C and 1250 °C, regulated by an S-type thermocouple. NH_3 gas was 99.98 % and obtained from Messer. The gas flow was set to 100 ml min^{-1}, controlled and mixed with Vögtlin Instruments "red-y" mass flow controllers. A sample mass of 10 mg in an open aluminum crucible was used for all experiments with heating and cooling rates of 10 °C min^{-1}. The DSC was calibrated according to the procedure suggested by Netzsch, using the In, Sn, Bi, Zn, Al and Ag standards provided by the manufacturer.

2.3 Reactor-setup

For the experiments in a closed system a reactor consisting of two separated chambers connected via a tap was used. Both chambers had an inner diameter of 40 mm and a length of 200 mm. The reaction chamber was fitted with a manometer to monitor the internal pressure, as well with two K-type thermocouples positioned in the middle of the chamber (T1 and T2) and a further K-type thermocouple on the outside (T3). The reaction chamber

was loaded with the dried copper salt / copper-loaded zeolite and the whole system was evacuated for 10 minutes. The tap between reaction chamber and NH_3-chamber was closed, and NH_3 liquified in the NH_3-chamber being cooled down to – 50 °C. After 10 minutes the tap to the NH_3 cylinder was closed and the NH_3-chamber warmed to room-temperature. Once the reactor had established a thermal equilibrium with the surrounding, the tap between NH_3-chamber and reaction chamber was opened to start the reaction (discharging of the storage material). Due to the excess of NH_3 during all experiments a pressure of 6 bar was obtained in the system.

For all experiments 250 ml of material were charged to the reactor.

2.4 Scanning Electron Microscopy

SEM images were recorded on gold coated samples with a Quanta 200 SEM instrument from FEI under low-vacuum at a water vapor pressure of 80 Pa to prevent electrostatic charging.

3. Results and Discussion

3.1 Reaction between NH_3 and $CuSO_4$ / $CuCl_2$

The reaction between NH_3 and $CuSO_4$ / $CuCl_2$ – although, mainly in aqueous solutions – is a well-known, colorful reaction for demonstration of simple coordination chemistry in undergraduate-laboratories. Even in the case of mixing the aqueous solutions of NH_3 and $CuSO_4$ an increase of the reaction temperature is observed.

For the gas-solid reaction between NH_3 and $CuSO_4$ / $CuCl_2$ energy-densities of 1.77 MJ kg^{-1} and 2.20 MJ kg^{-1} were obtained by differential scanning calorimetry. These values are highly comparable to the benchmark of metal-oxide redox-reactions, featuring the highest energy densities among the various TCES-materials. Even more important for a potential TCES-material, thermogravimetry evidenced a full reversibility of the NH_3- coordination, thus by heating the formed ammine-complexes to 350 °C the initial copper salts are restored (see figure S1). Based on the decomposition of the copper-ammine complexes their composition was determined as $[Cu(NH_3)_4]SO_4$ and $[Cu(NH_3)_6]Cl_2$, thus $CuSO_4$ reacting with 4 equivalents of NH_3, $CuCl_2$ with 6.

The experimental setup selected for the gas-solid reaction between NH_3 and the anhydrous copper salts on a laboratory scale is shown in figure 1.

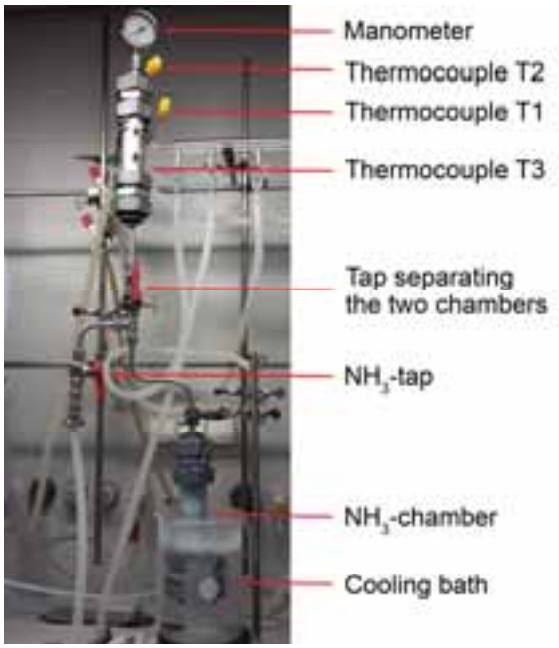

Fig. 1: Laboratory scale reactor for the gas-solid reaction between NH_3 and copper salts in a closed system

Based on the necessity of a closed system preventing the release of NH_3, a reactor with two chambers, separated

by a tap, was selected. The copper salt is situated in the reaction chamber (upper part). After evacuation of the complete system the tap between the two chambers is closed and NH_3 is condensed into the precooled NH_3-chamber. Once the NH_3-tap is closed, the NH_3-chamber is warmed to room-temperature and the reaction is started by opening the tap between the two chambers. The temperature gradient during the reaction was monitored by the 3 thermocouples T1-T3, T1 and T2 placed inside, in the middle of the reactor, T3 on the outside to follow the heat conductance. Due to the NH_3-excess used, through all experiments a constant pressure around 6 bar was obtained.

In figure 2 the temperature plots for the formation of $[Cu(NH_3)_4]SO_4$ (figure 2a) and $[Cu(NH_3)_6]Cl_2$ (figure 2b) are given.

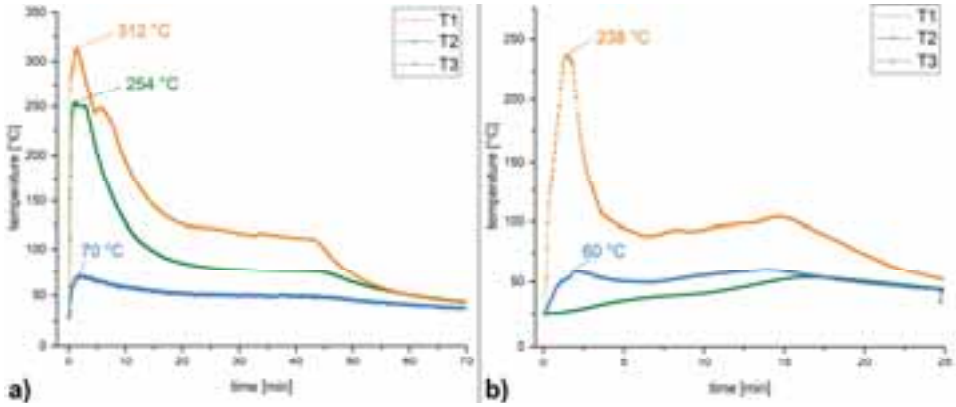

Fig. 2: Temperature plots for the formation of a) $[Cu(NH_3)_4]SO_4$ and b) $[Cu(NH_3)_6]Cl_2$ in the reactor

For both experiments starting with the opening of the tap between the two chambers an extremely fast increase of the internal temperature is observed. For $CuSO_4$ the peak temperature of 312 °C* is reached after 80 seconds, after 10 seconds T1 exceeds already 160 °C. In the case of $CuCl_2$ a peak temperature of 238 °C was reached after 90 seconds.

Both experiments are highly encouraging, as such extremely fast reactions with concomitant high temperature differences are notably rare for thermochemical energy storage materials. Nevertheless, the packed bed using the pure metal salts in the reaction chamber cannot be considered ideal, as due to the extreme volume work during the reaction a compacting / sintering process of the material occurs, deteriorating permeability of the packed bed and thus hampering the completeness of the reaction. In the case of $CuSO_4$ after the reaction the former loose powder had turned into a solid brick, which had to be removed mechanically from the reaction chamber. Additionally, from the bottom to the top of the packed bed the completeness of reaction was notably affected: Whereas, in the bottom the dark blue $[Cu(NH_3)_4]SO_4$ was formed, on the top only a slight blue color of the former white material was observed. The kinks and sudden increases in the temperature profile are attributed to the volume work of the material, varying permeability of the continuously expanding packed bed.

In the case of $CuCl_2$, although with the observed peak temperature of 238 °C the melting point of $[Cu(NH_3)_6]Cl_2$ was not exceeded, due to partial overheating near to the bottom of the reaction chamber a dark black-bluish molten residue in the reactor was formed immediately. As the thermocouple T1 was above this molten mass, the observed peak temperature was lower than in the case of $CuSO_4$ (see figure S2). Additional, nearly 2/3 of the reactors' content did not react, as the NH_3 could not pass the molten salt / ammoniate mass. Therefore, also thermocouple T2 featured only very low temperatures and the temperature in the reactor had dropped within 25 minutes significantly.

The slow decrease of the temperature profile, retaining for some extended period temperatures above 100 °C, followed by a sudden decrease of the temperature is caused by the stepwise reaction of the copper salts with NH_3. As seen from the thermogravimetric decomposition in figure S1, for the consecutive addition or removal of each of the NH_3-ligands different equilibrium / decomposition temperatures are found. Therefore, with the initial temperature rise the reaction temperature is too high to allow for complete reaction. Coming to lower

* The difference between T1 and T2 is attributed to the linear progression of the reaction zone and sintering of the material, notably affecting permeability of the packed bed.

temperatures, the further coordination of NH_3 is enabled, still releasing notable heat and thus keeping the temperature almost constant unless the reactant is consumed.

In figure 3 a time-dependent series of infrared-images, visualizing the temperature increase and slow decrease during the reaction of NH_3 with $CuSO_4$ at the outside of the reactor is shown.

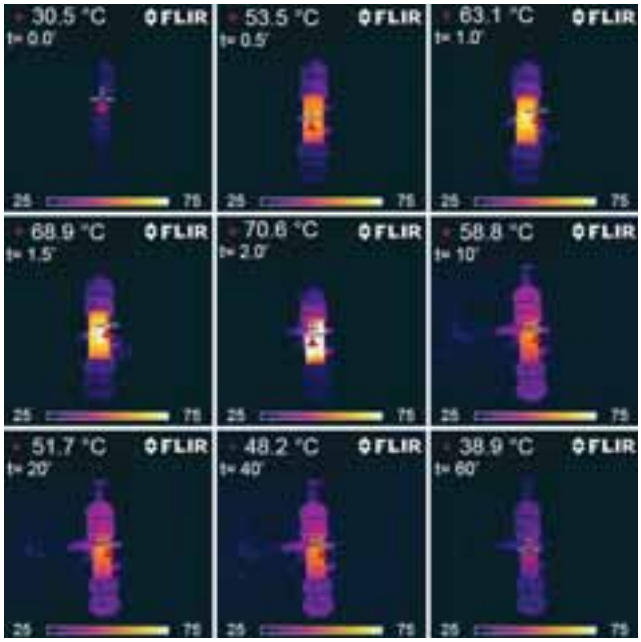

Fig. 3: Infrared-images of the reactor during the reaction of NH_3 with $CuSO_4$ at different time steps as indicated

Already after 30 seconds the temperature of the reactor walls had increased about 23 °C, reaching its maximum of 70.6 °C after 120 seconds. For the next 50 minutes a nearly constant temperature of 50 °C was observed. The temperature distribution in the IR-image after 40 minutes clearly shows, that the reaction was still ongoing.

The extreme volume work occurring on coordination of NH_3 to both copper salts becomes evident comparing the crystallographic parameters for the four different materials in table 1 (although, for $[Cu(NH_3)_4]SO_4$ only the monohydrate is found in the ICSD-database).

γ [°]	90	90	90	90

V [Å^3]	271.6	131.54	913.44	1020.54

Based on the unit-cell volumes given in table 1, for $CuSO_4$ a 3.4-fold, for $CuCl_2$ a 3.9-fold volume expansion during the reaction with NH_3 is obtained.

To circumvent, or at least decrease the expansion of the material, causing considerable issues on larger (or applicational) scale, allow for a better permeability of the packed bed and control the temperature release during the reaction, the impregnation of zeolite 13X with $CuSO_4$ and $CuCl_2$ was chosen.

3.2 Reaction between NH_3 and matrix-supported $CuSO_4$ / $CuCl_2$

The $CuSO_4$ / $CuCl_2$ loaded zeolite samples (**13X-SO_4** and **13X-Cl**) were obtained as described in the experimental section, having a greenish-brown color after drying in the furnace (see figure S3). The copper-loading was determined gravimetrically and by X-Ray fluorescence spectroscopy with 0.16 g $CuSO_4$, and 0.09 g $CuCl_2$ per gram of zeolite.

Of course, the better handling and limited volume expansion goes to the expense of a much lower copper content compared to the pure salts, relating to a lower energy content and thus decreased reaction temperature. Due to the matrix-support also the heat transfer is affected. Therefore, externally copper-coated samples were prepared by reducing the external layer of copper-salts on the zeolite by hydrazine hydrate (see experimental), which should improve the thermal conductivity of the material.

To compare the performance of the various matrix-supported copper salts in the reactor, the same approach as described for the pure copper salts was chosen. In figure 3 the temperature plots of the experiments using **13X-SO_4** (figure 4a) and **13X-Cl** (figure 4b), and their partially reduced equivalents **13X-SO_4_Cu** (figure 4c) and **13X-Cl_Cu** (figure 4d) are shown.

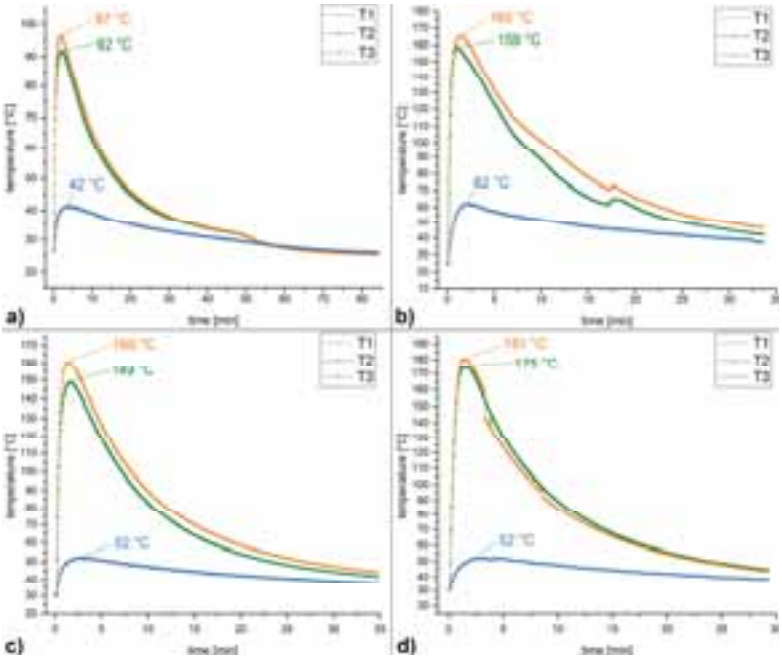

Fig. 4: Temperature plots for the reaction of NH_3 with a) 13X-SO_4 b) 13X-Cl c) 13X-SO_4_Cu d) 13X-Cl_Cu in the reactor

The prior observed temperature rise after opening the tap between the two chambers was also found in the present experiments, in all cases reaching the maximal temperature within 90 seconds. This finding is very promising, stating, that although the copper salts was heavily ‘diluted’ by loading on the matrix, its performance is still outstanding for a TCES-material. In these experiments also the temperature difference between T1 and T2 was reduced, as a notably better permeability of the packed bed was achieved. It should be emphasized, that due to the

particle shape of the zeolite the contact between thermocouple and material was less efficient as in the previous experiments. In this respect, the partial reduction of the copper salts on the zeolite matrix, yielding a better thermal conductivity was found quite efficient, as in the experiments with **13X-SO_4_Cu** (figure 4c) and **13X-Cl_Cu** (figure 4d) notably higher peak temperatures were observed. Especially, in the case of **13X-SO_4_Cu** (figure 4c) the impact of the external Cu-coating increased the measured temperature about 60 °C. The discontinuities in the temperature plots of **13X-Cl** and **13X-Cl_Cu** are attributed to slight movements of the packed bed, affecting the contact between thermocouple and zeolite particles.

A control experiment with a mixed packed bed loading of **13X-Cl** and 10 % copper turnings (figure S4) showed a decreased temperature output (figure S5) even compared to the experiment using unmodified **13X-Cl**. It seems, that in the case of the matrix-loaded copper salts even a further 10 % dilution has a negative impact on the highest achievable reaction temperature.

The use of matrix-supported copper salts in the reactor experiments turned out to be quite promising, as still the fast temperature increase and notably high peak temperature was retained, at the same time avoiding the volume expansion of the material during the reaction.

4. Conclusion

The reaction between NH_3 and $CuSO_4$ / $CuCl_2$ was investigated for their feasibility as thermochemical energy storage process. Initial requirement was the operation in a closed system to prevent release of NH_3 to the surrounding environment due to its toxicity. For this purpose, a two-chamber reactor setup with the reaction chamber and the NH_3-chamber – loaded by condensation of NH_3 at -50 °C – was chosen.

For the pure copper salts 80 seconds after beginning of the reaction the peak temperatures of 312 °C ($CuSO_4$) and 238 °C ($CuCl_2$) were obtained. Such an abrupt and remarkable temperature increase is quite outstanding and very promising for a high-end technological applicability of thermochemical storage materials. The reaction temperature is kept for about 40 minutes around 100 °C, as the stepwise coordination of NH_3-ligands to the copper salts continuously releases heat until the reaction is complete. The only and major drawback of such an operation is the extreme volume work during the reaction accounting up to a 3.9-fold volume expansion in the case of $CuCl_2$. This causes a sintering and condensing of the packed bed, affecting completeness of the reaction due to very limited permeability of the bed and complicates the handling, as the reacted material needs mechanical force to be removed from the reactor. In the case of $CuCl_2$ due to initial high reaction temperatures, exceeding locally the melting point of the $[Cu(NH_3)_6]Cl_2$ the reaction product is obtained as massive solid.

To allow for a better handling, but retain the promising reactivity, both $CuSO_4$ and $CuCl_2$ were loaded on zeolite 13X, resulting in matrix-supported copper salts. In this case the volume expansion during the reaction is nearly eliminated, concomitantly retaining high initial peak temperatures and fast energy release on reaction with NH_3. To ensure a better heat conductivity, partial reduction of the copper on the outside of the zeolite particles was accomplished by treatment of the composite materials with hydrazine hydrate. The thereby obtained externally copper coated, copper salt loaded materials revealed a much better thermal conductivity, leading to the observation of higher peak temperatures.

As the main objective of the present work was a feasibility study on the reaction of NH_3 with copper salts, respectively matrix-supported copper salts, the main subject of continuative studies will be the optimization of the heat output / heat transfer. Design and operation of the reactor / process will need some improvement to efficiently use and transfer the released heat.

Abstract

The thermal performance of locally available oils in Uganda have been experimentally investigated to determine their suitability for heat transfer and solar thermal energy storage. Sunflower oil and palm oil, both local vegetable vegetable oils and Shell thermia B, commonly used in the local industries as a heat transfer fluid were used in the study. The oils were heated in an insulated tank until temperatures close to their smoke points were attained and then heating was stopped; the tank temperature was recorded for 24 hours during the cooling. The second experiement involved charging the oil in a self-circulating system without the aid of a pump. It was observed that the vegetable oils gained heat faster than thermia B. Sunflower oil retained heat for a longer period compared to palm oil and thermia B. The total amount energy stored by sunflower was equally higher than palm oil while thermia B had the least energy stored. The results show that sunflower oil is the most suitable oil for solar thermal storage and heat transfer.

Key words: vegetable oil, sunflower, palm oil, thermia B, solar energy storage, cooking.

1. Introduction

Solar thermal storage systems for rural cooking applications require suitable heat transfer fluids capable of transferring heat to the storage during charging and to the cooker during discharging (Lovseth 1997; Heetkamp 2002). The choice of fluid for heat transfer depends on the storage medium and the choice for heat extraction. There are industrial fluids available for heat transfer in large scale solar thermal plants. However, such fluids are expensive for rural applications and therefore will increase the cost of the system. Air and water have been used as heat transfer media with rock bed storage systems as reported by (Okello et al. 2016; Nyeinga, et al. 2016). However, air has low heat capacity and water may pause high risks since it vaporizes at high temperatures and therefore not suitable for rural cooking application.

Vegetable oils can be used as both heat transfer fluid and heat storage medium for solar cooking applications. The advantage with vegetable oils is that they are not risky even if there are leakages in the system. Mawire et al. (2014) explored the use of sunflower as heat transfer medium; they studied the charging of the oil using high and low flow rates. For cooking applications, the interest is in oils which are capable of attaining temperatures of about $200^{o}C$. In this paper, thermal properties of selected oils were investigated

2. The Experimental set-up and procedure

2.1. Oil samples

Local vegetable oils namely refined sunflower oil and refined palm oil were used in this study in addition to thermial B, a mineral oil but readily available in the country. Table 1 shows the thermo-physical properties of the selected oils. It can be observed that the vegetable oils have high densities and specific heat capacities compared to thermia B.

Tab. 1: Thermo physical properties of the selected oils adapted from Mawire et al. (2014)

	Density $\left(kgm^{-3}\right)$	**Specific heat capacity** $\left(Jkg^{-1}K^{-1}\right)$	**Thermal conductivity** $\left(Wm^{-1}K^{-1}\right)$
Refined sunflower oil	$930.62-0.65T$	$2115.00+3.13T$	$0.061+0.018e\left(-T/26.142\right)$
Refined palm oil	$925.00-0.66T$	1861	0.1721
Thermia B	$870.00-0.65T$	$1798.00+3.58T$	$0.118+0.018e\left(-T/168.660\right)$

3.2. Determination of heat retention capacity

A cylindrical tank of about 4.5L fitted with a 1.5kVA electrical heater was used to heat 4L of the selected oil samples in turn. Three K-type thermocouples fitted in the tank at a distance of 5cm apart were used to measure the temperature along the tank. The thermocouples were connected to a TC-08 data logger interfaced with computer as shown in figure 1. The heater was connected to a 240V a.c main and the oil in the tank was heated to a temperature close to its smoke point and the heater switched off. The temperature of in the tank was recorded for about 25 hours.

Fig. 1: Showing the experimental setup. The oil is heated in an insulated tank and thermocouples connected to a data logger and a computer were used to monitor and record the temperature during heating and cooling.

The quantity of heat energy, Q stored in oil at any time is expressed as:

$$Q=\rho vc\left(T-T_o\right) \qquad \text{(eq. 1)}$$

where ρ, c, v are average density of the oil, average specific heat capacity of the oil and volume respectively. T is the average temperature at time, t and T_o is the initial temperature. The average temperature of the oil in the storage tank was considered in the computation of the energy content of the tank since the storage tank was short.

3.3. Self circulating charging unit

Figure 2 shows a storage tank of internal diameter 18cm and height 40cm made of steel and a boiler of internal diameter 18cm and height 20cm made of mild steel oriented at 60^o to the horizontal. The storage tank was charged based on self-circulating system. The main advantage with a self-circulating system is that you avoid the

use of pumps. A continuous copper pipe of internal diameter 0.9cm and total length measuring 150cm was inserted from the top of the storage tank to the bottom through the boiler.

Fig. 2: A self circulating system consisting of a storage tank and a boiler. Sunflower oil was used in the boiler and the three types of oil where put in the storage tank one after the other. The storage was filled with each type of oil and this got heated in the boiler and thereby charging the storage.

Seven k-type thermocouples each at an interval of 5cm were placed at the central axis of the storage tank. The storage tank was filled with 10 litres of sunflower oil followed by palm oil and finally thermia B as a heat storage fluid respectively. The boiler was filled with 4 litres of refined sunflower oil. An electrical heater of 1.5 kVA was used for heating the oil in the boiler. The temperature of the boiler was maintained in the range of $230^{o}C - 240^{o}C$ (just below the smoke point of sunflower oil) manually, by switching the electrical heater on and off. The storage tank was charged for 6 hours.

The total energy, *E* stored in a tank of, *n* segments during the charging process is given by

$$E = \rho c \sum_{i=1}^{n} v_i \Delta T_i \qquad \text{(eq. 2)}$$

where ρ, c are the density of the oil and the specific heat capacity of the oil respectively; v_i is the volume of oil in the i^{th} segment and T_i is temperature difference between two adjacent nodes of the i^{th} segment of a stratified tank.

3. Results and discussions

4.1 Heat retention

Refined sunflower oil and palm oil were both heated to a maximum temperature of about $236^{o}C$; these temperatures are slightly below their smoke points. Thermia B was heated to a maximum temperature of $220^{o}C$. After heating the oils to their maximum temperatures, the heater was switched off and the tank allowed to cool. Figure 4 shows the temperature profiles during heating and cooling. Refined sunflower oil and refined palm oil showed a rapid increase in temperature during the heating while thermia B gained heat slowly.

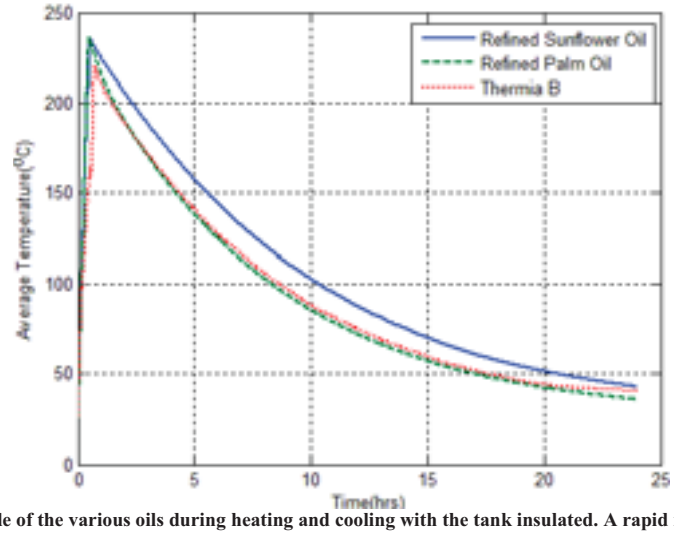

Fig. 4: Temperature profile of the various oils during heating and cooling with the tank insulated. A rapid increase in temperature of sunflower oil and palm oil are observed during heating. After 24hours, the temperature of sunflower oil can be seen to be higher than for palm oil and thermia B.

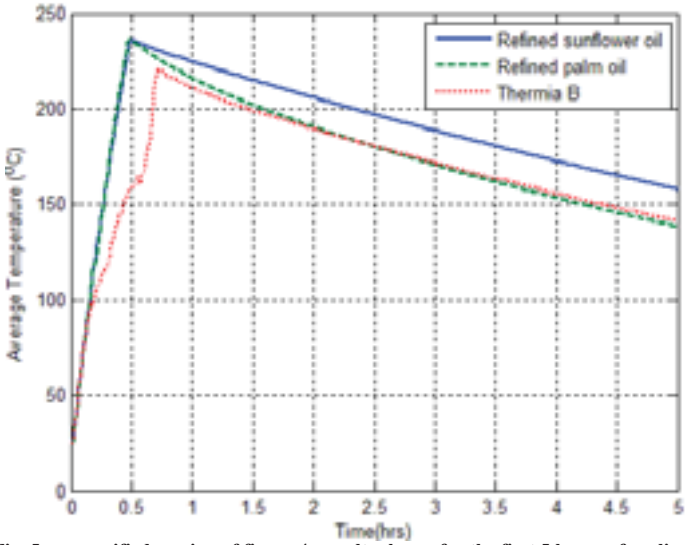

Fig. 5: a magnified version of figure 4; results shown for the first 5 hours of cooling.

Both refined sunflower oil and refined palm oil reached a maximum temperature of about $236^{o}C$ in 30 minutes. This high increase in temperature is attributed to fact that both refined sunflower oil and refined palm oil have high densities and specific heat capacities. However, thermia B took longer to attain its average maximum temperature of $220^{o}C$ in about 45 minutes because it has low density and specific heat capacity and this can be clearly seen in figure 5 which is an amplified version of in figure 4.

For solar thermal storage systems with cooking applications, we are interested in charging the storage in the shortest possible time since the solar radiation keeps varying with time. Fluids which can retain the heat for a longer period are to be preferred since this allows cooking to be done even after sunset. Both refined sunflower oil and refined palm oil absorbed heat faster than thermia B; but refined refined sunflower retains heat better than palm oil.

4.2 Energy distribution

Figure 6 shows the energy distribution during heating and retention computed using equation 1. The maximum energy attained by refined sunflower was 1.6MJ in 30 minutes, while for refined palm oil was 1.4MJ in 30 minutes, and thermia B attained the maximum energy of 1.2MJ in 45 minutes.

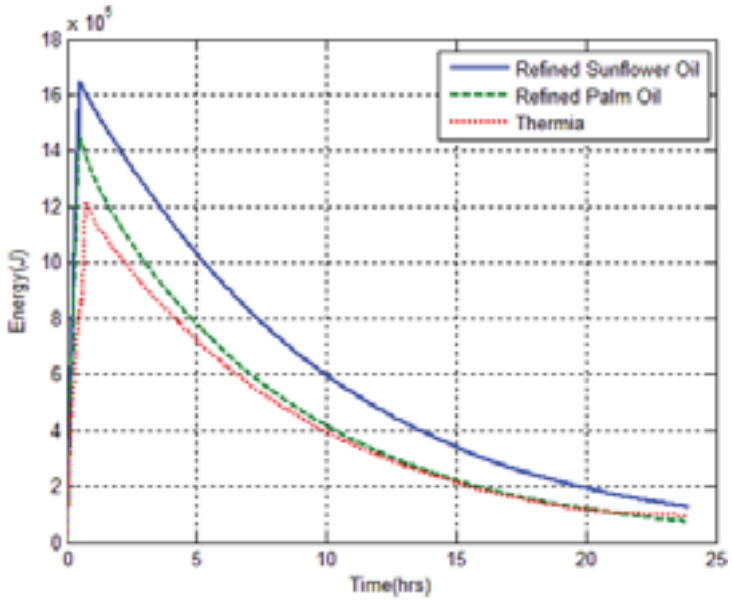

Fig. 6: energy distribution over time for oils heated for 30-45 minutes and thereafter the heater was switched off and allowed to cool for about 24 hours in an insulated tank.

From figure 6, it can be observed that at the end of the 24 hours, sunflower oil had much more energy than both palm oil and thermia B. This furthers shows that sunflower oil is more suitable for solar thermal energy applications.

4.3. Temperature profiles during charging

Figures 7 shows the temperature profiles in the storage tank based on the self-circulating charging system for 6 hours.

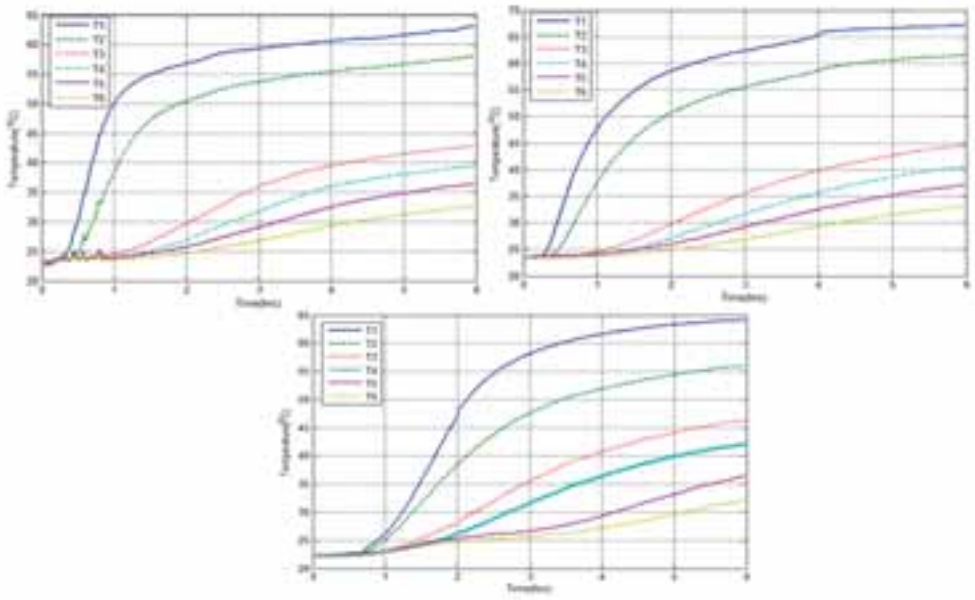

Fig. 7: Temperature profiles during charging of the storage tank using a self-circulating system for 6 hours using a self-circulating system. T_1 is temperature at the top of the storage while T_6 is at the bottom. The storage tank was not insulated since the aim was to compare the temperatures during charging of the three different oils under the same conditions.

In the first one hour, sunflower oil and palm charged very fast and attained temperatures of about $50^{o}C$ at the top of the tank; however, in the same period thermia B had a temperature below $30^{o}C$ at the top. The observed high rate of charging attained by sunflower oil and palm oil is attributed to their high densities and specific heat capacities which agrees with similar findings by Mawire et al. (2014).

4.4. Thermal energy profiles during charging

Figure 8 shows the energy distribution in the storage tank for the three different oils during charging by a self-circulating system. The energy profiles for both refined sunflower oil and refined palm oil increased rapidly in the first one hour until their peak values were attained.The maximum energy for refined sunflower oil was $0.13MJ$ attained in about 1.5 hours while for refined palm oil was $0.12MJ$ attained in about 2 hours. The energy profile for thermia B increased gradually until it attained a peak value of $0.10MJ$ in about 3 hours. The high energy gained in sunflower in a short time is again associated to its high density and specific heat capacity.

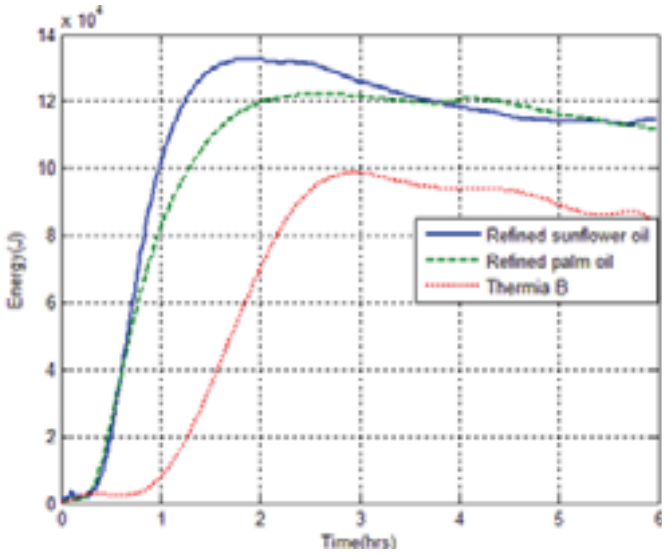

Fig.8: thermal energy stored in the tank by refined sunflower, refined palm oil and thermia B during charging for 6 hours using a self-circulating system. Sunflower oil the highest energy and thermia B had the least energy.

The drop in energy after 2.5 hours can be attributed to the fact that the density and specific heat capacity for oil decreases and increases respectively with increasing temperature; but the decrease in density overrides the increase in specific heat capacity as cited by Esteban et al. (2012).

5. Conclusion

The thermal performance of refined sunflower oil, refined palm oil, and thermia B was experimentally studied. The results show refined sunflower oil and palm oil gained heat faster than thermia B. However, refined sunflower oil retained more heat than palm oil. For solar energy applications, the solar radiation may be available over a period of time and therefore sunflower oil would be more suitable since it can absorb the heat faster and retain it longer. Further studies should be carried out on a hybrid storage system consisting of rock pebbles and sunflower oil. This will cut down the cost of the storage since rock pebbles are readily available and cheap. We also recommend further work on the number of cycles the sunflower oil can be heated and cooled without any major changes in its properties.

Test campaign and performance evaluation of a spiral latent storage module with Hitec® as PCM

M.M. Rodriguez-Garcia[1], E. Rojas[2] and R. Bayón[2]

[1] Ciemat - Plataforma Solar de Almería, Almería (Spain)

[2] Ciemat - Plataforma Solar de Almería, Madrid (Spain)

Abstract

A modified spiral plate heat exchanger for its use as thermal energy storage (TES) has been selected using Hitec® salt as storage medium within the activities of the REELCOOP project (7th Framework program of the European Union Ref N. 608466, www.reelcoop.com). After its installation at one of the storage test facility at PSA (Plataforma Solar of Almería) and its commissioning, the test campaign has been performed. The testing procedures and the results evaluation are presented in this paper. For a better understanding of the phase change process, thermal analyses of the commercial Hitec® salt have been carried out.

Keywords: Latent storage, spiral heat exchanger, Hitec® as phase change material.

1. Introduction

A modified design based on a spiral plate heat exchanger used as latent thermal energy storage module was proposed in the Prototype #3 of the REELCOOP project. In this project an organic ranking cycle (ORC) using parabolic trough solar collectors is to be driven with direct steam generation combined with a biogas boiler. In order to keep producing power in the necessary transient time to change from solar field to biomass boiler a latent storage module was included as part of this plant. The reliable phase change material (PCM) used to meet the temperature range needed for both ORC and solar field is the Hitec® salt.

Previous results regarding the phase change material selection were presented by Rodriguez-Garcia et al., 2016a, where several candidates PCMs in the range of 130 ºC to 170 ºC were studied. The commercial Hitec® salt was selected because it was the only one that showed chemical stability under cycling and despite its relatively low phase change enthalpy.

In the EuroSun congress (Rodriguez-Garcia and Rojas, 2016b) the settlement of the problems addressed during the commissioning was presented: mainly the filling of the spiral thermal energy storage module and the presence of water remaining from a previous mandatory pressure test.

In this paper the test campaign of the spiral storage module with Hitec® salt as PCM and a preliminary evaluation of the results are presented. Moreover, further thermal analyses of Hitec® like differential scanning calorimetry (DSC) measurements, melting/freezing cycles in the oven under air down to 40 ºC together with the analysis of salt composition after the cycles are presented as well.

2. Facility description

Patented by Rivas et al. (2011), the module tested in the REELCOOP project is an adaptation of a commercial spiral plate heat exchanger, due to limitations in budget and project time frame. With 825 mm external diameter and 1000 mm height, the spiral heat exchanger used as TES module has volume at the water/steam channel of 205 liters, and 230 liters at the molten salt channel. For more information see Rodriguez-Garcia and Rojas, 2016b.

The testing facility was designed to operate in both charging (see Fig. 1(a)) and discharging modes (see Fig. 1(b)) with water as heat transfer fluid (HTF). In nominal conditions, for the charging (discharging) mode a steam generator (water heater) provides saturated steam (warm water) to the storage module where energy is transferred to (from) the PCM. The storage module provides a mixture of steam and liquid water in an undetermined ratio or steam quality. This water-steam flow is later mixed with liquid water at known temperature and flow. The resulted

doi:10.18086/swc.2017.14.06 Available at http://proceedings.ises.org

water-liquid flow and its temperature are measured and the thermal cycle is closed.

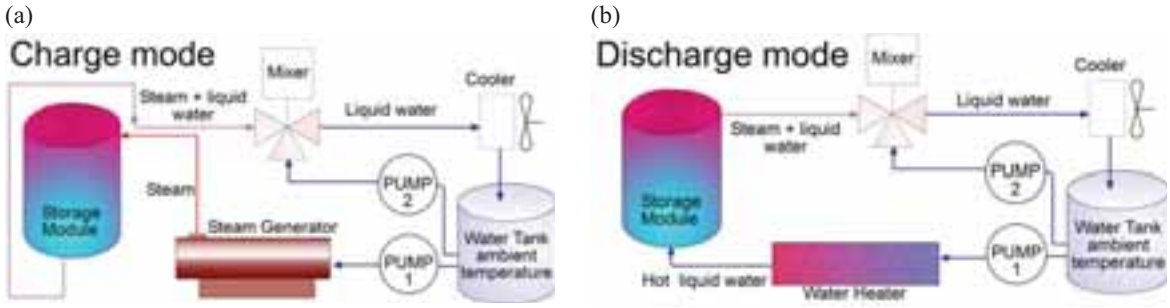

Fig. 1 Charge (a) and discharge (b) operation mode schemas of the test facility at Plataforma Solar de Almería. The facility is composed by: a water tank; a steam generator that provides saturated steam; an electric water heater; two pumps; a mixer; and a water cooler.

The pressure in the whole loop is given by the steam generator in charge or by the boiler in discharge and controlled by a pressure regulating valve situated at the mixed inlet. A 0.5 MPa pressure drop was calculated.

Theoretically, during the charge operation saturated steam at 150 °C enters the storage module prototype (TES) through the A2 conduction (see Fig. 2) and, once the heat is transferred to the PCM, saturated water at 140 °C exits the TES module through the A1 pipeline. During the discharge, the operation takes place in the contrary flow direction: saturated water at 130 °C enters the TES through the A1 conduction and, after evaporating in the TES, saturated steam at 130 °C leaves the module through A2. Tab. 1 shows a summary of the nominal operation conditions for both charge and discharge modes.

Tab. 1: Nominal operation conditions for the charge and discharge modes at TES module.

Charge mode				
	Temperature [°C]	Pressure [MPa]	Flow [kg/s]	Water phase
Inlet (A2)	150	0.47	0.04	Saturated steam
Outlet (A1)	140	0.36	0.04	Saturated water
Discharge mode				
	Temperature [°C]	Pressure [MPa]	Flow [kg/s]	Water phase
Inlet (A1)	130	0.27	0.05	Saturated water
Outlet (A2)	130	0.26	0.05	Saturated steam

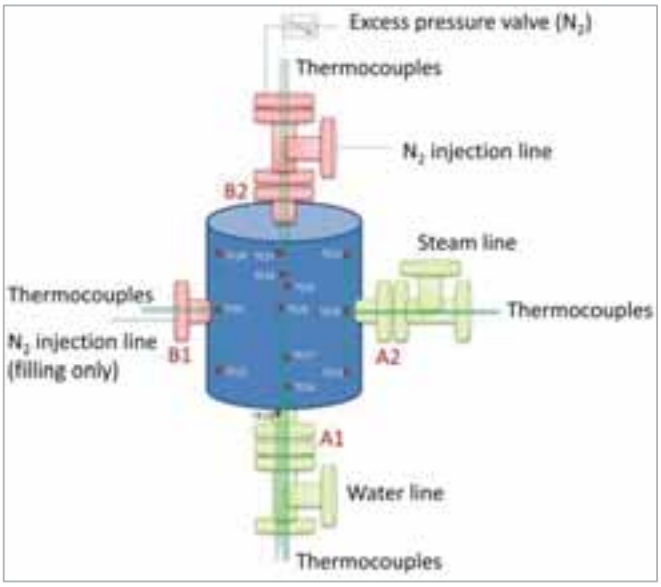

Fig. 2: TES module temperature sensors.

While water flow is measured with vortex flowmeters, steam flow is measured with a Coriolis-type flowmeter. The storage module tested here did not allow including temperature gauges at different radial positions, but at the center and outer radius of the equipment. The final distribution is shown in Fig. 2.

3. Storage module test campaign

After commissioning, test campaign took place from 23/11/2016 to 15/01/2017. The most remarkable aspects of the preoperational tests and the TES module filling with the selected PCM where presented in Rodriguez-Garcia and Rojas, 2016b. In this section, the thermal performance tests are presented, comparing the results with that theoretically expected. While January, 9th has been taken as reference day, the most important results are also observed in the rest of the days. A further work will present the details of repeatability and quality of the whole test campaign.

3.1. Charge mode

In this operation mode water should go into the storage module as saturated steam through the lateral upper entrance (A2 in Fig. 2) and flow through the spiral channel from the largest diameter to the smallest one. Along its way, water is expected to loss energy by melting the solid PCM, placed in the alternate spiral channel, and to condensate. The saturated water should be drained by gravity to the bottom.

During the commissioning testing days, some experience had to be acquired to control pressure and temperature inside the TES module. PCM temperature gauges showed the PCM did not melt when operating at nominal conditions, and hence, a change in the operation strategy had to be adopted by having 170 °C set point for the steam generator and adjusting the circuit pressure to the corresponding saturated steam pressure (0.89 MPa). Nominal mass flow was not achieved due to limitations in the steam generator.

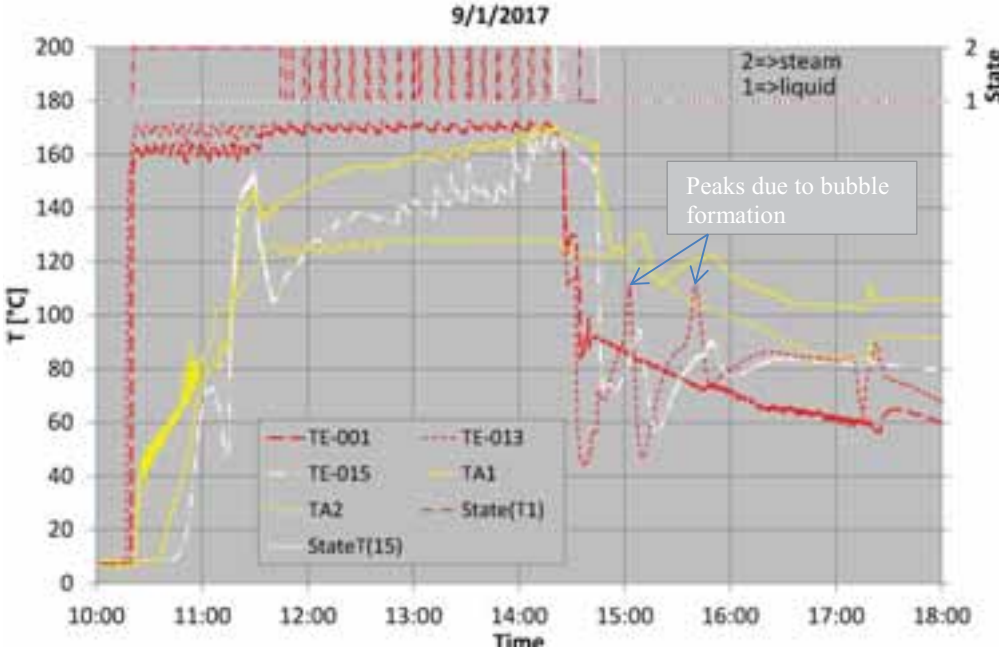

Fig. 3: Charging and discharging operation

In charging processes the steam generator continuously provides steam at 170 ºC and at a much lower pressure than 0.8 MPa, which is the saturation pressure at that temperature. Therefore, the mean HTF temperature within the module at its entrance increases with time as expected (TA1 and TA2 in Fig. 3). When the loop pressure was adjusted to get up to 0.8 MPa, the system reacts by changing the temperature at the outlet pipe of the module (TE-015) with a sudden drop down. Temperatures close to the outlet but within the module (TA1 and TA2) show a certain decrease, but not so important. When the gauge pressure becomes 0.4 MPa, the initial 0.025 kg/s steam decreases to 0.01 kg/s, which is in the range of the minimum steam mass flow the flowmeter can detect. 'State(T1)' variable shows if the water at the temperature (TE-001) prior to enter the storage module is steam (associated to value 2) or liquid (associated to a value 1). Working at pressures so close to saturation ones, implies that it may happen, as shown in Fig. 3, that steam is easily condensed prior to be supplied to the storage module.

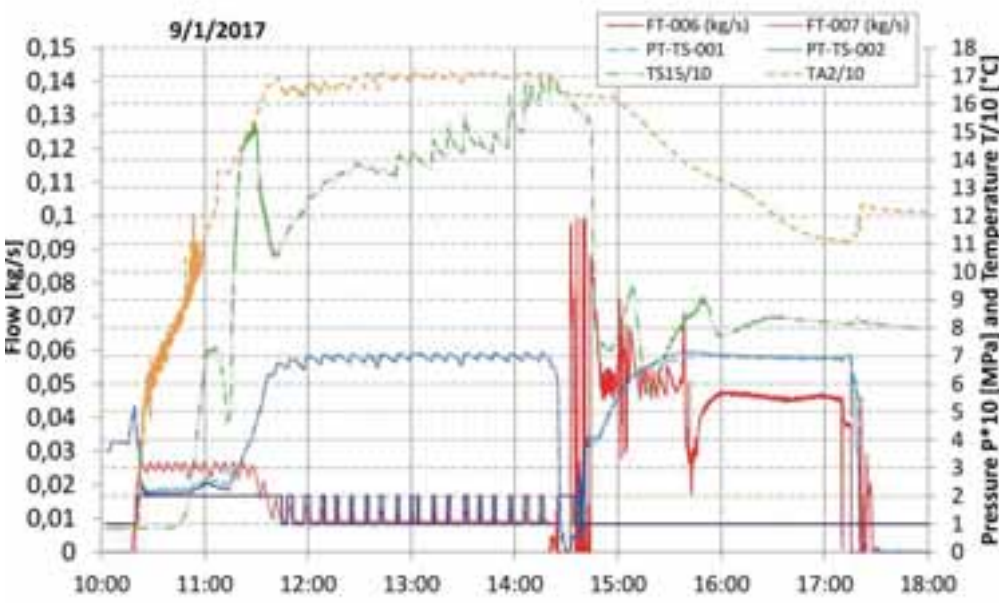

Fig. 4: Charging and discharging operation (flow, pressure and temperature/10)

3.2. Discharge mode

During the discharge, the operation takes place in the contrary flow direction: according to specifications saturated water at 130 °C enters the TES through the A1 conduction; being constant the power provided to the TES and producing, after evaporating in the TES, saturated steam at 130 °C. In this last case particular problems were found due to the electrical water heater used to preheat the water up to 130 °C, and finally, its set-point temperature had to be reduced to 85 °C in order to avoid an undesirable bubbles formation around the electrical resistance in the water heater. Temperature in the storage module was 160 °C, with a corresponding saturation pressure of 0.61 MPa, which is 0.2 MPa lower than the pressure in the circuit. Due to the imposed pressure loop, the water exiting the TES during the discharge is in liquid phase, even after exchanging enough energy with the PCM to be evaporated. Therefore, the foreseen methodology of testing and evaluation for discharging could not be applied.

3.3. Temperatures in the PCM

In the PCM channel of the storage module there are 6 thermocouples installed (see Fig.2): three in the central PCM channel (purple lines in Fig. 5) and another three close to the outer module surface at the opposite side at the horizontal entrance/exit of the HTF to the module (yellow lines in Fig. 5). These temperatures should reflect the fact that the PCM changes phase at a certain point.

According to the HITEC® study reported at 4.2 below, during charging (melting process) two phase transitions should be observed in the PCM: one at 90 ºC –which may correspond to a solid to solid transition- and another one at 140 ºC –corresponding to solid to liquid phase change-. The transition at around 90 ºC is observed in all these 6 thermocouples by a change in their profile slope. The 140 ºC transition is clearly observed only in TE-024. TE-027 may show a short of changing slope at that temperature but due to the fluctuations in the data it cannot be assured with certainty. TE-022 shows a transition but at around 130 ºC and TE-023, TE-025 and TE-026 seem to have no more transition but the one at 90 ºC.

During discharging (freezing the PCM) the above mentioned study supports to have two transitions: one at 140 ºC (liquid to solid) and another one at 60 ºC (corresponding to solid to solid phase change). The difference in the temperature at which the solid to solid transition takes placed is due to the supercooling effect. In discharging is the solid to liquid transition the one that is clearly identified in all the thermocouples that achieved 140 ºC. TE-024, TE-025 and TE-026 in the 9/1/2017 test, which is being used as example, do not reach but 160 ºC when the recording of experimental data stopped.

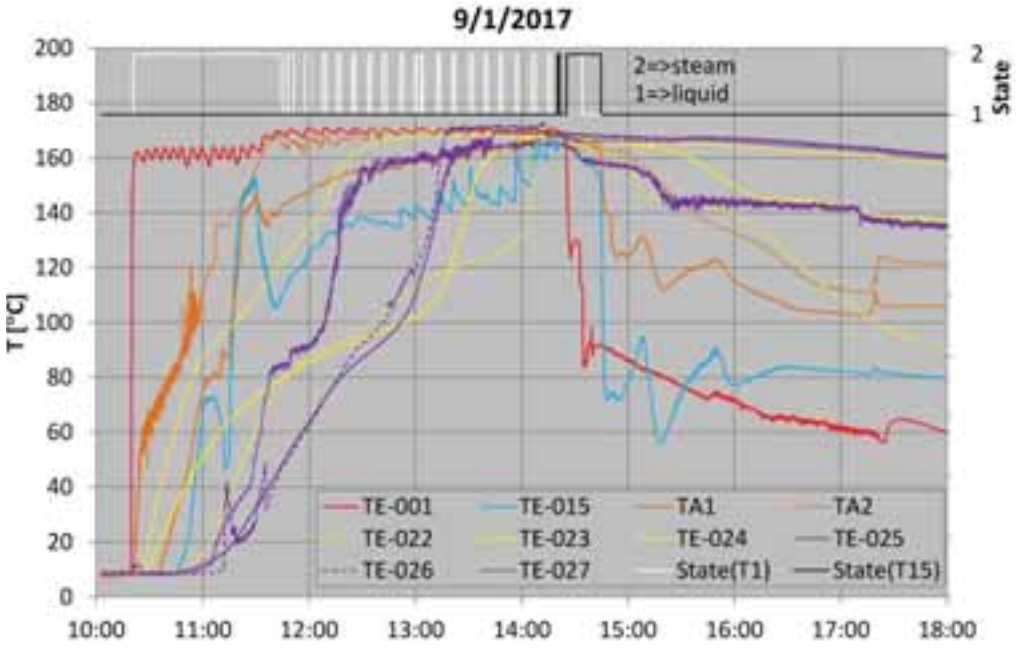

Fig. 5: PCM temperatures for charging and discharging on 9/1/2017.

During **charging**, temperature at the bottom (TE-022) and the top (TE-024) show the same profiles up to around 90 ºC, from which the steam boiler starts providing non-continuous steam at low mass flow and the value of the temperature gauges at the top began to increase more slowly than the bottom ones, reaching the solid to liquid transition temperature –around 140 ºC- 36 minutes later. This delay can be explained by considering that the steam supplied to the module stagnates at the upper part and, since steam has a poor heat transfer coefficient without changing phase, the PCM at this upper part requires more time to reach the same temperature level than at the bottom part when it condensate.

This inhomogeneous melting of the PCM within the storage module imposes a problem when determining the end of charging process. Depending on the period of time considered for charging, one of the following situations can occur at that point: part of the PCM at the top is still solid; part of the PCM at the bottom is superheated; or part of the PCM at the top is still solid and part at the bottom is superheated.

Looking at the temperatures or the state of the HTF at the exit of the storage module during charging (TE-016), this question is not clarified either. The end of charging may be assumed when steam is detected at the exit of the storage module; in this case the PCM gauges show a superheating behavior coming close and to around 170 ºC.

Discharging is assumed to start after a transition time, in which valves are closed/open to change to discharging HTF loop. In the case of the tests performed on 9/1/2017, at 15:37 pressure at the loop reaches 0.7 MPa but the cold mass water flow does not stabilized till 15:58 (see Fig. 4), thus discharging is assumed to start at that time. As mentioned in 3.1, due to the affordable loop pressure the water during discharge cannot be converted to steam, therefore the state of the corresponding HTF at the storage module exit does not give any clue on the end of discharging process.

Looking at PCM average temperatures, we can see that the three average profiles decrease their values with a different velocity as it happens during charging. While the PCM at the bottom of the storage module achieved the solidification temperature, 140 ºC, the PCM at the top of the module did not achieve such temperature when we stopped recording experimental data.

3.3. Thermal losses analysis

Idle thermal losses were expected to be calculated by the difference in discharged energy from a fully to a partially charged TES module situation, coming the partially charged situation from leaving the TES module for a certain time without any manipulation. As already mentioned, stablishing the end -and thus the associated energy- in a discharge process is not reliable due to the inhomogeneous behavior of the PCM. Thus, another procedure has to be applied.

One method for calculating idle thermal losses is to turn off all heating sources and track the rate of temperature

decay in average along certain time. By knowing the mass and enthalpy of storage media in the vessel, an estimation of the heat losses can be made by calculating the enthalpy variation in water and PCM from the starting time to the final time.

In Fig. 6 experimental results of the evolution of temperature during one week is shown. In those testing days some adjustments to the data acquisition system were performed so data is not continuously recorded along the whole day. These experimental data (- markers) is linked between them by an interpolation line. In this Figure, several "plateaus" at different temperatures can be observed for both water and PCM. It has been assumed that these plateaus are the result of a phase change occurring in the influence volume of the corresponding thermocouple. When the thermocouple is inserted in the PCM, the plateaus do not correspond necessary to its expected solid to liquid (around 140 °C) nor to its solid to solid (around 60 ºC) transitions, but keeps its temperature constant because some PCM around changes phases in spite that the PCM directly in contact does not. This assumption is a certainty with the thermocouples placed in water: no phase change takes place in the water at certain time period, but a plateau can be observed due to the phase change occurring in the adjacent PCM.

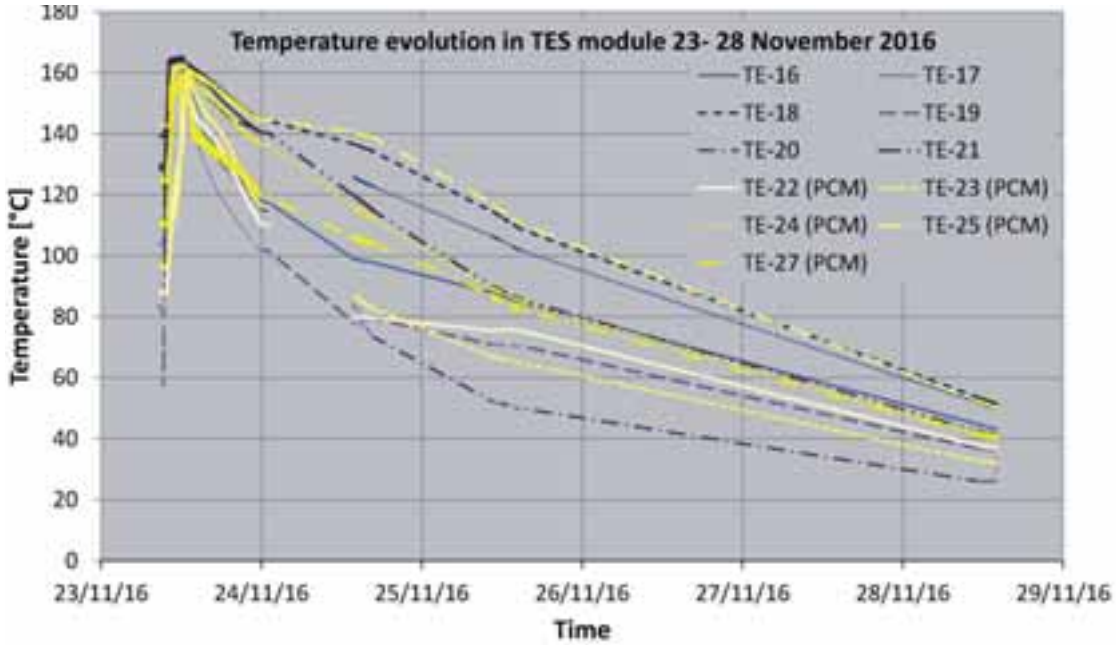

Fig. 6: Temperature evolution of water and PCM during the thermal losses test.

From these data, an estimation of 1.45 kW power thermal losses mean value has been found. This value is calculated by adding the thermal losses associated to the stainless steel conforming the TES module (25.6 kWh), the thermal losses of the PCM (23 kWh), those of the water (127.871.05 KWh) and knowing that these thermal losses have occurred along 121.78 hours. For sake of simplicity, ambient temperature has been considered the mean ambient temperature during the experiment (20 °C).

According to the authors, this method of calculating idle thermal losses by adding the idle thermal losses of the different components of the tank along a long period of time is the only possible way of calculating thermal losses of the while system, since it is not possible to define a representative temperature nor of the prototype nor of its surface in contact with ambient. This fact implies that it is not possible calculating a heat lost coefficient for a given TES module temperature (or time step) but just a mean value along a long period of time.

3.4. Charging and discharging power and stored energy

As already mentioned there is not a clear definition of the points at which charging and discharging processes end, since the storage module does not behave as a whole.

In Figure 7 the charging power for 9/1/2017 is shown. It is calculated by the mass flow measurement and the enthalpy change given by the HTF outlet conditions and HTF inlet conditions. Keeping in mind that the steam boiler provides steam at pulses, the obtained shawtooth profile is expected. The very low values from 11:25 onwards are due to the already mentioned decrease in steam mass flow production due to pressure loop and the limitations of the steam boiler. If there were not these disadvantages, a constant charging power would be expected.

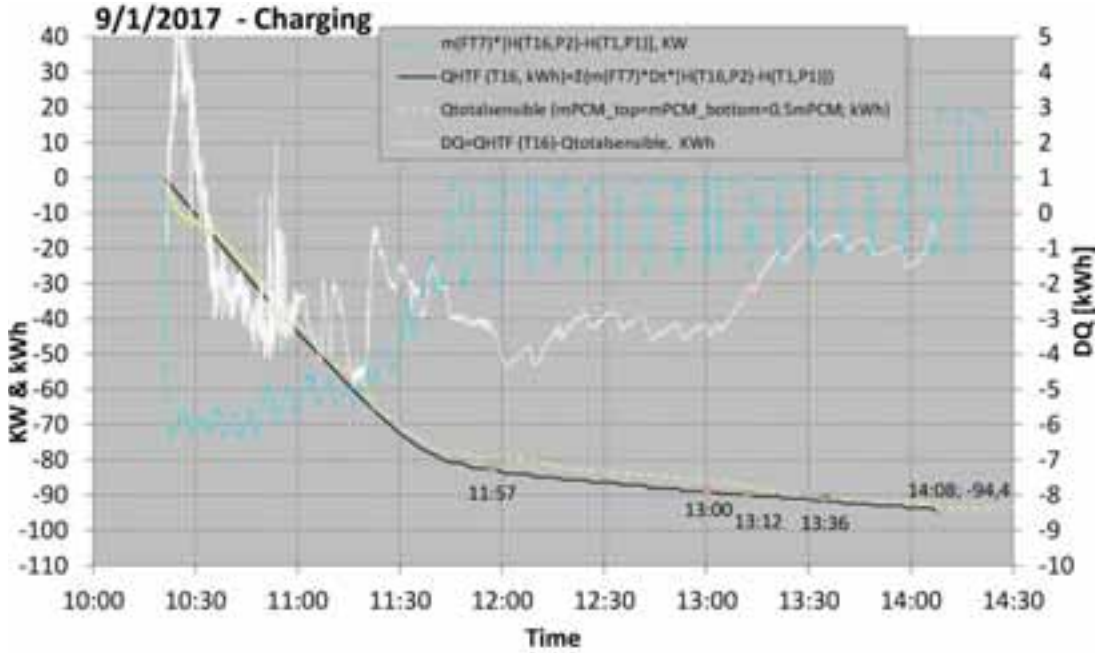

Fig. 7: HTF charging power, energy supplied by the HTF and estimated energy used for sensible heat.

In order to calculate the energy supplied by the HTF to the storage module, the above mentioned curve has been integrated in time (Q_{HTF}(T16), [kWh]). At the end of charging process, the HTF has supplied around 94.4 kWh to the whole system. Part of this energy has been used for increasing the temperature of the storage module ($Q_{sensible}$), [kWh], part for dealing with thermal losses (Q_{lost}),[kWh], and part has been stored in form of latent heat, by changing the phase of the PCM from solid to liquid (Q_{latent}), [kWh], i.e.,

$$Q_{HTF} = Q_{sensible} + Q_{lost} + Q_{latent} \qquad \text{(eq. 1)}$$

The sensible energy required to increase the temperature, $Q_{sensible}$, takes into account that the storage module is made of 1410 kg stainless steel (c_p=500 kJ/kgK) and 410 kg of HITEC (c_p=1560 kJ/kgK), which means that steel mass is more than 3 times PCM mass, while its heat capacity is around three times lower, giving similar thermal losses for both materials.

Considering that, as mentioned above, that mean heat loss power is 1.45 kW, the resulting energy for the latent heat is 1 kWh, which implies 9 kJ/kg specific latent heat of the PCM, which is much lower than the one expected up to now. This result makes Hitec salt not the most appropriate candidate for its use as PCM.

The main conclusion obtained is that with a module of this type it is necessary to know with certain accuracy a thermal map of the PCM. The storage module tested here did not allow including temperature gauges at different radial positions, but at the center and outer radius of the equipment. This would allow a better definition of the phase change moment for the different parts of the TES module, since one of the main conclusions of this work is the difficulty in defining ends of charging and discharging processes when inhomogeneous phase change processes take place.

4. Performance studies of Hitec® salt

As stated in a previous work (Rodríguez-García and Rojas, 2016), the selected PCM implemented in the spiral storage module was the commercial eutectic salt mixture Hitec® ($NaNO_3$-KNO_3-$NaNO_2$; 7/53/40 % w) (http://www.coastalchem.com/). This salt mixture has the melting point at 142 °C with a reported enthalpy of fusion of about 83 kJ/kg and is expected to be thermally stable up to 535 °C (http://stoppingclimatechange.com). Despite its relatively low phase change enthalpy, this salt was finally selected because its melting temperature fits the operating temperature range of the storage module but also because it has proven to be chemically stable upon daily melting/freezing cycles under inert atmosphere (Rodríguez-García and Rojas, 2016).

4.1. DSC measurements

For a preliminary stability study a Hitec® sample previously dried at 120 ºC for 48 hours was subsequently cycled between 130 ºC and 150 ºC at 2 ºC/min except for the first heating that was performed at 10 ºC/min. The resulting

curves are plotted in Fig.8 and the temperatures and enthalpies calculated for each cycle are recorded in Tab. 2.

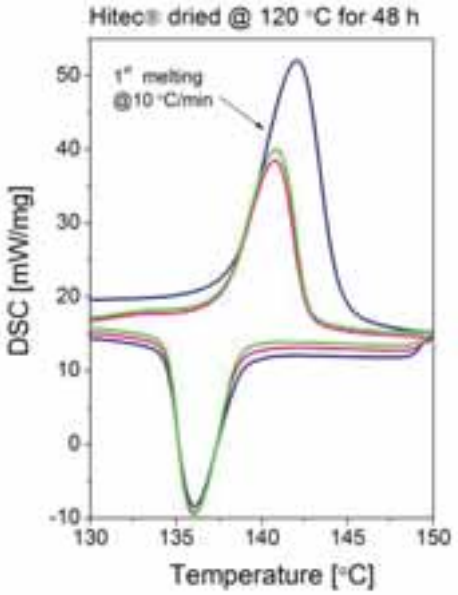

Fig. 8: Three DSC melting/freezing cycles performed from 130 ºC to 150 ºC for Hitec® commercial mixture dried at 120 ºC for 48 h.

Tab. 2: Results of DSC measurements displayed in Fig. 8

Cycle	$T_{melt-peak}$	ΔH_{melt}	$T_{freez-peak}$	ΔH_{feez}
1st	142 ºC*	56 kJ/kg*	136 ºC	51 kJ/kg
2nd	141 ºC	57 kJ/kg	136 ºC	49 kJ/kg
3rd	141 ºC	60 kJ/kg	136 ºC	47 kJ/kg
(*) Performed at 10 ºC/min				

As we can see thermal behavior is maintained during cycling and not only in terms of temperatures but also in terms of enthalpies. In this way, the mean melting temperature obtained is about 142 ºC while the freezing temperature is 136 ºC. This small difference between melting and freezing is usually observed in DSC measurements and does not correspond to any supercooling phenomenon. As for the enthalpy values they remain constant for all cycles being the values slightly higher for melting (57 kJ/kg) than for freezing (49 kJ/kg). It is important to remark that the melting enthalpy obtained experimentally is no higher than 60 kJ/kg and hence rather lower than the expected theoretical value of 80 kJ/kg. On the other hand the peak of the first heating cycle is much larger than the other peaks because this run was performed at 10 ºC/min and the others at 2 ºC/min. However the thermal result of this run is similar to the results of the other ones.

DSC measurements were also performed for Hitec® salt previously dried at 120 ºC for 48 hours in the temperature interval 50 ºC-160 ºC at 10 ºC/min rate. The curves obtained for the first heating and the second heating /cooling runs are displayed in Fig. 9. During the first heating run, we observe a sharp peak at around 131 °C that could correspond to adsorbed water evolution together with a broad peak corresponding to the melting of the bulk salt powder. During the first DSC run not much information about sample thermal properties can be obtained since the main goal is to make it homogeneous. During the second heating/cooling runs, if temperature is decreased down to 50 ºC, in addition to the melting/freezing process at ~140 ºC other transition is observed at 93 ºC upon heating and at 119 ºC upon cooling. It is interesting to note that the additional transition observed in the heating run (at 93 ºC) has an enthalpy almost in the range of the melting process. This would explain the plateau displayed by some of the thermocouples recording temperatures inside the REELCOOP P#3 storage prototype at a temperature lower than the melting one.

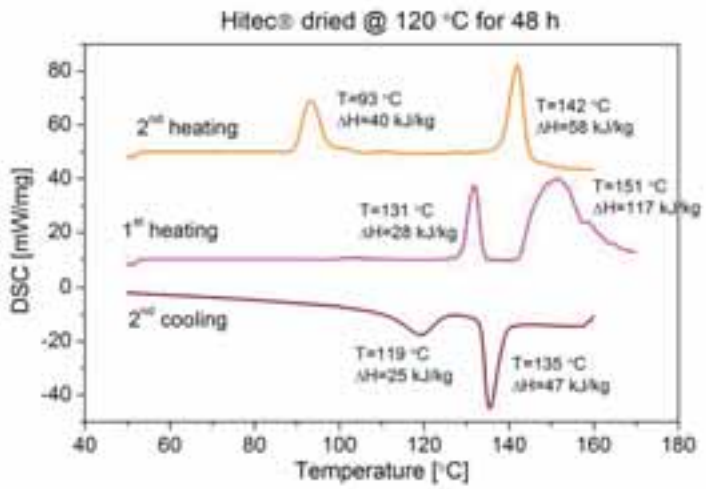

Fig. 9: DSC curves for 1st heating and 2nd heating/cooling runs for HITEC® mixture previously dried @ 120 ºC for 48 h.

4.2. Thermal cycles under air

In order to confirm that Hitec® has a transition that takes place at a temperature lower than the melting one, various daily heating/cooling cycles between 40 ºC and 170 ºC were performed under air in an oven with forced ventilation and hence with strict temperature control. Fig. 10 displays one of these cycles where it can be seen not only a shoulder at around 140 ºC that corresponds to the eutectic phase change but also other shoulder at lower temperature with apparently similar size. The shoulder associated to the melting/freezing transition appears at the same temperature during both heating and cooling processes, which confirms that Hitec® does not present supercooling. For the shoulder at lower temperature we can see that it appears at 90 ºC during the heating and at 60 ºC during the cooling. This is in agreement not only with the plateaus observed at around 90 ºC in the temperature curves recorded during the charging of REELCOOP P#3 storage prototype (Fig. 1.b) but also the DSC heating scan of Fig. 9. The fact that this transition appears at a lower temperature (60 ºC) during the cooling can be due to a supercooling phenomenon. This can be the reason why it was not observed in DSC scans since they were only performed down to 50 ºC and usually supercooling effect is larger in this kind of measurements due to the small amount of sample they use. On the other hand, since the oven has forced ventilation and Hitec® remained melted at 170 ºC for about 10 h and hence enough time and temperature to evolve any adsorbed water, this low temperature shoulder can be more likely associated to a solid to solid transition than to water exchange.

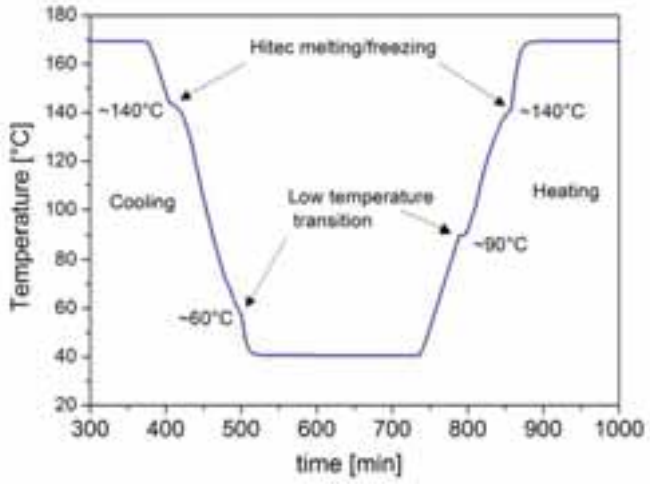

Fig. 10: Close view of a temperature-time curve for a daily heating/cooling cycle of a Hitec® sample between 40 ºC and 170 ºC.

4.3. Studies of thermal degradation

Hitec® salt is not a medium chemically stable since its components can react between them or with their environment (atmosphere or metallic walls) through processes strongly temperature dependent. One of the widest studies of Hitec® thermal degradation was published by Roche in 1980. This author observed that the main indicator of Hitec® degradation is the decrease of nitrite ions which leads to an increase of melting temperature in the salt mixture. Actually if all nitrites were converted in nitrates the final salt composition would be the eutectic mixture $NaNO_3$-KNO_3 47/53 %-w whose melting point is 220 ºC.

According to Roche 1980, the main degradation reactions of Hitec® mixture are the following:

$$(Na,K)NO_2 + \frac{1}{2}O_2 \leftrightarrow (Na,K)NO_3 \qquad \text{(eq. 2)}$$

$$5(Na,K)NO_2 \leftrightarrow 3(Na,K)NO_3 + (Na,K)_2O + N_2 \qquad \text{(eq. 3)}$$

The first one (eq. 2) is the oxidation of nitrite to nitrate by the oxygen, which is expected to take place in open systems exposed to air, whereas the second one (eq. 3) is the so called nitrite *thermolysis* in which nitrate, oxide and nitrogen are produced. In this case the presence of oxygen is not required and hence this reaction can take place in closed systems.

Assuming that only these two reactions are involved in Hitec® degradation, Roche (1980) obtained the thermodynamic equations governing the equilibrium and with them he calculate the mole percentage of all species involved in the equilibrium (nitrites, nitrates and oxides) as function of temperature for different environments. In this way, when molten Hitec® is kept under air at temperatures below 500 ºC, the predominant species are the nitrates and hence the risk of nitrite oxidation is very high. However, at temperatures above 500 ºC, nitrites become more stable and reaction (2) can even be reversed with the corresponding evolution of oxygen. For the case of oxides they start only appearing above 850 ºC. In contrast, if molten Hitec® is kept under N_2 with a very little amount of oxygen (0.001 atm) the amount of nitrites at 500 ºC increases dramatically (from 2.6 % in air to 27.3 % in N_2), which are good news, whereas oxides can appear already at 600 ºC increasing the corrosion risk and the possibility of other degradation reactions (Roche, 1980). It must be taken into account that these results correspond to the equilibrium composition of the molten Hitec but thermodynamic equations do not give any information about how long it takes until such equilibrium state is reached. For that information the kinetics of these degradation reactions must be studied.

In this way Olivares (2012) performed kinetic studies of Hitec® thermal degradation under different gas atmospheres by means of thermogravimetric analysis. In general it can be said that Hitec® seems to be stable under any gas atmosphere for temperatures lower than 370 ºC and this stability range is extended to about 470 ºC if it is kept under inert atmosphere (Ar or N_2). Under either O_2 or air atmospheres nitrites undergo slow oxidation at 370 ºC-390 ºC through eq. 2 but this process is not observed when inert gases are used. However, for all atmospheres once 450-500 ºC is reached, gas emission is produced although the strong weigh loss begins at about 610 ºC. The gases evolved during weight loss are NO, NO_2, O_2,, N_2, which are the expected products of both nitrate and nitrite thermal degradation. Roche 1980 also performed various test for determining Hitec® degradation rate under different atmospheres by monitoring the variation of NO^{2-} molar percentage versus the number of days it had been kept at a certain temperature. Again they obtained that degradation of Hitec® starts to be important at temperatures above 300 ºC not only under N_2 but also under air atmosphere. However, due to the operating conditions of the storage module of REELCOOP P#3 prototype, the highest working temperature of molten Hitec® is not expected to exceed 180 ºC. Therefore kinetic results of Olivares 2012 and Roche 1980 are not valid in our case. Moreover, the degradation experiments performed by both authors were not correlated to any kinetic equation and hence their extrapolation to low temperature region cannot be done directly.

Fortunately, it has been found in the literature that Freeman described the degradation kinetics of both $NaNO_2$/$NaNO_3$ (Freeman 1956) and KNO_2/KNO_3 systems (Freeman 1957) with similar equations. Therefore we can assume that the same expressions could be used for describing the thermal degradation of Hitec® mixture. By combining the experimental results of Roche (1980) and the kinetic equations of Freeman (1956 and 1957) for nitrites degradation, it was possible to obtain the dependence of the kinetic constant with temperature and hence estimate the degradation of Hitec® under air at temperatures close to the melting point. As displayed Fig. 11.a, in the time scale of a year, Hitec® mixture undergoes strong degradation under air when kept at temperatures higher than 400 ºC whereas for operation temperatures of 300 ºC, nitrite mole fraction remains at its initial value (0.49). When degradation curves of Hitec® are calculated for lower temperatures (see Fig. 11.b), degradation time scale has to be increased to several years. In this case we can see that for temperatures below 200 ºC, Hitec® shows no

decrease in nitrite content and hence no significant degradation should be expected for at least 10 years of operation in that temperature range.

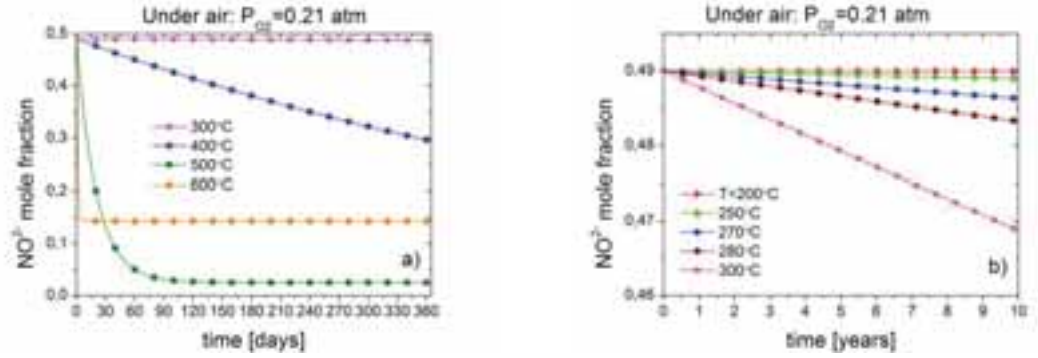

Fig. 11: Expected Hitec® degradation under air in the temperature range: 600 ºC-300 ºC (a) and in the range: 300 ºC-200 ºC (b).

From these calculations we can conclude that Hitec® mixture can be kept under ambient air without any risk of degradation due to nitrite oxidation when used as PCM for latent storage in the range of its melting temperature. However, although salt degradation is not expected in the presence or air, the metallic container might not behave in the same way and hence undergo corrosion due to the presence of air or to the molten salt itself. This could change the behavior of Hitec® salt and promote its degradation. This was one of the reasons why REELCOOP P#3 prototype inner cavity was kept under N_2 in order to avoid any atmosphere undesirable degradation process either in the salt or in the material container. The other reason was preventing moisture to be in contact with Hitec® mixture since we observed that it is quite hygroscopic in solid state.

In order to confirm that no degradation happened in Hitec® salt upon short-term cycling, we analyzed the composition of some samples by ionic chromatography before and after either consecutive or daily cycles performed under air or inert atmosphere (N_2 or Ar). The results in terms of ionic weight percentage are recorded in Tab. 3. The analysis of ionic composition of Hitec® showed a slight decrease of nitrite concentration after 50-60 daily melting/freezing cycles. However, the increase in nitrate composition is not so clear especially if we take into account that cation percentages do not remain constant. Hence, since the values are close to the theoretical ones, these variations could be within the limits of the experimental error specially if we take into account that the results for the cycles under air are the same as the results for the cycles under inert atmosphere.

Tab. 3: Results of Hitec® analysis by means of ionic chromatography.

	Na^+[w-%]	K^+[w-%]	NO_3^-[w-%]	NO_2^-[w-%]
Theoretical composition	15.2	20.4	37.6	26.7
As received Hitec® salt	17	18	33	31.7
After 5 consecutive cycles in air	16	20	36.5	28.7
After 25 consecutive cycles in air	16	19	35.8	28
After 60 daily cycles in air	17	20	37.4	26.7
After 50 daily cycles in N_2	17	20	37.5	25.8
After 53 daily cycles in Ar	17	20	37.3	26

5. Conclusions

In this article the experimental results of the REELCOOP project have been evaluated. In this project a PCM thermal energy storage with a spiral geometry is used. In terms of the behaviour of the storage prototype, it can be said that inhomogeneous melting/solidification processes of the PCM takes place due to the stagnation of steam in the upper part of the module. This inhomogeneous melting/solidification processes implies that the charging and discharging processes are difficult to be defined and limited in time, which results in not very accurate charge and discharge power and thermal losses calculations.

The obtained values for power and stored energy are much lower than the expected ones: 50 kWth as the lowest expected power against the 13 kWth as the largest experimentally calculated; 6 kWh expected thermal capacity against 1 kWh experimentally observed. This mismatch may be due to a lower specific latent heat of the PCM (9 kJ/kg) than the expected from DSC measurements (around 50 kJ/kg).

In spite of a well-designed insulation not only around the prototype but also by reducing thermal bridges by having two well-isolated storage module supports, thermal losses are 1.44 kW. Thermal losses related to the steel (tank and channeling) are of the same order as the ones of the PCM.

Considering the above, we have to conclude that neither the module design nor the PCM are appropriate options for storing latent energy.

The performance studies carried out Hitec® have shown that this salt does not display supercooling while its corresponding melting enthalpy is much lower than the reported value (55 kJ/kg vs. 80 kJ/kg). Hitec also displays an additional transition at a temperature lower than the melting temperature which is most probably associated to a solid-solid and not to water evolution. Kinetic calculations and salt analysis after short-term cycling have demonstrated that Hitec® was not expected to degrade due to nitrite to nitrate conversion during the prototype testing period.

The mismatch between the results obtained of the PCM at laboratory level -with small amounts of PCM and well controlled ambient conditions- and those obtained in a medium size storage module shows the importance of manufacturing prototypes and avoid claiming feasibility of materials for storing energy just by laboratory results.

Net Zero Energy Buildings

Renovation of Swedish single-family houses from the 1960s and 1970s to net-zero energy buildings – Case study

Tomas Ekström[1,2], Ricardo Bernardo[1], Henrik Davidsson[1] and Åke Blomsterberg[1]

[1] Department of Architecture and the Built Environment, Division of Energy and Building Design, Lund University, Lund 221 00, Sweden

Abstract

This paper evaluates whether a net-zero energy building (NZEB) can be attained by implementing on-site renewable electricity production when renovating to Passive House level. The assessment is based on the Swedish single-family housing stock constructed between 1961 and 1980, using two case study houses and three locations. Specific conditions of the houses, such as the type of heat generation and available roof area for installation of a photovoltaic system, determine whether a NZEB renovation is possible. Overall, the assessment showed that it is not cost-effective to aim for NZEB when implementing a PV system, based on the alternatives in this study.

Keywords: energy renovation, NZEB, single-family houses, renewable energy

1. Introduction

Single-family houses (SFHs) constructed between 1961 and 1980 account for approximately one-third of the total energy use, 31 TWh, for space heating and domestic hot water (DHW) in Swedish SFHs. These houses account for about 40 percent of the total energy use in buildings (Swedish Energy Agency, 2015b). There are roughly 715,000 houses from this period (Statistics Sweden, 2015) and they are largely homogeneous in technical terms, with low levels of thermal insulation, and ventilation with heat recovery is rare (Boverket, 2010a). The average energy use for houses from this period is about 40 percent higher than SFHs constructed between 2011 and 2013 (Swedish Energy Agency, 2015a). Many of these houses need to be renovated (Boverket, 2010b), providing an excellent opportunity to incorporate energy efficiency measures, to reduce both operational cost and greenhouse gas emissions related to energy use. A continuation of this is to also implement local renewable energy production to further reduce energy use.

National and international goals for a sustainable future are part of the overall objective to reduce greenhouse gas emissions and mitigate global warming and climate change (European Commission, 2011, SOU, 2016). The Swedish Government has set a target of a 50 percent reduction in total energy use per heated floor area by 2050, compared to the level in the reference year 1995 (Sahlin, 2006). Because of limitations in existing buildings, such as limited space, economic considerations, or preserving cultural heritage values, a 50 percent reduction of energy use is not possible in all buildings. To compensate for this, energy use must be reduced by more than 50 percent in some buildings to achieve an average of 50 percent energy use reduction. One way to achieve this is to renovate existing buildings to net-zero energy buildings (NZEB) whenever possible.

The purpose of this study was to determine whether a net-zero energy building (NZEB) could be attained for SFHs from 1960s and 1970s by implementing on-site renewable electricity production when implementing an extensive renovation package to Passive House level, based on the Swedish Passive House standard, FEBY 12 (Erlandsson et al., 2012).

doi:10.18086/swc.2017.15.01 Available at http://proceedings.ises.org

2. Method

A photovoltaics (PV) system for local renewable electricity production was installed on two reference houses to ascertain the viability of a NZEB renovation. The assessment involved comparing the electricity production from the PV system to the energy demand of the buildings after implementing extensive renovation packages to Passive House level. The reference houses were evaluated in three different locations in Sweden – from Malmö in the south (55.52 N, 13.37 E) to Kiruna in the north (67.82 N, 20.33 E).

When the Passive House standard is applied, thermal transmission and ventilation losses are reduced by about 70 percent (Ekström and Blomsterberg, 2016). The renovation measures used to achieve the Passive House level renovation are presented in Table 1. Based on the type of heat generation commonly used in Swedish SFHs from this period, the reference houses were evaluated with two alternatives: electric heating and a ground source heat pump. Non-electric heating such as pellets and district heating were excluded because of their reliance on other energy sources. Three locations were chosen to determine whether the difference in solar radiation and ambient conditions, such as temperature, impacted the possibility of achieving NZEB. These locations were Malmö in the south, Östersund located in central Sweden, and Kiruna in the north.

Table 1. Description of the Passive House renovation level with renovation measures and the required performance level.

	Renovation level	Passive House
Building envelope	Facades	New
	External walls	0.10 ±0.02 W/(m²·K)
	Roof	0.10 ±0.02 W/(m²·K)
	Foundation	Improved, see Table 3
	Cellar walls	+200 mm thermal insulation
	Windows	0.80 W/(m²·K)
	Doors	0.80 W/(m²·K)
	Thermal bridges	Calculated
	Airtightness, at ± 50 Pa	0.3 l/(s·m²)
	Drainage	New
Installations	Ventilation system	Balanced, with heat recovery
	Ducts	New air ducts
	Heating system	New, depends on heat generation used
	Heat generation	New, depends on evaluated heat generation
DHW	Heater	New
	Pipes	New
	Fixtures	New
	Household purpose electricity	Not included, new energy efficient appliances and lighting assumed

Two case study buildings represented the SFH building stock from the period (Table 2). These houses were used in earlier studies of energy savings potential (Ekström and Blomsterberg, 2016) and cost-effectiveness (Ekström et al., 2017) of renovations aimed at reaching Passive House level. More detailed information about the renovation measures can be found in those papers. The impact of renovation measures on the building envelope of the reference houses is shown in Table 3.

Table 2. Description and visualization for the two case study buildings before renovation.

Reference house 1		Year built:	1965	
Roof area:	169 m², inclination < 5 °	
A_{temp}:	230 m^2	
Ventilation:	Passive stack ventilation	
Description: One-storey house with a cellar and a pent roof, lightweight concrete walls and a concrete slab foundation.		
Reference house 2		
Year built:	1977	
Roof area:	80 m² + 80 m², inclination 45 °	
A_{temp}:	142 m^2	
Ventilation:	Balanced ventilation, with heat recovery	
Description: One-and-a-half storey house with a ridged roof, 45°, wood frame structure walls insulated with mineral wool and a concrete slab foundation.

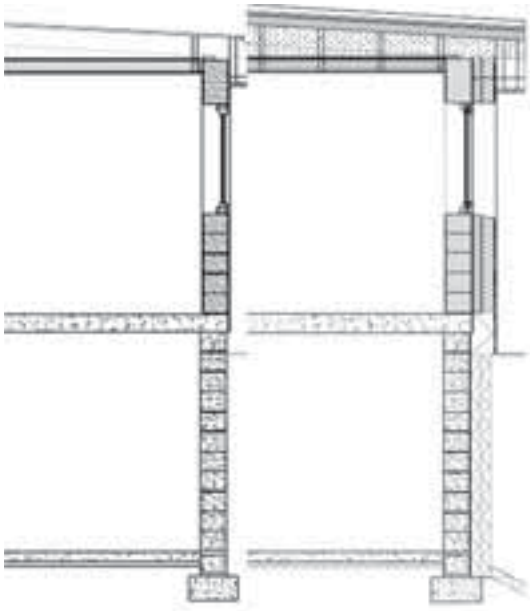
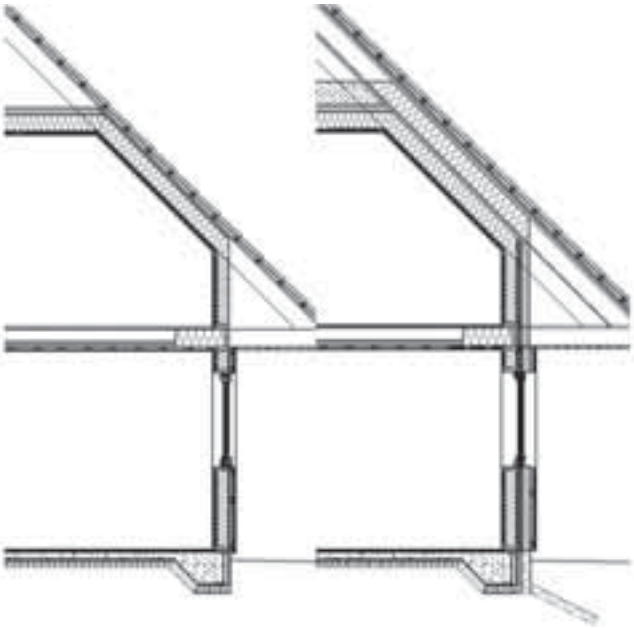
Before renovation	**After renovation**	**Before renovation**	**After renovation**
			





The building simulations include detailed models of the reference houses, with zones for each room. A specific building model was used for each alternative in the assessment. The input data regarding structures, thermal transmittance, airtightness, inhabitants, internal heat gains and shading was gathered from and prioritised as follows: 1) specific data for reference house; 2) Passive House requirements (Erlandsson et al., 2012); and 3) Sveby (Levin, 2012) was used for normalised user-related input data. The reference houses were assumed to be inhabited by two adults and two children. Weather data files included in the building energy simulation program (*IDA ICE 4.7*) from *SMHI (Swedish Meteorological and Hydrological Institute)*, with long-term measurements of climate and weather, were used for each location in the simulations. In Swedish conditions cooling is not commonly used in residential buildings, so is excluded from the analysis.

On-site production of renewable energy was evaluated by simulating the performance of the PV system, to ascertain whether it could cover the annual energy demand of the houses. A validated dynamic building energy simulation tool, *IDA ICE 4.7* (EQUA, 2016) was used to simulate energy demand, and the simulation program *SAM 2017.1.17* (NREL, 2017) was used to simulate the production from the PV system. The nominal efficiency of the PV panels was assumed to be 20.6 percent and an expected service life of 25 years (Lindahl, 2014), with a temperature coefficient of -0.3 percent per degree increase and an inverter with a maximum conversion efficiency of 96 percent. The PV panels were placed with the same tilt as the existing roof. The simulations used hourly values to compare self-consumption of the electricity from the PV system. The definition and equation for calculating the self-consumption, or solar fraction, used in this study is presented in equation (1):

$$\text{Solar fraction (\%)} = \frac{\text{energy from PV to load}}{\text{energy load}} \quad (1)$$

The total energy demand that production from the PV system needs to cover is the demand for household electricity, space heating, domestic hot water and facility electricity. The demand for household electricity is based on the annual average use in Swedish SFHs, 5900 kWh, and the domestic hot water demand is based on the normalised annual use in Swedish SFHs of 20 kWh per heated floor area, Sveby (Levin, 2012). The energy demand for space heating and facility electricity was simulated in *IDA ICE 4.7* for the specific case study buildings at the different locations and with the different types of heat generation. The assumed variation in the domestic hot water demand for the evaluation is presented in Figure 1 and Figure 2. Variation in household electricity demand was assumed as shown in Figure 3 and Figure 4.

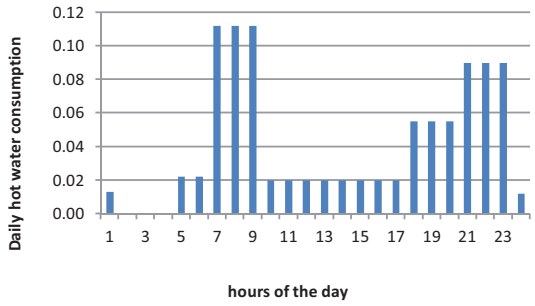


Figure 1. Daily variation of DHW consumption based on a simplification (Bernardo et al., 2012).

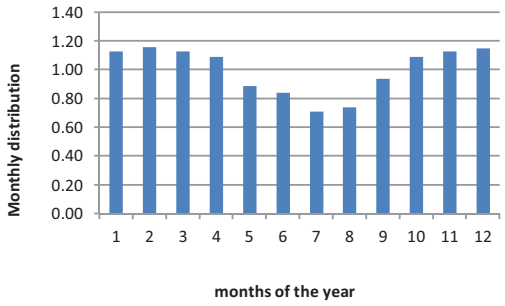

Figure 2. Annual variation of DHW consumption based on FEBY12 (Erlandsson et al., 2012).

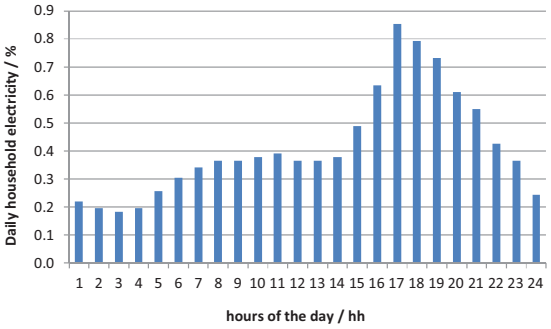

Figure 3. Assumed daily profile for household electricity use based on measurements of Swedish passive houses. This is not included in specific energy use (Nilsson and Westberg, 2012).

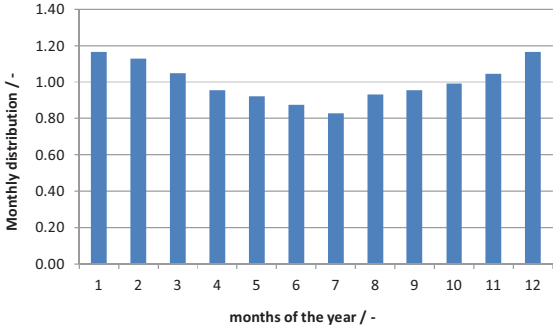

Figure 4. Assumed yearly distribution of household electricity use based on measurements of Swedish passive houses (Nilsson and Westberg, 2012).

The economic analysis, using the software *"Investment calculation for photovoltaics"* (Stridh, 2016), calculated the life cycle cost as net present value and internal rate of return. The investment cost of the system is based on the average prices, €1850 per installed kWp including VAT, presented in the software. A Government grant is available for installation of a PV system on a SFH, covering 20 percent of the investment costs (Svensk författningssamling 2016:900, 2009), which was included in the economic calculation. It was assumed that a loan was taken to cover the investment cost. The interest rate of the loan was assumed to be two percent higher than inflation, so the real interest rate used in the calculations of net present value was two percent.

The total price per kWh for bought electricity in Sweden is based on several parameters. In addition to the electricity price, there is also the grid service price, electricity certificate (Swedish Energy Agency, 2016), electricity tax (Swedish Tax Agency, 2017) plus VAT. The fixed fees were not included since they do not change with the energy demand, so they are not impacted by the reduced energy use from the renovation measures.

To determine the electricity price, information was gathered regarding average annual grid service price per kWh and monthly electricity prices per kWh for the variable price rate for SFHs (Statistics Sweden, 2017). The average electricity price depends on the electricity demand of the house – if the heat generation is based on electricity, electricity demand is higher and price per kWh lower, and if non-electric heat generation is used, electricity demand is lower and price per kWh higher. Only houses using electric heating were included in this study, so only electricity prices for such houses were included. Average electricity prices are about €0.13 per bought kWh for houses using electric heating (Figure 5). The price increase above inflation was assumed to zero.

The selling price for electricity sold to the grid, presented in Figure 6, was estimated based on the average price of €0.05 per kWh in *"Investment calculation for photovoltaics"*. Also included is the electricity certificate of €0.013, compensation for the grid owner of €0.005, certificate of origin of €0.0005, and a tax subsidy of €0.06 available for the first 15 years of production. All costs were estimated in Swedish Crowns (SEK) and converted to Euro (€) with a conversion rate of SEK 10 for €1.

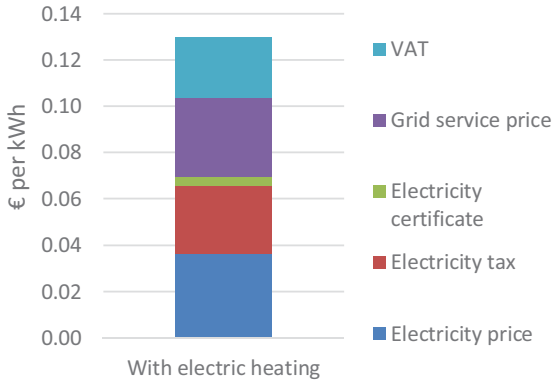

Figure 5. Average annual price for electricity bought from the grid for houses using electricity for heat generation.

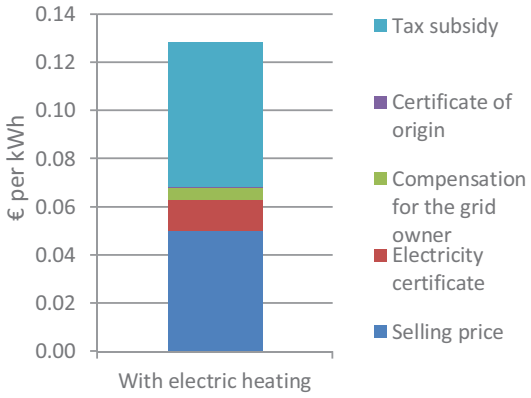

Figure 6. Average annual price for electricity sold to the grid for houses using electricity for heat generation.

3. Results and discussion

Results are presented, in Table 4 for Reference house 1 and in Table 5 for Reference house 2, as annual electricity demand (including space heating, domestic hot water, facility electricity and household electricity), annual electricity production from the PV system and self-consumption, based on the hourly demand and production. The aim was for the annual electricity production to equal that of the energy demand, to attain the NZEB level. The results are shown per location and type of heat generation. Also presented are the system size and the peak power of the evaluated systems. Alternatives presented in red do not attain the NZEB level.

Table 4. Results from simulation of the PV system production for Reference house 1 with roof tilt of < 5 degrees. Alternatives presented in red do not attain the NZEB level.

Heat generation	Location	PV system size m²	Peak power kWp	Annual demand kWh	Annual production kWh	Self-consumption %
Electric heating	Malmö	114*	23.5	18 400	19 000	31.1
	Östersund	114*	23.5	25 400	16 900	25.0
	Kiruna	114*	23.5	30 600	14 200	21.3
Ground source heat pump	Malmö	65	13.4	10 200	10 900	34.6
	Östersund	90	18.4	12 600	13 200	30.1
	Kiruna	114*	23.5	14 900	14 200	25.4

*Maximum available roof area.

Table 5. Results from simulation of the PV system production for Reference house 2 with roof tilt of 45 degrees and east-west orientation. Alternatives presented in red do not attain the NZEB level.

Heat generation	Location	PV system size m²	Peak power kWp	Annual demand kWh	Annual production kWh	Self-consumption %
Electric heating	Malmö	90	18.4	12 800	13 200	33.1
	Östersund	131	26.8	16 100	17 000	29.0
	Kiruna	163*	33.5	18 700	18 000	26.3
Ground source heat pump	Malmö	57	11.7	8 600	8 700	35.9
	Östersund	82	16.8	9 800	10 700	32.8
	Kiruna	98	20.1	10 800	10 800	29.6

*Maximum available roof area.

The results show that fulfilling the aim of a NZEB building depends both on location and type of heat generation. In the case of Reference house 1, the PV system was limited by the size of the roof in three cases: for electric heating in Östersund and Kiruna, and for the ground source heat pump in Kiruna. For Reference house 2, this was only the case for electric heating in Kiruna. The results reflect both the increased demand for space heating in the colder climate and the reduced production from the PV system in the northern parts of Sweden.

The results from the life cycle cost calculations are presented, in Table 6 for Reference house 1 and in Table 7 for Reference house 2, with the investment cost for each system and as net present value and internal rate of return. The results are shown per type of heat generation and location. Alternatives presented in red are not profitable.

Table 6. Profitability calculations for the implementation of PV systems on Reference house 1, presented with investment costs, net present value and internal rate of return. Alternatives presented in red are not profitable.

Heat generation	Location	Investment cost (€)	Net present value (€)	Internal rate of return (%)
Electric heating	Malmö	35 250	680	2.2
	Östersund	35 250	- 4 300	0.7
	Kiruna	35 250	- 10 200	- 2.4
Ground source heat pump	Malmö	20 100	710	2.4
	Östersund	27 600	- 3 100	0.8
	Kiruna	35 250	- 9 900	- 1.2

Table 7. Profitability calculations for the implementation of PV systems on Reference house 2, east-west orientation, presented with investment costs, net present value and internal rate of return. Alternatives presented in red are not profitable.

Heat generation	Location	Investment cost (€)	Net present value (€)	Internal rate of return (%)
Electric heating	Malmö	27 600	- 2 900	0.9
	Östersund	40 200	- 9 300	- 0.5
	Kiruna	50 300	- 17 200	- 1.9
Ground source heat pump	Malmö	17 600	- 1 100	1.4
	Östersund	25 200	- 5 500	- 0.4
	Kiruna	23 000	- 11 000	- 2.2

The cost-effectiveness is also shown to be dependent on both the location and type of heat generation. It is only cost-effective to install a PV system with a size to attain NZEB for Reference house 1 in Malmö in the south of Sweden. This is the case with both types of heat generation, although the investment cost for the electric heated house is higher.

4. Conclusion

Overall, the assessment showed that it is not cost-effective to aim for NZEB when implementing a PV system, based on the alternatives in this study, assuming a lifetime of 25 years and no electricity price increase above inflation. In many cases, the NZEB level could be attained with the roofs available, but this depended on the location and type of heat generation of the houses.

In this study, the aim was to maximise annual PV production, therefore the PV panels were installed flat on the roof for Reference house 1. The tilt of the PV system could be optimized to increase production per panel and cost-effectiveness. However, by doing this, the total annual PV production is reduced because of the limited space, so the NZEB level would not be attained.

Abstract

This work presents the performance analysis of the very first Energy+ building in Dubai certified by the German Passive House Institute. The analysis is presented as comparison between numerical predictions and the first available monitored data. Trnsys is the software used to create the energy model, including both thermal envelope and HVAC system. The use of highly insulating materials, together with a design aimed to reduce the solar heat gains, allows for minimizing cooling loads. A 40 kW PV field, coupled to a 25 kWh battery storage and to a high-efficiency air-cooled electric chiller, fulfills the electric and cooling demand, making the building energy-autonomous. The study demonstrates the high accuracy of the energy model, able to predict precisely the building cooling loads, the energy production and the cooling system performance. The Energy+ building, inaugurated in November 2016, is a pioneering pilot-project and it represents an advance in the field of sustainable construction for all Arabic area.

Keywords: energy+ building, solar cooling, PV, monitoring system, dynamic simulation.

1. Introduction

In many developed countries, buildings and their use are responsible for approximately one-third of the total primary energy consumption and carbon emissions. Governments and scientific communities are aiming for new paradigms for energy-efficient buildings: the goal is to reduce the environmental impact of the construction sector (Nejat et al., 2015). Many authors investigated the design principles for high-efficient buildings in cold climates (Thalfeldt et al., 2013; Justo Alonso et al., 2015). More recently, the interest in the development of passive buildings has grown also for hot regions (Fokaides et al., 2016; Schnieders et al., 2015).

The development of sustainable solutions goes through the construction of more and more efficient buildings. At this regard, new concepts have gained wide international attention, such as Passive Houses, Nearly Zero Energy Buildings, Net Zero Energy Buildings and Energy+ Buildings (Marszal et al., 2011). The first step in order to comply with all high-efficiency standards is to reduce the energy consumption in buildings. Passive design strategies contribute to improve the interior comfort conditions, reducing the requirement of energy supply from active systems (Rodriguez-Ubinas et al., 2014).

Besides the development of well-insulated thermal envelopes, an improvement of the building sustainability can be achieved by using high-efficiency cooling technologies coupled with renewable energy sources. Several types of solar cooling systems have been investigated in the open literature (Nanda and Panigrahi, 2016; Ghaith and Abusitta, 2014). Among the available technologies, the option based on compression chiller driven by a PV field assisted by a battery pack is highlighted. A remarkable comparison between this solution and thermal solar cooling systems was done by Lazzarin (2014). The results show that the performance is today comparable but the PV has a greater adaptability. Recently, huge investments in the electric storage technology have led to the spread of batteries for building applications and to the development of off-the-grid or stand-alone houses (Okoye and Solyalı, 2017; Fara and Craciunescu, 2017).

doi:10.18086/swc.2017.15.02 Available at http://proceedings.ises.org

In the Gulf area, the United Arab Emirates is one of the most active countries in the promotion of actions aiming to ensure a sustainable development while preserving the environment. The UAE Vision 2021 National Agenda focuses on improving the quality of air, preserving water resources, increasing the contribution of clean energy and implementing green growth plans. The UAE Energy Plan 2050 is an ambitious strategic plan aiming to cut carbon dioxide emissions by 70 per cent, to increase clean energy use by 50 per cent and to improve energy efficiency by 40 per cent by the middle of the century. Within this framework, the Government of Dubai is implementing policies and strategies in order to promote the energy efficiency and the use of renewable energy resources (Al-Amir and Abu-Hijleh, 2013). Recently, in the construction sector the Mohammed Bin Rashid Space Centre (MBRSC), a Dubai government R&D organization working in various fields of the scientific research including aerospace projects, started a Sustainable Energy Program. The goal was to build an autonomous house representing a model for the real-estate sector in the region. This project is the result of the collaboration of different players: the team of MBRSC engineers and scientists, University of Bergamo (modeling, simulations and scientific supervision), Casetta & Partners (executive design) and Wolf System (builder company). The present paper reports the modeling and simulation activities carried out to dictate the design choices for the building construction. All technologies used in this house are presented and the preliminary results of the monitoring data are shown. The building construction was completed in a record time of less than 100 days and was inaugurated in November 2016 by H.H. Sheikh Mohammed bin Rashid Al Maktoum, Vice President and Prime Minister of the United Arab Emirates, and ruler of the Emirate of Dubai.

2. Building description

The building is a two-floor office structure, with geometry and orientation aiming to reduce as much as possible the primary energy consumption. To do that, the surface to volume ratio is minimized. The solar irradiation on the walls during the day and across the seasons is accurately evaluated. A small patio shrinks the radiation on the glazed elements and keeps shaded the office areas. This solution allows for avoiding window shields even in daylight hours. The diffuse light naturally illuminates the 550 m^2 floor surface and – at the same time – the solar gains are minimized. A timber trimmed structure is designed to support a photovoltaic field (see Fig, 1), to promote the ventilation on PV modules and to shade the flat roof. The outline elements of the windows are protruding to limit direct radiation.

Fig. 1: The Energy+ Building unveiled in November 2016.

A lightweight load bearing structure made by wood supports timber walls and roof. The walls are designed to reduce as much as possible the building cooling load. The balance between mass and insulation improves the energy performance: the insulation thickness is designed to minimize thermal transmittance and the phase shift is controlled by adding mass layers. Walls are painted with a special reflective paint to curtail the absorption of solar radiation on the outer layer. Similarly, the roof is treated with a reflective film and infrared reflector films are inserted inside the walls. Windows are specific for warm climates with very low U and G values to limit the solar gains (see Table 1).

The prefab European timber platform frame technology made possible to realize the building in less than 100 days. The building envelope has been designed according to the Passive House standard and the energy systems have been selected to reach the level of Energy+ Building. Power supply is ensured by the rooftop PV field. A battery pack is available to store electricity during light hours and to supply electricity after sunset. The building is virtually off-grid (power import is possible for emergency) and the electric overproduction is delivered to the grid.

Table 1. Envelope thermal properties.

	unit	value
U_{wall}	W/(m^2 K)	0.063
Wall thickness	m	0.603
Wall solar absorptance	%/100	0.3
U_{roof}	W/(m^2 K)	0.061
Roof thickness	m	0.566
Roof solar absorptance	%/100	0.2
$U_{-value,w}$	W/(m^2 K)	0.7
$G_{-value,w}$	%/100	0.294

A high-efficient air-water reversible heat pump - specifically designed for hot-humid climates - meets the cooling and dehumidification demand, and the production of domestic hot water. The cooling system is based on a combination of three different technologies: floor cooling, mechanical ventilation and fan-coils. The radiant floor cooling maintains a high level of comfort, the air handling unit with high-efficient heat recovery controls temperature and humidity of the inlet air, and the fan-coils fulfill the cooling peak loads. The integration of high-efficient technologies both in the thermal envelope and energy systems is the key of the project performance.

3. Building model

The design of high-efficiency buildings in hot climates requires the accurate prediction of the cooling demand and of the energy plant performance. Fundamental is the development of simulation tools for assessing the building energy performance (Harish et al., 2016; Mihai et al. 2017). In a well-insulated building, the internal loads play a crucial role. The prediction of the energy consumption due to the electrical equipment is very important, as documented by Widen (2014). Moreover, Hoxha and Jusselme (2017) showed the relevance of using efficient lights and appliances adapted to new high-efficiency buildings. Furthermore, the analysis of occupancy reveals its relevant impact on the energy performance (Blight and Coley, 2013).

In the energy-efficient buildings a primary interest is the comfort perception: predictive techniques for quantifying and qualifying the indoor comfort are included in several building models (Wang et al., 2017; Satake et al., 2016). Frequently the goal of a high level of comfort perception is achieved through radiant floor cooling systems (Zhao et al., 2016).

The models developed for the simulation of building envelop and solar cooling system performance are based on Trnsys v.17. Weather data with hourly resolution have been provided by the Mohammed Bin Rashid Space Center.

3.1 Envelope model

The detailed architectural building model is based on Trnsys Multizone Building Type and developed by the 3D cad software Google Sketch Up®, with the plug-in Trnsys3D for geometry and shading. The building model includes 10 homogeneous thermal zones and all main comfort parameters are listed in Table 2.

Table 2. Comfort settings and internal gains.

	unit	value
Set point temperature	°C	24
Set point RH	%	50
Mean ventilation ratio	Vol/hr	0.60
HX efficiency	%	80
Infiltration	Vol/hr	0.06
Lighting (peak)	W/m^2	5
Internal gains (peak)	kW	6
Occupancy	Nr.	20

In the computer model the technical data of all the construction materials have been included, thus allowing a realistic prediction of the building envelope behavior. Internal loads due to lights and appliances have been carefully evaluated. The occupancy is considered as an average attendance including random occurrence of overload events.

The Trnsys model allowed to predict the cooling demand all over the year. This is crucial for a correct sizing of the energy plants. The simulation results show the strong impact of latent loads due to high relative humidity levels. The dehumidification demand influences both the peak load and the annual demand respectively by 60% and 30% (Table 3). The total cooling load and the latent load are shown in Fig 2: the peak cooling demand is about 27 kW. The short load duration curve (limited to 4000 hours per year) testifies the high performance of the building envelope.

Table 3. Building cooling loads.

Peak Load		
	unit	value
Air Load - sensible	kW	6.83
Air Load - latent	kW	20.49
Floor Load	kW	8.42
Total Load	kW	27.03

Annual Load		
	unit	value
Air Load - sensible	kWh	7954.6
Air Load - latent	kWh	11920.7
Floor Load	kWh	13844.5
Total Load	kWh	33719.9

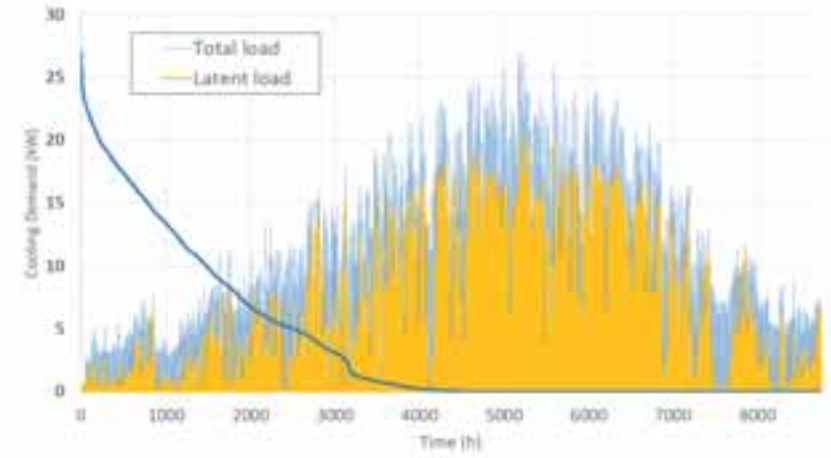

Fig. 2: Cooling load and duration curve.

In addition to the calculation of the global building performance, the Trnsys model permits to carry out detailed analysis of the thermal behavior of each single wall. For instance, Figure 3 reports for two consecutive summer days the temperature trends of a portion of flat roof not shaded by PV modules. It can be noted that, in spite of a strong temperature variation in the external side (with peak higher than 42°C), the temperature level on the internal side is predicted to be stable at 25°C.

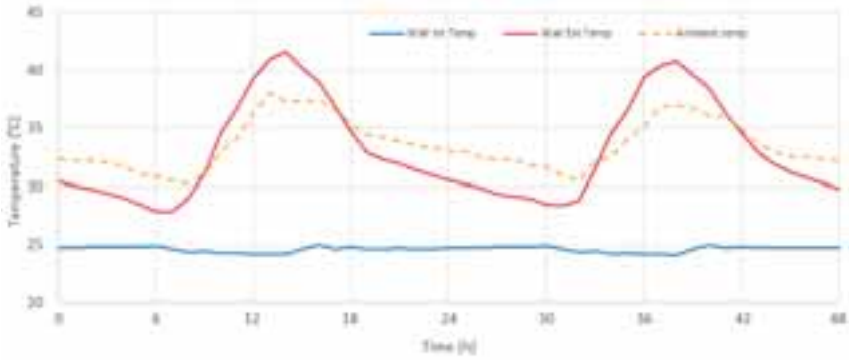

Fig. 3: Roof temperature.

Fanger's comfort parameters were also considered to improve the design quality. Table 4 shows the calculated comfort indexes: the excellent level is achieved thanks to the integration of different air conditioning systems. The predicted mean vote is very near to the ideal value (0) and the maximum deviation (0.27) is very small compared to the comfort region (-0.5 to 0.5) range. Furthermore, the value of the percentage of person dissatisfied is close to the minimum value.

Table 4. Building comfort parameters.

	Unit	Max	Min	Average
Mean Radiant Temperature	°C	24.23	22.34	23.66
Operative Temperature	°C	24.11	22.25	23.75
Predicted Mean Vote	[-3 ; 3]	0.26	-0.27	0.16
Percentage of Person Dissatisfied	% [5 ; 100]	6.51	5.00	5.69

3.2 Energy system model

The energy system is based on multi-crystalline PV panels coupled to a battery pack. Power PV-generated drives an air-cooled reversible heat pump and all technical devices. An electric energy storage (battery pack) has been designed to ensure the autonomous operation, assuring 24/7 power supply to A/C system, lighting and appliances. The electricity overproduction is exported into the grid when batteries are at full capacity. An additional small thermal energy storage (1 m^3 cold tank) compensates for cooling load fluctuations. The specifications of the PV system are reported in Table 5.

Table 5. PV field and battery specifications.

	unit	value
Area	m^2	268
Nominal efficiency	-	14.9%
Efficiency modif. temp.	1/°C	-0.0041
Voltage at P_{max}	V	30.5
Open circuit voltage	V	37.6
Battery capacity	kWh	25

The cooling plant model includes the heat pump performance map provided by the manufacturer. The chiller is designed to operate with an outdoor temperature up to 50 deg. C and the cooling capacity was selected to fulfill the peak demand of the building. The chiller specifications are reported in Table 5.

Table 6. Chiller specifications.

	unit	value
Chiller capacity*	kW	27.51
COP*	-	2.38
Power input*	kW	11.55
Cold tank volume	m^3	1
Tank insulation (EPS)	m	0.2

* Ambient temperature 30 deg. C; chilled water 7-12 deg. C.

The results of the transient simulation carried out for a one-year period are shown in Table 7. It can be seen that power consumption for air conditioning is about half of the total electricity consumption. The electricity production to meet the off-the-grid requirement results to be more than twice the Net-Zero Energy standard (export = import over one-year period). This has a heavy impact on the design of the photovoltaic field. Because the energy import must be zero at any time, PV system must be large enough to ensure the energy autonomy of the building.

Table 7. Electric production and consumption.

	unit	value
Chiller consumption	kWh	11400.3
Light and appliances	kWh	11914.7
Total electric load	kWh	23315.0

	unit	value
PV production	kWh	56460.2
Grid import	kWh	0.0
Grid export	kWh	33123.7

The simulation results document that the battery charge level (see Fig. 4) is always above 60% of the full capacity (25 kWh), even in the peak periods. The power demand exhibits a daily peak of about 3 kW in the winter months, whilst the annual peak taking place in August (when the cooling demand is maximum) is 10 kW. The daily curves of power production and consumption are shown in Figure 5. The energy demand is met according to the following priority order: by PV (when available and sufficient), by batteries and, in the last case, by import from the grid (emergency only). Power consumption for appliances and lighting depends on the occupancy and the activities in the thermal zones. The PV field drives the heat pump as priority and the surplus recharges the battery pack. The electricity overproduction, when the battery level is full, is delivered to the grid according to a net-metering scheme. Figure 6 shows the annual energy fluxes: PV production, total power consumption (heat pump, lighting and appliances) and the export to the network on a monthly basis. In winter months, when the cooling request is low and the heat pump efficiency is high thanks to the low ambient temperature, the electric energy delivered to the grid is around 70% of the global PV production. During the warm season this ratio decreases to 50%.

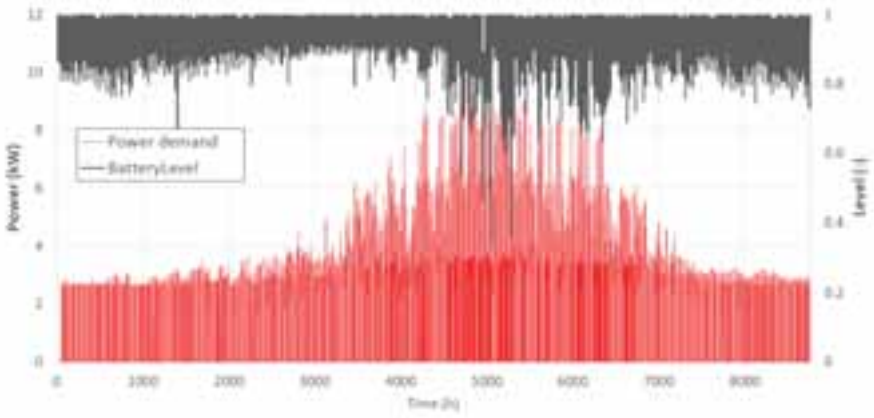

Fig. 4: Power demand and battery level.

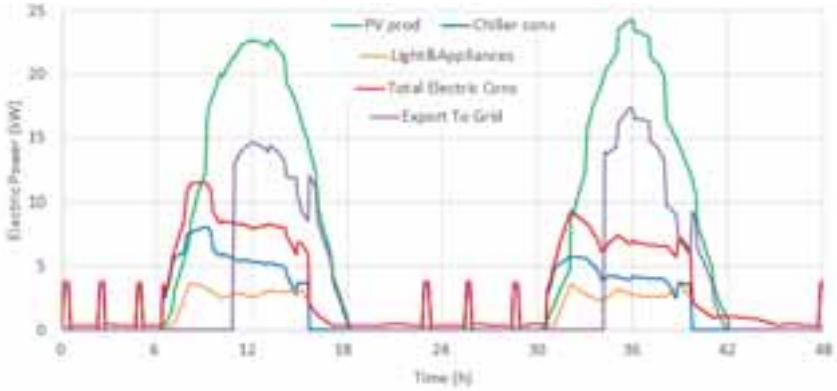

Fig. 5: Power demand and production.

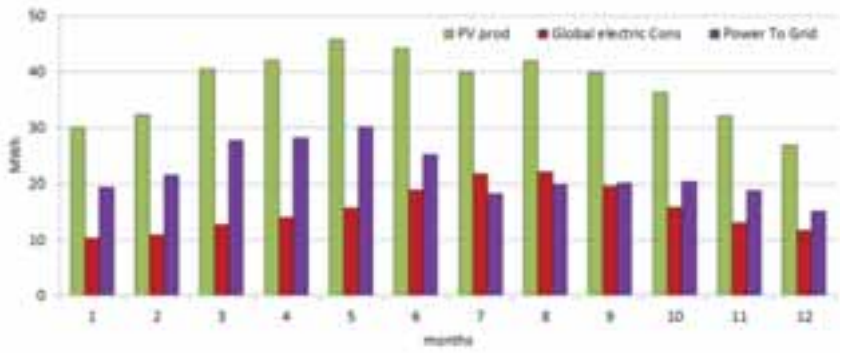

Fig. 6: Monthly energy production, consumption and export.

4. Comparison model prediction vs. monitoring data

The Plus-Energy building has been fully instrumented. A monitoring system has been installed for a remote real time access to all collected data (with a frequency of 1 sample per second). This equipment makes possible to monitor with high level of detail the building energy performance under real operating conditions. The monitoring system includes thermocouples in the wall layers, thermo-hygrometers in the rooms, power meters on the PV field, the battery package and all electric boards, temperature and flow rate sensors in all circuits of the HVAC system. Table 8 summarizes the main monitoring data.

Tab. 8: Monitoring System Equipment

Weather	Ambient temperature, Ambient humidity, Global solar radiation
Building Envelope	Room temperatures, Humidity, CO_2, External/Internal side Walls/Roof temperature
PV Field & Grid	PV production, Grid Import/Export, Appliances and auxiliary consumption
Cooling Plant	Cooling production, Chiller electric consumption, AHU in/out temperatures, Floor cooling in/out temperatures

It has to be reminded that this building is a pioneering pilot-project. The goal is to prove that new sustainable construction standards are possible in the UAE and that this is a viable solution to reduce the carbon footprint in the region. The monitoring activity is fundamental to demonstrate that the predicted performance is confirmed under real operating conditions. Moreover, the measurement campaign is important also for the model validation. Currently, the monitoring activity is going on and some weeks of collected data are available for analysis. This paper reports the comparison between the model predictions and the first available data.

Figures 7-10 show the simulation results and the experimental data for two consecutive days in September. Figure 7 refers to the cooling demand. The curves related to the model prediction (dashed line) and the measurements (solid line) exhibit a very good superposition: the model appears able to estimate the peak values, the hourly trend and the daily integral value. As mentioned before, in addition to the overall thermal loads the Trnsys model can predict the trend of detailed parameters, like wall and roof temperatures. Figure 8 shows the trend of internal and external temperatures for the well-insulated roof. The daily pattern for the outer side temperature (influenced by the incident solar radiation and the ambient temperature) is well predicted, in spite of a small time shift. The inner side temperature is perfectly estimated.

Moving to the energy systems, Figure 9 reports the 48-hour trend of the PV production and the power consumption due to light and appliances and for the chiller operation. The chart shows a small underestimation of the PV power output (-9.5% as integral value), whilst the power consumption for lighting and electrical equipment is very well predicted. A far as the chiller consumption is concerned, the monitored data show slightly different patterns during the day and higher peak levels. The hourly variation of the power input is related to the trend of the real cooling demand documented in Fig. 7, while the higher peak levels and the higher daily integral values indicate a lower-than-expected chiller efficiency (-12.8%).

As mentioned in the previous paragraphs, when the batteries are full charged the electricity surplus is supplied to the grid. Figure 10 shows the power export compared to the PV production. The model exhibits a good capability to predict the amount of electricity delivered to the grid and the time interval of the power exchange. When the battery package is full (at 11.30 a.m.) the model predicts an instantaneous shift to the exportation mode, whilst monitoring data show a soft ramp starting 2 hours before achieving the full capacity condition: this is due to the control system of the electric storage that is not implemented in the model. Nevertheless, the integral value of the exported electricity is well predicted: the error model vs. monitoring is only 2.0%.

5. Conclusions

This work presents the very first Energy+ building certified by the Passive House Institute in the Dubai area. The building is a pioneering pilot-project aiming to prove that high comfort levels can be achieved by using solar energy as unique energy source. A 40 kW PV field, coupled to a 25 kWh battery storage and to a high-efficiency air-cooled electric chiller, fulfills the electric and cooling demand, making the building energy-autonomous. A preliminary activity of modeling and simulation dictated the design of the building envelope and of the energy systems. Trnsys is the software used to create the energy model and to predict the building performance. Starting from its inauguration, the building has been monitored to measure the actual performance under real operating conditions. The first available measurements confirm that the model predictions are very accurate and very close to the monitoring data. Therefore, it can be concluded that the expected targets in terms of energy savings and carbon footprint reduction have been successfully achieved.

Abstract

Thermal response of building envelope exerts a substantial influence on the formation of overall indoor comfort conditions as well as on the energy performance of buildings. For the majority of Central and Northern European countries it can be said that legislators as well as designers focus primarily on the optimization of building performance in heating season. Nevertheless, predictions for the future show the potential for large increase in cooling demand due to overheating of buildings. In this context, the focus of the presented work was to evaluate the non-stationary performance of different façade walls (lightweight and heavyweight construction systems) during typical Central European summer conditions. In addition to the influence of wall composition, the impact of orientation and high intensity passive cooling on thermal response was also investigated. The results showed differences in the summer time performance of lightweight and heavyweight envelopes, whereas lightweight façade walls had worse summer time thermal response. Furthermore, substantial differences in thermal behaviour of east, south and west faced walls were identified, with wall orientation having greater effect in the cases of walls with higher thermal transmittance and when constant ventilation regimes were used. However, among all the analysed parameters, high intensity passive cooling was identified to have the greatest influence on the summer time thermal behaviour of façade walls.

Keywords: external façade walls, transient thermal performance, night-time ventilation, thermal mass, FEM thermal analysis, Central European climate

1. Introduction

Indoor thermal environment in buildings during cooling season is becoming an ever more increasing concern in EU due to projected increase in the application of active cooling in the decades to come (STRATEGO, 2015). Current statistical data for EU (RESCUE, 2014) show that active cooling systems are installed in 7% of the total floor area in case of residential buildings, while the share for the tertiary sector is 40%. In the light of increasing influence of climate change and ever-higher demands for indoor occupant comfort, the growth in space cooling applications and their potential influence on energy consumption could be substantial. As an alternative, less energy demanding solutions for providing adequate indoor thermal conditions during summer time should be investigated in order to evaluate their overall efficiency. Best results can be attained by passive solutions on the level of building envelope, such as high thermal mass, and on the level of building functioning, for example night-time ventilation (Santamouris et al., 2010). Both approaches have a large potential in reduction of overheating occurrence, especially in temperate (i.e. Central Europe) and cold (i.e. Northern Europe) parts of Europe. In order to evaluate the potential influence of such passive solutions during free-run conditions (i.e. building is not mechanically cooled), a non-stationary analysis must be used due to the dynamic nature of the thermo-physical problem.

Several studies have investigated summer time thermal response of different construction types, with most of them studying lightweight constructions (i.e. constructions that lack or have low thermal mass). The overheating of buildings during cooling season most likely occurs in timber buildings (Adekunle and Nikolopoulou, 2016), in buildings located in highly urbanized environments (due to the occurrence of heat islands) (Paolini et al.,

doi:10.18086/swc.2017.15.03 Available at http://proceedings.ises.org

2016), in hot climates (Stazi et al., 2017) or in the case of a combination of all the stated. Pekdogan and Basaran (2017) investigated thermal performance of external walls during winter and summer. They emphasized that heat loss and gain values were significantly reduced with thicker insulation and that different thermal insulation positions (external, internal, sandwich) and wall orientations influenced the heat flow through the wall. Similar study was also conducted by Tzoulis and Kontoleon (2017), which highlighted that varying wall orientation has lower effect on the value of decrement factor compared to the time lag. Therefore, the composition and orientation of building's external wall are extremely important in the context of overheating prevention.

The objective of the analysis presented in this paper was to evaluate the thermal response of selected typical external façade walls under Central European (i.e. Ljubljana, Slovenia) summer time climatic conditions. The importance of thermal insulation position and wall composition, especially the presence or absence of thermal mass, was already emphasized by Al-Sanea and Zedan (2011). In this context, the executed study focused on the investigation of the influence of multi-layer wall composition on its non-stationary thermal response and consequential indoor conditions. Special focus was on the performance of walls with low U values (U = 0.20 $Wm^{-2}K^{-1}$), which are becoming a standard in Central Europe for the newly constructed as well renovated buildings. Simultaneously, the effect of high intensity passive cooling (i.e. night-time ventilation) and façade orientation was included in the analysis and their effect on thermal response of walls was evaluated. Calculations were conducted by an in-house developed finite element method.

2. Methodology

2.1. Selection of wall construction systems

The selected heavyweight (HWC) and lightweight (LWC) external wall construction types were analysed. As a representative construction of typical LWC envelope systems, a wall used in timber-framed buildings was selected. Such wall construction consists of an external thermal insulation and additional thermal insulation between elements of the wood load-bearing construction. Both the internal and external surfaces are finished with a construction board (e.g. OSB board). For a HWC, multiple materials, such as brick, reinforced concrete (RC), stone and hollow brick as a load bearing construction layer were investigated (Hudobivnik et al., 2016). Nonetheless, for the purpose of the presented analysis only the HWC with RC load bearing construction will be presented. In the case of RC, HWC thermal insulation is placed on external (RC_E) or internal surface (RC_I) of the load bearing construction. Because all the analysed façade walls and results of their thermal performance simulation have to be directly comparable, each construction system was, unless otherwise specified, insulated with appropriate thermal insulation thickness in order to have identical overall thermal transmittance of 0.20 $Wm^{-2}K^{-1}$.

2.2. Climate data and time interval of analysis

Calculations were made using climate data for the city of Ljubljana (46°03'N, 14°30'E), Slovenia. Necessary weather parameters (i.e. hourly air temperatures and solar radiation data) were obtained from EnergyPlus weather files (EnergyPlus, 2016) and were directly transferred into the numerical model. Ljubljana has a typical Central European climate with slight influence of northern Mediterranean due to the relative proximity of the Adriatic Sea. According to Köppen-Geiger climatic classification, it is classified as Cfb and can be described as a fully humid, warm temperate climate with cold winters and warm summers. According to ASHRAE Standards 90.1 and 90.2 (ASHRAE Standards 90.1-2004, 2004; ASHRAE Standards 90.2-2004, 2004) the climate of Ljubljana may be designated as type 5A. The average monthly air temperature (T_{avg}) varies between 20.4°C in July and – 1.2°C in January, while the average monthly maximum air temperatures ($T_{max,avg}$) reach up to 26.4°C, and minimum monthly average air temperatures ($T_{min,avg}$) reach down to – 4.9°C. The average daily global horizontal solar irradiation (G_{sol}) varies between the maximum values of 359 Whm^{-2} (July) and 73 Whm^{-2} (December). The climatological averages of Ljubljana for the period between 2005 and 2014 are presented in Figure 1. If the historical overview of trends in the average yearly values of T_{avg}, $T_{max,avg}$ and $T_{min,avg}$ are observed for the last 54 years (Fig. 2), it becomes evident that ambient air temperatures are on the rise. In regards to the observed trend it can be concluded that for the location of Ljubljana the importance of overheating protection is on the rise, while the duration of heating period is being reduced (Pajek and Košir, 2017). The stated underlines the importance of the proposed study.

The executed analysis was conducted for the summer period between the 21st of June and 11th of August with a

model's 10 days warm up period. In order to clearly present the calculated results, only a short period between the 2nd and 10th of August will be presented. During this time the external air temperatures were extremely high with daily maximums reaching above 30°C, while the last three days mark the beginning of a cooler period.

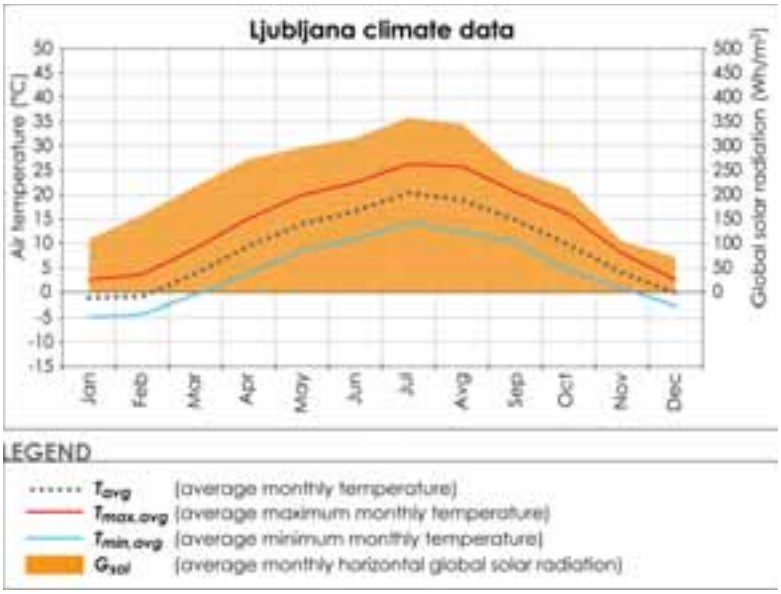

Fig. 1: Climate characteristics of Ljubljana (2005-2014 period).

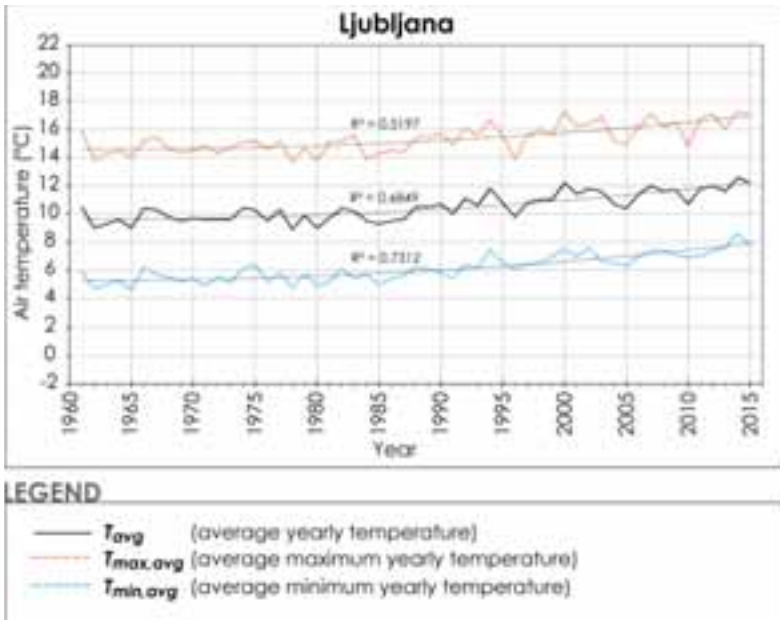

Fig. 2: Historical (1961-2015) overview of increase in average temperatures in Ljubljana.

2.3. Model and boundary conditions

The numerical model used to study the non-stationary response of the selected wall constructions was modelled in computer algebra system Mathematica (Wolfram Research, Inc., 2013) with finite element code derived using AceGen (Korelc, 2011) and finite model solved by AceFEM (Korelc, 2011). The model represents a 1 m^2 (i.e. 1 m by 1 m) of the external wall with an associated building interior of 2 m^3 and a 3.6 mm thick air boundary layer. The mass of internal partitions and furnishing as well as all internal heat gains were appropriately scaled in order to represent a typical residential house. The numerical model characteristics are presented in Figure 3 and in more depth also in a paper by Hudobivnik et al. (2016).

Additional model boundary conditions were defined in order to accurately study the non-stationary thermal behaviour of selected wall types. Solar radiation heat gains on wall's external surface were calculated, and the

constant solar absorptivity of the exterior surface was set as $\alpha = 0.40$ (solar reflectance $\rho = 0.60$), as suggested by Al-Sanea and Zedan (2011) for light-coloured surfaces (e.g. beige, cream, sand, etc.), commonly used in External Thermal Insulation Composite System (ETICS) façade renderings. In addition, the radiation losses to the environment were considered. Heat gains from occupants and appliances (including their intensity and timetable of occurrence) in internal space were defined in accordance with the values stated for residential buildings (living rooms and kitchens) in EN ISO 13790, Annex G (EN ISO 13790:2008, 2008, p. 137). Natural ventilation (0.7 ACH) as well as high intensity passive cooling (0.7/7.0 ACH) were taken into account, because ventilation regime has a significant impact on internal thermal conditions, consequently affecting heat flow through wall construction. When high intensity passive cooling is used, it is presumed that, during periods when external air temperatures are higher than internal, lower values of ventilation rates are applied (i.e. 0.7 ACH). The value of minimal ventilation rate in the simulations was defined in accordance to EN 15251 (EN 15251:2010, 2010) standard recommendation for residential buildings. In addition to the above, the orientation of façade walls was modified as well in order to evaluate the influence of received solar radiation on the thermal response of analysed walls. Orientations from east-northeast (azimuth 75°) through south (azimuth 180°) to west-northwest (azimuth 285°) were calculated in 15° steps (Fig. 3).

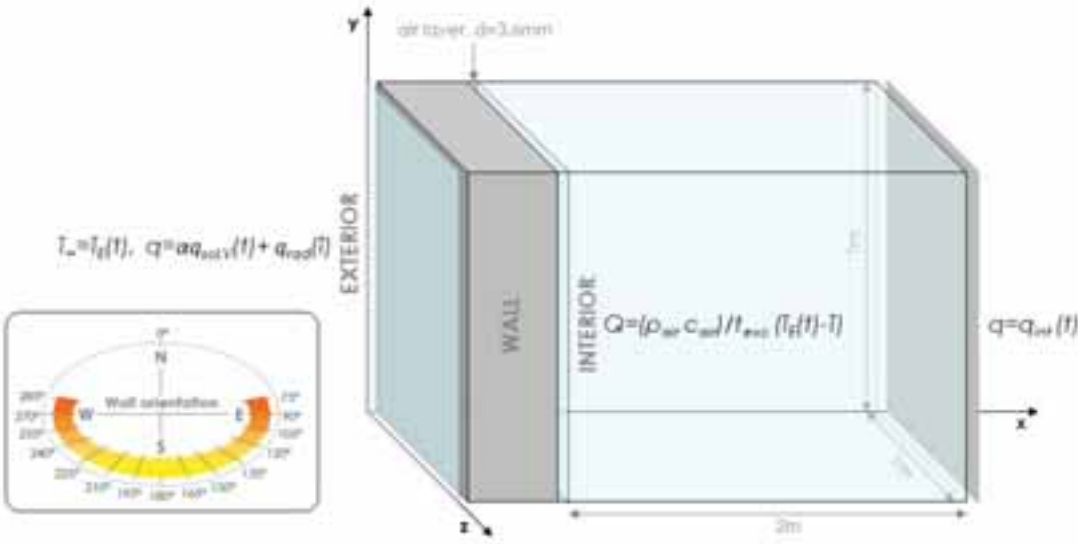

Fig. 3: Numerical model and boundary conditions with representation of analysed wall orientations.

3. Results and discussion of non-stationary analysis

The objective of the executed study was to evaluate the thermal performance of three different external façade walls (i.e. LWC, RC_E and RC_I) in relation to their loadbearing construction system type and thermal insulation position as well as wall orientation and the influence of ventilation regime (i.e. constant or high intensity passive cooling natural ventilation). The numerical model used to simulate the thermal response of the analysed external walls was run under summer climatic conditions in Central Europe (Ljubljana, Slovenia) with presumption that the building is not actively cooled and is therefore in a free-run mode. The latter enabled a study on the influence of the analysed passive strategies (i.e. wall composition, orientation and ventilation mode) on the internal temperatures. Specifically, the internal wall surface temperature was monitored (T_{surf}).

3.1. Influence of high intensity passive cooling on the internal temperatures

The results (Fig. 4) showed that indoor air change intensity has a significant impact on heat flow through external multi-layer building envelopes and the corresponding internal surface temperatures. Therefore, the effect of (natural) ventilation should not be neglected in the evaluation of the thermal response of building envelopes, especially when high intensity night ventilation is used as a passive cooling strategy (i.e. buildings in a free-run mode). When using constant ventilation rates (i.e. 0.7 ACH) for the south faced wall (i.e. azimuth 180°), the highest average T_{surf}, during the analysed period of 28.9°C was reached equivalently in the case of LWC and RC_I (Fig. 4). In the case of RC_E the average T_{surf} is 1.8 K lower (i.e. 27.1°C). In the case of externally insulated wall RC_E the average daily surface temperature fluctuations are the lowest ($\Delta T_{surf\_mean,RCE,0.7ACH} = 0.82$

K), which is the consequence of high thermal mass positioned on the internal side of the building envelope. In the other two cases, where thermal mass is positioned on the external side (RC_I) or there is overall lack of thermal mass (LWC), the average daily surface temperature fluctuations are higher and are $\Delta T_{surf\_mean,LWC,0.7ACH}$ = 1.58 K and $\Delta T_{surf\_mean,RCI,0.7ACH}$ = 1.68 K for LWC and RC_I, respectively.

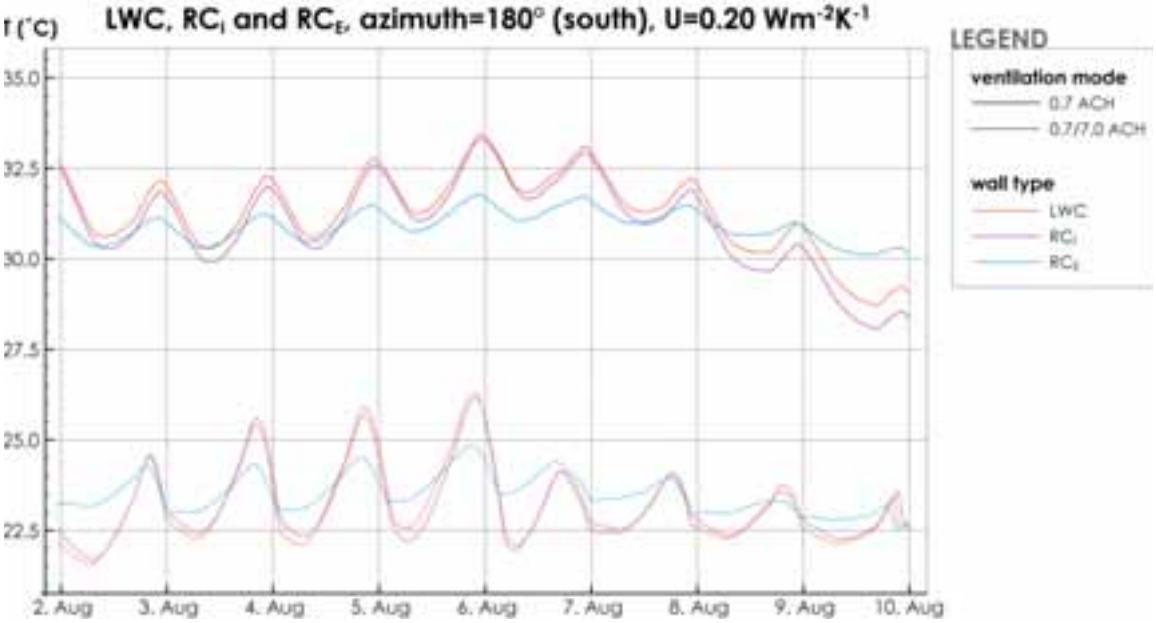

Fig. 4: Impact of high intensity passive cooling (0.7/7.0 ACH) in comparison to constant ventilation (0.7 ACH) on the internal surface temperatures for RC_E, RC_I and LWC at U = 0.2 $Wm^{-2}K^{-1}$ and azimuth 180° (south).

Observing the thermal response of the same three constructions under high intensity ventilation regime (i.e. 0.7/7.0 ACH) in Fig. 4, it can be noticed that the maximum T_{surf} in each case drops by approximately 7 K, compared to the case with constant ventilation. Nonetheless, all three constructions exhibit higher average fluctuations of surface temperature under high intensity ventilation regime, which amount to $\Delta T_{surf\_mean,RCE,0.7/7ACH}$ = 0.96 K, $\Delta T_{surf\_mean,LWC,\ 0.7/7\ ACH}$ = 2.23 K and $\Delta T_{surf\_mean,RCI,\ 0.7/7\ ACH}$ = 2.39 K. However, the mentioned increase in ΔT_{surf_mean} is most pronounced in the cases of LWC and RC_I constructions, which lack thermal mass on the internal side. The comparison between LWC (i.e. timber framed wall), RC_E and RC_I façade envelopes with and without the application of high intensity passive cooling demonstrated that, although passive cooling is beneficial in all cases, its absolute effectiveness on the indoor thermal conditions is, however, primarily still dependent on the selection of building envelope type. For example, observing Fig. 4 it can be seen that RC_E exhibits lower surface temperature fluctuations in both cases, whereas the maximum T_{surf} is always reached in the case of LWC, which is 33.3°C and 26.2°C without and with high intensity ventilation, respectively. This means that passive cooling was far more efficient in the case of RC_E than it was with LWC as well as RC_I façade walls, as a result of internally positioned thermal storage capacity in case of RC_E.

3.2. Influence of wall orientation on the internal temperatures

In the next stage of the analysis the influence of wall orientation was investigated for each of the three wall compositions using constant and high intensity ventilation mode. The main point of interest was to study how the combination of external temperatures and received solar radiation influences the internal surface temperatures with respect to the ventilation mode. Wall orientation as a variable was altered from east-northeast (i.e. azimuth = 75°) and west-northwest (i.e. azimuth = 285°) in steps of 15°. The results for each of the constructions are presented in Figs. 5–7.

The results in Fig. 5 represent variations of T_{surf} for RC_E wall construction as a function of orientation and ventilation regime. During the entire analysed period, the maximum T_{surf} in the case of RC_E with constant ventilation (i.e. 0.7 ACH) was reached at azimuth 255° and amounted to 33.5°C, while the minimum T_{surf} of 29.1°C was achieved at azimuth 75°. The mentioned orientations define the upper and lower boundary of a family of curves defining the extent of T_{surf} for all analysed orientations. The average difference between the upper and lower boundary of the defined envelope is 1.7 K. Moreover, several orientations presented in Fig. 5

give similar results. For instance, such orientations are western azimuths between 240° and 270° and east-southeast to south azimuths between 105° and 180°. In the case of RC_E with high intensity ventilation (0.7/7.0 ACH), the overall maximum and minimum T_{surf} of 25.3°C and 22.4°C are reached at different orientations of 240° and at azimuths between 90° and 150°, respectively. The average difference between the upper and the bottom line of a family of curves during the entire analysed period is 0.2 K. From the results presented in Fig. 5 it becomes evident that in the case of high intensity ventilation the impact of wall orientation is no longer significant.

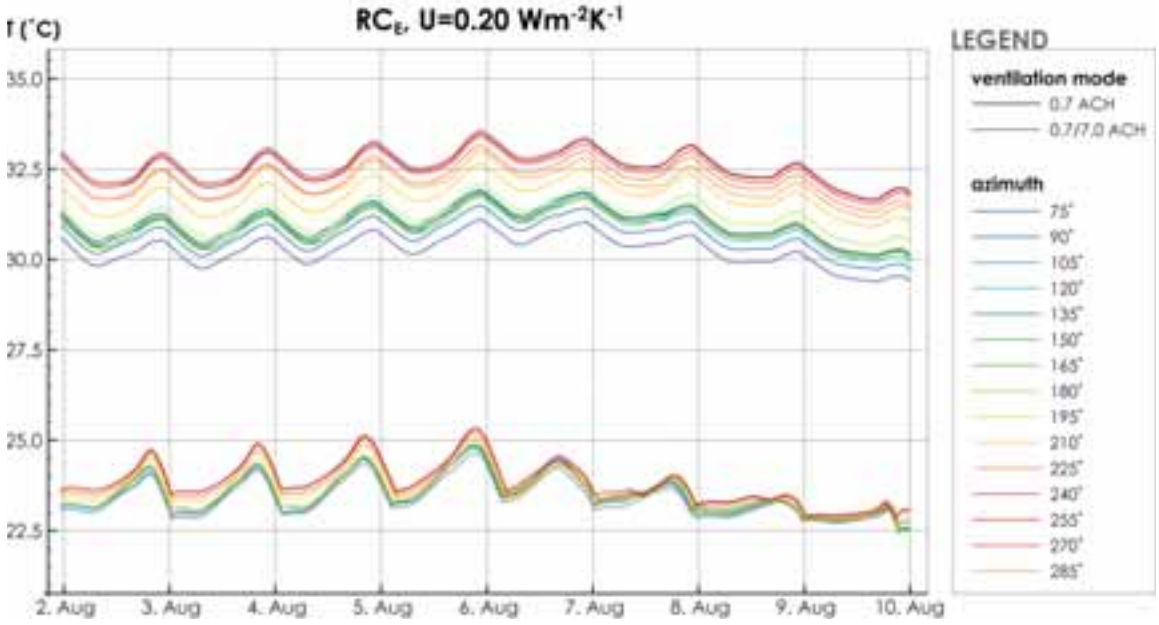

Fig. 5: Impact of wall orientation and ventilation mode (0.7 or 0.7/7.0 ACH) on the internal surface temperatures of RC_E with U value of 0.2 $Wm^{-2}K^{-1}$.

Fig. 6 shows the results for the RC_I construction, where variations of T_{surf} as a function of wall orientation and ventilation regime can be examined. During the entire analysed period, the maximum and minimum reached temperatures for RC_I in the case of constant ventilation (0.7 ACH) and at different orientations are 35.0°C (at azimuth 240°) and 27.1°C (at azimuth 75°), respectively. The average difference between the upper and the bottom line of a family of curves for RC_I during the entire analysed period is 2.0 K. In the same manner as it was observed in the case of RC_E, several orientations for RC_I construction presented in Fig. 6 give similar results. These orientations are again western azimuths between 240°and 270° (maximum T_{surf}) and eastern-southern azimuths between 105°and 180° (minimum T_{surf}). In the case of high intensity ventilation (0.7/7.0 ACH), the maximum and minimum reached temperatures at different orientations for RC_I are 26.6°C (at azimuths 240° and 270°) and 21.4°C (at azimuth 90°), respectively. The average difference between the upper and the bottom line of a family of curves is 0.4 K, effectively making orientation irrelevant when high intensity ventilation is used.

Finally, the results for the LWC wall construction are presented in Fig. 7, where variations of T_{surf} as a function of wall orientation and ventilation regime can be observed. During the entire analysed period, the maximum and minimum reached T_{surf} for LWC in the case of constant, 0.7 ACH ventilation and at different orientations are 35.1°C (at azimuth 255°) and 27.7°C (at azimuth 75°), respectively, while the average difference between the upper and the bottom line of a family of curves for LWC during the entire analysed period is 1.9 K. The same as in the cases of RC_E and RC_I, several orientations for LWC construction presented in Fig. 7 give similar results. These orientations are western azimuths between 240° and 255° and eastern-southeastern azimuths between 105° and 180°. In the case of high intensity ventilation (0.7/7.0 ACH), the maximum (i.e. 26.5°C) and minimum (i.e. 21.4°C) T_{surf} are reached at azimuths between 240° and 255° and at azimuth 105°, respectively, while the average difference between the upper and the bottom line of a family of curves is 0.3 K. Altogether, the results for LWC and RC_I are almost identical.

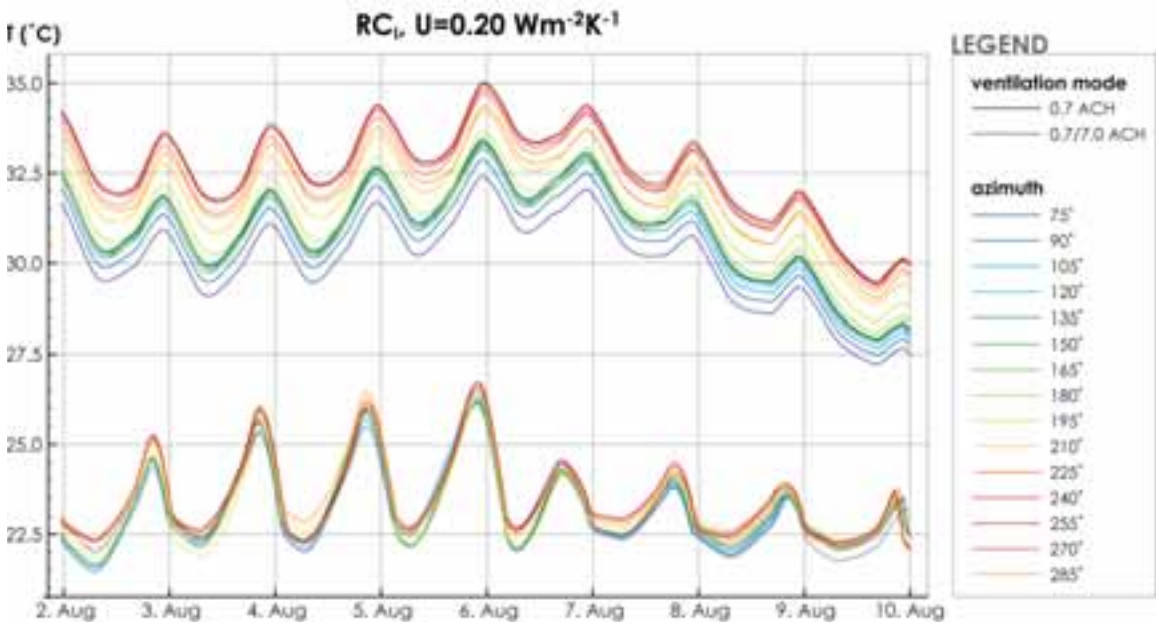

Fig. 6: Impact of wall orientation and ventilation mode (0.7 or 0.7/7.0 ACH) on the internal surface temperatures of RC_I with *U* value of 0.2 $Wm^{-2}K^{-1}$.

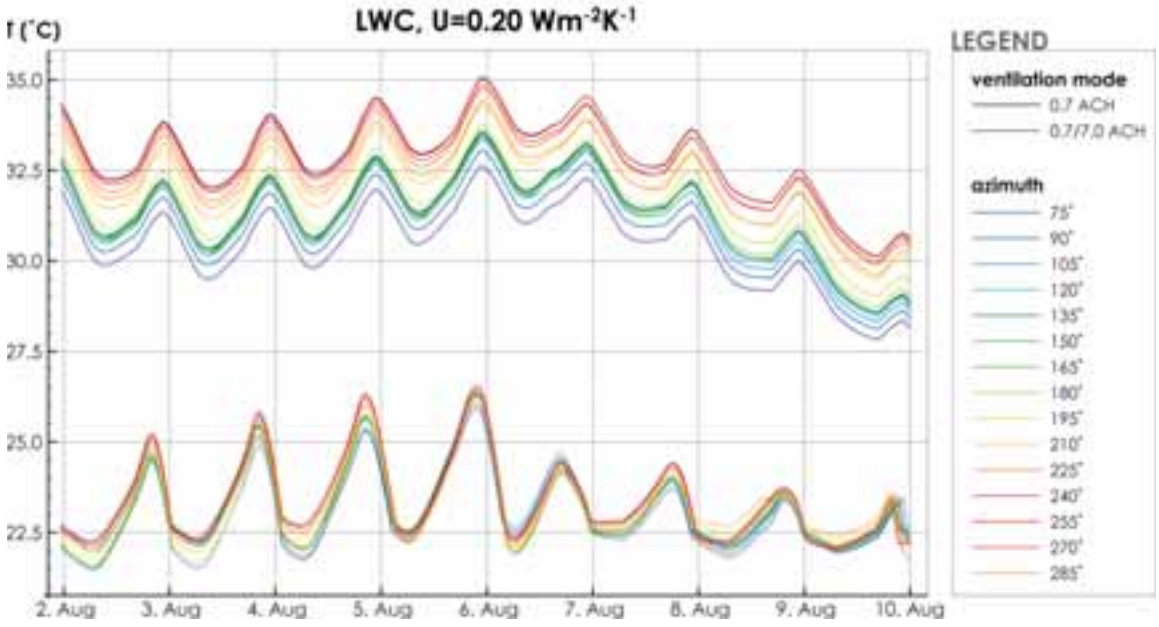

Fig. 7: Impact of wall orientation and ventilation mode (0.7 or 0.7/7.0 ACH) on the internal surface temperatures of LWC with *U* value of 0.2 $Wm^{-2}K^{-1}$.

The influence of wall orientation plays a role in performance of the analysed constructions as clear differences in internal surface temperatures can be identified at different orientations (Figs. 5–7). In general, for cases with constant natural ventilation (0.7 ACH), eastern orientations (i.e. azimuths 75–90°) exhibited up to 3 K lower T_{surf} in comparison to western oriented walls (i.e. azimuths 240–270°), while southern orientations fall between the two extremes. The orientation plays an insignificant role when high intensity passive cooling is used (Figs. 5–7) as average differences between minimum and maximum T_{surf} for all three analysed cases do not exceed 0.3 K, which is a tenfold reduction in comparison to constant ventilation mode. In general, the externally insulated wall with internally positioned thermal mass (i.e. RC_E) outperforms both lightweight (i.e. LWC) as well as internally insulated (i.e. RC_I) wall constructions in regards to their thermal response. Despite this fact, it should be stressed that constructions with higher thermal mass on the internal side cool down much slower when constant ventilation is applied. This effect can be observed if the results for RC_E and RC_I (or LWC) are

compared (Figs. 4–7) for the days from 8th till 10th of August. Such thermal behaviour is in this case unfavourable. However, if high intensity ventilation is used, the RC_E wall construction outperforms LWC and RCI even in this respect.

In the case of well insulated envelopes, solar gains through façade walls generally have moderate impact on the overall thermal performance. The results presented above were made for constructions with thermal transmittance of 0.2 $Wm^{-2}K^{-1}$. However, thermal response would be different if higher thermal transmittance of the wall was used, as was demonstrated by a study conducted by Corrado and Paduos (2016). Therefore, section 3.3 discusses this issue on the example of RC_E.

3.3. Discussion

Because the analyses presented in previous chapters were made with a fixed U value of 0.2 $Wm^{-2}K^{-1}$, it was of further interest to investigate how higher U value would influence the thermal response of the wall construction in regards to its orientation and ventilation mode. Therefore, an additional study was made with the RC_E wall construction, where its U value was set to 0.6 $Wm^{-2}K^{-1}$. The results presented in Fig. 8 are plotted as an envelope of a family of curves made for the wall orientations with azimuths between 75° and 285° for U values of 0.2 and 0.6 $Wm^{-2}K^{-1}$. The results in Fig. 8 show that wall orientation plays much greater role, when thermal transmittance of the construction is higher and even more so, if constant ventilation regime (i.e. 0.7 ACH) is used. In particular, the average difference between the upper and the bottom line of a family of curves for constant ventilation and U = 0.6 $Wm^{-2}K^{-1}$ is 3.3 K, while for U = 0.2 $Wm^{-2}K^{-1}$ this value is equal to 1.7 K. In the case of high intensity ventilation (i.e. 0.7/7.0 ACH) the average difference between the upper and the bottom line of a family of curves for U = 0.6 $Wm^{-2}K^{-1}$ is 0.8 K, while for U = 0.2 $Wm^{-2}K^{-1}$ this value is equal to 0.2 K. Comparing RC_E constructions in Fig. 8 at azimuth 180° (i.e. south) it can be said that in the case of constant ventilation higher U values of walls can results in lower T_{surf} and faster thermal response (e.g. the T_{surf} is reduced faster during the cooling down period from 8th to 10th of August). However, the situation is reversed when high intensity ventilation is used.

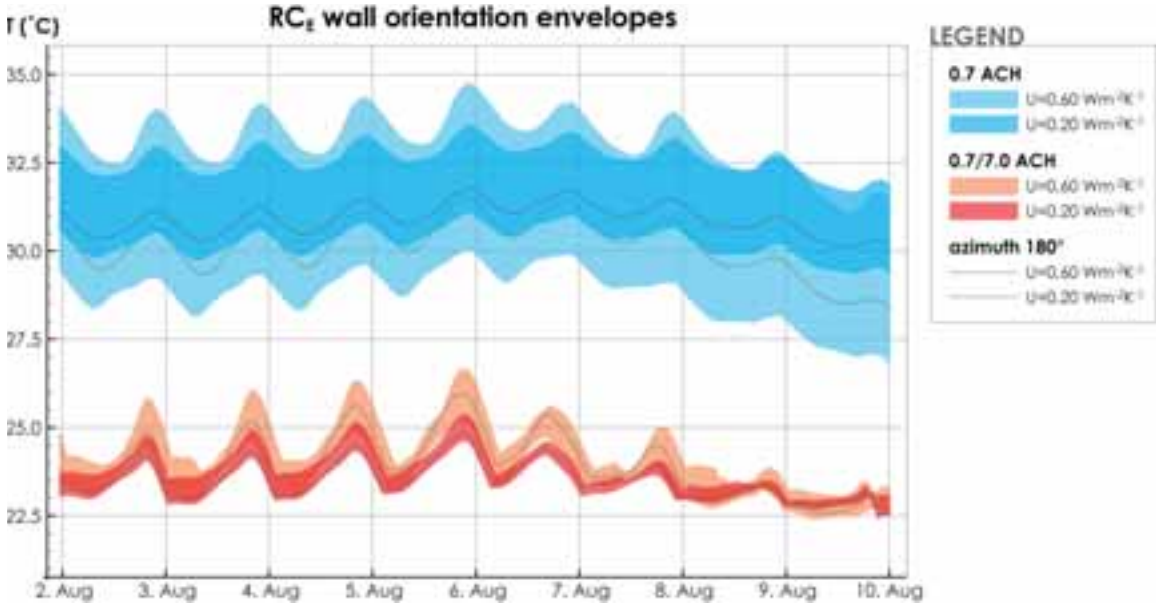

Fig. 8: Comparison of wall orientation envelopes of internal surface temperatures for RC_E at different ventilation modes (0.7 and 0.7/7.0 ACH) and different U values (0.60 and 0.20 $Wm^{-2}K^{-1}$).

Observing Fig. 8 it can be concluded that in temperate climate it would be better to use higher thermal transmittance of walls in order to better control indoor wall surface temperatures during summer. Conversely, buildings in such climate zones are mostly optimized for the winter conditions, thus having low or extremely low U values. The latter is also prescribed by the legislation. Therefore, high intensity cooling can play a vital role in enhancing the summer time thermal performance od wall constructions with low U values, as using it results in a better performing construction (i.e. lower T_{surf}) (Fig. 8). This specifically applies to all the considered orientations under the presumption that high intensity ventilation (passive cooling) is used.

The results of the conducted study showed that even in cases with low *U* values of the walls, orientation of the façade has an impact on the thermal response of non-transparent building envelope elements. In particular, substantial differences between east, south and west orientations were identified. Especially the south-west orientation of the façade was shown as extremely unfavourable in the case of LWC and RC_I. Although wall composition (especially thermal mass) and orientation play a role in the thermal response of the analysed façade walls, high intensity passive cooling proved as the most decisive factor, whereas the potential of diurnal temperature fluctuations is used to passively cool down buildings. Nevertheless, even here the effectiveness is linked to the configuration and type of the façade wall.

4. Conclusions

The trend of using lightweight building envelope components, especially in residential buildings, will probably continue during the forthcoming years (Kitek Kuzman et al., 2013). The biggest growth is expected in the market of timber framed and cross-laminated construction systems. Consequentially, the importance of assuring satisfactory thermal response of such envelope systems during summer conditions will become crucial. The latter is highlighted through the presented study as LWC external façade wall systems have been shown to exhibit inferior thermal performance in comparison to externally insulated heavy weight envelopes (HWCs). In the light of EU policies for the reduction of building stock's influence on the energy consumption and the decrease of environmental impact, it is crucial to develop and implement passive solutions for the reduction of cooling loads. Results of the conducted analysis show that lack of thermal mass in lightweight construction systems should be addressed. In addition, it was shown that, although both wall composition and orientation influence the thermal response of the façade envelope, the greatest effect can be achieved by using appropriate passive cooling ventilation technique. After all, prospective solutions can be found in applications of materials with high thermal storage potential and relatively small thickness in the form of interior cladding (Jeanjean et al., 2013). However, in this context the appropriate use of PCMs (Kheradmand et al., 2016) and/or other efficient enhancements of thermal performance of lightweight constructions (Pajek et al., 2017) can be a viable alternative as well. The findings of the conducted study can represent guidelines for design decisions when the objective is to design better performing buildings. Although each building is unique, set in its individual environmental context, the general performance principle of selected wall constructions remains the same.

Design, Development and Thermal Performance Analysis of Ultra-Low Heat Loss Triple Vacuum Glazing

Saim Memon[1], Philip C. Eames[2]

[1] London South Bank University, London (UK)

[2] Loughborough University, Loughborough (UK)

Abstract

Heat loss through windows of buildings is one of the significant causes of high-energy consumption that require intervention to advance their thermal performance in a move towards net-zero energy buildings. High-performance triple vacuum glazing features ultra-low heat loss that maintains the transparency, regardless of tiny pillar spots, and slimness due to its narrow evacuated cavities. This study reports the design and development of high-vacuum system with the modified vacuum cup which provides an effective pump-out hole sealing and has an achievable vacuum pressure of $4.02 \cdot 10^{-5}$ Pa. A new dual-edge seal (low temperature melt 186˚C) consists of Cerasolzer CS186 alloy as a main and J-B Weld epoxy steel adhesive as a support seal is developed and the triple vacuum glazing (area of 300·300mm) samples are fabricated, in which the vacuum pressure of 4.8×10^{-2} Pa is achieved. A 3D FEM of the fabricated triple vacuum glazed is developed and the centre-of-pane and overall U-value of 0.33$Wm^{-2}K^{-1}$ and 1.05 $Wm^{-2}K^{-1}$, respectively, are predicted.

Keywords: Smart Window, Vacuum Glazing, High-Vacuum System, Finite Element Modelling, Sustainable Building, Solar Energy, Energy Efficiency.

1. Introduction

An increase of global annual average surface temperature to 0.99˚C in 2016 (Lee et al, 2017) is due to the CO_2 level that reached 400 ppm, breaking the 1950's level threshold of 300 ppm (Andric et al, 2017). More than 30 % of the total global final energy consumption is in the building sector (Piccolo and Simone, 2015). Advanced insulation technologies and retrofitting measures have already minimized the building energy consumption but yet require more energy-efficient technologies that bring the building sector towards zero-carbon sustainable buildings (Memon and Eames, 2017). To achieve this, glazed windows are of particular interest in this paper specifically in cold arid climate. It's one thing a need of high visual light transmittance, above 70%, and reasonable solar heat gain coefficient, G-Value, range from 0.4 to 0.7 through glazed windows and another thing a significant heat loss through glazed windows. The heat loss through glazed windows is the result of the heat transfer by conduction, convection and radiation and is determined by the thermal transmittance value (U-value). Smart glazing technologies such as thermotropic glazing or double air-filled glazing have identical U-values of 2.7 $Wm^{-2}K^{-1}$ (Allen et al, 2017). A smart double glazing with low-e glass and a photochromic coated glass achieved a G-value of 0.26 and U-value of 1.58 $Wm^{-2}K^{-1}$ (Wu et al, 2017). Glazed windows with cavities filled with heavy gases (Argon, Krypton or Xenon) improves thermal performance from 3.5 to 1.4 $Wm^{-2}K^{-1}$, depends on the cavity thickness, e.g. the best predicted U-value of the Xenon-gas filled double glazing at the cavity width of 20mm was reported to be 1.4 $Wm^{-2}K^{-1}$ (Manz, 2008). Aerogel-gas filled double glazing made of granular aerogel sandwiched in a 16mm wide polymethyl methacrylate (PMMA) double skin-sheet and two 12mm layers of krypton gas between two glass sheets (total cavity thickness of 38 mm) achieved the best possible U-value of 0.5 $Wm^{-2}K^{-1}$ (Baetens et al, 2011). Due to its semi transparency, greater thickness than conventional glazing and high cost of aerogel materials, they were not deployed in the UK.

doi:10.18086/swc.2017.15.04 Available at http://proceedings.ises.org

Vacuum glazing has the potential to provide a clear transparent view except for tiny dots due to support pillars, narrow width of about 8.3 mm and the space between the two glass sheets is evacuated to a pressure of less than 0.1 Pa rather than including any medium or material (Memon, 2014). With vacuum glazing, the centre-of-pane U-value can be reduced down to 0.8 $Wm^{-2}K^{-1}$ (Eames, 2008) when evacuating the space between two low-e coated glass panes, e.g. tin-oxide coating emissivity of 0.15. A pressure of less than 0.1 Pa reduces gaseous conductive and convective heat transfer to a negligible level (except heat conduction through support pillars and edges) and radiative heat transfer can be reduced using soft low-e coatings, e.g. silver coating emissivity of 0.02. To reduce the U-value below 0.5 $Wm^{-2}K^{-1}$, a concept of triple vacuum glazing was reported by Wuethrich (2005). In this paper, the design, development, fabrication methods and U-value predictions of a new dual-edge sealed triple vacuum glazing are reported. A dual-edge seal is hermetic and it consists of Cerasolzer alloy CS186 as a main seal and J-B weld epoxy steel resin as a support seal (Memon et al, 2015). A triple vacuum glazing consists of three SnO_2 coated k-glass sheets, air-tight sealed around the edges, with evacuated two narrow (0.15mm high) cavities having a pressure of 0.01 Pa. A regular square array of stainless steel support pillars, typically 0.15mm high and 0.3mm diameter spaced at 24mm, maintains the separation of three glass sheets under the effects of atmospheric and vacuum pressure.

2. High-Vacuum System Design and Development

A high-vacuum system was designed for the fabrication of ultra-low heat loss triple vacuum glazing as shown in Fig. 1. A dry type turbo-molecular with backing pump with an achievable pressure of $5 \cdot 10^{-6}$Pa was chosen. This is because the vacuum pump should be of an oil free/dry type as the contamination in the oil type with oil molecules could occur on the surfaces of tubes, valves, hose and/or vacuum cup preventing an effective vacuum level from being achieved. A turbo-molecular vacuum pump has a pumping speed of 200-300litre/min. The ATV (Atmosphere to Vacuum) transducer type 979, connected to the PDR 900 digital pressure measurement readout, is used in the present study for the measurement of vacuum pressure in the designed vacuum system. This pressure gauge is located at the closest possible location to the vacuum cup to measure the approximate pressure in the cavity/cavities of the triple vacuum glazing as illustrated in Fig. 2. The ATV transducer enables measurement of a wide pressure range from ultrahigh vacuum ($1.33 \cdot 10^{-8}$ Pa) to atmospheric pressure ($101.33 \cdot 10^{3}$Pa). In order to regulate or isolate the gas load either from the vacuum pump or Nitrogen gas cylinder, a Swagelok adapter is assembled; angle valves were located at the two positions of U joint as shown in Fig. 1.

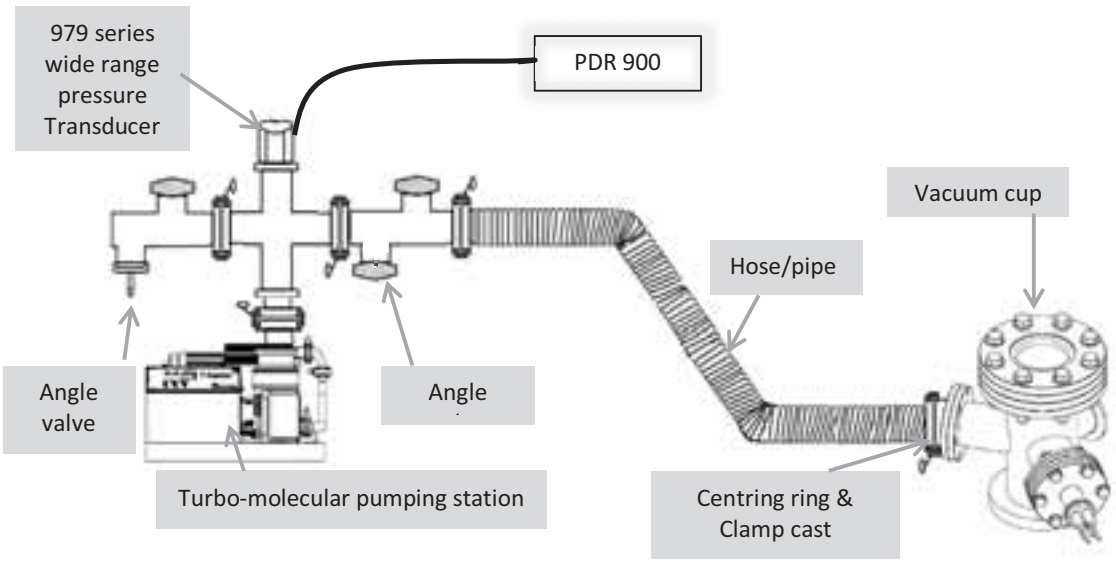

Fig. 1: A schematic diagram of the vacuum system showing the turbo-molecular pump connected via hose to the vacuum cup.

The laboratory vacuum glazing fabrication system developed as shown in Fig. 2. This is based on the design presented in Fig. 1. The vacuum system was experimentally tested and the minimum achievable vacuum pressure was recorded to be $4.35 \cdot 10^{-5}$ Pa. This deviates by 7.7% with the ultimate vacuum pressure of the turbo molecular pump due to the internal space conductance.

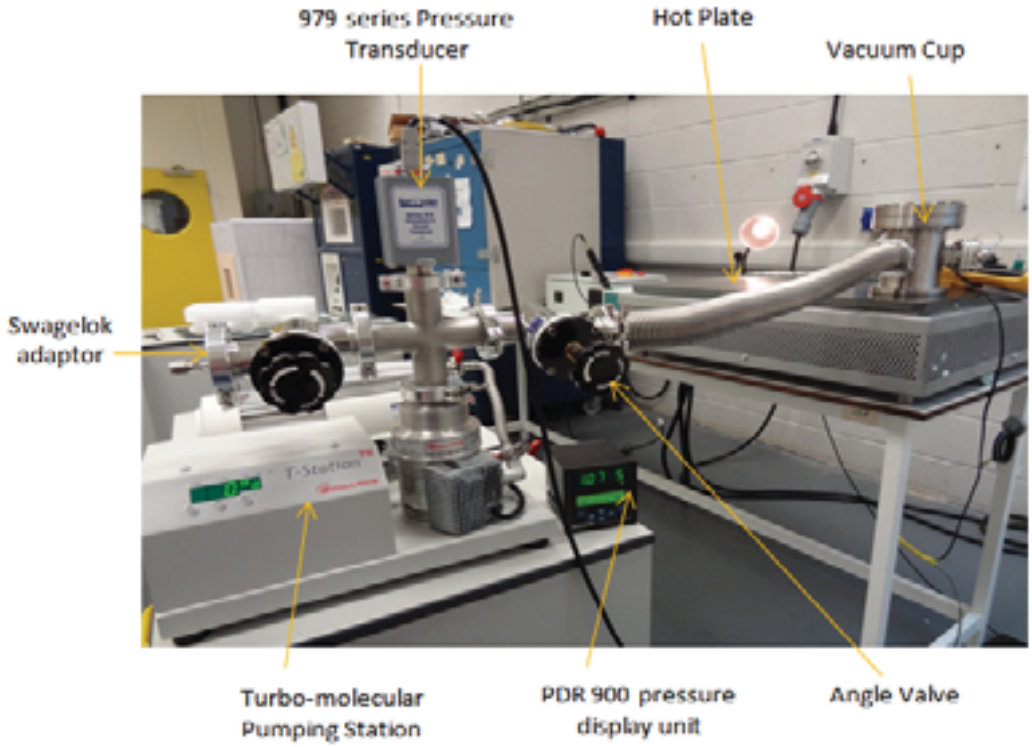

Fig. 2: A photograph of the vacuum system developed based on the design presented in Fig.1.

The vacuum cup was designed and constructed with dimensions of 100 mm diameter and 150 mm height for evacuation and pump-out hole sealing of the triple vacuum glazing as shown in Fig. 3. CF (conflat) metal seal flanges were used to provide an ultra-high vacuum (more than $1 \cdot 10^{-7}$Pa) seal between the two components. Only two CF flanges were used on the vacuum cup with an O ring seal on other joints. The modified pump-out mechanism, as illustrated in Fig. 3, requires a square cover slip (around 10·10mm) pre-soldered with Cerasolzer alloy (CS186) to be placed over the pump-out hole. Heating block, cartridge heater and thermocouple mounted on a metallic rod controlled through a supporting Y shaped block provides up and down motion of up to 10mm. A K type thermocouple fixed to the heating block measures the approximate glass disc/square temperature. Heat transfer at high vacuum occurs through both radiation and conduction due to the contact of the heating block over the glass disc. The required temperature should be approximately 40˚C more than the melting temperature of the pump-out sealing material to seal the pump-out hole. In this modified design, the risk of dislocation of the heating block and the degradation of O rings due to continuous heating in the vacuum cup was reduced. Different types of materials such as silicone, Buna-N, Teflon or Viton are available, among which the Viton type is capable of sustaining temperatures up to 250˚C. The Viton O ring decomposes at temperature above 250°C causing ingress of gas molecules from the atmosphere, to reduce this the O ring was selected to be around 100mm in diameter, placing the O ring sufficiently away from the heating element to avoid degradation.

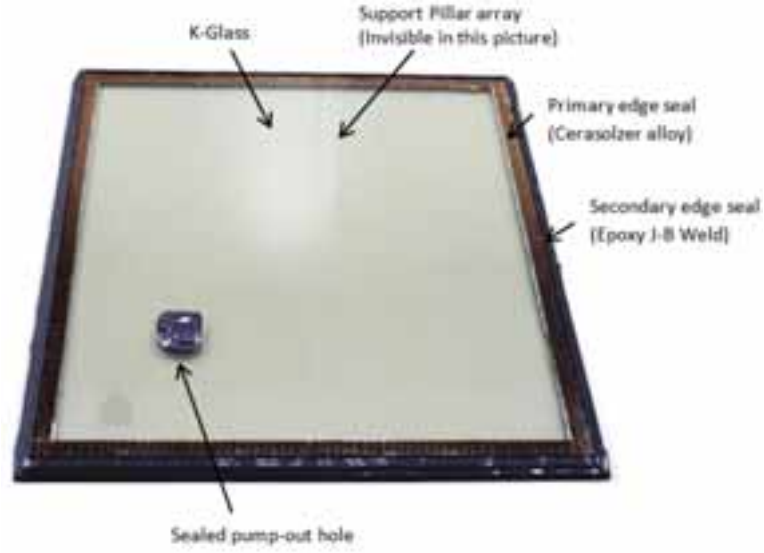
Fig. 3: Photographs of the vacuum cup system for the evacuation and sealing of the pump-out hole of a triple vacuum glazing.

3. Fabrication Method

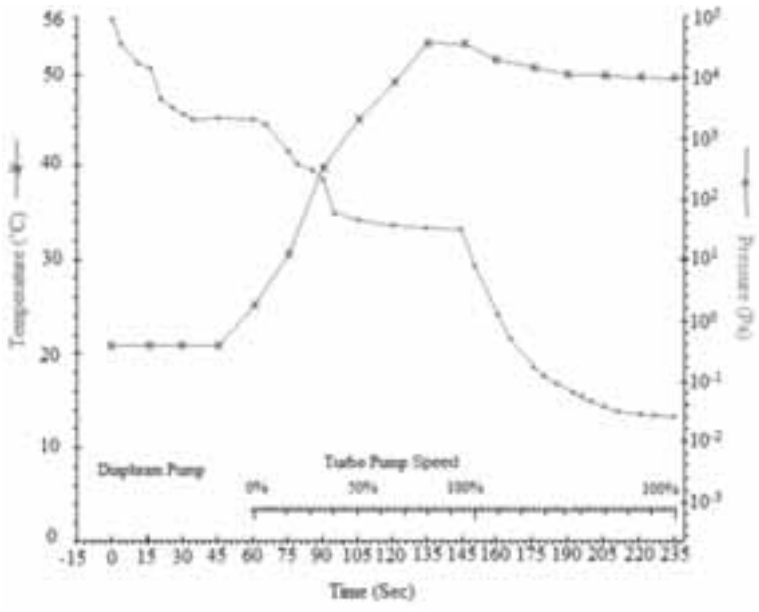
A multiple stage fabrication method was developed, in which a number of samples were fabricated by using a newly developed dual-edge (low melt-temperature i.e. 186˚C) seal. It consists of 10mm wide Cerasolzer CS186 as a main hermetic seal and a 4mm wide J-B Weld epoxy steel resin as a support seal. This is because, under temperature gradients and high internal compressive and external tensile stresses, such support seal provides mechanical strength to the main seal. The fabrication method developed is as follows: (a) the glass sheets and glass-square cover slip for pump-out hole sealing were prepared by drilling a pump-out hole on the upper glass sheet, cleaning all three glass sheets with water, isopropanol and acetone and shaping the glass-square cover slip (Zhao et al, 2007); (b) the main seal around the periphery of bottom and middle glass sheet and on the glass-square (18mmx18mm) was uniformly soldered; (c) the support pillars (0.15mm in height and 0.3mm in diameter) in the square array spaced at 24mm on the middle and lower glass sheets were placed (d) the three glass sheets were joined together by heating at 186˚C for up to 2 hours in the oven (e) the assembly was allowed to cool down to ambient temperature of around 21˚C followed by the use of epoxy J-B Weld to form the support seal (f) Two cavities between three hermetically sealed glass sheets were evacuated, using the high vacuum pump-out system, shown in Fig. 1; and (g) after the evacuation of ~ 6 hours at 50˚C the pump-out hole was sealed by heating the glass square using the cartridge heater located inside the vacuum cup pump-out assembly. The hot plate was used to maintain the narrow temperature gradients on the glass surfaces to avoid glass facture.

4. Experimental Results

A fabricated sample of size 300 mm·300 mm, shown in Fig. 2a, is a result after four repeated trials and the sealing characteristics were found similar where the stress patterns, due to internal compressive and external tensile stresses, across the support pillars were observed indicated a vacuum-tight seal. The evacuated pressure achieved was $4.8 \cdot 10^{-2}$ Pa when subjected to the hot-plate temperatures set to 50˚C as it improved the out-gassing and avoided any damage to the glass sheets due to temperature gradients. However, temperature control has significance as when it increases above 50˚C a high level of internal compressive stresses and external tensile stresses were observed that may cause a glass fracture. The evacuation pressure and hot plate temperature readings were recorded with respect to time at which the diaphragm and turbo-molecular pump achieves its ultimate pumping speed of up to 61 litres/sec as illustrated in Fig. 2b.



(a)



(b)

Fig. 2: (a) Fabricated dual-edge sealed triple vacuum glazing (300mm˙300mm) and (b) the evacuation pressure and hot plate temperature readings with respect to the increment of pumping speed with diaphragm to the full-load pumping speed with turbo-molecular pump.

5. Thermal Performance Predictions

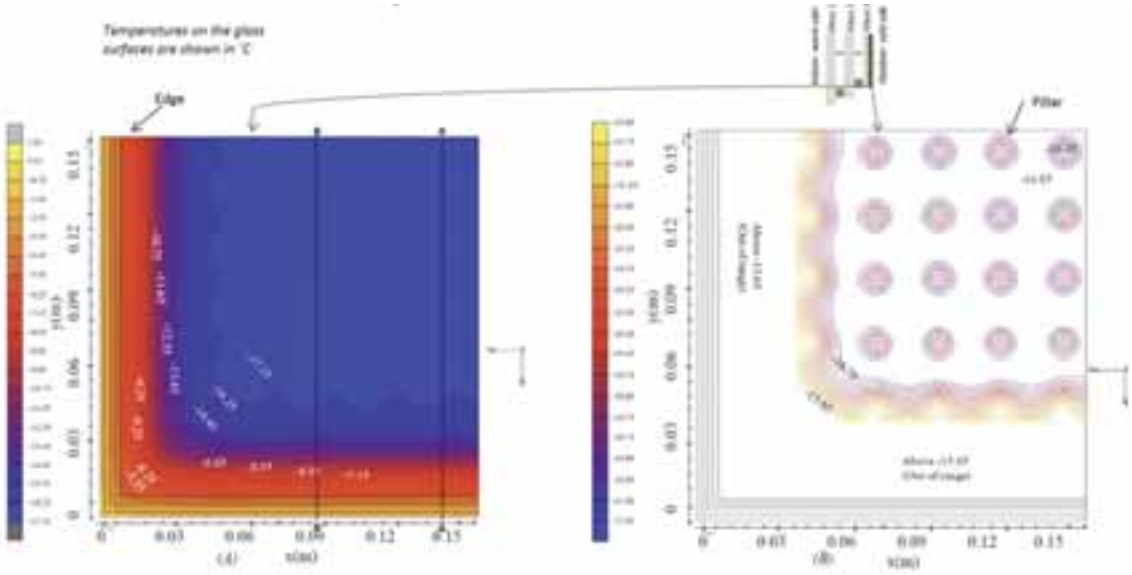
A 3D finite-element model was developed, initially reported in Memon et al (2015), to predict the thermal performance based on the achievable vacuum pressure of $4.8 \cdot 10^{-2}$ Pa of the fabricated sample of size 300 mm·300mm. In order to reduce the computational time, only one quarter (150 mm·150 mm) of the triple vacuum glazing sample was modelled and simulated. The ASTM weather indoor and outdoor boundary conditions were employed in which the indoor and outdoor surface air temperatures were set to be at 21.1˚C and -17.8˚C respectively in winter conditions. The internal and external surface heat transfer coefficients were set to 8.3 $Wm^{-2}K^{-1}$ and 30 $Wm^{-2}K^{-1}$ respectively. The total U value and centre-of-pane U value equations employed are expressed in eq. 1 and eq. 2.

$$U_{centre} = \frac{1}{Rsi_{centre} + \frac{A_{centre}(Ti_{centre} + To_{centre})}{Q_{centre}} + Rso_{centre}} \quad (eq.1)$$

$$U_{total} = \frac{1}{Rsi_{total} + \frac{A_{total}(Ti_{total} + To_{total})}{Q_{total}} + Rso_{total}} \quad (eq.2)$$

Where, Rsi and Rso are the indoor and outdoor glazing surface thermal resistances, in m^2KW^{-1}. A_{centre} (m^2) is the total glazing area minus the edge of glass areas (Fang *et al*, 2007). The thermal conductivity of Cerasolzer CS-186(Primary seal) and J-B Weld (secondary support seal) employed in the 3D finite element model are 46.49 $Wm^{-2}K^{-1}$ and 7.47 $Wm^{-2}K^{-1}$, respectively. The details of the experimental measurements of thermal conductivities of the edge sealing materials are reported elsewhere (Memon, 2017).

The centre-of-pane and overall U-value of 0.33 $Wm^{-2}K^{-1}$ and 1.05 $Wm^{-2}K^{-1}$ for the fabricated triple vacuum glazing sample were predicted at the evacuated pressure of $4.8 \cdot 10^{-2}$ Pa having three k glass sheets (thermal conductivity of each 4mm thick glass 1 $Wm^{-1}K^{-1}$) coated with SnO_2 layer on the inner glass surfaces (emissivity of 0.15). The G value was predicted to be 0.71. It was predicted in (Manz et al, 2006 and Fang et al, 2010) and demonstrated here that the glazing size, due to edge effects, influences the total U-value. A typical cold side isotherm of the model is shown in Fig 3a and the temperature distribution across support pillars is shown in Fig. 3b.



(a) (b)

Fig. 3: The isotherms on the cold glass surface illustrates (a) the temperature changes from the edge sightline towards the centre of glass and (b) the temperature changes around support pillars on the centre of glass area of the triple vacuum glazing.

6. Conclusions

The experimental testing results have shown the achievable vacuum pressure in the vacuum system to be $4.35 \cdot 10^{-5}$ Pa. This deviates by 7.7% with the ultimate vacuum pressure of the turbo molecular pump due to the molecular air flow conductances through the vacuum system. A vacuum cup designed to reduce the risk of dislocation of the heating block and the degradation of O rings due to continuous heating with the pump-out hole evacuation. The outcome of the design and development of high-vacuum system was the successful fabrication of ultra-low heat loss triple vacuum glazing with a pump-out hole sealing material using Cerasolzer CS-186. A new method of fabricating triple vacuum glazing based on a low melt temperature (186ºC) dual-edge seal was designed and experimentally validated, consisting of Cerasolzer CS186 alloy as a main seal and J-B Weld epoxy steel resin as a support seal. A vacuum pressure of $4.8 \cdot 10^{-2}$Pa was achieved. A 3D FEM of the fabricated design of triple vacuum glazing was developed in which the centre-of-pane and overall U-values of a triple vacuum glazing (300mm·300mm) were predicted to be 0.33$Wm^{-2}K^{-1}$ and 1.05 $Wm^{-2}K^{-1}$, respectively, based on three SnO_2 coated K-glass sheets, these results are in agreement with the preceding reported results. Triple vacuum glazing has the potential in future, if manufactured at the mass production level, because of its slimness (12.6 mm) compared to the conventional glazings and due to its lowest achievable thermal transmittance value.

Abstract

The development of modern nearly zero-energy buildings (NZEB) has become possible due to the combination of high quality architecture design and the addition of renewable energies (especially solar thermal and photovoltaic). The Renewable energies can cover all the energy consumption of the year. Solar thermal with Heat Pump and photovoltaic (PV) systems for buildings have been designed to achieve different values of the fraction of primary energy saving. The Flat Plate Collectors (FPC) for Solar Thermal (ST) and Solar Photovoltaic (PV) have to be used in order the system to have higher efficiency with zero energy consumption. 13 different combinations have been studied in order to obtain higher savings with minimum investment.

Keywords: Zero Energy Buildings, Solar Thermal, Photovoltaic, heat pump, combisystems,

1. Introduction

The Article 9 of the European Union Directive 2010/3 which was incorporated in Spanish legislation requires that by the 31st December 2020, all new constructions must be nearly zero-energy buildings. This requires a new concept and a big effort to be made by the construction sector, mainly engineers and architects.

Recently, increasing efficiency of the heat pumps for Heating, Cooling and Domestic Hot Water with decrease in electric PV costs have provided a new model: solar-electric heat pumps. The ST energy has lost installed power during the last few years against other technologies, like PV. The development of modern net zero-energy buildings (NZEB) has become possible not only through the progress made in new renewable energies and construction technologies and techniques, but as well it has also been significantly improved by the combination of heat pump and solar systems (Moià-Pol et alt 2012). There are some simulation programs that can be useful to simulate different combinations of technologies and make it easy to choose the best in each case in order to archive the highest efficiency and renewable energy usage. (fraction). Counting that a modern compression machine with an evaporator up to 7ºC (usually at Mediterranean weather), has a 3-5 Coefficient of Performance (COP), with a Seasonal Coefficient of Performance over 5, and according to the Directive 2010/31/EU it's considered to be similar to another kind of Renewable energy. The actual cost of thermal production with Heat Pump is similar to the Solar Thermal, depending on the working temperatures, refrigerant and quality of the machine (ASHRAE). In Mediterranean areas almost all the villa houses have a swimming pool, Heating Ventilation and Air Conditioning system for a higher comfort. Some of these houses need to warm the outdoor pool in order to extend the swimming period in autumn and spring months, which is translated into a higher energetic demand. This kind of houses according to the Spanish law (CTE) have to use waste energy or renewable energies for the heating system of Domestic Hot Water (DHW) and the pool. For this it´s necessary a bigger installed surface of solar collectors which will allow to take profit of the solar collectors all the year, with a low overheating. However, in order to avoid a big energy consumption, it´s necessary to insulate and cover the pool, and not use it during the coldest Mediterranean months (December, January and February), when the average temperature is lower than 10ºC. The energy of the solar collectors can be used to help the heating system.

2. Simulation and Results

The study case house has a built surface of 400 m^2, of which only 300 m^2 require heating and cooling: the simulation has been made supposing a need for simultaneous heating for 150 m^2 with Fan coils and Radiant system. The pool has a surface of 80m^2 with a volume of 120 m^3. There is a limitation of useful surface for the installation of Solar Collectors -only one roof of 160 m^2 is available. However we have to take into account shadows and the distance between the Solar Collectors which leave us with a useful surface of nearly 80 m^2. This limitation has been taken into account in all the scenarios. The PV system has been designed with monocrystalline panels equivalent to an efficiency of 166 W/m^2 (η =16,60 %) and the solar thermal with good Flat Plate Collectors (A_0 = 0,807, A_1= 3,075, A_2= 0,022) .

The FPC sends the excess of energy to the pool, increasing the set point temperature, and consequently extending the swimming season. In the investment cost there have only been considered the solar collectors, structure, pipes and cables, without storage tank, heat pump and batteries, in order to be able to compare without auxiliary systems or other necessary elements for the basic system. However, PVT system wasn't analyzed due to limited roof surface; the results showed that it was better to use PV and ST systems with higher efficiency. The cost of the PV in Spain for medium systems (5- 20 kWp) is about 1500 €/kWp (including installation work, cable, structure and inverter without storage), similar to other EU countries, like Germany and Italy (source EIA and REN21, 2016), with efficient solar panel (15 to 20%) the price in square meter will be near 300 €/m^2.

Solar Thermal cost varies greatly according to the installation peculiarities (distances, roof,..) and other factors (labor, components,..) . In Spain a pumped system of FPC can cost from 300 to 600 €/m^2 (including pipes, pump and control system). Apart from that we have to add the storage. For Spain a storage system between 50-180 L/m^2 is recommended. Pumped systems until 6 m^2 are very expensive with the thermosiphon being cheaper. For larger systems the bigger the surface the cheaper are the prices per square meter.

The best scenario is a combination between Solar Thermal and Photovoltaic: in our case between 12-16 m^2 of FPC will provide the 16% of all the thermal energy, with almost 100% of the DHW and 31% of the pool and heating system. The PV will provide a 70% of the electricity for the heat pump. PV system has a peak power near 9-11 kWp in order to provide the electricity for the HVAC and use the excess for the rest of the

consumption. The FPC has a surface of 16 m^2 and the PV of 58 m^2, almost four times bigger.

The designers are working in two scenarios: the first one connected to the grid with batteries and the other a grid system without batteries in order to have the maximum energy production and less CO_2 emissions. The batteries increase a 33% the cost of the PV system (Gallo et al. 2014). Solar thermal technology has to be designed with storage and the advantage in Spain is that PV doesn't need storage, the excess can go to the grid free or with a low charge. For this reason the storage is a better option which offers higher savings.

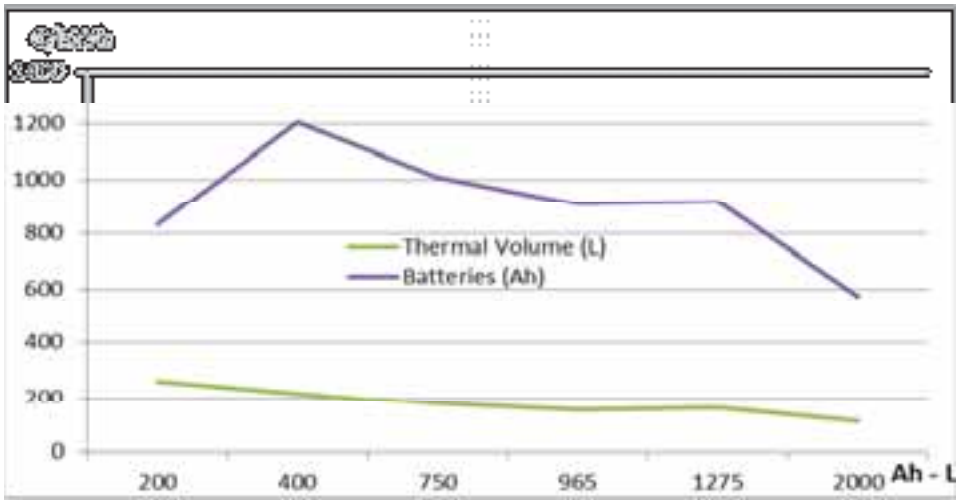

Fig. 2: Cost of Energy Storage Batteries vs. Thermal Storage water (Spanish prices from local suppliers)

In our case, it´s better to increase the storage with thermal energy (water tanks and pool) and install a few batteries in order to increase the self-consumption: the installation cost is 5 times cheaper. Grid parity has been achieved in Spain and the integration of PV systems in nearly ZEB is feasible today (Gallo et alt 2014). The system doesn´t overheat or waste electricity if we provide a good control system. The available roof limits the solar fraction so for higher solar fraction we need a bigger surface or most efficient heat pumps, for instance shallow geothermal or other combinations could be 100% with renewable energies. The PV has a better perspective, for two reasons: the simplicity of systems and the possibility to share the punctual excess (some days or months) to the grid with the net metering policies. Figure 3 has the results of 13 combinations and two different qualities of FPC and PV, Invest (high quality-first brand) and Invest 2 (lower quality-second brand). The Invest and savings are higher when we use the best quality brands. The efficiency of the solar system is the main difference, the initial investment has an average of 18% of difference and the savings are nearly a 47%.

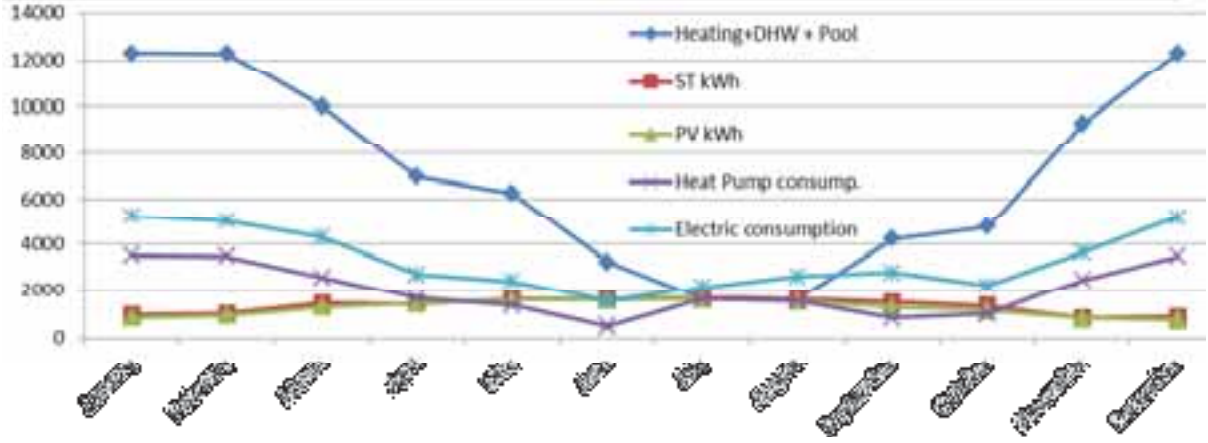

Fig.4: Annual energy simulated results in Final energy [kWh]

The total investment is less than a 5% of the total cost of the villa, which is technically and economically feasible so as to arrive to almost zero energy buildings.

3. Conclusions

The two solar technologies, Photovoltaic and Solar Thermal, are necessary for NZEB from a technical and an economic point of view. The investment cost and savings are better according to the monthly demand. In these cases the best scenario is 14 m^2 of Solar Thermal and 9 kWp of Photovoltaic. Limited space for solar systems make it necessary to use more efficient systems, however with a good control strategy, batteries and overheating systems are not necessary.

Simulation and Monitoring Results of two MFHs in PH Standard with Heat Pump, Solar Thermal and PV

Fabian Ochs[1], Georgios Dermentzis[1], Alexandra Ksiezyk[1]

[1] University of Innsbruck, Unit Energy Efficient Buildings, Innsbruck

Abstract

In the city of Innsbruck, the project Vögelebichl of the social housing company Neue Heimat Tirol (NHT), consists of two multi-family houses (MFH) in Passive House (PH) Standard and aims at operation with minimum CO_2 emissions for heating and domestic hot water (DHW) preparation. Net zero energy building (NZEB) was the goal of NHT for this project. The heat emission system, a floor heating with very low flow temperature, together with very well insulated heat distribution network allows a high performance of the ground water sourced heat pump (HP). The separate DHW distribution with flat-wise fresh water preparation is also designed for minimum possible flow temperature. DHW preparation is covered by solar thermal (ST) to a large extend. The electricity demand of the HP should be covered as much as possible by on-site PV. The optimum configuration of ST and PV with respect to energetic and economic performance was determined by means of simulation in a previous study Ochs et al. 2014. This paper presents the technical details of the two MFHs, the hydraulic concept and monitoring results after the first two years of operation, and a monthly primary energy evaluation.

Keywords: nearly zero energy building, Passive House, Multi-Family House, Heat Pump Solar Thermal, PV

1. Introduction

1.1 EPBD - Heat pump and PV for nZEBs

The recast of the European building directive (EPBD Recast, 2010) defined the path to nearly zero energy buildings (nZEB). Three aspects are addressed:

- New buildings will have a very high energy performance.
- The remaining very low energy demand will be provided to a very significant share by renewable energies and
- Cost-optimal levels for minimum energy performance are requested.

Hence, the aim of the EPBD recast is the minimization of the residual energy demand and achieving maximum reduction of CO_2-emissions considering economics. Hence, future buildings should have a very high-energy performance, such as Passive Houses and should be operated with a heat pump together with significant amount of energy from cost-effective renewable energy sources (PV and/or solar thermal).

However, the implementation of the EPBD in the member countries is far less ambitious (see BPIE 2016). The more important is it to demonstrate best practice examples and highlight non-renewable primary energy and CO_2-savings.

A dominating concept to reach the zero energy balance over an annual period for a nearly Zero Energy Building (nZEB) is the combination of solar PV systems and heat pumps. In the IEA HPT Annex 49, a follow-up of the Annex 40 heat pump integration options for nZEBs are investigated as well as the design and control for heat pumps in nZEB and the integration into energy systems. Solar thermal can be relevant as it is technically and economically less challenging to store heat compared to storage of electricity. Storage is relevant in order to reduce the remaining electricity usage in winter, which has generally a higher fossil (and/or nuclear) share. Hence, nZEBs should be evaluated considering the time of electricity usage from the grid.

doi:10.18086/swc.2017.15.06 Available at http://proceedings.ises.org

1.2 nZEB vs. NZEB

The goal of both, nZEBs and NZEBs are comparable in the sense that CO_2-emissions and non-RE primary energy use shall be minimized, nevertheless, the definitions differ quite much in detail and the performance might be quite different eventually.

nZEB: nearly zero Energy Building according to EPBD, 2010, see above. Each member state has a national definition, with significant differences with respect to the energy use considered (heating, cooling, DHW, auxiliary, appliances), the maximum limits, the conversion factors etc. (see BPIE, 2016).

NZEB: Net Zero Energy Building, generally a NZEB is a "grid-connected building which produces the same amount of energy on-site by renewable energy sources as it consumes on annual basis." (IEA SHC Task 40, IEA HPT Annex 40). There is a fuzziness in this definition regarding the interpretation of the system boundary, the energy flows, the weighting/conversion factors etc.

Usually, Net Zero includes

- Heating (and cooling)
- DHW
- aux. energies (MVHR, pumps, control, etc.)

but excludes appliances. Even though appliances, have a large contribution to the overall electricity consumption (1500 kWh/a to 4500 kWh/a depending on the number of persons per household for a typical central European household, Statistik Austria 2016, BEDW 2013).

According to this definition, a NZEB can consume relative high amount of (electric) energy in winter, when correspondingly a large PV area produces this amount as excess electricity in summer. This means, that according to the NZEB concept, the electric grid is considered as a loss free seasonal storage, which is obviously not the case. In order to account for this weakness in this concept, additional performance indicators such as the load match factor or fraction of PV own consumption are suggested.

Remark: „net-zero“ as a goal can be a misleading concept, anyway as optimization for net-zero may lead to one storey buildings, because reaching the net zero balance is more difficult compared to a multi-storey building (with smaller roof and façade area related to treated area). However, MFHs, which are more compact, are favorable from the overall energetic and macro-economic point of view, compare also Feist et al. 2014.

1.3 Monthly primary energy values

A possible approach of balancing primary energy demand and CO_2 emissions of a building with renewable energy generation is shown schematically in Fig. 1.Solar thermal (ST) energy is used to reduce the energy demand (heating, DHW + storage and distribution losses) that has to be covered by e.g. a heat pump (HP). Onsite PV can be used directly for appliances and auxiliary energies or to drive the HP, for higher own consumption a battery storage is required, which is subject to losses.

For the electricity mix, the share of renewables within the time frame of consideration (e.g. 20 years) should be included and not as usually done the current or past status. A significantly increased share of renewable electricity can be expected in the near future in particular in summer (PV), while in winter only a moderate increase is likely (further extension of wind power) unless seasonal storage capacities are strongly build up.

If a large number of buildings use heat pumps (and ST) for space heating and DHW preparation and produce electricity (with PV), both, the purchased electric energy and the share of renewables in the electricity mix and thus the CO_2 conversion factor of the electricity are dependent. Electricity that is used on site is not available in the grid and an increased share of fossil fuels in the energy mix have to be considered. PV electricity sold to the grid will replace fossil fuels more likely in winter, spring and autumn than in summer.

Heating and DHW preparation do not yet contribute significantly to the electric grid load in central European countries such as Germany and Austria (electric heating and heat pumps have a share in the range of 5 %, BEDW 2013, Statistik Austria, 2016)

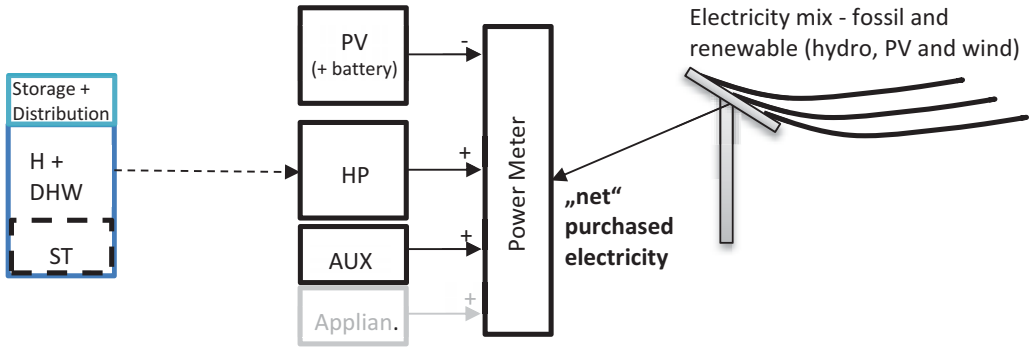

Fig. 1. One of different possible approaches for the energy balance for the calculation of the net energy balance with Heating (H) and domestic hot water (DHW) demand covered partly by ST; the remaining demand is covered by a heat pump (HP), which is partly powered by onsite PV, the remaining electricity demand for the HP auxiliary energies (and appliances) is covered by the grid with volatile shares of renewable electricity

Due to the volatile share of renewable energy in the grid (see e.g. the energy balance for Germany in 2015 (e.g. data from ENTSO-E), a net energy balance to evaluate different efficiency and energy concepts can be misleading.

National conversion factors for PE/CO_2 are not purely based on facts, but are partly politically motivated. They differ significantly between the EU member states and are subject to change, e.g. Germany (ENeV) 1.8 since 2016 (2.4 before), Austria 1.91 since 2015, 2.62 before (OIB-6, 2015, (OIB-6, 2011). Seasonal variations are not considered at all. Instead, a monthly evaluation based on monthly primary energy factors is proposed, which can be used to calculate a more representative environmental impact. The specific primary energy e_{PE} is

$$e_{PE} = f_{PE} \cdot w_{el} \qquad \text{(eq. 1)}$$

With different shares of hydro, wind, PV and fossil energy the primary energy conversion factor can be calculated on monthly basis.

$$f_{PE} = f_{PE,hyd.} \cdot \frac{w_{el,hyd.}}{w_{el}} + f_{PE,wind} \cdot \frac{w_{el,wind}}{w_{el}} + f_{PE,PV} \cdot \frac{w_{el,PV}}{w_{el}} + f_{PE,fos.} \cdot \frac{w_{el,fos.}}{w_{el}} \qquad \text{(eq. 2)}$$

Tab. 1: Monthly primary energy factors calculated exemplarily for two cases, A: a share of 10 % hydro, 10 % wind and 10 % PV, and the load of a PH with a HP for heating and DHW preparation as shown in Fig. 2 and B a share of 10 % hydro, 10 % wind and 10 % PV; $f_{PEhyd.}$ = 0.01 kWh_{PE}/kWh_{el}; f_{PEwind} = 0.05 kWh_{PE}/kWh_{el}; f_{PEPV}= 0.1 kWh_{PE}/kWh_{el}; $f_{PEfos.}$ = 2.4 kWh_{PE}/kWh_{el}

2. NZEB Project NHT Vögelebichl in Innsbruck

For the Passive House project Vögelebichl in Innsbruck (two multi-family houses with together 26 flats of the social housing company NHT see Fig. 3 and Fig. 4) the optimum share of PV and Solar Thermal (ST) was determined for the given boundary conditions. One roof of the multi-family houses is covered by PV (16 KWp) only. The other roof space was partly used for PV and partly for solar thermal (ST). The primary energy demand was determined for different shares of solar thermal collectors with regard to the maximum available unshaded roof space. For the optimal performance of the ground water heat pump a low temperature distribution system (floor heating) and separate DHW loop with decentral heat exchanger was proposed. Compared to the 2-pipe system, the 4-pipe system allows better performance of the HP and offers the possibility for some cooling in summer. Instead of the initially proposed 4 pipe system a 3 pipe system with common return pipe of the DHW and the heating loop was installed.

By means of a simulation study the share of PV (max 19 KWp) and solar thermal collectors (ST) was varied in order to determine the maximum possible energy yield considering PV and ST system efficiencies including heat pump performance and distribution losses. The optimal design (from energetic point of view) was found to be 74 m² ST and correspondingly 53 m² PV on the north roof, see Ochs et al. 2014.

Tab. 2: Characteristic data of the two buildings NHT Vögelebichl (as planed)

	North	South
No. of Flats	16	10
Treated area	1269.8 m²	818.8 m²
Heating Demand (PHPP)	13.5 kWh/(m² a)	17.0 kWh/(m² a)
Heating Load (PHPP)	12.0 W/m²	13.9 W/m²
PV size	8.5 kWp	16 kWp
ST area	50 m² (ca. 35 % of roof area)	-

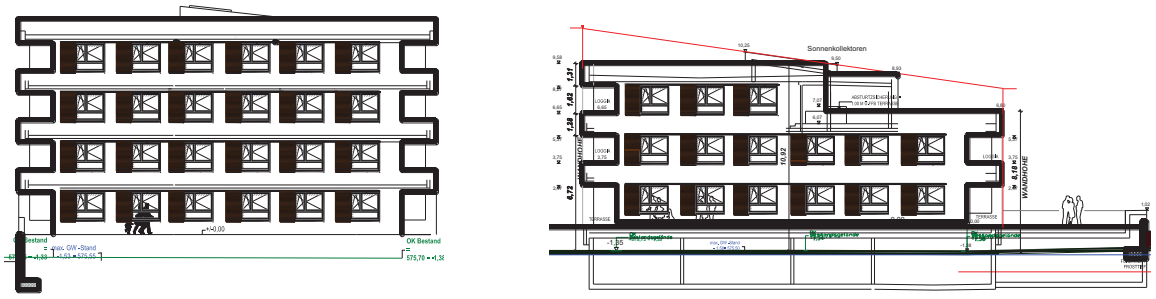

Fig. 3. West view of the two multi-family houses in Innsbruck Vögelebichl, NHT Tirol; two multi-Family PHs with ground water heat pump and PV (and opt. ST for DHW) with 4 pipe distribution system, low temperature system and fresh water modules in each flat

Fig. 4: Photos of the two MFHs in PH Standard (source: NHT)

During the final design process and the construction of the two buildings, some parameters changed with respect to the original planning. The treated area is 1295.6 m² (North) + 853.2 m² (South). The ST area is 73.6 m² (North) and the PV area is 52.5 m² (North) + 99.8 m² (South). The floor heating flow temperature is 30 °C (30/26 °C instead of 28/24 °C) and DHW flow temperature is 55 °C. A 3-pipe system (common return flow of floor heating and DHW) was realized (instead of the proposed 4-pipe system).

Fig. 5 shows a simplified hydraulic scheme including the GW heat pump (two stage), solar thermal collector field (SC) as well as the low temperature heat distribution and the separate decentral fresh water preparation (DHW plate HX). The double stage heat pump is equipped with a hydraulic circuit enabling hot gas (HG) de-superheating. Depending on the operation mode (heating or DHW preparation), the flow of the heat pump enters the buffer store (BS) at the top or at 1/3 of the height from the top. The combined return of the heating and DHW loop enters the large 6 m³ buffer store depending on the temperature level either at the bottom or at about 1/3 of the height of the store in order to enhance stratification. The electric backup heater (BH) is currently not used.

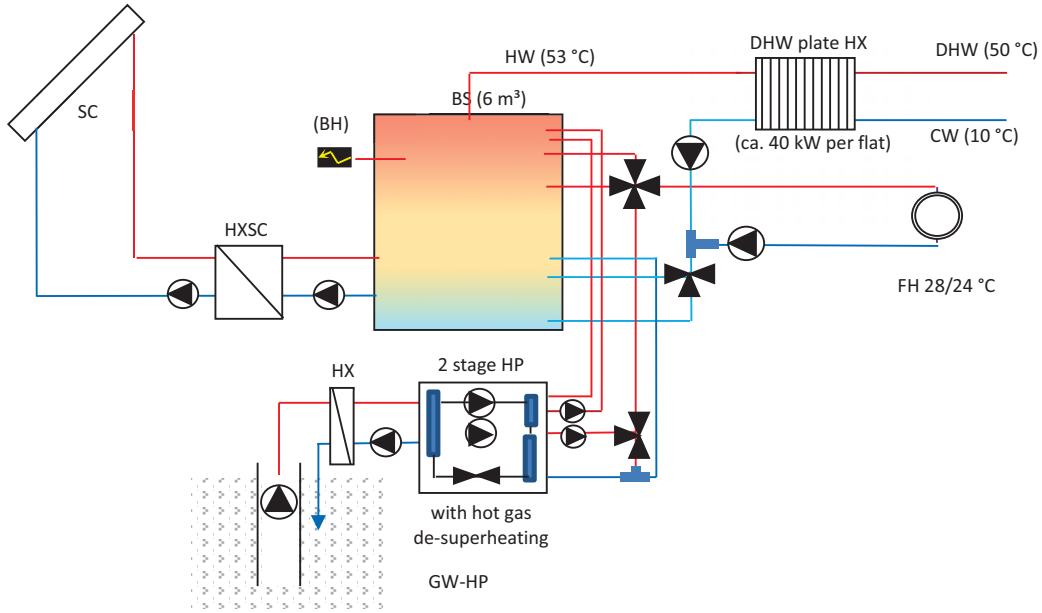

Fig. 5: Simplified Hydraulic Scheme with Solar Collectors (SC), Buffer Store (BS), 2-stage ground water heat pump (HP) with hot gas HG) de-superheating in heating mode with floor heating (FH) and decentral heat exchanger (HX) for domestic hot water (DHW) preparation

3. Monitoring Results

3.1 Climate

The climate during the monitoring period was rather typical. However, there was a relative cold January in 2017. The other months were in the range of average years. During the heating period in average the measured ambient temperature was 2.6 K higher than the design climate used in PHPP. The measured global horizontal solar radiation was with 1192 kWh/(m² a) very close to the design values.

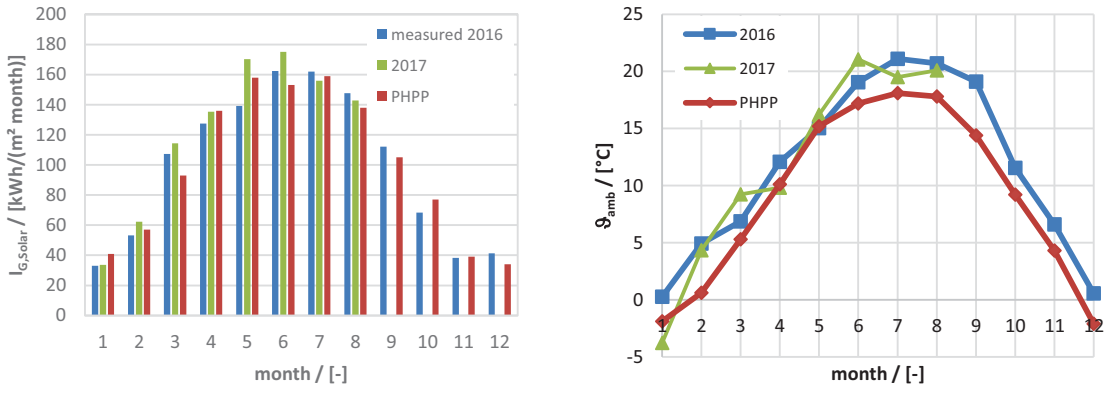

Fig. 6: Measured and design (PHPP) global horizontal solar radiation (left) and ambient temperatures (right)

3.2 Indoor Temperatures

The monitoring system is connected to the building management system (BMS), data of every relevant flow and return temperature, mass flow and energy flow is stored every 15 min. In addition, the temperature is recorded in each flat of the south building. The average temperature of the north building can be estimated by comparing the

measured extract air temperature of the south and the north building. The monthly temperatures are reported in the following figure:

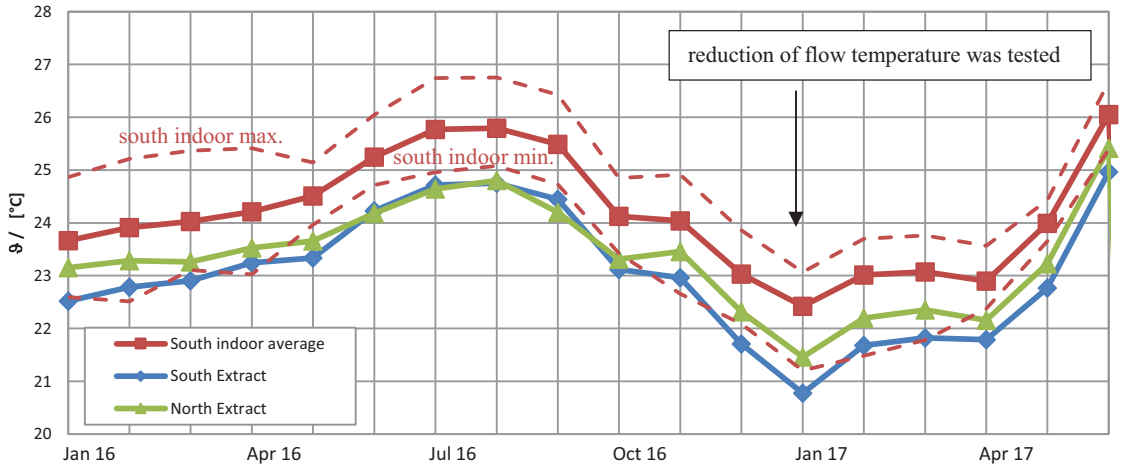

Fig. 7: Measured average, max. and min. indoor temperatures of 9 (of 10) flats of the south building and the corresponding extract air temperature as well as the extract air temperature of the north building

By comparing the average south building temperature and the extract air temperature of the south building and seeing that the extract air temperature of the north building is in winter about 0.5 K higher than the extract air of the south building, it can be expected that the average indoor temperatures were also slightly higher in the north building. In winter 2017, the average indoor temperature of the south building was in the range of 23 °C, while it can be expected that the temperature of the north building was in the range of 23.5 °C, which is 3.5 K higher than the design value. The difference between maximum and minimum indoor temperature of the flats of the south building was reduced significantly in the second winter (with 1.1 K compared to 2.4 in the first months).

In early winter 2017 (month 13 in Fig.7) the flow temperature of the floor heating system was reduced in order to reduce distribution losses. However, at least this sudden change in the indoor temperature together with the fact that January 2017 was a very cold month (average temperature -3.8 °C) was not accepted by most of the tenants and as consequence the flow temperature had to be increased again. It remains an open question, whether a smoother change of the temperature would have been recognized or not.

3.3 Energy Balance

The thermal energy balance for both buildings is shown in Fig. 8 for 2016. The HD for both buildings is with 31.1 kWh/(m² a) higher than design value of 12.2 kWh/(m² a) acc. to PHPP calculations (14 kWh/(m² a) for the south (853.2 m²) and 11 kWh/(m² a) for the north (1295.6 m²) building).

The main reason for an increased heating demand in the first year of operation is usually the construction moisture. Hence, it can be expected that the average annual heating demand decreases with respect to the first year of operation and will settle within the second year. In addition, the influence of the actual climate (compared to the reference climate) and the elevated indoor temperatures have to be considered. Furthermore, deviations from design values might be caused by the user (window ventilation, shading, occupation, equipment). Finally, the actual construction could differ from the design in terms of air-tightness, thermal bridges etc., but this can be practically excluded as the principles of Passive House design were followed and quality control such as blower door tests was conducted.

It is obvious that during the first winter of operation of such a building, there are effects that should be considered with care and general conclusions should be avoided. A HD closer to the design value can be expected for the next winter season, which is already indicated by the significantly lower HD in winter 16/17 than winter 15/16.

The domestic hot water demand (DHW) was with 24.7 kWh/(m² a) slightly higher than the design value, distribution losses are included and cannot be quantified by the available measurement equipment. Storage losses can be determined by energy balancing of measured heat flows from HP, ST, DHW and heating, and were relatively high: 1030 kWh/month in average throughout the measurement period, which is about a factor of three higher than expected even when a storage with relative poor insulation is assumed.

ST covers summer load including losses, so there is (theoretically) no need for HP operation in summer and PV electricity production can only be used for auxiliary energies and appliances (theoretically).

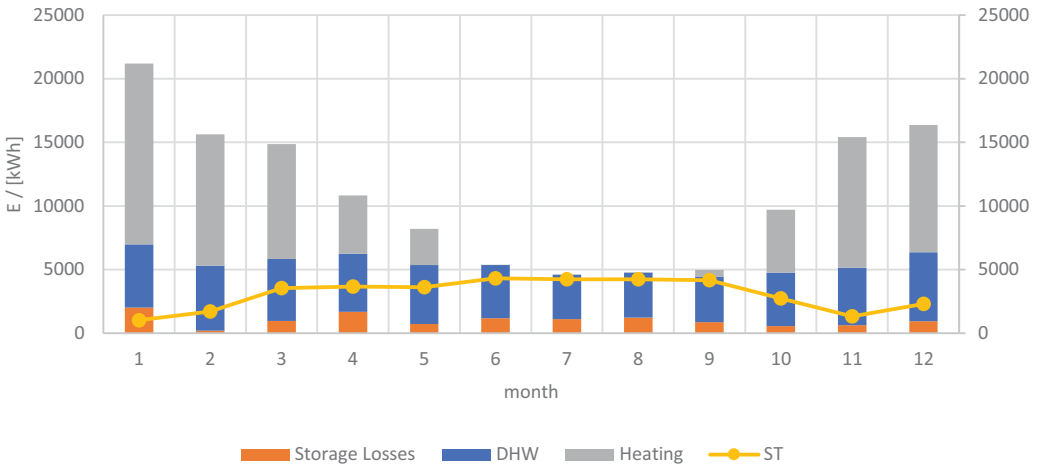

Fig. 8: Thermal energy balance (year 2016), DHW and heating is measured at storage outlet and this includes distribution losses

3.4 Heat Pump Performances

The performance of the ground water heat pump was with an SCOP of 2.9 poorer than expected. HP operation was not optimal for several reasons: heating and DHW flow/return temperatures were higher than planned. The two-stage compressor HP with de-superheating was operated mainly in DHW mode in the first winter. De-superheating contributed with 17 % to the total energy delivered by the HP. Storage stratification was poor in some operation modes and storage (and pipe) losses were too high. The ground water pump (well) was slightly over-dimensioned. Thermal losses of the HP were 16 % in winter and the HP was operated in summer without significant contribution (because of high contribution of ST, see above). The control of the HP and the system was optimized during summer 2016 and in winter 2016/2017 the COP could be increased to 3.4. Further system optimization is possible and an improved sCOP can be expected for 2017.

The average monthly temperature deceases from spring/autumn towards winter because of the higher share of operation in heating mode with flow temperatures of about 35 °C compared to the higher temperatures in DHW mode, see Tab. 3. The calculated monthly average COPs follow the trend of the measured COPs (based on values of 2017) but there is an offset of about 0.7 in average. This remaining difference between the calculation and the measurement can be explained by thermal losses and by the auxiliary electricity demand of the circulation pumps and the well pump and the temperature drop in the heat exchanger. An average COP of 3.6 to 3.7 can be expected based on the calculated values, while from the measurements an average COP of not more than 3.3 to 3.4 can be expected.

Tab. 3: Measured monthly COP in the heating season vs. calculated with Carnot performance factor of 0.5 acc. to data sheet; DHW mode in Mar. and Oct. with 60 °C, 50 % heating and 50 % DHW mode in Jan. and Dec.

	Jan	Feb	Mar	…	Oct	Nov	Dec
Meas. 2016	2.8	2.7	2.9		3.1	3.4	3.4
Meas. 2017	3.7	3.1	2.6				
Calc.	3.9	3.5	3.1		3.5	3.7	4.0
ϑ_{cold}	9	8	7		12	11	10
ϑ_{hot}	50	55	60		60	55	50

3.5 Performance of ST and PV

The performance of both, ST and of PV was relatively good. For a fair comparison, PV electricity has to be converted to thermal energy by means of running the heat pump with PV electricity and charging the storage. So

$$q_{PV} = sCOP \cdot w_{el,PV} \qquad \text{(eq. 3)}$$

Peak power limits and storage losses have to be accounted for. Furthermore, ST delivers temperatures up to 95 °C while with a heat pump the maximum temperature is below 60 °C. The power of the heat pump is limited (here 40 kW_{th}, correspondingly ca. 12 kW_{el}), i.e. for higher power (peak power of PV is ca. 23 kW_{peak}) either direct electric heating rods (with COP = 1) or batteries (with storage losses) have to be used.

A thermal energy storage is required for domestic hot water preparation, but for heating the HP could work directly on the floor heating system (ST contribution to heating is anyway very limited as can be seen in Fig. 8). Assuming 250 l per household, the 26 flats with a simultaneity factor of 0.2 and 50 % distribution losses, a storage volume of about 2 m³ would be sufficient. Hence, the additional volume of 4 m³ can be accounted to the solar thermal system. However, if the electricity generated by the PV area should also be used for DHW preparation (and heating) also in this case thermal energy storage would be required.

In this case, where ST is used for DHW preparation in summer, the monthly COPs of the heat pump should not be taken for further comparisons as the performance of the heat pump in summer was poor because of the very high contribution of ST and correspondingly low contribution of the HP. Therefore, the delivered energy is calculated with the average COP, which is with 2.9 rather low for a ground water heat pump. In this comparison, storage losses are disregarded and then the performance of both ST and PV (+ HP) is in the same order of magnitude as shown in Fig. 9. The specific yield of solar thermal without loses is q_{ST} = 500.8 kWh/(m^2_{ST} a) and reduces to $q_{ST\text{-}loss}$ = 336.5 kWh/(m^2_{ST} a) if all storage losses are accounted to the ST. The specific yield of PV is $q_{PV(COPav)}$ = 484.5 kWh/(m^2_{ST} a) based on the average COP of 2.9 and is $q_{PV(COPM)}$ = 428.5 kWh/(m^2_{ST} a) based on the monthly measured COPs (from 2016). With improved system design and control, a COP of the GW_HP of at least 3.2 should be possible (see section above) which would give PV a slight advantage over ST on annual basis, but ST would still perform slightly better in winter.

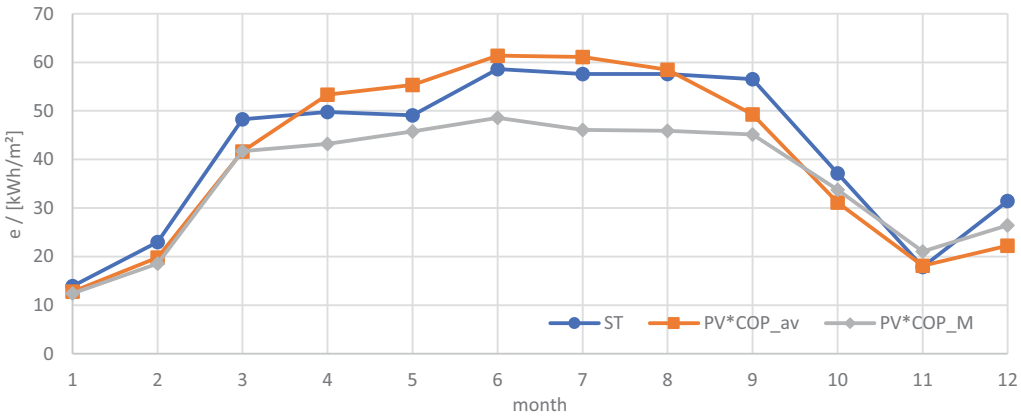

Fig. 9: Specific thermal energy (related to 1 sqm. of ST or PV, respectively) delivered by ST and by PV (with HP, with average and monthly COP of 2.9) (year 2016), storage losses are excluded

3.6 Electricity Consumption and Auxiliary Energies

The electricity consumed by the HP for heating and DHW is shown in Fig. 10. Aux. energies (pumps, MVHR, control, monitoring, etc.) are relative high. Electricity consumption is 15.3 kWh/(m² a) or 33 MWh w\o aux. and 22.9 kWh/(m²) or 49 MWh w\ aux. energy.

It can be seen in Fig. 10 that the first optimization measures proposed after the first winter already led to significantly reduced energy demand for heating and DHW and also to reduced auxiliary energy demand (5.6 MWh in December compared to 9.7 MWh in January, but still further optimization is required. The ambient temperature (and thus the heating degree days) and the global solar radiation were comparable in January 2016 and December 2016, see section 3.1, above.

PV yield is 167.6 kWh/(m^2_{PV} a) or 27 MWh or 12.6 kWh/(m^2_{AT} a) and is not even sufficient to cover the electricity for the heat pump. For heat pump and the auxiliary energies almost double the PV field size would be required. In December (where the el. consumption could already be significantly reduced with respect to January), on monthly basis, PV can cover 30 % of the electricity consumed by the heat pump and only 22 % if aux. energies are included. The remaining electricity has to be purchased from the grid.

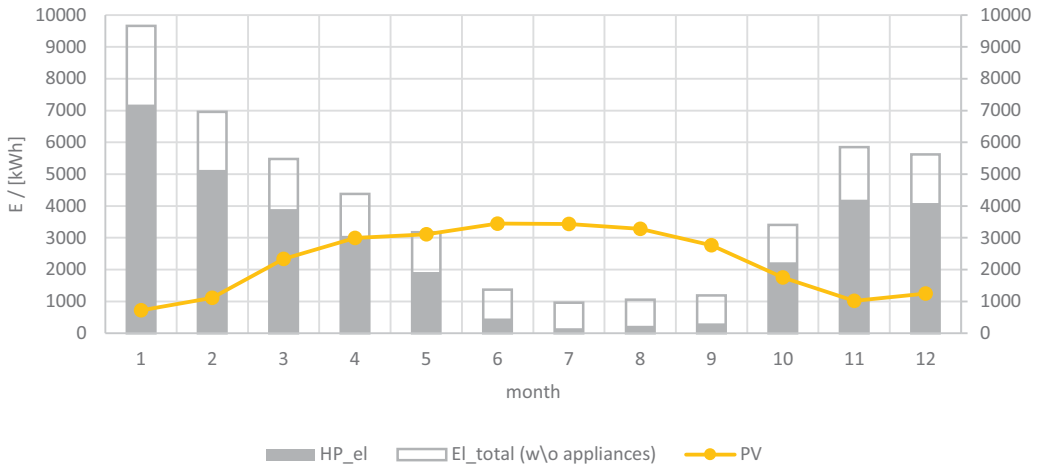

Fig. 10: Electric energy consumed by HP (grey bars), with auxiliary energies (white bars, appliances not included), and monthly electric energy produced by PV, monitoring results from 2016

4. Discussion

4.1 NZEB for heating, DHW (without appliances)

The goal of achieving a net zero energy balance (NZEB) for heating and DHW was not reached in the first monitoring period (2016) for several reasons: The higher HD in the first year (mainly because of construction moisture) and the relative high thermal losses of the storage led to a higher load. Furthermore, control settings were not optimal (e.g. not enabling good stratification) resulting in rel. poor performance of the heat pump. During the first year of monitoring some improvements were implemented and an increased performance of the HP can be expected. By avoiding thermal bridges of pipes and valves and convection (by heat traps) and by reducing storage set pint temperature, storage losses can be reduced.

If the heating demand can be reduced to PH-level (i.e. 15 kWh/(m² a)) and if further storage losses can be limited, higher solar fraction can be expected and the load for the heat pump can be reduced. If moreover, because of reduced set points and improved stratification, better performance of the HP can be achieved and finally aux. energies can be reduced, the electricity consumption could be reduced from ca. 22.8 kWh/(m² a) to the design level of ca. 11.8 kWh/(m² a). With all these possible improvements and optimization measures, the goal of NZEB could be achieved, as is shown in the prediction in Fig. 11. The annual yield of PV (167.6 kWh/(m^2_{PV} a) or 12.6 kWh/(m^2_{AT} a)) is enough to cover the consumed electricity on annual basis. However, the remaining purchased electricity in December would still be 3.1 MWh or 71 % (compared to 4.4 MWh or 78 % from the measurements).

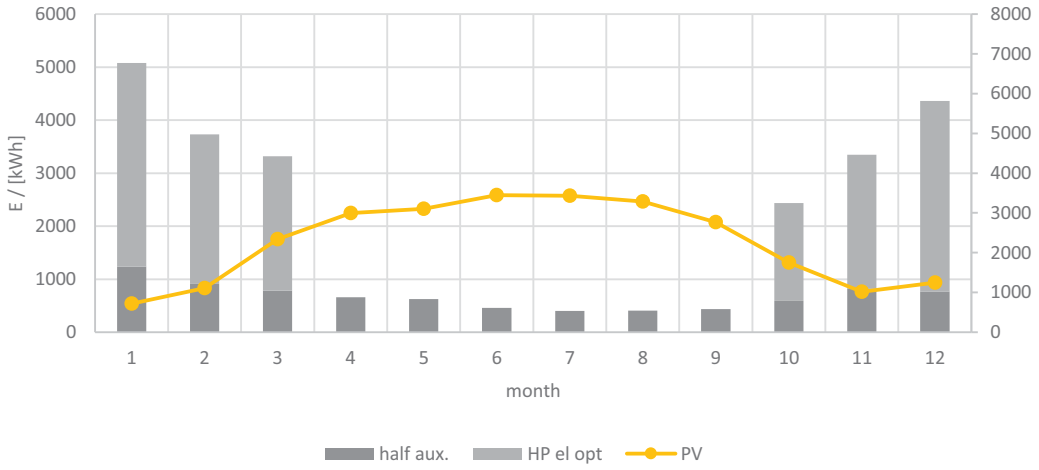

Fig. 11: Net-zero energy balance; prediction after optimization (50 % of auxiliary energies with respect to measurements, HD acc. to PH standard and improved HP performance (sCOP = 3.7)) Load is 25.2 MWh or 11.8 kWh/(m² a); PV yield is 167.6 kWh/(m^2_{PV} a) or 12.7 kWh/(m^2_{AT} a), respectively

4.2 NZEB for heating, DHW and appliances

Annual PV yield is not enough to cover appliances, even if only 1500 kWh/a are assumed per household (appliances are not measured, but European average is about 1500 kWh/person/year, see above in section 1.2). The monthly balance after optimization (prediction) but including appliances is shown in Fig. 12. If appliances are included, the net balance cannot be fulfilled. It is obvious, that in the winter months there is no PV electricity left for HP and auxiliary energies. Instead, 100 % has to be purchased from the grid. Only in summer, there is slight PV excess electricity which can be used to cover auxiliary energies and a small amount of PV has to be sold to the grid (again on basis of monthly balance). If higher consumption of appliances are assumed (e.g. 2500 kWh), on monthly basis, there would be no excess PV at all.

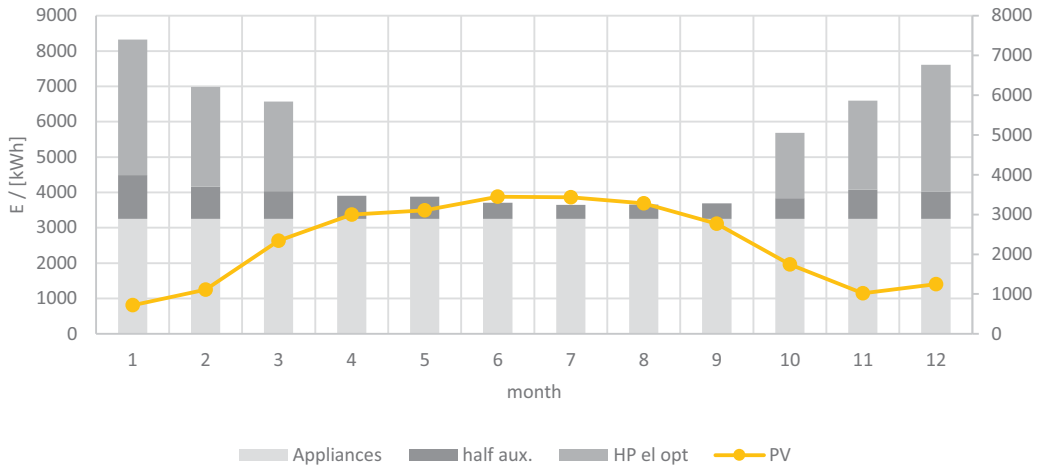

Fig. 12: Prediction of electric energy balance after optimization (as in Fig. 11 but with appliances; 1500 kWh/household; remark: electricity consumption for appliances is not measured (contract between electricity provider and the tenants); 64.3 MWh or 29.9 kWh/(m^2_{AT} a), respectively

For a NZEB with appliances, PV must be used in addition in the façades. An additional theoretical area of 300 m² (ca. 45 kW_{peak}) would be required in the south facades.

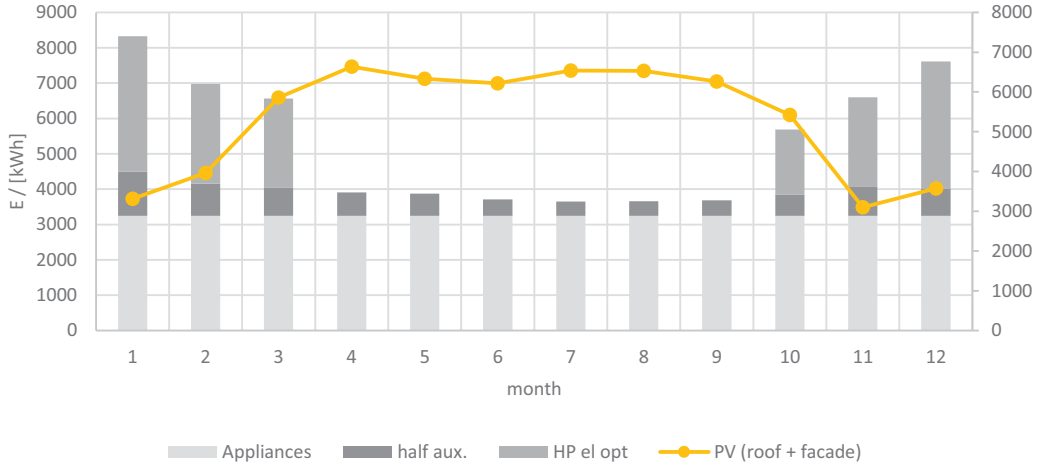

Fig. 13: Prediction of electric energy balance after optimization with appliances (as in Fig. 12) but with additional theoretical 300 m² PV on south facades (ca. 45 kW_{peak})

4.3 PE balance

The specific primary energy (e_{PE}) for heating and DHW production with the HP, for the case with the improved system, with appliances without and with 300 m³ of PV in south facades is calculated assuming two scenarios, see section 1.3:

- case A with 10 % hydro, 10 % wind and 10 % PV and
- case B with 10 % hydro, 30 % wind and 30 % PV.

It can be seen in Fig. 14 that in scenario B with higher share of renewables in the grid(all together 70 %), the additional PV in the façade yields less primary energy savings then in the case A with all together 30 % of renewables. In scenario A the additional PV in the façade reduces the annual specific PE demand from 32.7 $kWh_{PE}/(m^2\ a)$ to 15.2 $kWh_{PE}/(m^2\ a)$, or by 53.5 % while in scenario B, it reduces from 21.9 $kWh_{PE}/(m^2\ a)$ to 11.2 $kWh_{PE}/(m^2\ a)$ or by 49.2 %. As discussed in section 1.3, the state of the art is using a constant primary energy conversion factor, e.g. 1.91 as in At (OIB). PE savings with a constant PE conversion factor are 58 % (13.8 $kWh_{PE}/(m^2\ a)$ with compared to 32.9 $kWh_{PE}/(m^2\ a)$ without PV in the facade). With constant primary energy conversion factor, savings are accounted for with the same weighting independent of the season. Therefore, savings in summer are overrated.

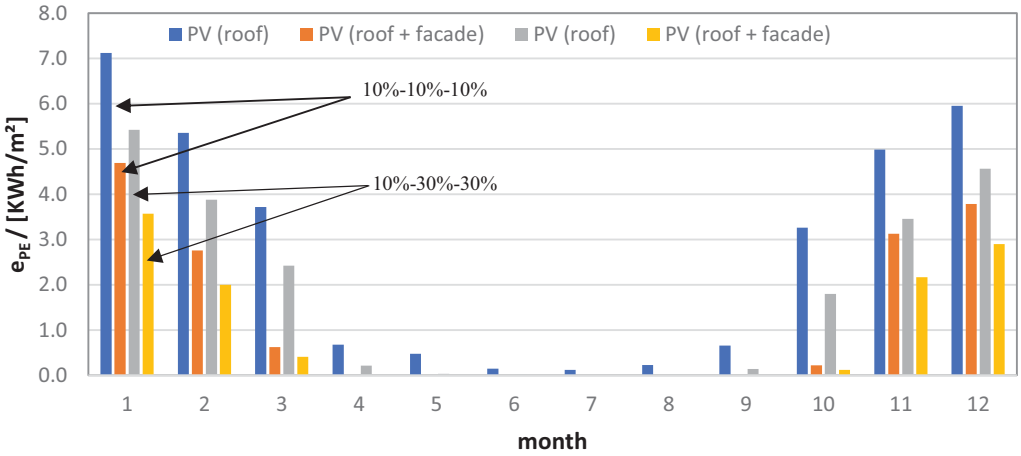

Fig. 14: Specific primary energy (e_{PE}) for heating and DHW production with the HP, improved system, with appliances without and with 300 m³ of PV in south facades for case A with 10 % hydro, 10 % wind and 10 % PV and case B with 10 % hydro, 30 % wind and 30 % PV.

5. Conclusions and Outlook

Two MFHs in PH Standard were implemented with solar thermal and heat pump system and PV to achieve maximum primary energy savings. Thus, the project can represent a best practice example for future nZEBs. PH standard is key for achieving real nZEB/NZEB level. ST has energetic benefits over PV in case of relatively small systems (i.e. $f_{sol}(DHW) < 40$ %). However, system complexity increases and a well-tuned control strategy is of major importance. Stratification of the buffer storage is crucial for optimal performance of the solar thermal plant and the heat pump. Obviously, storage size (i.e. volume) and connections must be carefully designed in order to avoid excessive storage losses. The reduction of the flow and return temperatures and the minimization of the distribution losses is also very relevant. Finally, also auxiliary energies have to be kept to minimum level.

In the paper monitoring results of the buildings (heating and DHW demand) and of the system (distribution losses, performance factors, solar thermal and PV yield) are reported and improvements after the first year of operation were discussed and design recommendations based on monitoring data and simulation results were given.

Net zero energy balance (for heating and DHW and auxiliary energies) could not be achieved during the first year of monitoring (2016), but predictions based on results after some improvements show that with it could be achieved. However, it is also highlighted in the paper, that electricity of appliances cannot be excluded from the energy balance and that NZEB do not significantly reduce winter grid load.

The mismatch between (electricity) demand and PV yield has to be considered, e.g. by means of different electricity prices for purchase and sell or by seasonal/monthly primary energy conversion factors. A method is discussed allowing to compare different nZEB/NZEB concepts considering the time (season) of the electricity purchase from the grid in order to be able to optimize concepts towards reduced non-renewable primary energy demand or CO_2 emissions in winter when renewable electricity is rare. In this sense, also concept of net zero energy buildings (NZEB, e.g. IEA SHC Task 40) can be critically discussed.

There is a need to develop design guidelines for HP design, HP and system control. Performance monitoring for fault detection and system optimization is strongly recommended.

On Behavioral Action Hierarchy for Understanding Occupants' Attitudes Driving Indoor Thermal Comfort in Office Buildings

Jessica Romanelli[1] and Anna Laura Pisello[1,2]

[1] CIRIAF – Interuniversity Research Center, University of Perugia, Perugia (Italy)

Abstract

Occupant behavior is one of the major factors influencing building energy consumption and contributing to uncertainty in building energy use prediction and simulation. Currently, the understanding of occupant behavior is insufficient in building design, operation, and retrofit, leading to incorrect simplifications in modeling and analysis. Recently, the need to integrate social science aspects into energy research has brought more awareness about the role of occupants in buildings and how their actions may be driven. Within this study, we identify a sort of behavioral actions' temporal sequence in a form of timing priority action logic to represent progressive occupants' decisions. This work will contribute to the scientific investigation about the impact of occupants' behavior in building energy assessments by determining a novel behavioral action hierarchy, useful for future advanced algorithm development in dynamic thermal-energy building simulation.

Keywords: Occupants' Behavior, Hierarchy Actions, Buildings' energetic behavior, Continuous monitoring

1. Research Background

The energy-efficiency analysis of buildings today takes into account building energy behavior underestimating the human factor. One of the main objectives of the research is therefore to analyze the behavior of occupants (in terms of their energy need) to understand how this affects the overall energy performance and how much it affects the difference between the expected energy consumption and the actual energy consumption.

Occupational Behavior, for example in offices, include a number of actions that can significantly affect energy consumption, such as adjusting thermostat settings, opening / closing windows, opening / closing curtains or shutters, switching on / off heating / cooling systems and finally moving from one room to another. In addition, behavioral habits, such as changes in clothing, drink consumption and different metabolism, directly affect the individual comfort that influences energy consumption.

The behavior of occupants in buildings is a multidisciplinary research topic that covers social and behavioral sciences, building physics, detection and control technologies, computational science and statistics. One of the greatest difficulties in collecting information is the lack of standardized data as well as privacy issues.

In order to overcome the uncertainty of occupant behavior, (O'Brien and Gunay, 2015) have proposed a design method for modeling actions to make people better adaptive to natural light and shading of a construction of a simulation of energy performance in a building. (Fabi, 2012), on the other hand, investigate the collection of numerous data obtained from experimental campaigns aimed at verifying the predictive precision of the various existing window-opening models in buildings.

Considering also the behavior of occupants on the manual adjustment system according to the presence of shadows, (Yao et al., 2015) have developed a stochastic model for integration with EnergyPlus (dynamic design software). Their results have shown that frequent and inappropriate use of open-cast walls in buildings has resulted in a decrease in internal thermal comfort.

Because of the uncertainty of occupant behavior, the results of dynamic-thermal-energy simulation often greatly vary from the actual energy consumption of the building. (Eguaras-Martínez,et al., 2014) indeed suggested that inclusion or exclusion of occupant behavior in simulations can result in differences up to 30%.

doi:10.18086/swc.2017.15.07 Available at http://proceedings.ises.org

A comparison between the energy consumption simulated at the design stage and the energy measured for the LEED certification (Leadership in Energy and Environmental Design), shows a significant error (mean square error of 18%) in a group of 62 buildings. The forecast error is even greater for low-energy buildings using passive systems, such as natural ventilation; in this case, the behavior of occupants could compromise the final energy consumption. Therefore, the behavior of occupants is one of the main sources of uncertainty in predicting the use of energy.

(Motuziene and Vilutiene, 2013) used four different employment profiles of housing in Lithuania, to show that the heating strategies can lead to savings of up to 31%. In addition, high efficiency can be achieved by optimizing energy consumption during vacation periods. For example, South Korean dorms use up to 31.5% less energy when they are not unoccupied. (Webber et al., 2001) observed, in offices in Washington DC and San Francisco, only 44% of the computers, 32% of monitors and 25% of the printers were turned off at night.

The quantification of energy saving imputable to occupant behavior remains a primary challenge. It was estimated that savings could be made between 10% and 20% for home and between 5% and 30% for commercial buildings (ie private offices) by acting on occupant behavior.

Previous Scientific Research has shown that the role of Occupant Behavior has a major influence on the energy performance of the building. In this work, an office building has been monitored for more than one year in terms of indoor-outdoor microclimate and energy needs. More in details, several rooms were monitored with similar characteristics in terms of their intended use, dimensional characteristics, exposure, constructive features, and presenting devices. By analyzing several key boundary conditions, occupants can be considered as peers (equal) by being related to formation, age, habits and customs and carrying out similar activities.

2. Research Scope

Compared to the state of the art, this study attempts to analyze and identify a sort of timing priority sequence in occupant behavior triggering after perceiving a potential discomfort situation.

Determining the sequence of actions that include subjectivity is complex, especially in the analysis of the progressive feeling-to-decision-to-action of occupants. Therefore, this work will contribute to the scientific research envisaged in the Annex 66 program, which aims to identify the state of the art in terms of Occupational Behavior modelling in buildings energy prediction.

The goal is therefore to determine a temporal hierarchy of behavioral actions that is also valid for a predictive and reliable energy evaluation, since the typical reactions may be energy-needy and their time prediction influences building final energy use.

3. Methodology

The methodology implemented in this paper consists of the following main steps:

- *Definition of the research statement,*
- *Selection of the case study,*
- *Continuous experimental monitoring of the main parameters of the internal microclimate and occupancy within each office during a year from April 2016 to March 2017,*
- *Statistical analysis of data and comparison of results.*

The following sections describe the above-mentioned work phases.

3.1. Field Monitoring

In order to study and analyze the different behavior of "peers" and the hierarchy of actions that are carried out within the building, they were considered a group of peers working in some office buildings that houses the University Research Center "CIRIAF" (Perugia, Italy). In particular, five office environments characterized by the same orientation, same architectural layout, size, construction technology, and HVAC system were selected. Consequently, the behaviors of the occupants were continuously monitored by means of special sensors installed in the various offices

selected as a case study.

More in detail, the experimental monitoring system was installed in September 2015 and consists of internal microclimate sensors capable of collecting data such as indoor air temperature, workplace illumination, electrical consumption, door / window opening. Therefore, data on the behavior and daily habits of occupants were collected and analyzed in terms of the use of electricity, lights on / off, opening / closing of doors / windows. In particular, the aforementioned monitoring system consists of a set of Wireless Network Sensors (WSNs), consisting of five indoor microclimate monitoring stations, each equipped with several sensors and a collector node (Fig. 1) connected to the cable sensors. The monitoring stations are located each within the five offices. Nodes communicate the data collected via radio to a collection gateway and then they are real-time available within the office web portal managed by the authors.

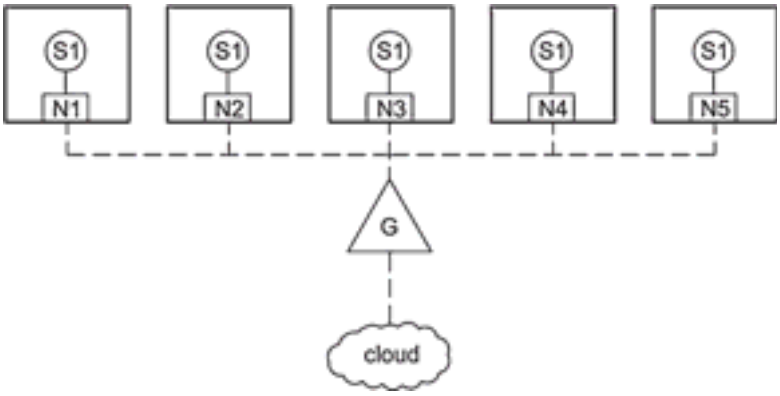

Fig. 1. Functional Diagram of the Wireless Monitoring System (n = nodes, S = sensors, G = Gateway, 1-5 = Monitored Offices (Pisello et al., 2016)

For the purpose of this research work, four types of sensors have been used in order to analyze the following internal parameters (Fig. 2):

- O*pening / closing of doors and windows (magnetic sensors),*
- I*lluminance level above the desk (luxmeter),*
- *Indoor air temperature (air temperature probe),*
- *Use of electricity (amperometer).*

Each sensor can record data every five minutes by sending the signal it to its node and finally to the gateway.

Fig. 2. Sensors installed in each office: (a) opening and closing windows, (b) luxmeter, (c) air temperature probe, (d) ammeter (Pisello et al., 2016).

4. Case Study

The building selected as a case study is represented by a building hosting the Research Center of the Department of Engineering of the University of Perugia, Italy (Latitude: 43 °'0'0'0 " N; Longitude: 12 ° 21'03 ' 'E) (Fig. 3). It has a two-story rectangular plan, which houses ground floor laboratories, while all the offices of researchers and professors are located at the first floor. The five monitored offices are all located on the first floor and are oriented to the South-West; they have rectangular plan and have the same dimensions (about 4 × 4 × 2.9-h m). Each office has two windows-doors on the South-West façade facing a terrace connecting all the rooms at the same floor. Lighting system is characterized by 4 ceiling lamps manageable from the entrance of each office as 2 groups of 2 lamps. The HVAC system is a centralized heating-cooling air system for the whole building. Each office is provided with a thermostat able to regulate both temperature (+/- 3°C compared to the setpoint centralized temperature) and air volumes (in a graduate scale of 3 steps).

The heating season is officially operating from 10-15 to 04-15, while summer cooling operates from 06-15 to 09-30 by law. Then, every office occupants may regulate their ambient thermostat according to personal needs and occupational perceptions of occupants.

In each office there are two or three computers and two or three people. (Fig. 3-4)

Fig. 3. Planimetry of Monitoring Offices (Pisello et al., 2016).

Fig. 4. Typical Offices (Pisello et al., 2016).

4.1 Data analysis scheme in the building

This analysis, which considers peers as occupants having similar characteristics (in terms of age, occupation, activity, and timetable) under the same environmental conditions, highlights how the attitudes and personal habits of different occupants differently affect the overall building behavior given their intrinsic variability. The table below describes (Tab. 1) the main features of each monitored office.

Tab. 1. Main features for each monitored Office.

Room	People in the office (n°)	Doors/Windows	PCs
1	3	1 D, 1 W	3 pc
2	2	1 D, 1 W	2 pc
3	2	1 D, 1 W	2 pc
4	3	1 D, 1 W	3 pc

Considering all the possible actions that can be taken, such as resulting in energy consumption or a different behavior of the building, the analysis was carried out by identifying macro categories and focusing on the opening and closing of the door and the window. The aim was to identify, where possible, a temporal correlation between the thermal discomfort and the occupation action.

First, the processing of collected data was carried out with reference to the continuously monitored weather data provided by the weather station positioned on the roof of the building that houses the offices.

Specifically, the correlation level analysis between the monitored internal parameters and the external microclimate was performed considering the outside air temperature, the total solar radiation on horizontal plane, the maximum internal temperature and the opening / closing of the doors / windows. The analysis of how internal parameters are influenced by external environmental conditions shows that there is always a time shift between the maximum incident solar radiation and the maximum internal temperature, as expected. From the monitored data analysis, the maximum incident solar radiation occurs between 11:00 am and 1:00 pm on average, while the maximum internal temperature is recorded between 3:00 pm and 6:00 pm. Of course, there are exceptional cases due to the use of technological installations and / or the change of external atmospheric conditions to vary this trend. additionally, the analysis of collected data has been made by considering the behavior of occupants in order to assess how personal attitudes and specific peer peaks can affect internal environmental parameters equal conditions.

In this regard, 12-month monitoring data, specifically from April 2016 to March 2017, were analyzed and the Global Maximum Incident Solar Radiation and the External Temperature were identified as the two key variables for each day. At the same time, the maximum internal temperature and external temperature and global radiation were selected as indoor feedback every day. For each day, based on these data, the opening of the door and the window timing was assessed and correlated to radiation and temperature profiles and peaks, by also investigating the time span of the action and the possible consequential relation.

5. Results and Discussion

5.1. Analysis of occupants' behavior

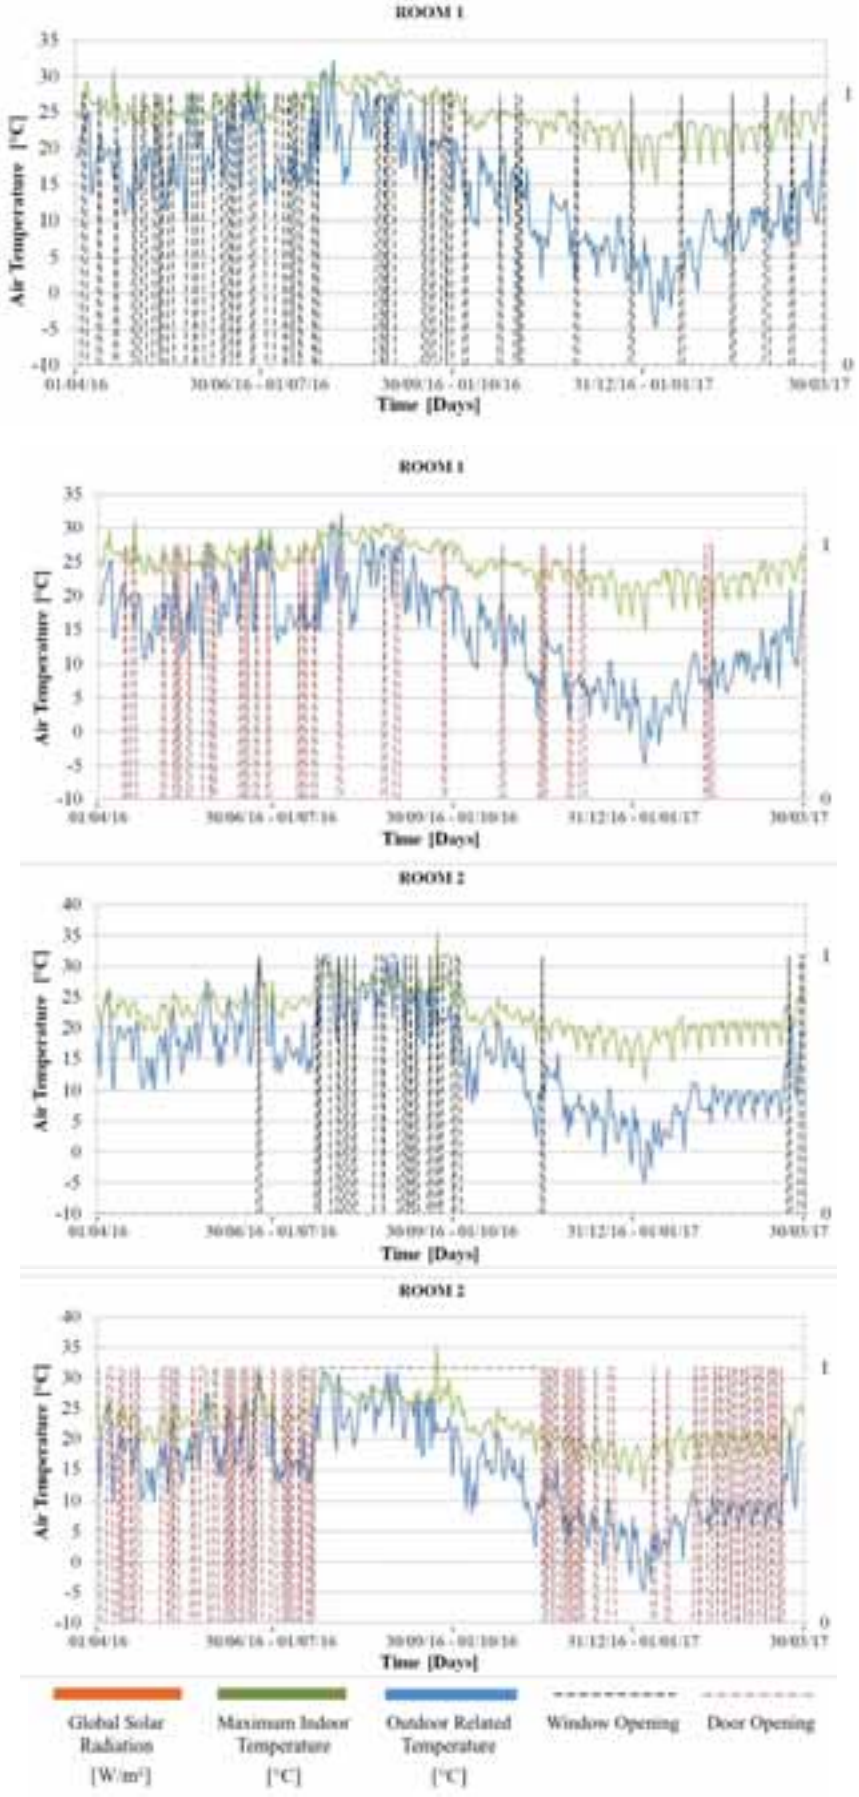
As mentioned, the present study aims to demonstrate that peers, i.e. persons of the same age, origin, activity and working hours, have different behavior from the thermo-energy point of view despite their theoretical similarities and the common work environment and how they react to environmental stimuli by implementing a temporal series of actions.

Room 1 and Room 3 office occupants often use window and door opening to adjust the temperature (openings normally coincide with indoor maximum indoor temperatures). Room 2 Office users do not use the window opening (there is only one opening in June at the peak of the measured temperature, about 30 ° C, and during September), but they act on the door opening to respond to the condition of overheating discomfort and adjust the internal temperature.

In "Room 4" office, the sensor data show that except for a few times, the window remained open throughout the day, even at night. In this case, the measurement was considered as not significant as this result may be due to a malfunction of the sensor or, if not, the action of opening the window is not a result of temperature variation.

However, occupants of the "Room 4" office used door opening as a solution to counteract environmental discomfort caused by rising temperature in the room. The Room 5 office is a synthesis of the previous ones; the opening of the window is recorded for long periods (especially during Spring and Summer), while the door opening does not always happen at the temperature peaks.

Another highlighted information to note is the behavior of the occupants of the office "Room 3", which, between May and June, with a temperature around 25°C, have constantly used the opening of the window while always closing the door. However, the internal temperature was on average around 25°C. It is likely that the opening of the window was not due to the air conditioning of the room, but to the need for occupants to breathe fresh outside air due to the pleasant temperature. As said many times, despite the fact that the "occupants" are potentially "peers", it emerges that the action is subjective or linked to its momentary and personal perception, privacy, etc. The following charts show the results of how each office occupants (Room1-2-3-4-5) react to the conditions just described.



ROOM 1

ROOM 4
Air Temperature [°C]
Time [Days]
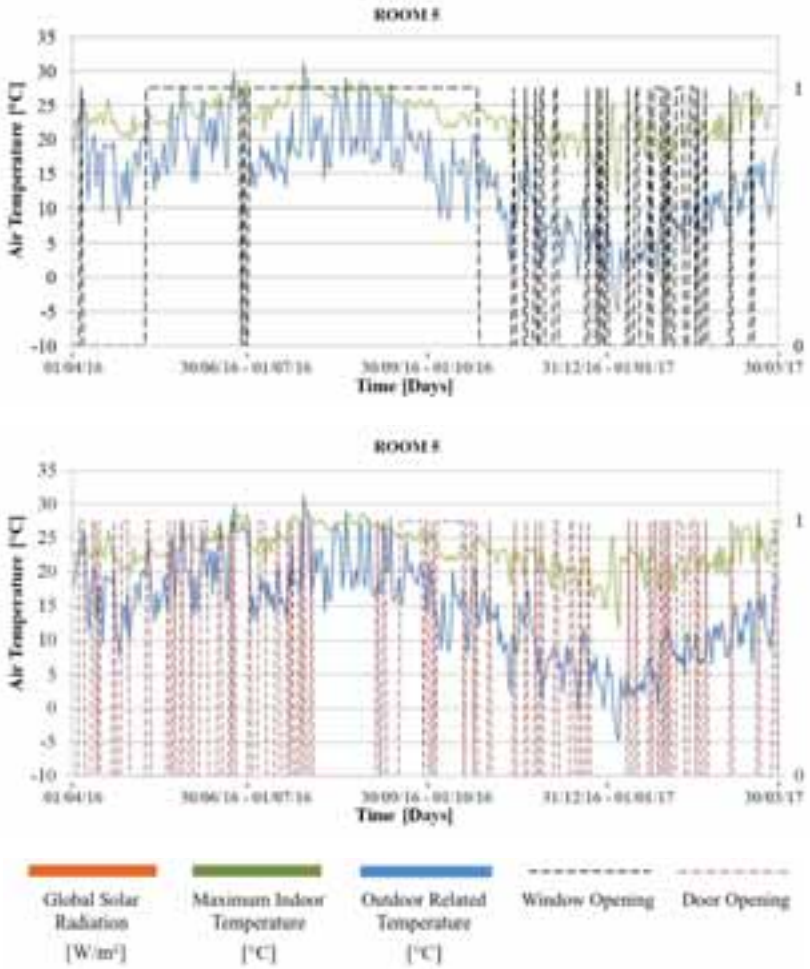
Global Solar Radiation [W/m²]
Maximum Indoor Temperature [°C]
Outdoor Related Temperature [°C]
Window Opening
Door Opening



A further point to note is that the analysis of the opening of doors and windows at the maximum internal temperature is not significant during the winter season where the maximum indoor temperatures are consistently higher than the external ones and the user's action is not directly proportional to the discomfort.

The occupants are also able to use the thermostat (user autonomy ± 3 ° C) to raise the temperature during working hours as a measure of the minimum internal temperature. However, a sensor has not been installed yet, that monitors user action on the thermostat itself.

Analyzing the results, there is a clear difference in actions at the Maximum Solar Radiation (W / m²) that normally does not correspond to a condition of internal discomfort and therefore a noticeable non-action (Fig. 5). The Maximum Solar Radiation is recorded around 12:00pm-1:00pm daily, the time when the indoor temperature is normally lower. The Maximum Indoor Temperature, however, occurs almost always in the afternoon. This constancy is justified by the specific orientation of the offices being analyzed and the internal gains progressively heating the room.

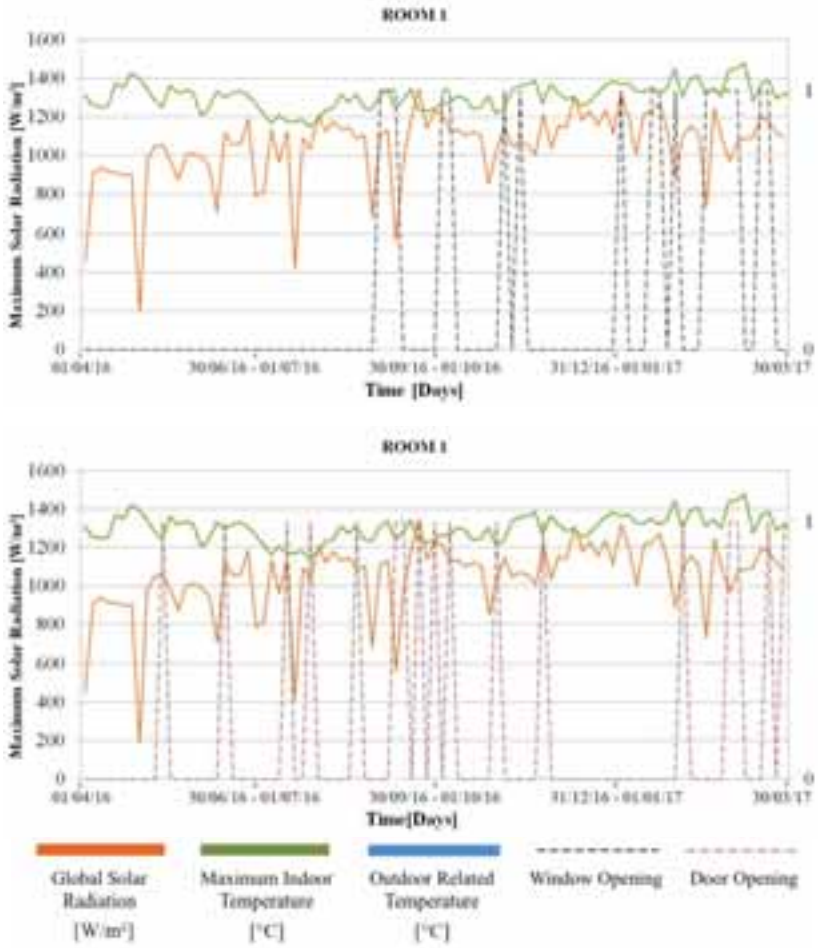


Fig. 5. Door and Window's Opening related to the Maximum Solar Radiation and Indoor Temperature.

In the following table, a synthesis of one year actions collected data for each office is described (Tab. 2).

Tab. 2. Results for each office of the analysis considering 365 days including 16 holidays.

Rooms	External Global Solar Radiation (W/m²)			Maximum Interior Temperature (°C)		
	Door	**Window**	**Door + Window**	**Door**	**Window**	**Door + Window**
1	37	52	12	32	74	21
2	148	28	28	137	34	34
3	47	99	15	48	94	17
4	74	237	42	69	233	32
5	103	188	94	106	203	89

5.2. Temporal Hierarchy Actions

Analyzing the results of occupancy actions, attention was focused on registered actions and time correspondence with recorded discomfort.

Starting from the specific action, it was analyzed whether the specific action occurred at the maximum internal temperature or if there was a time shift when the action was coming.

Results in Figs. 6-7 show how, starting from a situation of discomfort, subjective actions of the occupants are implemented. The subjectivity consists of the type of action, e.g. the fact that some occupants facing high internal temperature were opening the door while others, for privacy reasons, only managed the window. A further result is represented by the fact that not all the occupants reacted at the same moment of maximum internal temperature, but that

within a given temporal order (5-10-15 minutes) the action was usually widely implemented. However, the goal is to extend the time interval, up to about 2h, in order to understand and identify a possible recurring attitudes in the actions. The work in progress consists of the elaboration of an algorithm to quickly locate this correlation.

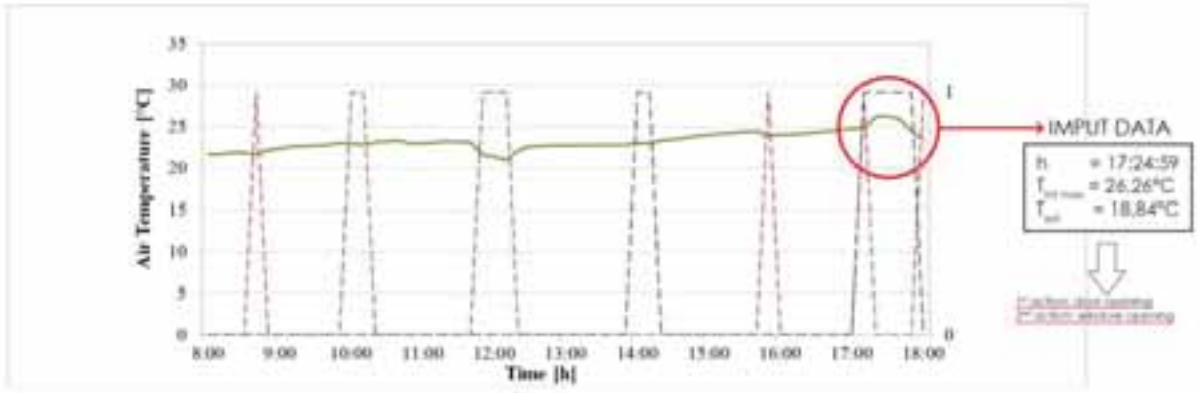

Fig.6: Daily Hourly table where are indicated Occupants' actions when the indoor temperature is maximum.

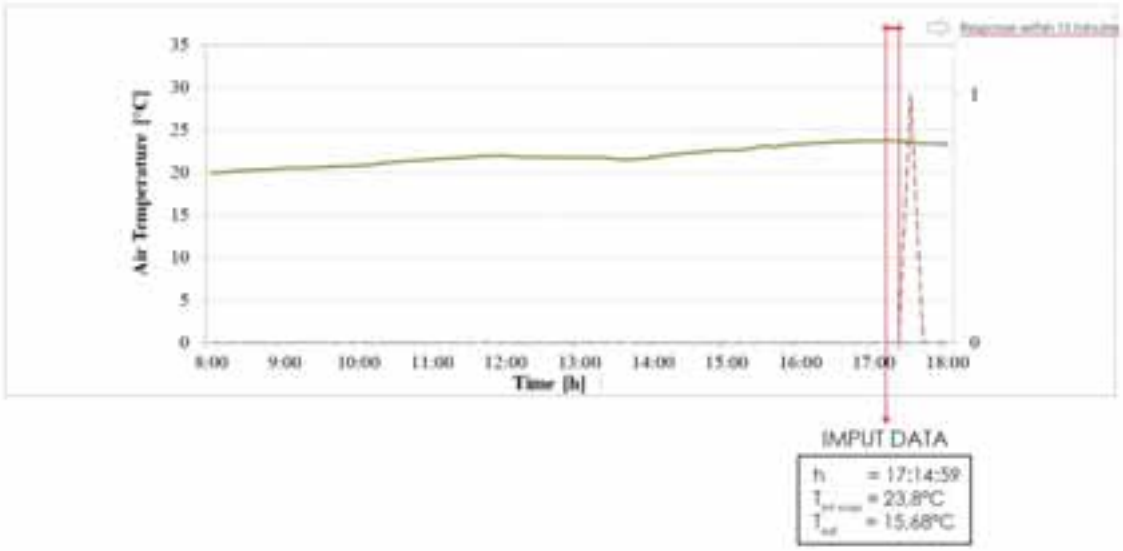

Fig. 7: Daily Hourly table where are indicated Occupants' actions with 15 minutes' time reaction range after the maximum indoor temperature.

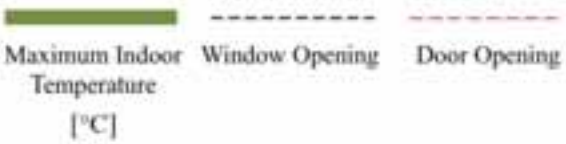

6. Conclusion and Future Development

The present study analyzed the possibility of establishing a sequence in the actions of occupants of an office building in order to assess the impact of subjectivity and time-hierarchy of user actions responsible for the variability of indoor air temperature in close proximity to each working station.

The results show how, in discomfortable situations, the subjective actions of the occupants find a common matrix of doing a subjective action. Subjectivity was found in the type of action, i.e. in the fact that for example some occupants reacted to high internal temperature with opening the door, while others, for privacy, the window.

Another result is that not all occupants reacted at the same time, but within a given time order (5-10 to 15 minutes) the action was completed. It is also important to note the difference in the actions at the maximum solar radiation (W/m²) that normally does not match an internal discomfort and therefore a noticeable non-action.

Being the subject of deep interest and study, the understanding of occupant behavior represents a new opportunity to shape the future evolution of building energy prediction models and technology, to improve the energy efficiency and comfort of occupants of buildings,.

Solar Energy Development and Implementation in Nigeria: Drivers and Barriers

D Abdullahi[1], S Suresh[2], S Renukappa[3], and D Oloke[4]

School of Architecture and Built Environment, Faculty of Science and Engineering, University of Wolverhampton, WV1 1LY

Abstract

The over dependency on fossil fuel in Nigeria could be one big reason for the total failure of the power sector. The country's economic development which depends on productivity output is in peril due to the imminent energy crisis from gas shortage, vandalism, diminishing fossil fuel reserve and energy insecurity. Therefore, a strategic initiative to diversify the power sector into the energy mix to withstand the socioeconomic development has not indicated a positive progress. The insufficient electricity generation at the highest point was only in capacity put at 5000 MW in April 2015 to support a teeming population of about 184 million people. Nigeria is endowed with plentiful natural resources in which solar energy received more attention due to its potential, especially the rural communities. It is estimated that the solar potential deposit raises to 4,849, 782 kWh/m^2 days for the entire country of around 923,768 km2 areas. The theoretical framework is based on critical literature reviews being part of a PhD research. The research discusses the motivational drivers to the solar energy development and the barriers hindering the implementation. The key drivers were climate change, energy demand, power sector reform Act, energy security, supply versus demand conflicts, job opportunities, technology growth and market potentials. On the other hand, the key barriers are technical, social, economical, institutional and political. Recommendations of measures to surmount the barriers to facilitate implementation are also proffered.

Keywords: Solar energy, energy access, solar barriers, solar drivers, implementation

1. Introduction

There is little or no doubt that access to electricity is crucial to people, not only in the urban developed cities, but also to the development of rural areas. Even though, Nigeria is the biggest producer of Oil and Gas in Africa, 65% of its population lives in rural areas as peasant farmers without access to electricity (Duke, et al. 2016). Surprisingly, the total installed solar power in Germany is seven times more than the highest peak ever generated electricity from all sources in Nigeria, being 5000 MW in April 2015 (Edkins, et al. 2014). Nigeria located on the equator is within a high sunshine belt where solar radiation is potentially well distributed, especially over the Northern part of the country (Okoye and Taylan, 2017). Even though, the solar radiation distribution varies from 3.5kWh/m2/day within the coastal area and 7.0 kWh/m2/day in the northern part of the country (Ohunakin, et al., 2014). This result to earn the country a total solar radiation of 4,849, 782 kWh/m2 day covering the area of 923, 768 Km2of landmark (Akinyele, et al. 2007). Despite the potential solar radiation in the country, the technology is yet to find a sustainable strategy to be harnessed and put into the energy mix to solve the alarming energy crisis especially the electricity.

2. Status of Solar Energy in Nigeria

The whole of the continent is blessed with a great sunshine radiation, excluding the large areas of tropical rainforests (the Guinean Forests of West Africa and much of the Congo Basin), since desert and savannah regions of Africa stand up as the Earth's largest cloud-free area. The eastern Sahara/northeastern Africa is particularly noted for its world sunshine records: the area experiences not only the greatest mean annual duration of bright sunshine approximately as much as 4,300 hours, which is equal to 97% of the possible total but also the highest mean annual values of solar radiation (the maximum recorded was over 220 kcal/cm²) (Edkins, et al. 2014).

The distribution of solar resources across Africa is uniform, with more than 85% of the continent's landscape receiving a global solar horizontal irradiation at or over 2,000 kWh/ (m² year). Also, the theoretical reserves of Africa's solar energy are estimated at 60,000,000 TWh/year, which accounts for almost 40% of the global total, thus definitely making Africa the most sun-rich continent in the world (Nevin, 2016). Declining solar equipment

doi:10.18086/swc.2017.16.01 Available at http://proceedings.ises.org

costs are expected to significantly increase solar installations in Africa with an industry projection forecasting that the continent's annual PV market will expand to 2.2 GW by 2018 (Obeng, 2015).

Furthermore, harvesting solar energy in Africa tend not to be found within the equatorial and subequatorial climate zones, that are located in the western part of Central Africa usually near the equator, but that extends as far north and south as the 8th or 9th parallel in both hemispheres, since they are systematically linked with almost permanent cloud cover and only intermittent bright sunshine (Sharife, 2014). Therefore, African countries that entirely lie in this wet-humid zone, such as the Republic of the Congo, Equatorial Guinea, Gabon, Liberia and Sierra Leone are by far the least favoured in solar power of the entire continent. In contrast, many perpetually sunny African nations like Egypt, Libya, Niger and Namibia could rely on developing their tremendous solar resources on a large scale and at reduced prices (Sharife, 2014).

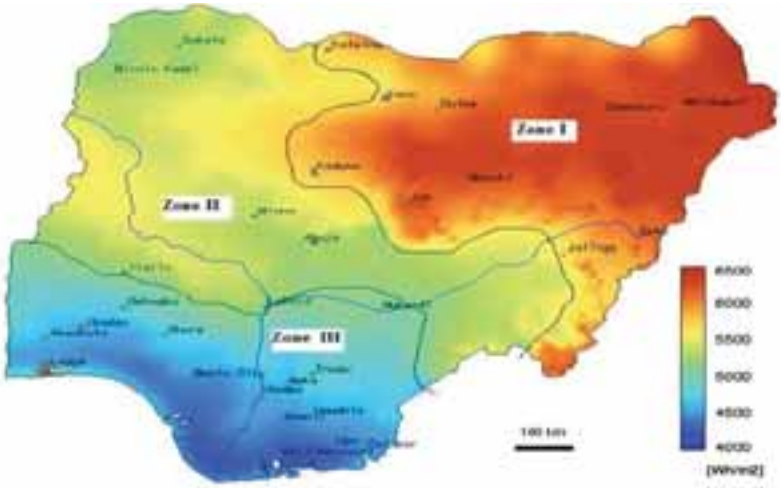
Source: Emodi and Boo, 2015

Table 1 above, is a view of Nigerian maximum and minimum sun radiation in various zones with highest radiation in the North-East Zone Nguru, Maiduguri, Kano and Azare in Bauchi state. However, other cities also possess high sun radiation making it equally potential for solar energy resources. Even the leas radiation

cities such as Warri and Calabar, the solar energy can potentially be harnessed by many users for household and small and medium businesses.

Figure 1 bellow shows the solar radiation distribution across Nigeria, where each zone is labelled to ascertain solar radiation contribution if the technology is harnessed. The three-different solar zone can be defined viz: Zone I, II and III where each zone having a diverse level of radiation that can be articulated for a specific project selection across the 36 states of the federation. It is evident that Zone I which comprises the states in the northeast zone have the highest solar radiation occurrence with excellent solar PV potential. Equally, zone II, which consist of the North-central and North-West have viable solar radiation while zone III has low solar radiation potential for big solar project selection in the country.

Figure 1: Solar Irradiation levels in Nigeria



Source: NESP, 2015

It is evident that the northern part of Nigeria can generate substantial solar energy as seen in table1; with annual radiation rising up to 6.966 maximum in Nguru Yobe state in the North- East and 3.78 minimum in the Wari Delta state, South- South of Nigeria. The next table will show the major solar projects both public and private with license to generate, operate and commercialise solar energy in Nigeria.

3. Solar Energy Projects in Nigeria

There are more than 58 energy mix projects going on in Nigeria, of which 35 are Solar-based from licensed solar energy promoters, including rural electrification projects, with a total capacity of 115 MW of Photovoltaic combining mini-grids and stand-alone installed (ECN, 2014). The Solar-based projects are installed for residential and commercial purpose respectively. Even though, the Ministry of Power launch a project in 2014, known as ‘‘Operation Light Up Rural Nigeria’’ most of the Solar projects is targeted for rural communities which are estimated only 10% of the population have access to electricity. Other off-grid projects include the 37 Federal Universities and University teaching hospital projects are underway to complement the electricity supply. Four of the Universities and a teaching hospital has already signed the Engineering, Procurement and Construction (EPC) agreement to develop mini-grid solution to power facilities of up to 9.3MW of solar PV and 5,760 battery cells will be deployed for the projects. Other projects are monitored by the federal ministry of power and the rural electrification agency, energy commission and the regulator (NERC) accordingly (ECN, 2018).

The table above shows some solar energy promoters, they have applied, met the requirement stipulated by the Federal Ministry of Power, Nigerian Electricity Regulatory Commission and other Ministries, Departments and Agencies responsible for initiation of solar energy initiatives in Nigeria. The approval and issuance of licenses to solar energy companies is an indicator of the government and it agencies commitment to achieving a sustainable energy mix. The next paragraph will discuss factors that drives the solar energy implementation in Nigeria.

4. Drivers for solar energy initiatives in Nigeria

Beside the location of Nigeria on a belt where solar radiation is high, there are other factors which help in driving the opportunity for the deployment of solar energy initiative in the country.

Tab 3: key drivers for solar energy in Nigeria.

Drivers	Drivers Remarks
Sustainability demands (CO_2 footprint and Climate change)	Climate change is the main driver for solar energy and other renewable and the main trigger for the called for the Millenium Development Goals (MDGs) and Sustainable Development Goals (SDGs) over the Years (Uken, 2013). Nigeria is lying on the coastline of about 800 km, with sea level raised to 0.2 m and approximately 3400km sq. several kilometres of land have been found to lose annually (Ohunakin, et al. 2014). The raising of the sea level and the desertification is resulting from the burning issues of the rapid greenhouse emission caused by the other unsustainable means of electricity. The application and development of solar PV, could reduce the impact to a minimal level while tapping the free and clean energy and making our environment friendly, more sustainable and green (Darmani, et al. 2014).
Increased energy demand	Growth is expected to reach 270 million by 2030 at an average annual rate growth of 4.0% between 2000 and 2030. Population growth, therefore, is the main driver vis – a - vis the energy demand and the socioeconomic activities measured by the GDP (Oseni, 2012). Therefore, the rapidly growing demand for energy will create more opportunities for solar PV development in Nigeria, since the conventional source will be inadequate to feed the high demand of the energy in the country. Solar energy deployment is also a very big opportunity for the rural area socioeconomic activities, because most the rural communities are neither connected nor faced with an epileptic supply of electricity (Sambo and Bala, 2012).
Power Sector Reforms Laws	The Electric Power Sector Reform Act (EPSRA) 2005, made provisions of law, to allow private individuals to construct, operate, own and generate electricity not exceeding 1000 kW at a site without a license (Amankwah, 2015). The order for the exception is meant to ease the process protocol and delays in acquiring licenses and to empower young entrepreneurs to invest in the standalone power generation. The facility is also part of the electricity expansion of a national grid, facilitation of off-grid power system, generates renewable energy and coordinates other energy mix (Ohunakin, et al. 2014). The abundance of solar radiation makes solar potentially the most important source driven by the high demand of population in the country (Okoye and Taylan, 2017).
Energy Security and access	Nigeria is estimated to have 80% demand/supply gap in electricity, and it is also, estimated that only 10% of the rural communities have access to the electricity from the national grid (Aliyu, et al. 2015). Most public and private businesses are run by self-generated electricity using gasoline and diesel generators which emit high unhealthy greenhouse gases to the environment and unbearable noise to the society. Electricity energy is lost via a transmission through distribution to the end users (Emodi, 2015). Frequent, high voltage cable vandalism, cable theft, illegal connections, and inadequate maintenance of the power sector facilities and lack of trained human capacity development (Ohunakin, et al. 2014). Therefore, solar PV and solar thermal constitute safe, enabling, reliable and affordable alternative energy widely used.
To Neutralise the energy conflict	The Nigerian power sector plant is crippled with the inconsistence in the supply and demand of gas to power plant's equipment. The common cause is associated with sabotage and destruction by the militants around the oil and gas producing area; Niger Delta (Sambo and Bala, 2012. The solar energy source is free from sunlight, and requires no transport as it is produced near where it is consumed (Aliyu, et al. 2015). Therefore, the ability to generate, transmit and develop the solar energy free of conflict zone can be a pushing factor for solar and other renewable energy technology deployment and implementation in Nigeria.
Job Creation and Opportunities	The promotion of solar energy in Nigeria will contribute enormously to poverty reduction by engaging young people in local communities to participate and benefit from the opportunity in skills development, technology transfer and investment opportunities (Darman, et al. 2014). Many alternative energy pilot projects in developing countries give positive evidence of impact on socioeconomic development, especially the rural communities in Nigeria with abundant, natural resources Ohunakin, et al. 2014). The increase in the investment in the solar battery manufacturing, installations, maintenance and repair skills, and the manufacture of various solar devices leads to the creation of massive job opportunities.

Source: Alam, et al. 2010; Darmani, et al. 2014; Ohunakin, et al. 2014; Uken, 2013 and Zahedi, 2011; Akinyele, et al. 2017; Okoye and Taylan, 2017.

Tab. 4: Other drivers for solar energy in Nigeria

Drivers	Drivers Remarks
Local value-added potential	Developing countries like Nigeria will yield local added value for solar energy penetration, considering that less than 40% of the population are connected to the national grid. Most of the population is in the rural area where fuel wood is the main source of energy (Emodi and Boo, 2015). There is a potential for the solar applications technology to be developed locally by the rural dwellers to support an energy mix in various forms such as cooking, water pumping and other agricultural activities (Dittmar, 2008). Solar energy is also potential for promoting socioeconomic stability, skill acquisition and job creation.
Growth in Education and Technology	Growth in technology and widespread of technical knowledge of solar technology could be a reason driving the initiative in Nigeria (Amankwah, Amoah, 2015). Besides, energy research centres in Nsuka, Sokoto, Lagos, Ilorin, Bauchi and Port Harcourt are the roots to awareness and skills development for solar and other renewable energies in Nigeria (Oseni, 2012). The growth in technical knowhow about the technology locally, is a pulling actor potentially responsible for continued interest in solar energy.
Stakeholders Involvement	Solar and other renewable energy projects cannot succeed without the intervention of local stakeholders. When local entrepreneurs, explicitly integrates their investment towards solar energy technology, the success of the technology is achievable (Zahedi, 2011; Marques and Fuinhas, 2011. Therefore, local investors, entrepreneurs and end users are encouraged to fully participate in the promotion, generation, production and implementation of solar energy in Nigeria to help mitigate the appalling electricity shortage in the country (Ohunakin, et al. 2014).
Financing opportunities and Market potential	One of the barriers to solar and renewable implementation in developing countries are the inability to penetrate a market because the technology is yet to be known and accepted in many countries including Nigeria (Rettere and Kelley, 2010). However, incentive mechanism such as subsidies towards the initial financial cost of solar could play a vital role in promoting the technology. In Nigeria, solar projects are funded by World Bank Projects, Central Bank of Nigeria (CBN), USAID, and many other international development funding institutions to support the promotion and development of solar energy (Ohunakin, et al. 2014). These projects drive interest from young entrepreneurs and investors to diversify into the energy mix to support the mitigation of power outage in the country.

Source: Darmani, et al. 2014; Dittmar, 2008; Marques and Fuinhas, 2011; Ohunakin, et al. 2014; Uken, 2013; Akinyele, et al. 2017; Okoye and Taylan, 2017.

The table above discussed the driving forces for solar energy implementation in Nigeria. Each country's location might have potential factors that drive the implementation of the solar energy initiative. For developing countries solar energy can bring major benefits for socio-economic development, especially in the rural communities where access to electricity has become the biggest challenge. A switch from other oil and gas energy sources can reduce the over dependency on oil and gas supply with issues of insecurities and vandalisation. In the south and other developed countries gain the advantages to driving the renewable energy from international climate change agreements like the Kyoto Protocol, SDGs and from socioeconomic interest. In other words, fast economic growth countries like China, India, and Brazil are mandated to meet their energy demand while the poorer nations must meet the international poverty reduction goals which implies the reduction of energy poverty especially in the rural areas in Africa particularly Nigeria. These forces include the declining cost of RET capital cost, integration of private public partnership in the energy industry, growth in population and the increase in demand for energy, needs for the mitigation of climate change and the achievement of the SDGs targets, energy security, job creation and financing opportunities for RET projects by international organisations.

5. Key Barriers to Solar Initiatives in Nigeria

Despite the many benefits that can be accrued from the use of solar energy potential and uses, is still very low. The major impediments to the solar energy initiative's adoption are series of barriers identified through critical review of literature which makes it difficult to implement.

Table 4; Barriers to Solar energy implementation in Nigeria

Barriers category	Barriers	Remarks	Sources
Technical Barriers	Lack of skilled personnel, lack of code of standard, lack of maintenance and operation, lack of training facilities and entrepreneur's development mechanism, lack of reliable framework for sustainability.	The barriers lead to poor plans, poor standard, and constraints of the competitive market, inadequate knowledge to know-how for the technology and risk of acceptance resulting in technology locked -up.	Sambo & Bala, 2012; Painly, 2001; Luthra, et al. 2015. Ozoegwu, 2017
Social; Cultural Behaviour	Lack of consumer awareness about the product, lack of understanding of benefit of solar PV and public resistance to chance for new technology.	The barrier, affect the market projection negatively, cultural and religious faith controversies towards economic development and sustainability.	Pasqualetti, 2011; Pollmann, et al. 2014; Akinwale, et al. 2014. Akinyele et al. 2017
Economic/ Financial Barriers	Lack of access to capital, credit to consumers and financial instrument. Lack of support to R & D, high interest rate, import duties subsidies to support local manufacturing.	At the early stage, solar projects need incentives to encourage entrepreneurs. The barriers make it difficult to adopt and sustain due to financial constraints.	Shaaban & Petinrin, 2014; Emodi &Boo, 2015; Kar & Sharma, 2015.
Institutional / Legal barriers	Institutional barriers, legal framework, regulatory issues, non-integration of energy mix, non-participation of private sector, poor R & D culture and stakeholder's non-interference.	High risk of uncertainty for solar support, lobbies against RET, a poor mechanism to reach the institutional policy makers for improvement and negative perception about the technology.	Aliyu, et al. 2015; Charles, 2014.
Political/ Policies Issues	Lack of long term policies, lack of political will to diversify into clean energy, constantly changing of government and re-shuffling of institutions.	These barriers serve as a deterrent to future planning for solar and other renewable energy adoption and sustainability. There is the fear of uncertainty in government.	Sambo & Bala, 2012; Ohunakin, et al. 2014; Painuly, 2001.
Market Distortions Issues	Trade barrier for new product, energy sector controlled, lack of access to diversified technology, lack of facilities and backup technology, non-market oriented research for solar energy technology and application.	The barriers cause hindrance to market penetration and hence new technology failed at some point.	Ohunakin, et al. 2014; Fagbenle, et al. 2011. Ikejemba and Schuur, 2016

Even though, Nigeria possesses potential driving factors for solar energy players to promote the initiatives throughout the country, the deployment and implementation of the initiatives still faces major obstacles making the implementation very challenging. It is hoped that the private sector participation will help the government to come out with an achievable solar energy roadmap. The next section will discuss the method by which this research was carried out

6. Methodology

The method adopted for this inquiry was based on desk study, otherwise recognised as literature-based from peered-reviews. Rather, many of secondary based were searched from published resources 2003 through 2017, with key articles obtained from PsyCho Info, ERIC, ProQuest, Science Direct, SocSci Search, EBSCO and COPAC, which are systematically narrowed to a search of any information related to the driving factors responsible for solar energy initiatives and the barriers which served as an obstacle for the implementation. Relevant literature was themed for critical analysis in order to produce a research outcome. The outcome from the critical literature review is analysed and discussed in the next paragraph.

7. Findings

From the literature, it is evident that Nigeria has huge potentials for solar energy almost throughout the year especially the North-East zone of the country. In accordance with literature findings, the factors driving the solar energy technology include a demand for a sustainable environment to achieve the SDGs, increase in energy demand due to increase in population, Power sector reforms Act, which suggested energy mix, challenges of energy security and access, job creation, financing and market potential, the establishment of energy research centers and stakeholders in the public private partnership deals. Even though, the drivers failed the potential for solar energy initiatives in Nigeria, the industry is encircled by barriers which makes the implementation difficult and almost impossible. Lack of skill personnel, consumer awareness about the product, lack of access to financing, lack of institutional framework, lack of long term policies for sustainable energy and trade barriers are hindering the deployment of solar energy initiatives in Nigeria. The Nigerian socio-economic activities cannot achieve its maximum potential unless the electricity challenges are adequately address by harnessing the available solar energy potential.

8. Conclusion and Recommendation

In conclusion, Nigeria, being a country within the belt of high solar radiation, a huge potential for solar energy could be grabbed to help support the epileptic conventional electricity in the country. The country possessed enormous solar energy drivers, making it a big opportunity to harness the potential solar energy to integrate into other renewable available in the country. In spite of the driving forces for the solar radiation in the country, the implementation process is constricted with many barriers, making it implementation chances very narrow. Even though, the power sector reform saw a progress for diversifying strategy to help bailout the power sector, to the energy mix, the progress indicator traced little or no significant to nearly achieving its objectives.

The Nigerian government together with integration of public private partnership (PPP) need to aggressively pursue measures to mitigate the barriers for sustainable solar energy initiatives in the country by supporting local solar panels and batteries manufacturers and distributors. The abundant solar energy in Nigeria need to be harnessed effectively and integrated with other renewable energy such as wind, biomass and mini-grid to help solve the electricity challenges tumbling the economic development of the country.

Abstract

Direct drive solar milk chillers have been successfully developed and demonstrated with two and a half years field of operational experience in the Nakuru milk shed of Kenya. These innovative solar farm milk chillers (FMCs) are the first such units ever to be deployed and have been successfully operating with no issues or failures. The FMCs enable dairy farmers to boost incomes by selling chilled evening milk which would otherwise not be sold to dairy processors the next morning due to overnight spoilage. Milk is a highly nutritious, but perishable food, the storage quality of which cannot be improved once it has left the farm; thus, it is imperative to chill milk to below 10°C within 4 hours after milking at the point-of-production (on the farm) to protect quality. The solar FMC technology as been used to chill from about 25 to 40 liters of milk overnight to about 4°C. No overnight solar chilled milk was rejected by milk buyers in the 2-year study (traders and dairy cooperatives) and farmer incomes were significantly increased by over 30 percent.

Keywords: photovoltaics, direct drive solar refrigeration, milk chilling, Kenya

1. Introduction

SunDanzer Refrigeration, Inc. (SDZR) and Winrock International (WI) have partnered to develop and deploy the world's first solar farm milk chillers (FMCs) to help East African dairy farmers sell their evening milk to dairy processors that otherwise would spoil or forced consumed. The ***Photovoltaics for Sustainable Milk for Africa through Refrigeration Technology (PV-SMART)*** project aims to tackle off-grid milk cooling under the United States Agency for International Development (USAID) Powering Agriculture Energy Grand Challenge Program (PAEGC). PV-SMART began in 2013 to develop the world's first on-farm solar milk chiller. The SDZR/WI team is working in collaboration withthe County Governments of Baringo, the Department of Dairy and Food Science and Technology at Egerton University, and with dairy cooperatives and LLCs in Mogotio and Ngorika, and with the Happy Cow dairy processor in Nakuru. Chloride-Exide is the local firm representing SDZR and installing the FMCs.

Direct drive PV refrigerators were developed nearly 20 years ago and are commonly used for vaccine refrigerators for remote clinics (Foster, 2001). This project has scaled up this concept to develop an affordable direct drive with thermal ice storage capable of chilling up to about 40 liters of evening milk. The project has piloted 80 of these innovative milk chillers in Kenya and two units in Rwanda with UNIDO, allowing farmers to sell between 5 to 40 extra liters per day of higher quality evening milk. This results in additional farmer income, ranging from US$60 to US$500 extra incomes per month, depending on the number of cows per farm. Solar equipment investment payback averages about 6 to 12 months for these smallholder farmers based on increased evening milk sales.

There are over 850,000 smallholder dairy farmers in Kenya, about 85 percent of who do not have access to the national electric power grid. Diesel fuel is expensive and logistics difficult to deliver to small rural dairy farmers and uneconomical to use for small scale refrigeration. Thus, there has not been an economical method available for on-farm milk chilling for the vast majority smallholder dairy farmers in Kenya and other less developed regions globally. The typical Kenyan dairy farmer has about 3 to 5 cows, producing an average of about 8 liters per day of milk per cow (typically ~60% as morning milk and ~40% as evening milk). Dairy cooperatives have an

doi:10.18086/swc.2017.16.02 Available at http://proceedings.ises.org

organized morning milk collection system, but normally do not accept evening milk since by morning due to high bacteriological counts growing overnight. Due to the lack of on-farm refrigeration, evening milk is either forced consumed, sold cheaply to nearby neighbors or hawkers, or spoils. Only about 40% of milk produced nationally is processed in Kenya.

Fig.1: Dairy farmer training for solar farm milk chillers (FMCs) in Ngorika, Kenya.

This failing in upstream milk production causes milk spoilage and lost farm earnings. It also causes poor quality milk and further losses in earnings along the downstream dairy value chain. Of the milk that does arrive, much of it still has a high bacterial count due to lack of refrigeration, resulting in poor quality dairy products. Farmers could receive a premium price for better quality, refrigerated milk; dairy processors could charge a premium for better quality products if milk can be kept cool all the way from cow to consumer; especially during the all-important first four hours after milking that determine quality.

In order to enhance the value of milk from remote producers, *PV-SMART* has developed an affordable solar powered farm milk chiller (FMC) so these producers can deliver cool milk rather than warm to the central collection stations. The farmers also use FMCs on the farm to preserve other produce such as eggs, meat, fruits and vegetables. Besides demonstrating the technology proof of concept, *PV-SMART* is also working with stakeholders like Kenyan SACCOs (Savings and Credit Cooperative Associations) to provide financing for solar technologies like FMCs that can increase on-farm productivity and incomes. Farmers often need access to technology and credit on reasonable terms to finance the initial purchase of solar power systems, which have higher capital costs but lower operating costs when compared to traditional remote generation energy technologies like diesel gen-sets.

PV-SMART has a four-phase implementation strategy for developing, disseminating, and financing FMCs in Kenya:

- Year 1—Technology Development: Designed and tested prototype solar farm milk chiller (FMC) by scaling up an off-the shelf photovoltaic refrigerator (PVR) model. Surveys were conducted of smallholder dairy farmer's needs, and besides milk chilling, a wire basket was added for perishable household food items, as well as two 5V USB ports for daytime cell phone, radio, and LED lantern charging.

- Year 2—Pilot Phase 1: Piloted the world's first solar FMCs to 39 smallholder dairy farms in Baringo and Nyandarua Counties of Kenya. A baseline control unit was also installed at the Egerton University (EU) Department of Dairy and Food Science for more in-depth testing and milk quality evaluations. Field evaluations and farmer surveys were conducted by EU.

- Year 3— Field Testing Pilot Phase 2: Based on Phase 1 field experience, design and testing of a next generation prototype was developed with 40 units deployed to Kenya and 2 in Rwanda with UNIDO: (i) design adaptations notably moving from a ground to roof mounted PV system; (ii) established a local dealer network with Chloride-Exide; and (iii) begin financing units to farmer with Kenyan Savings and Credit Cooperative Associations (SACCOs), starting with Skyline SACCO in Mogotio. Demonstrations are also expanding to new regions with Mercy Corps and GiZ, including for camel milk chilling.

- Year 4— Commercial Rollout Phase 3: Planning is underway to expand the solar FMC technology commercially in Kenya with Chloride-Exide. Encourage more SACCOS to finance FMCs to more dairy farmers throughout Kenya. Expand FMCs to Rwanda and Tanzania.

2. Direct Drive Photovoltaic Refrigeration

The SunDanzer solar FMC is a direct drive refrigeration unit with no batteries that uses thermal phase change material (ice) energy storage. The technology was originally developed in support of NASA's future planetary mission's refrigeration requirements 20 years ago (Ewert, 2002), and later commercialized for vaccine battery free refrigeration. This is accomplished by integrating water as a phase-change material into a well-insulated refrigerator cabinet and by developing a microprocessor-based control system that allows direct connection of a PV panel to a fixed or variable speed dc compressor. By storing ice in the walls of the refrigerator, it eliminates the needs for electro-chemical energy storage. The solar refrigerator uses a vapor compression cooling cycle with an integral thermal storage liner, PV modules, and a controller. The Kenyan solar FMC employs a fixed speed dc compressor. By storing ice in the walls of the refrigerator, it eliminates the needs of battery storage; ice never wears out and provides sufficient energy storage to cool 40L of milk overnight.

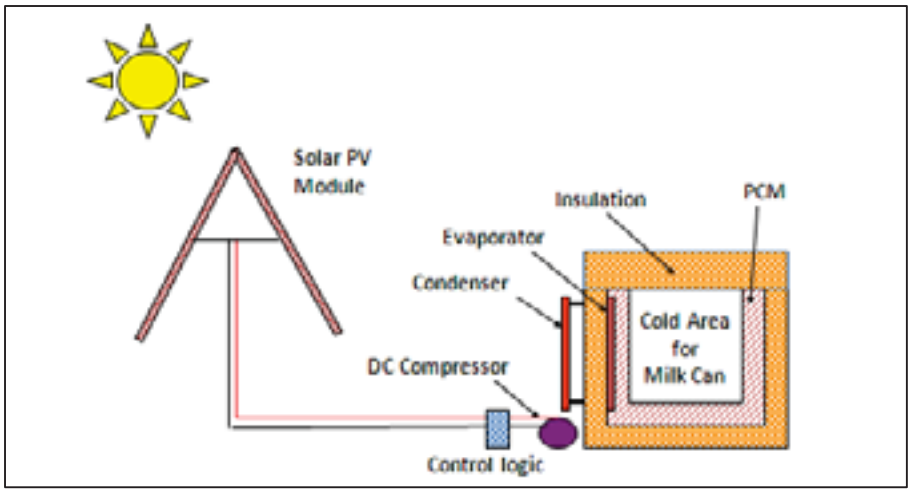

Fig. 2: Solar direct drive refrigerator with DC compressor and E-W "fixed tracking" array (Foster, 2015).

In addition to increasing the quality of product for farmers, the solar FMC has two 5 V USB plug ports capable of charging cell phones, radios, and solar lanterns which farmers use for themselves or rent out. Likewise, there are dietary and health benefits for farmer families to store vegetables, fruits, meat, etc. in the solar FMCs, which also reduces the frequency of trips to town to purchase fresh produce.

Fig. 2: PV Powered Chiller Using Thermal Ice Storage and Brine Bags to Chill Evening Milk

Figure 1. Rooftop PV Installation for Mogotio Dairy Farmer FMC

2.1. "Fixed Tracking" Array

The solar FMC system also uses an innovative East-West "fixed tracking" array to maximize compressor run time and not daily energy production. Conventional tracking increases both capital and operating costs due to additional hardware and maintenance requirements for moving parts. While a conventional equatorial facing PV array power output is well over the required power requirements for the FMC at solar noon; the East-West array's output wattage supplies the required compressor power for a longer period. Thus, increasing compressor run time providing longer operating hours for farmers to chill more milk. While this approach does not maximize energy usage, it does maximize ice production over the course of the day. PV prices have come down sufficiently that fixed tracking is a viable economic option over tracking without the future maintenance concerns. This type of approach works especially well in equatorial latitudes like Kenya. This simple approach provides reliable performance [4].

Fig. 5. FMC PV array (510 Wp) with unique East-West fixed tracking array under test at Egerton University Dairy Science Unit.

With the compressor running most of the daylight hours due to the E-W "fixed tracking" array (the array is not actually moving like a conventional tracker, but is fixed with half the array facing East and the other half facing West to maximize daily compressor run time). Ice is formed and stored into the walls of the PVR. Thus, there is no need for expensive battery storage and replacements. Ice does not wear out. Testing at New Mexico State University for NASA and SDZR on an early prototype PVR with ice storage was successful [2] and led to the development of direct drive vaccine PVRs using ice storage. The proven PVR technology was then increased in size for larger scale milk chilling.

In order to maximize heat transfer, the solar FMC incorporates brine bags, which do not freeze at 0°C, that are placed around the milk cans to increase heat transfer and cool milk quickly. Milk naturally contains antibacterial agents to protect the suckling young from potential infectious diseases; these antibacterial agents also slow bacteriological growth – the cause of milk souring. This effective natural protection is called the lactoperoxidase system, and has both bacteriostatic and bactericidal effects against some milk spoilage microflora for about the first four hours after milking. Bacteriological growth is further retarded when milk temperatures fall below 10°C and is essentially halted at 4°C. The FMC chills 25 liters of milk down to 10°C in a couple of hours, and the milk temperature by morning is about 4°C [4].

Since dairy farmers typically milk cows twice a day, once in the morning (~60%) and again in the evening (~40%), evening milk must be consumed or sold to neighbors or hawkers at a cut price. Even so, much of the evening milk spoils overnight. About 60% of milk in Kenya is not processed mostly due to the lack of on-farm chilling options. Solar FMCs increase farmer incomes from selling milk that would otherwise spoil, and some innovative dairy processors making cheese and yoghurt who need better quality product offer a Quality Milk Payment system incentive to dairy farmers. Solar chilling provides farmers the means to improve their milk quality and overall sales.

Fig. 6: Kenyan dairy farmer with her solar farm milk chiller (FMC), which has become a prized possession in her home.

3. Operational Findings

WI in collaboration with Egerton University Dairy and Food Sciences Department has been monitoring and evaluating (M&E) the performance and benefits of the Solar FMCs installed on the Mogotio and Ngorika Cooperative dairy farms. *PV-SMART* team is also monitoring solar irradiance at Ngorika and Egerton University sites. A few selected milk cans have a Hobo data logger installed on them to monitor milk can temperature data. The temperature probe is installed on the can with foam over it so that it measures true milk can temperature only.

The findings are based on milk can temperature data collected, co-op milk sales, surveys with the end-users, milk can temperature data, and field observations by the WI and Egerton University team. All of the original 40 piloted solar FMCs have functioned for 2.5 years with no failures, and no failures in the next 40 Phase 2 units as well. There was one Phase 1 unit which had a refrigerant leak upon delivery due to springing a refrigerant leak over some extremely rough roads traversed for delivery; this was easily repaired by a local refrigeration technician from Chloride-Exide for US$40 and the unit has functioned with no issues ever since. The solar FMC technology couples mature PV technology with mature vapor-compression technology and is very reliable.

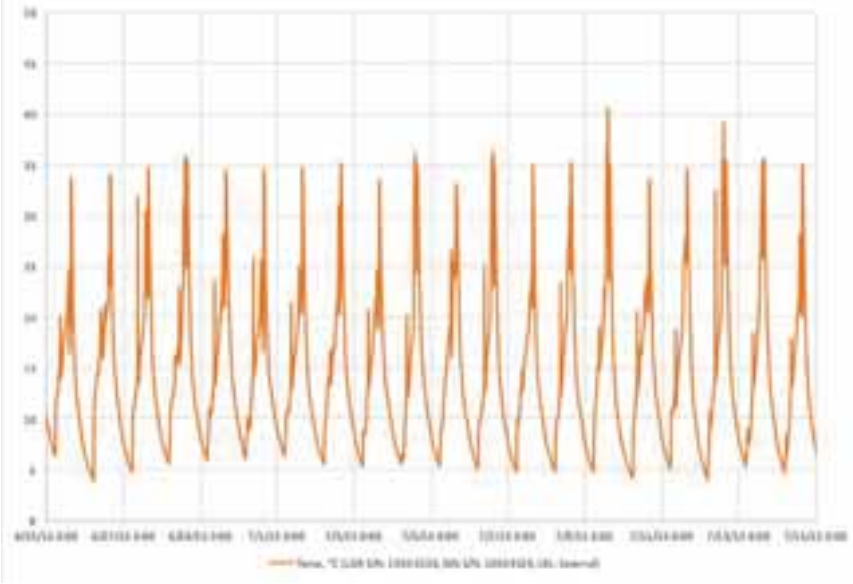

Fig. 7: Example Daily Milk Can Temperature Cycles (daytime high when can is drying in the sun and nightimg low with milk).

Milk temperature: The FMCs work well to chill 25 liters of evening milk to 4^{O}C and lower. If some milk is not removed the next morning and left throughout the day, small quantities of milk can freeze, indicating the prototype FMC may have 'spare' cooling capacity for Kenya. The figure below shows daily milk cooling cycle for one of the farmers, milk temperature is repeatedly cooled to about 5°C. Note that the farmer puts the milk can outside in the direct sunlight for drying after cleaning so the can heats up to above ambient peak temperatures during the daytime.

4. Impacts and Results

PV-SMART is piloting 80 solar FMCs in Baringo, Kisumu, Nakuru, Nyandarua, and Wajir counties, as well as one control unit at Egerton University. The first 40 Phase 1 Pilot solar FMCs have operated flawlessly in the Nakuru milkshed of Kenya with no equipment failures in the first 2.5 years. The second Phase Unit are being installed from August – November, 2017.

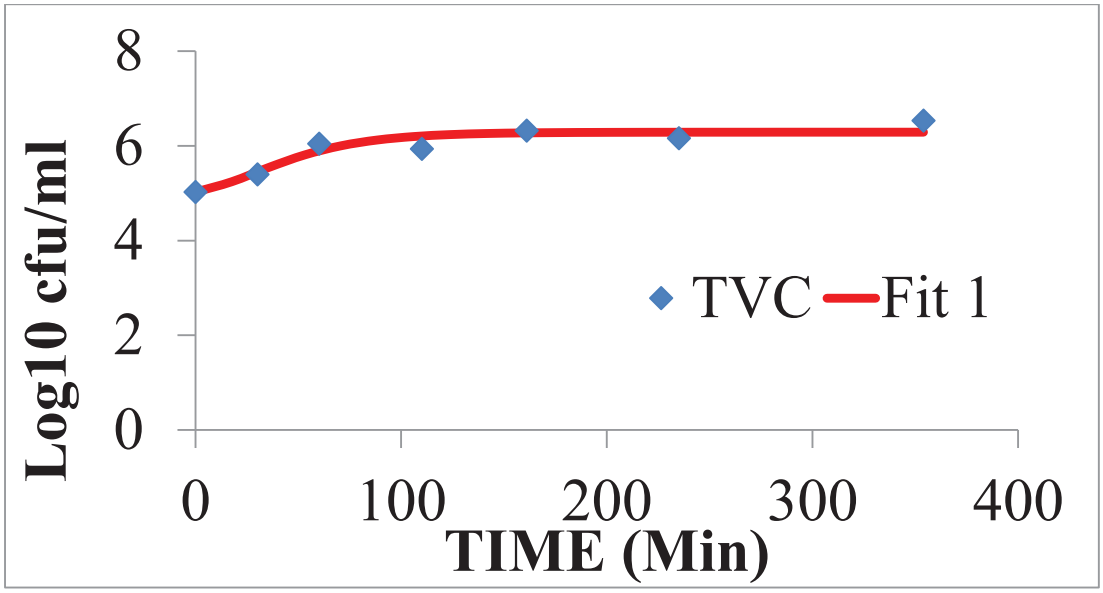

Fig. 8: Total Viable Count (TVD) of Bacteria shows that once the milk is introduced to the solar milk chiller, bacteria growth is halted.

The average dairy farmer chilled about 25 L of evening milk to 4°C; a few farmers chill as much as 40 L every night. Milk quality is maintained after milking and there have been zero rejections of solar chilled milk for any of the participating dairy farmers using solar FMCs, unlike from before. An informal farmer-to-farmer milk supply network was also organically created by solar FMC owners with excess capacity provided to their neighbors through FMC sharing (rent, barter, or purchase).

Over 92 percent of Mogotio farmers (lower elevation and hotter climate) and 67 percent of Ngorika farmers (higher elevation and cooler climate) reported increased milk sales directly attributable to chilling evening milk using solar FMCs. Other on-farm production factors include a severe drought in 2017 reducing forage and milk production for some farmers.

FMC field evaluations were conducted by WI in collaboration with the Department of Dairy and Food Science and Technology at Egerton University for units installed at the Mogotio Farmers' Cooperative Society Ltd. and New Ngorika Milk Producers Ltd. The farmer companies collect, bulk and deliver milk to two processors in Nakuru: Happy Cow Ltd and New Kenya Cooperative Creameries Ltd. Both are piloting quality-based milk quality payment (QBMP) schemes to incentivize farmers to improve milk quality. Based on solar FMC experience to date the key findings are below and summarized in Tables 1, 2, and 3.

- All 40 Phase 1 FMCs performed well and according to design, i.e. chilled 25 kg of warm evening milk to <10^{O}C within two hours, and to <4^{O}C by next morning collection.

- Some farmers were chilling up to 40 kg milk in plastic barrels to <10^{O}C prior by next morning collection – indicating potential to chill more than the designed 25 kg milk (ambient conditions vary).
- Some milk collector-transporter-farmers use the FMC to aggregate and chill up to 40 kg evening milk from 3 to 5 nearby farmers, charging additional KES 2 (~2 US cents) per kg.
- After homestead use of evening milk (for home and calves), the Phase 1 users are selling between 2 and 45 kg 'extra' milk daily – indicating gross incremental income gains ranging from KES 1,800 to 40,500 (US$18 to 400) per month based on an average farmgate milk price of KES 30/kg. Cows produce milk in the evening regardless of whether there is a market or not.
- Two head of household ladies earn 'extra' income from FMCs charging neighbour's cellphones - ~KES10 per charge x 10 = KES100 (US$1) per day.
- The FMC kept milk fresh until morning with zero rejections reported in two years.

Table 1: Evening Milk Sales Increased Dramatically to Dairy Processors

Location	Did Milk Sales increase?	Evening Milk Usage and Sales			
		Before FMC Installation		AfterFMC Installation	
		Home Consumption	Local sales	Home consumption /local sales	Sales to Dairy Processors
Mogotio n=19	No (7.7%	69%	31%	8%	92%
	Yes (92.3%)				
Ngorika n=20	No (16.7%)	27%	73%		100%
	Yes (66.7%				

Table 2: Comparison of milk stored in the Solar FMC

Parameter	Farm 1		Farm 2		Bench Sample	
	Evening	Morning	Evening	Morning	Evening	Morning
Room Temperature °C	19.0	17.4	20.6	19.1	19.1	18.1
Milk Temperature °C	29.6	3.5	28.4	0.2	29.5	17.2
Acidity (% Lactic acid)	0.162	0.174	0.155	0.164	0.161	0.195
pH	6.64	6.59	6.59	6.57	6.64	6.24

Table3: Milk quality change during overnight storage from Egerton University Dairy Lab

Parameter	Farm 1	Farm 2	Bench Sample
Time in storage (Hours)	14.946 ± 0.168a	15.361 ± 0.298a	14.946 ± 0.168a
Titratable acidity (%LA)	0.012 ± 0.012b	0.009 ± 0.006b	0.033 ± 0.022a

Red figures indicate did not meet KEBS norms.			

The key takeaway is that the solar FMC works and improves on-farm milk quality at point-of-production on the farm potentially enabling more quality milk to enter the dairy supply chain. The returns from investing in solar FMCs appear are under a year, even for smallholder dairy farmers. WI is working with the Skyline SACCO and other partners to finance solar FMCs in 2017 as there is a good business case with relatively low repayment default risk facilitated by the well embedded existing milk 'check-off' repayment system.

Thus, milk quantity and potential incremental gross earnings gain at current milk prices is excellent for these pilot units, with simple payback ranging anywhere from six months to one year depending on user milk production. From the initial surveys users sell between 5 and 45 liters of extra evening milk each day, indicating gross incremental income gains ranging from US$50 to $650 per month. Kenyan small scale financial credit institutions (SACCOs) have begun financing PVRs during Phase 2 of PV-SMART at an initial selling price of about US$1,850 per installed unit if roof mounted (pole mounting is more). The final commercial price may vary. Field surveys found that 83 percent of the Phase 1 pilot FMC farmers felt the solar FMC technology was worth the initial cost and is a worthwhile investment. Financing is key as over 70 percent of small holder farmers prefer a short-term (1 year) loan mechanism to purchase solar FMCs.

5. Conclusions

PV direct drive solar milk chillers (FMCs) have been successfully introduced and used in Kenya with zero failures in the first 2.5 years of operation. There is a significant increase in amount of milk sold and the farmer income accruing from the extra liters of milk sold. Smallholder dairy farmers have sold between 5 and 40 extra liters of evening milk each day, depending on their dairy herd size. The FMC kept milk fresh until morning with zero rejections reported from the milk collection center. Resulting farmer income gains ranged from US$60 to $500 per month, with expected FMC payback typically in less than a year. This type of solar milk chilling uses no batteries and has no regular maintenance requirements. There are over 5 million smallholder dairy farmers in East Africa who can benefit from this technology, not to mention the millions more of other off-grid smallholder dairy farmers in the rest of Africa, Asia, and Latin America that can also benefit from solar FMCs to improve livelihoods and delivered milk quality.

Integration and management of solar energy for electric vehicle charging station

Asif Khan[1], Saim Memon[1], Tariq Sattar[1]

[1] London South Bank University, London (United Kingdom)

Abstract

A rise of electric vehicles and consequent increase of charging stations in the UK has widely been acknowledged due to its negligible carbon emissions leading to the transformation of low-carbon economy. A dynamic increase in the wind and solar power systems installation and grid-integration to the charging stations of electric vehicles has led uncertainty issues in the power distribution grid e.g voltage fluctuations, transients/harmonics. This paper addresses the uncertainty scenario aiming to contribute and propose a potential model focusing on the design of the route in which solar electric power is delivered to the electric vehicle charging station. A specialised system containing an electrical control system is proposed using MATLAB and SIMULINK. A system was designed for improving the interaction among electric-vehicle charging points and battery storage system in which electrical control system assists in developing the correct duty cycle in order to stabilise and regulate the voltage at the DC/DC power conversion station. The proposed system is very effective and significant contribution in understanding and reducing the load on the converter untimely enabling reduction of charging time for electric vehicles. The implemented electrical control system manages the electric power on the grid such as during the peak times it draws power from the batteries and then charges up the batteries in the off-peak times. A constant voltage is achieved on the micro grid irrespective of fluctuations in solar energy generation and in the load.

Keywords: Solar system, Power conversion, Electric vehicles, storage system, charging station

1. Introduction

Around 550000 hybrid electric vehicles are reported to be registered in 2015 by the centre of solar energy and hydrogen research (Shaaban et al, 2015). The storage energy based electric-vehicles are classified into plug-in hybrid electric vehicles (Han et al, 2017).The main factor in the revolution of electric-vehicles is due to the improvement in power electronics components, better performance of electric machines and the storage system (Shen et al, 2014). The power electronics components such as switches, converters and drives increase the performance of power conversion. Beside this, development of software for hybrid electric vehicles is a silent revolution. The hybrid electric vehicles combine the motor of propulsion and ICE (Guan and Chen, 2017). An increase of plug-in electric vehicles are due to the several reasons such as it generates no carbon emissions due to the usage of no fossil fuels and long-term sustainable mission of transforming cities towards 100% renewable and make cities better economically (Yu, 2017 and Zhang, 2016) because the carbon dioxide emissions was 407.70 ppm in May 2016 and is continuously increasing (Cheng et al, 2015). Currently, the state of art uses to charge up the batteries in the hybrid electric vehicles are fuel cells, regenerative breaking system, and the vehicles charging station. These vehicle charging stations are connected to the National transmission energy network (Dubarry et al, 2017). Charging up the electric vehicles from the distribution network is not suitable as it increases the electrical demand on the network and creates power flow issues on the distribution network such as transients, harmonics and voltage reductions (Sheng et al, 2017). The power supply to the electric-vehicles can be AC or DC type. AC type power flow is not suitable for the electric-vehicle (EV) charging station as it increases charging time. The DC type power flow reduces the charging time and increases the performance of the electric-vehicles (Tan, 2016) and (Yong, 2015). DC power flow system also reduces the power losses due to shorter in length for the EV charging station. The purpose of designing such system is to reduce the power flow issues such as voltage fluctuations and transients/harmonics and issues at the existing transmission system. The DC grid is fed from the solar energy where power generation is always fluctuating, therefore, a control system required that transmits the signal at a very faster rate (Liu and Sun, 2014).

doi:10.18086/swc.2017.16.03 Available at http://proceedings.ises.org

This paper presents the Simulink model for the solar storage system that transmits high DC voltage to the charging station. This is due to the unpredictable power generation from the solar system, it is a challenge to supply the constant required voltage to the electric vehicle. Beside this, quality ratings and stability are the main factors to charge up the large numbers of electric vehicle instantly. Due to these issues imbalances occur and harmonics and voltage sags arise. The research investigates the voltage efficiency and power flow management of solar energy transmission to the electric-vehicle charging station. This system has the ability to manage the power flow between generation and the loads. Under normal conditions, it is connected to the solar energy system and the storage battery bank and can be linked with fuel generator if required.

2. Methodology

A PV solar system of nominal energy geneation capacity 200 kWh is simulated on MATLAB/SIMULINK in which the 200 kWh storage system is added to balance the energy demands during the higher temperatures and low irradiance.This storage system is charged up from the solar system and the fuel generator. The fuel generator has the energy generation capacity 200 kWh that charging up the storage system after the energy falls to 60%. The storage system supplies power to the electric-vehicle charging station during the disturbances. The electric-vehicle charging station has maximum power consumption capacity of 103.50 kWh consisted of four charging points. DC/DC power conversion is carried out by using insulated gate bipolar transistors (IGBT) where MATLAB function coding environment is used to control the frequency of the IGBT and to stabalize the voltage from the solar system. By using low pass filter, spikes and transients are mitigated to achieve power quality. It is investigated how the temperature, irradiance, and over loading affects the power regulation on the system. Specifically, voltage instability and the transients are investigated. Programmable protection circuit breakers are placed to protect the charging terminal. Controlled power conversion system and analytical techniques are implemented to control the power flow in the system.

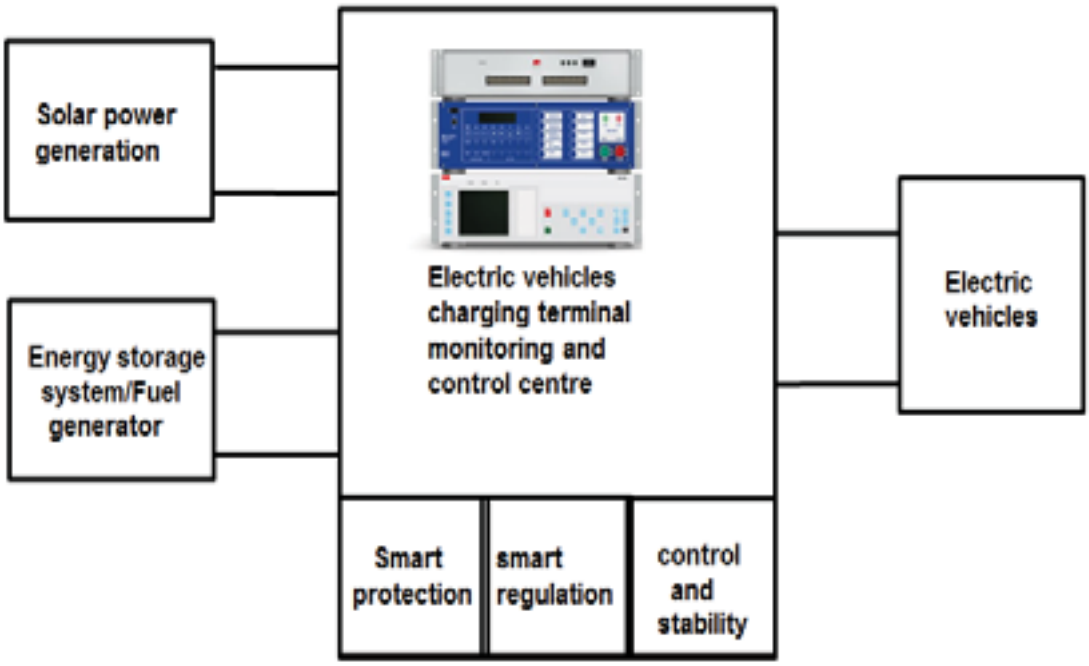

Fig. 1: illustrates the schematic model of the proposed system in which solar energy/storage system are maintaining the energy demands at the electric-vehicle charging station, smart monitoring and control system are used to convert and regulate the power flow from the storage and the solar system consisting of controlled DC/DC converter that is connected with the energy resources and the electric-vehicle loads

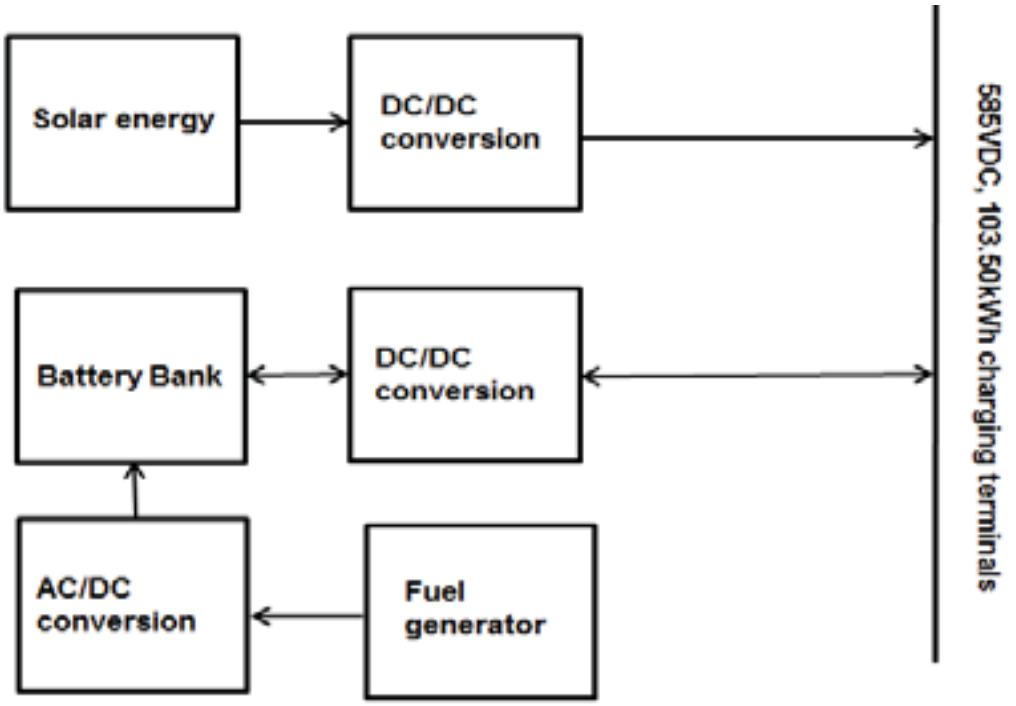

Fig. 2: is the block diagram of the power conversion for the solar system, fuel generator and the storage system in which the power flow between the storage system and the charging station is considered to be dual flow, meaning storage system can supply and receive energy from the charging station.

3. Discussion

The proposed structure consists of solar energy system, monitoring and control structure, measurements units, energy storage system, fuel based electric power generation system and power conversion system. The EV charging terminal consists of programmable protection system and a voltage regulator that assists to supply the quality power. The electric-vehicle charging station is receiving the electric power from the solar and storage system. The nominal power generated by the solar system is 200 kWh. The voltage from the solar system is converted to 585VDC that reduces the charging time for the electric vehicles. Irradiance and temperature block is used to provide sun power to the panels. Input from the irradiance is varying. Voltage source converters are used to convert the power from the solar farm. Then this power was added to the DC/DC converter station where a buck-boost converter is placed to balance the voltage. Low pass filter is applied to remove the transients and harmonics. It also supports to control the current and maintain the DC voltage level. A bi-directional converter is placed between the DC microgrid and the battery bank that charges up and discharges the batteries from the microgrid and it monitors the power flow at the grid and battery bank. During the peak time, battery storage system is dependent on the solar power generation unit, the fuel generator takeover to meet the energy demand. This topology is considered to improve the power flow on the transmission network due to the reduction in harmonics and voltage fluctuations. Transients and spikes arise in the system are also due to the installations of super capacitors at the electric-vehicles storage system. This reduces the efficiency of the power flow on the system because inductively behaves superlative at lower frequencies and capacitance load show good performance at higher frequencies. Due to DC power system, there is no phase shift between current and voltage but the voltage stability needs attention which can be maintained by supplying the correct pulses to the power converter switches.

List of energy converters connected to the electric-vehicle terminal.

- DC/DC energy conversion system for the solar energy system.
- AC/DC energy conversion system from the fuel generator.
- DC/DC power conversion system for the storage system.
- Monitoring and control centre energy measurement and regulation system

The DC/DC buck converters are used to transmit the regulated voltage to the electric-vehicles. To create the mathematical formulation constant voltage and constant power is assumed to be flowing out from the energy converter terminals. The constant voltage is achieved by applying the 50 kHz frequencies at the converter switches. The resistance of the tranmsitted conductor is considered constant. The capacitance and inductance are neglected due to DC type power flow system.

The power flow into the terminals is splitted into three subsets $\{V, R, P\}$ and the constant controlled voltage is received from the solar system/storage system. Branches of the terminal for voltage source converters are represented by $V = N \times N$ included the constant resistance of the conductor. The electric vehicle charging terminal converts the 585VDC into the voltage required to charge the electric-vehicle batteries and the supercapacitors. The terminal voltage and current admittance matrix on the system $G \in R^{N \times N}$ is expressed as follows,

$$\begin{bmatrix} I_V \\ I_R \\ I_P \end{bmatrix} = \begin{bmatrix} G_{VV} & G_{VR} & G_{VP} \\ G_{RV} & G_{RR} & G_{RP} \\ G_{PV} & G_{PR} & G_{PP} \end{bmatrix} . \begin{bmatrix} V_V \\ V_P \\ V_R \end{bmatrix} \quad \text{(eq. 1)}$$

Where $\mathbf{I_R} = -\mathbf{D_{RR}}.\mathbf{V_R}$ (eq. 2)

For the electric-vehicle charging terminal singular matrix can be written as shown in equation 3. Where B is the susceptance and D_{RR} is a diagonal matrix is for admittance.

$$V_R = -(D_{RR} + G_{RR})^{-1}(G_{RV} .\ V_V + G_{RP} . V_P) \quad \text{(eq. 3)}$$

$$I_P = J_P + B_{PP}. V_P \quad \text{(eq. 4)}$$

The voltage received from the storage/solar system is 585VDC. Power links are evaluated by the following equations where I_P is the current level and V_P is the voltage flow on the system.

$$P_P = \text{diag}(V_P) . I_P \quad \text{(eq. 5)}$$

The storage system is balancing the power flow on the system during the peak times and reduction in power generation from the designed solar system. The electric-vehicle charging terminal detects the power deficiency and switches ON the storage system. P_P is evaluated to

$$\mathbf{P_P} = \mathbf{diag}(\mathbf{V_P}) . (\mathbf{J_P} + \mathbf{B_{PP}}. \mathbf{V_P}) \quad \text{(eq. 6)}$$

With $\mathbf{J_p} = \mathbf{G_{PV}} - \mathbf{G_{PR}}. (\mathbf{D_{RR}} + \mathbf{G_{RR}})^{-1}. \mathbf{G_{RV}}) . \mathbf{V_V}$ (eq. 7)

$$B_{PP} = G_{PP} - G_{PR}. (D_{RR} + G_{RR})^{-1}. G_{RP} \quad \text{(eq. 8)}$$

The voltage in the terminals can be set by the solving the equation 9.

$$\mathbf{V_P} = \mathbf{B_{PP}^{-1}}. \left(\mathbf{diag}\left(\mathbf{V_P^{-1}}\right) . \mathbf{P_P} - \mathbf{J_P}\right) \quad \text{(eq. 9)}$$

To investigate the V_P, let consider $T \rightarrow R_P$

$$TV_P = B_{PP}^{-1}. (\text{diag}(V_P^{-1}) . P_P - J_P) \quad \text{(eq. 10)}$$

The voltage is stabilised at the monitoring and control centre in order to maintain the energy flow for the electric-vehicles at the station. The reduction in voltage is maintained by correcting the applied frequency to the converter switches. Fuel generator is connected with the battery to maintain the power storage on the storage system during the energy shortages.

Energy resources	Capacity
Solar system	200kWh
Storage system	200kWh
Fuel Generator	200kVA

3.1 System performance

With the rapid increase in power consumption at the EV charging terminal, following are the three issues linked with the storage/solar system.

- Quick energy supply from the storage system into the EV charging terminal
- Quick energy injection from the solar system to the charging station.
- Dynamic behaviour instead of long term serving capacity of the storage system.

There are four EV charging points taken for this system. These charging points are associated with the faster charging because of connection with the higher DC voltage of 585 VDC. The charging point consumes 50 kWh, 43 kWh, 7 kWh, 3.5 kWh. The proportion is selected based on the charging points being installed several places in the UK such as 2×50 kWh and 1×43 kWh in Toddington Dunstable at M1 motorway and similar are installed at the china town at London, charter street at Leicester and many other places in the UK. The batteries in the electric vehicles support to run the machines, but the batteries take longer to charge up. During the running period engine are used to charge up the batteries in the electric vehicles. To solve the faster charging for the EV batteries a new system is investigated. Higher voltage DC power supply is found more appropriate to solve this issue. The investigated system has the features to supply the energy during peak/off-peak times at the EV charging station by means of solar and storage system.

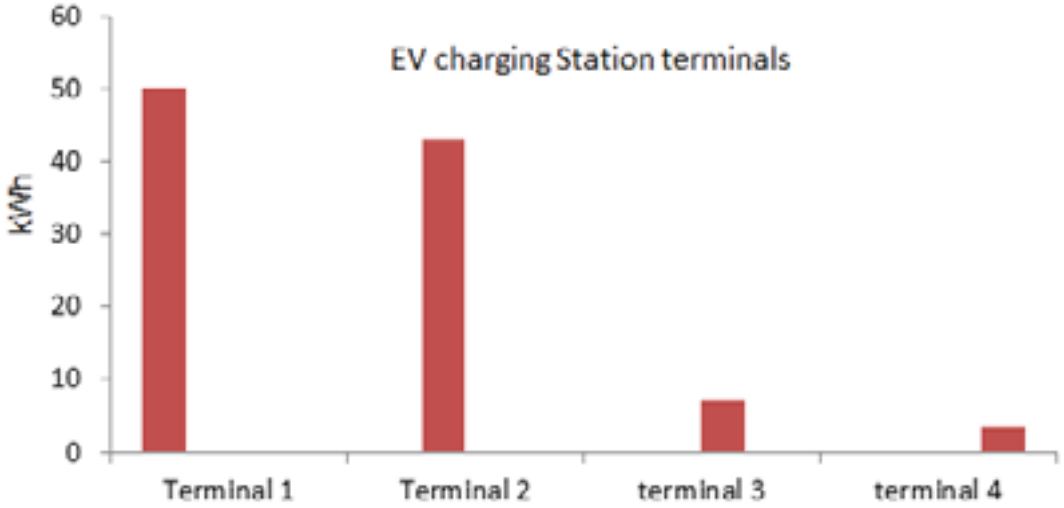

Fig. 4: Illustrates the Electric vehicles charging points at the EV station.

There are four scenarios considered to examine and analyse the energy system performance.

- When the solar system is independently supplying power to the EV charging terminal. In this case, the storage system is in off-mode. This is the best feature as energy demand is completely achieved by the renewable energy/solar system. This system also improves the environment by minimising the carbon emissions generated from the fuel generator. The energy losses are very small due to the shorter length of the electric power transmitted conductor. This scenario has the capacity to meet the energy demands at the EV station during the Peak and off-peak times.

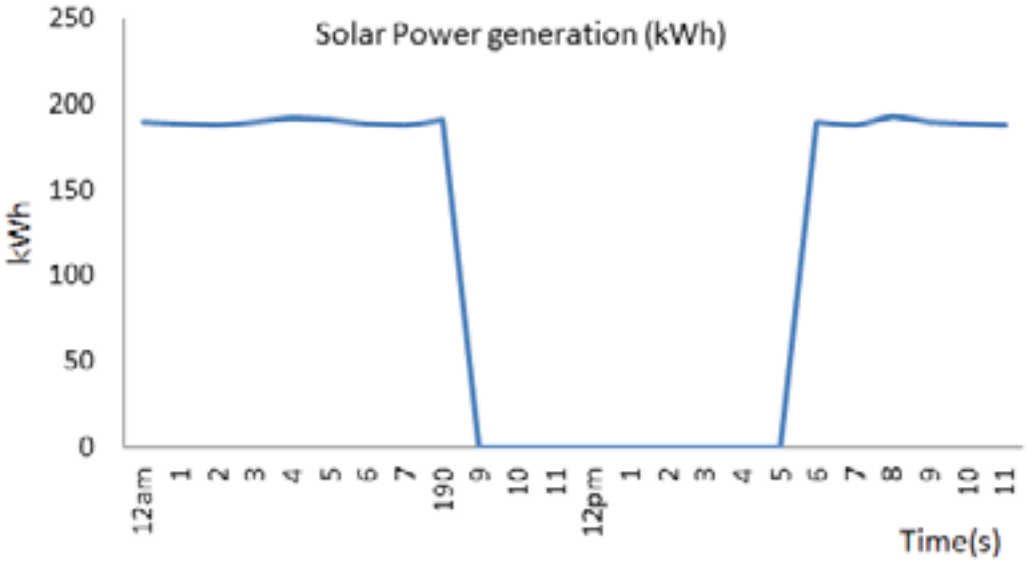

Fig. 5: The power generation by the solar system between 9pm and 5am no power is generated by the solar system. In this case the storage system and fuel generator will meet the energy demands at that time.

- The generated energy from the solar system is charging up the solar system in peak times. In this case, the EV charging terminal is consuming the energy at full capacity.

- When the storage system and fuel generator are meeting the energy demands at the EV charging station. At this point, the solar system is in off-mode and not generating any power. Fuel generator

charges up the storages when energy level falls below 60%. Storage system degradation is normally measured by three main features, such as the depth of discharge, temperature, and the conditions of charge. These three factors affect the performance of batteries used in the storage system.

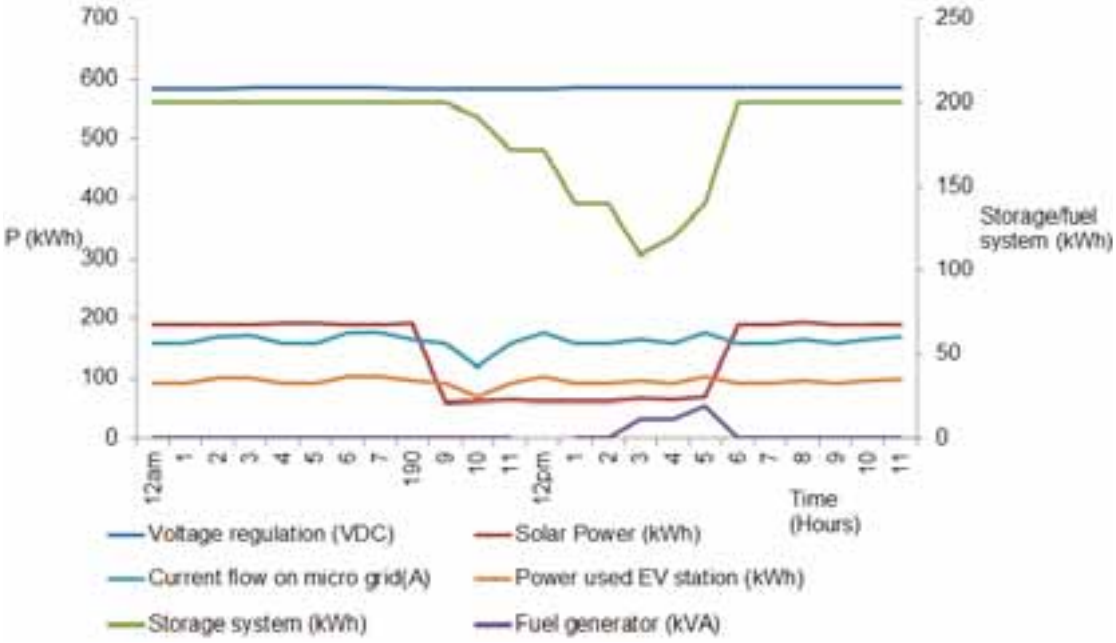

Fig. 6: The energy management at the EV charging station. In this case, the nominal power from the solar system is mitigated from 9pm to 5am where storage system is independently meeting the energy demands at the EV station. Fuel generator switched ON to charge up the storage system as the energy level falls below 60%.

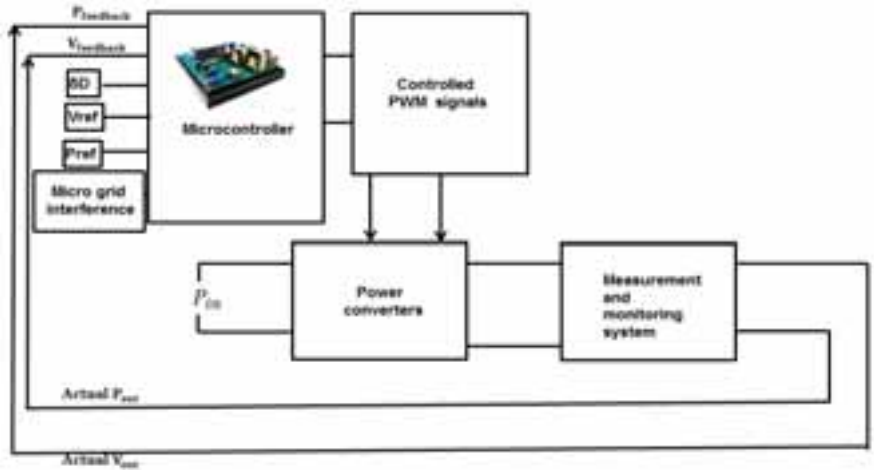

Fig. 7: The implemented control system to apply the correct duty cycle for regulating the voltage.

4. Simulation Results

The spikes and oscillations are detected in the voltage due to the usage of inductance and capacitance in the DC/DC power conversion and on the load side. The lower switching frequency created the higher ripples in the power supply because of the DC/DC buck converter and control system implementation in the electric vehicle charging terminal is featuring to supply the converted and regulated voltage to the electric vehicles. It is noticed that the higher inductance values reduing the losses and created lower ripples currents and to removes the transients low pass filter are used that are improving the sum of power flow relates to the numbers of vehicles being charged up at the electric-vehicles charging station. The losses in the entire

system are very lower due to the shorter length of the transmitted conductor. At the start of the simulation, a transient in the voltage is noticed due to charging up of inductance, the capacitance in the converters and in the line. Power availability is maintained constantly at the electric-vehicle charging station irrespective of changes in temperature/irradiance at the solar charging station. The controllable bidirectional converter is maintaining the power on the EV charging terminal and charges up the storage system. To measure the power flow, measurements components are used at several points of the system. The circuit breaker is used to protect the system from the faults and short circuit current. The system is enabling the electric-vehicles to be charged up all the time from the terminal.

5. Conclusion

A solar energy based electric-vehicle charging station is proposed in this paper. The proposed system is capable of managing the regulated voltage to supply the required energy during the peak/off-peak times. The applied electrical control techniques improve the voltage performance irrespective of the intermittent solar energy due to the changes in irradiation/temperature. The applied electrical control system is the advancement of maximum power point tracking algorithm based incremental conductance. The advancement is the addition interference between the solar, storage and fuel based energy generation system with the micro grid control centre and the application of higher frequency to achieve the quality results. The regulation in voltage is achieved by applying the correct duty cycle to the DC/DC power converter switches where the spike/oscillations and transients are minimised by using the low pass filters. It is found that losses in the system are reduced to 1% due to shorter transmission conductor length and lesser implementation of power converters After examining the simulation results, it is concluded that DC high voltage based electric-vehicle charging station reduces the charging time for the batteries of the electric vehicle. The simulation results are validated by the mathematical modelling and theoretical analysis. During the normal environmental conditions, the solar system has generated the electrical energy at full capacity that is considered to be sufficient for the EV charging station. The direction of future work is to incorporate the communication system at the electric-vehicle charging station to examine the energy flow from the solar/storage system. This communication should be linked with the smart sensors that are implemented at several points such as DC/DC solar converter, DC/DC storage converters and at the grid. This will improve the protection for the EV charging terminal during the disturbances from solar/storage or at the converters.

Abstract

Although all energy produced by grid-tied renewable energy systems can be delivered to the grid for consumption by a wide user base, energy delivered by an islanded renewable energy system is limited by the time varying consumption of those served. A set of metrics is proposed to better evaluate this impact on the economic value of the system. This impact can be very significant in developing countries.

Smart systems can reduce energy consumption during periods of high demand through load shedding, but this technology is expensive and unproven in the context of a developing country. Smart systems typically do not add loads during periods of low demand, partly due to the incremental cost of electrical energy from non-renewables. A prioritized dump load control scheme is proposed that strategically diverts excess energy in a 100% renewable energy system to a set of loads useful to the community, first to satisfy the needs of the most valuable use, then to the next most valuable use, etc. A low cost architecture including hardware and software is introduced as a means to implement this scheme, appropriate in the context of developing communities so their economies can more rapidly evolve.

Keywords: 100% Renewables; Hybrid renewable energy system; Islanding; Pico-Hydro; Prioritized Dump Load; Holistic Community Development

1. Metrics Used to Evaluate Performance of Islanded Renewable Energy Systems

Renewable energy systems powered by 100% renewable resources do not run continuously at full capacity due to maintenance, variable weather conditions such as wind and solar irradiance, and variable availability of water to run hydro turbines. Utilization factor k_u is defined (Sivanagaraju and Sreenivasan, 2010) as the energy generated divided by the plant capacity (nameplate kW power rating) integrated over a period of time. It is used to evaluate the design and operational performance of an energy system, to derate its benefits, and to determine its unit cost through an economic life cycle cost analysis over the power plant's lifetime. According to Bhattacharyya (2013) the utilization factor of micro/mini hydro systems in India can be low due to the unavailability of sufficient water during the dry season versus what is available during the monsoons.

Renewable energy producers can usually deliver all their available power if connected to a large scale utility grid. Conversely, renewable energy producers in an islanded system can deliver no more than what can be consumed at that time, assuming we consider energy storage as a load while being charged. Either energy production must be reduced in times of low consumption, or excess energy must be dissipated in dump loads. Solar energy production is reduced by letting the operating voltage rise from its maximum power point toward V_{OC}. Wind and hydro energy production is typically reduced through braking, regulating the supply of water, or by diverting excess energy to dump resistors heating air or turbine exhaust water, with no use to the users. The latter, shown in Figure 1, is very common in Nepal for micro and pico-hydro systems.

doi:10.18086/swc.2017.16.04 Available at http://proceedings.ises.org

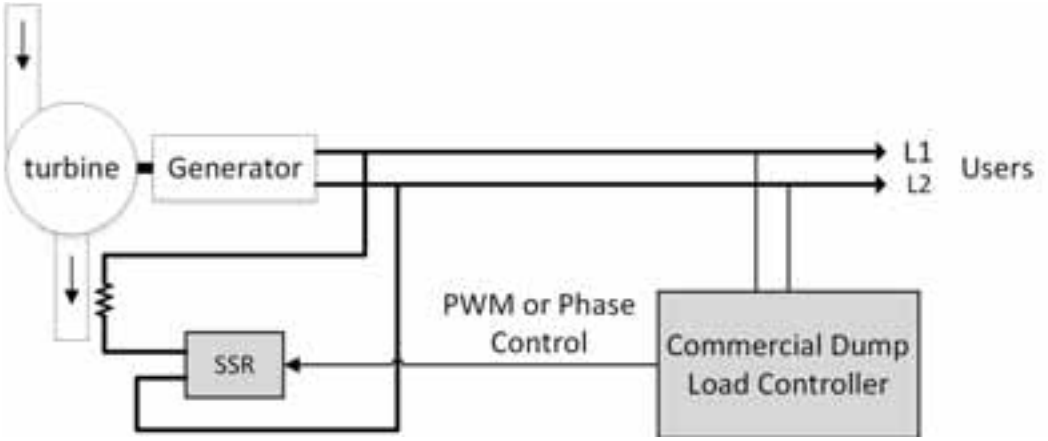

Fig. 1: Traditional Diversion in Pico or Micro Hydro Facilities in Developing Countries

Fig. 2: Traditional water heater "dumb" dump load in MHP (micro-hydro-power) plant in Nepal

Fig. 3: Resistive water heater elements are used to dissipate energy into the turbine's exhaust water.

The value of an islanded renewable energy system must be derated by any diversion or reduction in production required during times of low demand. Although this could be lumped into the utilization factor k_u, that would hide the impact of limited demand. Therefore, two new measures are introduced, the 'production factor' k_p, and the 'consumption factor' k_c.

The production factor k_p is defined as

$$k_p = \frac{E_p}{P_{capacity} * T} \qquad \text{(eq. 1)}$$

Where E_p is the islanded system's energy (MJ) that could have been produced at the pertaining meteorological and environmental conditions if consumption was unconstrained. $P_{capacity}$ is the nameplate power rating of the system. T is the time k_p is evaluated over.

The consumption factor k_c is defined as

$$k_c = \frac{E_d}{E_p} \qquad \text{(eq. 2)}$$

Where E_d is the energy actually delivered to useful loads.

$$E_d = P_{capacity} * T * k_u \quad \text{for grid-tied systems} \quad \text{(eq. 3)}$$

$$E_d = P_{capacity} * T * k_p * k_c \quad \text{for islanded systems} \quad \text{(eq. 4)}$$

k_p is the derating factor due to limits on power generation due primarily to variable and less than optimum weather and water supply, while k_c is the derating factor due to variable consumption in an islanded renewable energy system.

Sivanagaraju and Sreenivasan (2010) also define the load factor as the ratio of average demand to the maximum demand. Although somewhat related to consumption factor k_c, its denominator is the maximum energy demand, not the demand that could have been supported by the system under the environmental conditions over the evaluation period. Consumption factor k_c is a more appropriate metric to understand the impact of limited consumption.

RIDS-Nepal has been working in the Jumla district in Northwest Nepal since 1996, and has observed that during the day most people are working in the fields, so the value of k_c is so low during these periods that production is not warranted. Indeed, many of the hydroelectric systems in this region are shut down during the day to reduce wear and resulting repair and maintenance costs. Furthermore, RIDS-Nepal has observed that the turbine capacity of many of these systems is considerably more than the peak demand of the village it serves, so they are purposely run with constricted water flow to reduce maintenance and the amount of excess energy dumped into the river as heat. RIDS-Nepal has observed that in some cases the turbines are run at approximately 50% of their capacity while still satisfying the peak load. Furthermore, the village consumption varies over the 16 hours the system operates (4pm – 8am), from near its peak (~45% of capacity) consumption for ~4 hours around dinner (5pm - 9pm), to only ~10% of peak to provide minimal lighting throughout the rest of the day (4pm – 5pm) and night (9pm – 8am).

$$k_c \cong \frac{(0.45*4)+(0.045*12)}{24} \quad \text{(eq. 5)}$$

$$k_c \cong 0.10 \quad \text{(eq. 6)}$$

This surprisingly low consumption factor k_c significantly impacts the sustainability of these systems in several ways. First, the funding of operations and maintenance expenses are more difficult to justify due to the reduced benefits delivered by the system. Second, the reduced utilization during the day, and the resulting shutdown of the system during that period, stymies the economic development needed to ease the burden of the needed tariffs. Indeed, RIDS-Nepal has observed that many of the pico- and micro-hydro systems in this area are in service for only a few months to as much as 2 years maximum until significant maintenance expenses arise, at which time the system becomes inoperable or its performance significantly degrades.

The effect of consumption factor k_c is not limited to hydro and wind renewable energy systems. Once a solar system's batteries are fully charged, any excess production must be curtailed or dumped, reducing k_c. Although not as drastic as the example of hydro systems in the Jumla district described above, it can still be significant.

2. Improving the Consumption Factor in Developing Countries

The developed world is just now addressing the consumption factor k_c through smart metering which can shed optional loads or shift demand to times of low consumption. Although not directly increasing the consumption factor, load shedding allows a higher base load than normally could be supported without brownout, which does directly increase the consumption factor k_c. Unfortunately not all loads are considered to be optional by the consumers, so the impact of load shedding is limited.

Adding demand where there otherwise was little, which we'll call "Load Adding" as opposed to "Load Shedding", is not normally used, partly due to the incremental cost of electricity with non-renewable energy sources.

Many micro-grids in the developing world are powered by 100% renewables since hydrocarbon-based fuels are so expensive, especially considering transportation costs. 100% renewable energy sources have an exceedingly low incremental cost of electricity delivered, assuming system capacity isn't exceeded. Incremental energy

utilization is also very valuable in developing nations, for example to help solve basic needs such as:

- Powering pumps to supply clean water or irrigation
- Heating water for hygiene and cooking
- Maintaining the temperature of the slurry in a high-altitude biogas digester to the needed mesophilic (~25°C - ~40°C) or even thermophilic conditions (~40°C - ~60°C) for optimum performance
- Refrigerating fruit for long term storage
- Heating air and powering grow lights in greenhouses to provide year-long nutrition.

This list is not exhaustive, and each village will have to determine the most valuable uses of this excess energy based on their particular needs. Due to low incremental cost and the high value of energy utilization, load adding not only can, but should, be used in islanded pic/micro-grids in developing countries.

3. Prioritized Useful Dump Load Control

Given the number of potential uses for inexpensive, excess energy in the developing world, some mechanism is needed to ensure that the energy is routed to the most valuable load. Due to the dynamic nature of the consumer load profile, the mechanism has to be automatic, with no required decision making by distributed customers to turn useful loads on and off. Because production and consumption are already being balanced in many islanded systems, usually by heating water in dump loads useless to the users, the prioritization of a set of useful dump loads is pursued in this paper.

3.1 Simple Useful Dump Load Control

Figure 4 shows the schematic of a low cost and context-appropriate scheme using ubiquitous water heater thermostats to route excess power to the highest priority useful load needing power as determined by the temperature setting of the thermostat mounted to the water bath associated with that load. For example, thermostat TH1, solid state relay SSR1, and water heater element WHE1 are the components needed to support the highest priority useful dump load. For example, WHE1 and TH1 might be mounted to a hot water tank in a community bathing facility. Similarly TH2, SSR2, and WHE2 are needed to support the next highest priority useful dump load, and SSR3 and WHE3 would be needed to support the lowest priority load which must be able to absorb all available power.

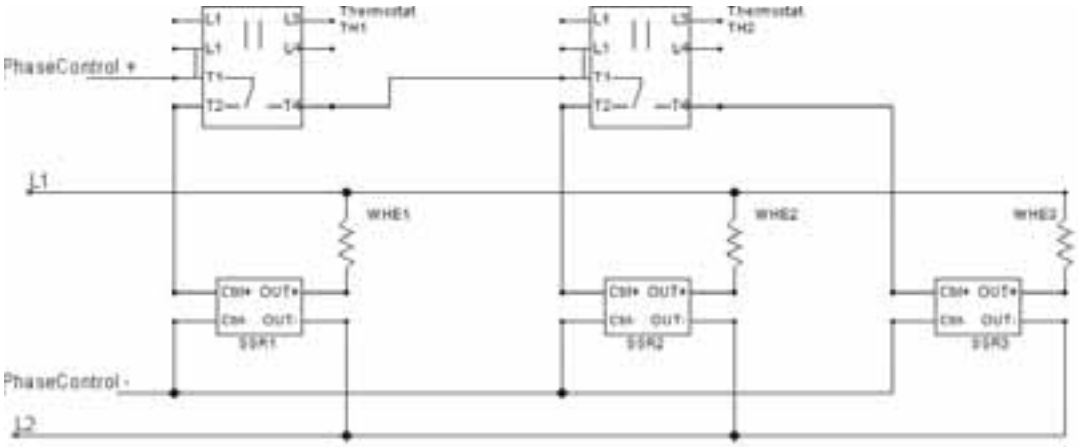

Fig. 4: Example Hardware Architecture of Simple Dump Load Control

This scheme can utilize a high percentage of all the available power generated by a 100% renewable energy system during periods of low consumption in the village served. This helps justify operation of the system 24 hours a day, increases the value of the facility, provides consistent energy to drive economic development, and helps the local population justify the funds needed to maintain the system. This scheme routes excess energy to

a set of useful dump loads, starting with the highest defined priority load needing power, and shifting power to the next highest priority load once the first useful dump load is met, e.g. the water is hot enough, etc. Conceptually there is no limit to the number of useful dump loads that can be included to obtain values of k_c approaching unity, a 10x improvement over the k_c seen by RIDS-Nepal in Northwestern Nepal.

This scheme's primary advantage is its simplicity and use of ubiquitously available hardware. However, water heater thermostats are not particularly accurate, have significant fixed hysteresis, and have limited range making them inappropriate for regulating the temperature in some applications, e.g. the lower limit of most hot water thermostats is too high for heating a greenhouse. Furthermore, the priority and temperature thresholds cannot practically be adjusted throughout the day and seasons. All these disadvantages can be addressed with a programmable dump load controller.

3.2 Programmable Useful Dump Load Control

The temperature accuracy, hysteresis, and range issues can be addressed by using electronic temperature sensors on the water bath associated with each useful dump load. Temperature sensors utilizing a DS18B20 integrated circuit are inexpensive, ubiquitous, reliable, and accurate. They are easily connected to a wide range of microcontrollers using the 1-wire serial interface standard. Figure 5 shows a hardware architecture implementing such a system.

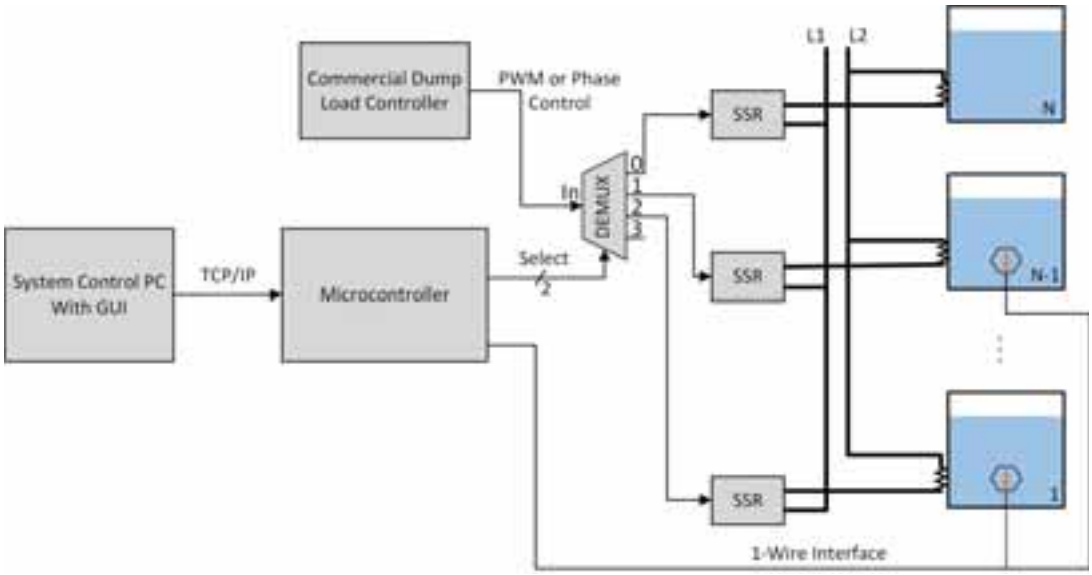

Fig. 5: Example Hardware Architecture of Programmable Dump Load Control

Figure 6 shows an example of the software architecture in the programmable controller. Grey objects are included to show how the firmware entities map to hardware.

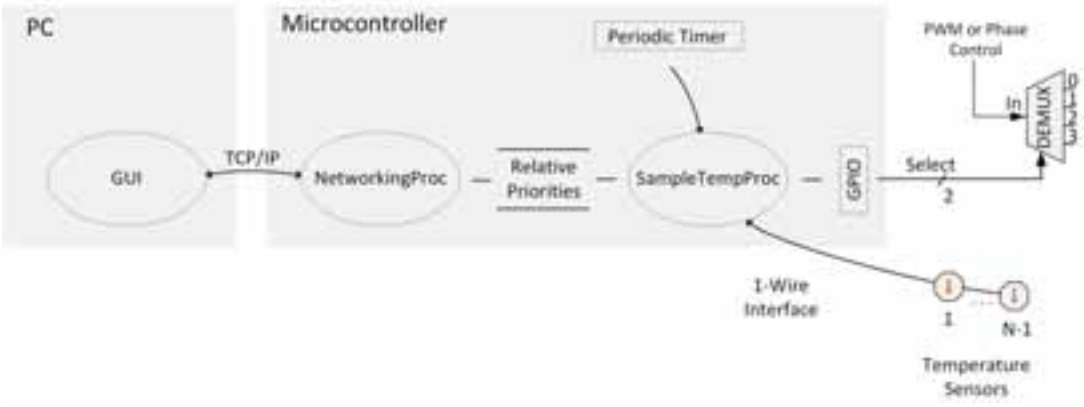

Fig. 6: Microcontroller Firmware Architecture

The PWM or phase control signal from the commercial dump load controller is used to modulate the amount of power consumed by the useful dump loads. Useful dump loads on either DC or AC lines can be supported with the selection and configuration of the appropriate commercial dump load controller and SSRs.

A System Control PC, located at a convenient place in the village such as the pay-as-you-go vending office, provides a GUI used to specify the relative priority and temperature thresholds of the various useful dump loads using a time, date, and/or season schedule. This schedule can be easily modified by local operators based on village requirements. The current prioritization and threshold information is communicated over a TCP/IP communication channel to the NetworkingProc process on the microcontroller. The use of TCP/IP allows this microcontroller to reside close to the useful dump loads, while the PC and GUI can be at a location more convenient to the villagers.

All useful dump loads incorporate a temperature sensor except the lowest priority one which must be able to continuously absorb all potential excess power. For example resistive elements could be included in greenhouses to heat the air or soil by several degrees. There are a large number of rugged, waterproof, and low cost temperature sensors available utilizing the DS18B20 temperature sensor IC. Their accuracy is typically 0.5 to 1 °C which should be quite acceptable and much more accurate than thermostats used in hot water heaters. Although the 1-wire serial interface is slow, the temperature of the water bath or air associated with each load changes slowly, so the sensors can be sampled at a relatively slow periodic rate by the SampleTempProc process. This process determines the highest priority dump load needing additional power, and updates a set of GPIO pins to drive the 'Select' value to the demultiplexer (DEMUX) as shown in figure 5. The demultiplexer routes the PWM or phase control signal to the appropriate SSR.

1-wire interface drivers are available for many microcontrollers. Hysteresis can be controlled programmatically based on village input via the GUI.

Figure 5 only shows dump loads utilizing tanks of water and water heater resistors, suitable for a wide range of useful loads including hot water for bathing and cooking, and to stabilize a biogas digester at its optimum temperature. However, other loads can also be used since the DS18B20 thermometers are accurate over a wide range and can measure other substances including soil or air. For example, a solid state refrigeration unit could be used to maintain the temperatures of apples in cold storage.

Fig. 7: Warm/hot water as "useful" dump load for improved personal hygiene, very welcomed in cold areas.

Fig. 8: Heating water for increased anaerobic process in the production of biogas and heating a high-altitude greenhouse.

4. Summary

The current utilization factor for many pico and micro hydro systems in Northwest Nepal is a surprisingly low value of around 10% based on observations by an NGO working in the area, RIDS-Nepal. This low utilization significantly impacts the benefits of the systems making it difficult for the villagers served to grow economically and to maintain and operate them.

Two different 'smart' dump load control schemes are described that can utilize the energy that would otherwise be wasted. One scheme using hot water heater thermostats is extremely simple, inexpensive, and context-appropriate. However, it hard-wires a fixed prioritization among the loads and suffers from fixed hysteresis and relatively poor temperature accuracy. The other scheme uses a small microcontroller, DS18B20 based temperature sensors, a PC-based GUI, and SSRs. It removes the limitations of the water heater thermostat implementation. Although more complex than the simple scheme, it is still context-appropriate.

RIDS-Nepal is planning to implement the microcontroller-based solution in a pico-hydro facility in the village of Moharigaun in the Jumla district of Nepal. Useful dump loads will be used:

- To heat bathing water for showers and personal hygiene to eradicate the most common skin sicknesses
- To maintain the temperature of a high-altitude biogas digester for an increased anaerobic process under mesophilic (~25°C - ~40°C) or even thermophilic conditions (~40°C - ~60°C)
- To heat water to reduce the amount of wood needed to cook rice and tea
- To heat and power grow lights in a greenhouse to improve year-round nutrition.

Extensive monitoring will be employed to quantitatively measure the impact of the prioritized dump load control scheme.

Fig. 9: The village of Moharigaun in the remote North-East of the Jumla district of Nepal will use a variety of useful dump loads

Abstract

This work reviews solar energy inclusion in Africa using Nigeria as a case study. It reviewed studies made on viability, challenges and solutions associated with making solar energy a viable energy option in Nigeria. The study highlighted data on current industry capacity of solar energy, installed PV capacity, and solar energy application distribution. It sheds light on solar energy initiatives and projects in Nigeria and solar energy capacity development in Nigeria. Success stories of solar energy and solar cell fabrication in Nigeria are presented. Existing government policies and legislation are discussed. The authors consider the challenges faced and the current and future prospects of solar power in Nigeria, and make recommendations regarding the speedy and seamless inclusion of solar energy in Nigeria and Africa as a whole.

Keywords: solar, domestication, Nigeria, energy, Africa

1. Introduction

Sub-Sahara Africa is home to about 85 % of the 1.3 billion people in developing countries without access to electricity [1], with an estimated electrification rate of 64 % in urban and 13 % in rural areas [2]. Sub-Sahara Africa has many of the world's least electrified nations [3, 4]. A total of 70 % of such those without access to electricity reside in countries like Nigeria where the rural populace is mostly affected [5]. Nigeria is ranked seventh in world population and cannot provide electricity access to her populace both in the urban and rural areas [6, 7]. Nigeria's rural population is estimated to be about 42 % of the total population [8]. Over 60 % of the Nigerian population does not have power supply, with 40 % not on the nation's grid [9, 10]. The Nigerian grid supply of electricity is on average six hours per day rationed among inhabitants of the cities [11]. Almost all rural dwellers in Nigeria have little or no access to electricity. The majority of the electricity supply in Nigeria is generated by Kainji dam which produces about 3.2×10^8 W and 9.6×10^8 W at its peak [12, 13]. This is due to underperforming hydro dams in the country. Another factor is the high cost of distribution across the country which covers an area of 924 000 km^2 [14]. There is no uniformity in distribution of grid connection and electricity in Nigeria. About 61.2 % of households in Lagos in South-West are without access to electricity. The figure is different in Taraba in North-East where 81.3 % lack access to electricity [15]. Similarly, South-South have 61.2 % and South-East has 60 %. About 38.1 % of the rural population, 12.1% of the rural poor and 29.8% of the urban poor in Nigeria have access to electricity [16].

Erratic power supply has caused many of the inhabitants and companies in Nigeria to generate their own power. Nigeria has about 32 outages in a month with over 35 hours' outage of electricity supply [17]. Figure 1 shows the electrical outages per month and average duration in Africa [18]. Erratic supply is due to high energy losses caused by physical deterioration of the facilities for transmission and distribution, and theft of power equipment. Other causes are vandalism, the high cost of electricity production, insufficient metering system and ease of by-passing of the metering system by the consumers, poor billing system and low available capacity (only 40 % of the installed capacity of 6 000 MW) [19].

Individuals have resorted to using generators powered by petroleum fuel or diesel. This accounts for the increase in the price of petroleum products price by 70 % in 2012 [20]. The cost of generators has risen on a regular basis from 5.8 % in 2007 to 7.6 % in 2009 [21]. Generators also increase environmental pollution [22]. Electricity access has direct links to clean drinking water, good health and agricultural activities for rural dwellers [23, 24]. The lack of electricity has created, and is still responsible for, high levels of underdevelopment and poverty in the rural areas [25, 26]. Several studies attest to the fact that stable and affordable electricity contributes to higher levels of economic development [27-33].

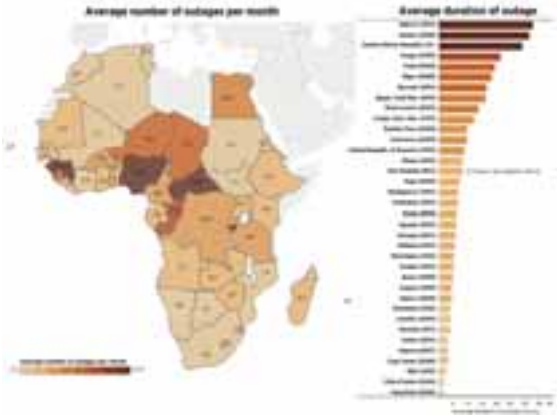

Fig. 1: Electrical outages per month and average duration in Africa [18]

Renewable energy is a tool that can end global electricity problems because supply exceeds world electricity demand [34]. It is an energy source that can be renewed indefinitely. Renewable energy sources include solar, ocean tides, geothermal, wind, hydro, and biomass [35-37]. They are used as electricity, thermal energy, fuels, mechanical force and hydrogen. These energy sources are obtained from non-fossil and non-nuclear sources [38]. They are sustainable and not harmful to the environment. Table 1 shows the vast potential of solar energy inclusion in Nigeria, shedding light on Nigeria's solar energy resources. From the data in Table 1 one can see that Nigeria only needs 0.1 % of the total solar radiation converted at 1 % efficiency to be able to meet her energy demand [39]. On average, Nigeria gets solar radiation of 20 MJ/m^2/day with minimal variation all year.

Tab. 1: Nigeria's solar energy resources [39]

Resource type	Reserves		Production	Domestic utilization
Natural units	Energy units	Energy units (BTOE)		
Solar Radiation	3.5 KWh/m^2/day to 7.0 KWh/m^2/day (4.2 million MWh/day using 0.1% Nigeria land area)	5.2 (40 years and 0.1% Nigeria land area)	Approximately 6 MWh/day solar Photovoltaic	Approximately 6 MWh/day solar Photovoltaic

Power generation involves the conversion of energy from an available source (sun in this case) to electrical energy in a form that is suitable for distribution, consumption and storage [40]. Solar PV is capable of powering off-grid single homes, and mini-grids incorporating from several kW to many MW [18]. Power generation using solar energy can be done in two ways, namely, solar-thermal conversion [41] and solar electric (photovoltaic) conversion [42]. Solar energy is one of the renewable energy endowments of Nigeria [43]. It can be used for powering remote villages disconnected from the nation's grid and its power can also be fed into the national grid [44]. Solar energy is used in rural clinics, powering of schools, vaccine refrigeration, street lighting, traffic lights, kiosks, among others. Solar technology is gradually being implemented in Nigeria. It is already implemented for solar crop drying, solar incubators, solar chick brooding, solar evaporative cooling and so on.

Renewable energy is capable of solving Nigeria's energy challenges [45, 46]. Several studies have looked at the viability and challenges of implementing solar energy in Nigeria. Chilakpu [47] examined renewable energy sources benefits, potentials and challenges in Nigeria. The study stated that renewable energy improves the security of a country, and reduces greenhouse gases. The study aligned with Körbitz [48] in stating that renewable energy reduces greenhouse gases by at least 3.2 kg carbon dioxide equivalents per one kilogram of biodiesel. The study observed that the challenges working against the full-scale implementation of solar energy in Nigeria include available technology, the political climate, and the weather conditions of the country. Körbitz study dwells

most on hydropower and fails to shed light on other renewable energy sources, especially solar energy. Olaoye et al. [49] studied the energy crisis in Nigeria and suggested a renewable energy mix as a solution. Attention was given to the installed capacity and licensing of on-grid power generation companies. The study provided two tables which summarized the renewable energy potential of Nigeria. The data provided is limited to the capacity of solar PV panels in Nigeria. Ajayi and Ajanaku [50] examined the energy challenge and power development in Nigeria and proposed a way forward. The study suggested that 80 % of hydropower in the country is untapped, and 5.5 KW-hr/m^2/day of solar radiation is not being utilized as well as unexploited wind energy resources and the gases being flared. The study believes that utilizing these resources will put an end to the energy challenge of Nigeria. Akinboro et al. [51] studied solar energy installations in Nigeria in terms of their prospects, problems and solutions. The study set out to study the use of solar energy as an alternative energy source in Nigeria. Emphasis was on stand-alone and hybrid installations and the problems encountered during domestic and industrial solar installation. In the end, the study was only able to enumerate the challenges confronting the implementation of solar energy, its prospects and possible solutions. However, the study shed light on waste generated from gas turbines, diesel plants, solar plants, biogas plants, nuclear and small hydropower plants. There was no mention of solar installations as stated in the beginning of the study. Ezugwu [52] discussed renewable energy in Nigeria with a focus on their sources, problems and prospects. The study was able to theoretically discuss the key renewable energy sources but lacked relevant data regarding Nigeria. Emodi and Yusuf [53] discussed the need for standardization of renewable energy technologies in Nigeria. They opined that renewable energy technologies are imported into Nigeria and there are no existing local standards. The study recommended standardization as a solution to check the influx of renewable energy technologies into Nigeria. Ikem et al. [54] studied integration of renewable energy sources into the Nigerian national grid as being a way out of the power crisis. It suggested a way forward for Nigeria's government to improve the current power supply of the country by investing in renewable energy. The study encouraged the government to review the power sector. Ozoegwu et al. [43] studied the status of solar energy integration and policy in Nigeria. It did a good job in reviewing the past, the current and future status of solar integration in Nigeria. It was able to combine several data related to solar energy in Nigeria. This provided a firm basis for the case of giving solar energy a high priority in mitigating the energy problem of Nigeria. Table 2 grouped the different categories of solar PV applications under different headings.

Tab. 2: Categories of Solar PV applications (adapted from [18])

Item	**Stand-alone**			**Grids**		
	DC		**AC**	**AC/DC**		**AC**
System	Solar lighting Solar kits or system lanterns	DC	AC solar system: single-facility AC systems	Nano-grid grid Pico-grid	Micro-Mini-	National/regional grid
Application	**Off-grid**			**Off-grid or on-grid**		**On-grid**
	Lighting	Lighting and appliances	Lighting and appliances	Lighting and appliances, emergency power	All uses (including industrial)	All uses (including industrial)
Key component	Generation, storage, lighting, phone charger	Generation, storage, DC special appliances	Generation, storage, lighting, AC appliances, building wiring	Generation plus single phase distribution	Generation plus three phase distribution	Generation plus three-phase distribution plus transmission

Typical size	0.10 W	11 W to 5 kW	100 W to < 5 kW	5 kW to 1 MW	Residential (100 W to < 5 kW) Mini grid (5 kW to < 1 MW) and Utility scale (> 1 MW)

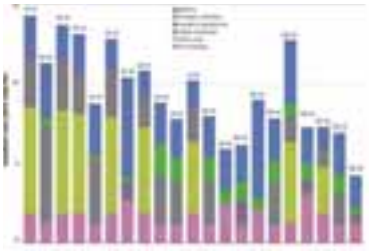

Fig. 2: Small solar system (<1 kW) cost breakdown by cost component, 2012-2015 [18]

Figure 2 presents the cost breakdown for sub-1 kW where the data are available. Battery costs account for the largest single share of these Small Household Solar Supply (SHS), with a simple average of 29 % of the total costs (USD 2.7 /W). The PV modules themselves, as well as the lighting fixtures and wiring, average around 20 % (USD 2.2 /W) of the total installed costs together, soft costs 22% (USD 2/W), other hardware 21% (USD 2 /W) and the charge controller 7% (USD 0.7/W).

Several researchers have proposed various ways in which the technology of solar can be used in Nigeria. This includes but is not limited to the following: Cota et al. [55] proposed the use of solar energy for street lighting and water pumping in the rural community of Igbelaba and Jigawa state. Kumar et al. [56] presented suggestion for replacing the usage of fossil fuel energy with solar energy for street lighting of Fugar city in Edo state of Nigeria. Ike Chinelo et al. [57] suggested the use of solar to power security lights in school hostels in Nigeria.

1.1 Data on solar energy capacity in Nigeria

The industry capacity of solar energy was a total of 33 active companies by 1999. There are no vendors or contractors for the supply and installation of solar equipment. Nigeria cannot boast of a company that manufactures the major components of solar systems, not even the basic solar cells [58]. However, NASENI assembles PV panels in Karachi, close to Abuja. Nevertheless, the country can boast about 200 installed solar PV installations with a capacity of about 3.5 kW to 7.2 kW [59]. This is insignificant when compared with the population of Nigeria and installed capacity in other Africa countries like South Africa. Figure 3 provides a vivid picture of installed solar PV capacity in watts per capita in Africa in 2015.

A survey was conducted in the northern part of Nigeria to show the application distribution [58]. It shows that domestic water pumping accounts for 57%, domestic lighting and rural for 8%, experimental room air conditioning for 1%, rural clinic refrigeration of clinic items like vaccines and lighting of the clinic and surrounding for 24%, and communications (TV and radio) for 10% (see Table 3).

In terms of installed PV in regions of Nigeria, Lagos has the highest with 23.6% closely followed by Yobe state with 16.3%. Kano and Akwa Ibom have 8.6%. The funding of such installations is principally by the federal government, state, local government, and international donors like the European union, Mobil and in some states like Lagos by private individuals. There are about one or two PV installations working or moribund in the 26 states out of the 36 states in Nigeria including the capital Abuja [59].

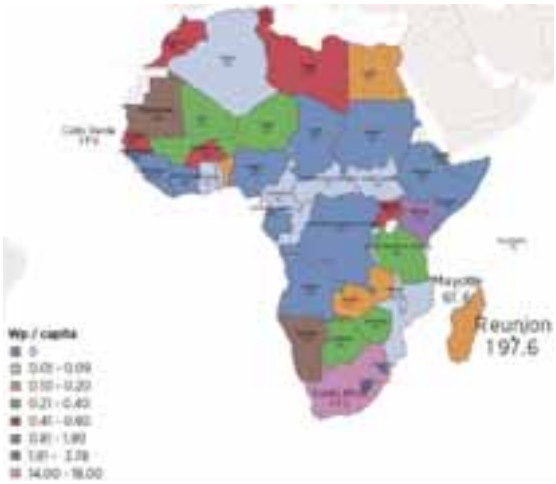

Fig. 3: Map of installed solar PV capacity in watts per capita, 2015

Tab. 3: Installed capacity of PV technology in Nigeria [59]

S/N	APPLICATIONS	PV CAPACITY (%)
1.	Residential (mostly lighting)	6.9
2.	Rural electrification and Television	3.9
3.	Commercial lighting and equipment	3.1
4.	Street, Billboard and other lighting	1.2
5.	**All lighting**	15.1
6.	Industrial	0.4
7.	Health center/clinic	8.7
8.	Telecom and radio	23.6
9.	Water pumping	52.2
	Total	**100**

2. Solar Project initiative in Nigeria

Some striking projects on solar energy have been executed in Nigeria. The Jigawa state government embarked on a project of rural electrification of the state [60]. This was funded 60 % by the United States government through USAID and department of Energy (DOE) and 40 % by the Jigawa state government. This project demonstrated inclusive solar usage for electricity generation in rural communities. The project targeted water supply, education, health, agriculture, security, opportunities for trade and commerce [61]. Several PV water pumping, electrification, and solar thermal installations have been executed by Sokoto Energy Research Center (SERC) and the National Center for Energy Research and Development (NCERD) under the supervision of the Energy Commission of Nigeria (ECN) [62]. A breakdown of the pilot projects by ECN include the 7.2 kWp solar-PV village electrification in Kwalkwalawa in Sokoto state, 1.87 kWp village electrification and TV viewing centre in Iheakpu, 1.5 kWp water pumping scheme in Nangere, Sokoto state. Solar dryer projects in Nigeria include: 2-tonnes solar rice dryer in Adani, Enugu state and 1.5 tonnes solar forage dryer in Yauri, Kebbi state.

The World Solar Programme designed for promotion of solar energy penetration worldwide has also provided about five high priority projects in Nigeria. They are; (i) the solar village; (ii) the upgrading of facilities and personnel of renewable energy R & D establishments, and development of renewable energy curricula; (iii) training workshops and colleges in renewable energy technologies (solar-PV and solar-thermal); (iv) Rural health

delivery and potable water supply using solar-PV; and (v) International Solar Energy Institute. The projects are threatened by inadequate funding. As a result, only projects (i) and (iv) have made significant progress.

2.1 Solar energy capacity development in Nigeria

The federal government of Nigeria has mandated the ECN with the responsibility to carry out research and development of the nation's energy needs. ECN has two centers dedicated to renewable energy spread evenly in the north and south of the country, namely, the National Centre for Energy Research and Development (NCERD) at Nsukka, in the south of Nigeria, and the Sokoto Energy Research centre (SERC) in Sokoto state, in the north of Nigeria. Apart from the research and development mandate of the centres, they are also responsible for personnel development, dissemination and promotion of renewable and alternative energy technologies. The other government agencies that have renewable energy components in their mandates are: Federal Department of Meteorological Services (FDMS), Power Holding Corporation of Nigeria (PHCN). Others are Project Development Institute (PRODA) Enugu, Nigerian Building and Road Research Institute (NBRRI), Federal and state owned Universities and Polytechnics, and the Federal Institute of Industrial Research, Oshodi (FIIRO), National Centre for Energy Research and Development (NCERD), Nsukka, Centre for Energy Research and Training (CERT), located in Ahmadu Bello University, Zaria, Centre for Energy Research and Development (CERD), located in Obafemi Awolowo University, Ile-Ife.

Some successes have been achieved in solar energy technology development in the country. These include, but are not limited to, solar crop dryers of various capacities. Worthy of note is the 2-tonne capacity rice dryer developed at the NCERD and a 2-tonne capacity forage dryer constructed by the SERC. Also, a solar manure dryer for poultry waste developed by NCERD, Nsukka. The dryer was able to reduce moisture content of manure from 71 % to 35 % in 22 hours of peak solar intensity of 600 W/m^2. Flat and concentrated solar cookers have been constructed and tested at NCERD and SERC. The flat plate cooker attained a record cooking time of 4.5 minutes at solar intensities of 850 W/m^2. Solar water heaters comprising horizontal and vertical tanks with natural circulation have also been constructed and are available at Usman Danfodiyo University, Sokoto, and solar chick brooders at NCERD, Nsukka.

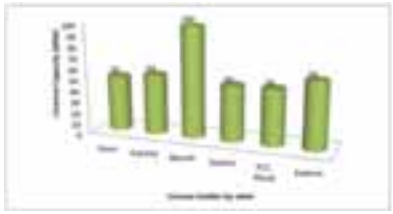

Fig. 4: Nigerian Electricity Regulatory Commission licensed solar power projects in Nigeria

Licenses for solar energy projects in the country have been awarded by the Nigerian Electricity Regulatory Commission as shown in Figure 4. As at 2014, seven companies have been awarded licenses in different states of Nigeria. Bauchi has the highest capacity with 100 MW awarded to Nigeria Solar Capital Partners. Kaduna have two licenses awarded to Quaint Global Nigeria Ltd and Anjeed Kafanchan Solar Ltd with a capacity of 50 MW and 10 MW respectively. Others are Lloyd and Baxter LP in Abuja, KVK Power Pyt Limited in Sokoto state, Pan African Solar in Katsina and Rock Solar Investment Company in Osun state. Due to fluctuation in generation capacity caused by water shortages in the dry season, Shiroro Hydroelectric Power Station in Niger State of Nigeria plans to construct a 300 MW PV solar power plant.

Some memorandums of understanding have been signed for solar projects in Nigeria. New Horizon Energy Resources proposed the building of a 100 MW solar plant in Nasarawa. Delta state government signed an MoU with Yutal Li Ltd for a 100 MW solar power plant in 2016 in addition to a 300 MW power plant signed for in 2014 with SkyPower FAS Energy. The federal government of Nigeria also signed a 300 MW solar power with Super Solar.

2.1.1 Solar cell fabrication and research in Nigeria

Limited work has been done on materials for solar cell fabrication and thin film growth in Nigeria at Obafemi Awolowo University (OAU, Ile Ife) and NCERD, Nsukka respectively and in some laboratories in the country.

Soboyejo and Kana have led some research studies at Africa University of Science and Technology (AUST, Abuja) and Sheda Science and Technology Complex (SHESTCO, Sheda), on organic solar cell materials fabrication. Fabian Ezema has worked extensively on Chemical Bath Deposition (CBD) for solar cell deposition at the University of Nigeria, Nsukka. The National Agency for Science and Engineering Infrastructure (NASENI) is also worthy of mention in terms of solar cells research and development and solar panels. NASENI, in Nigeria is leading the effort to make solar panels available at a reduced cost. It has a dedicated solar panel assembly plant in Karachi, Nigeria. Most of the solar PV studies conducted in Nigeria are on solar PV components and system testing, pilot plants and other application projects. The KwalkwalaWa 7.2 kW village electrification in Sokoto state is the largest single pilot plant established by the Energy Commission. It is used for pumping water, powering health centres and rural lighting and entertainment. Other developments include solar air heaters, solar stills for water purification, solar absorption and absorption refrigerators.

2.1.2 Solar data collection in Nigeria

Efforts are being intensified in solar energy data collection in Nigeria. Data such as solar radiation intensities (such as global, direct and diffuse), relative humidity, precipitation and ambient temperatures have been collected for over 64 towns by the Meteorological Services Department. About 33 % of these stations have been in existence for over 50 years. About twelve research institutes and centres located in and outside universities in the country are also involved in solar data collection and analysis. The Energy Commission is currently developing an Energy Data Bank for renewable energy data.

3. Existing government policies and legislation

A National Energy Policy was developed in 2003 by the Nigerian government, primarily for efficient management of the country's energy resources. It focuses on conventional and renewable energy sources for sustainable development of the country with full private sector participation.

The policy is summarized as; extensive crude oil and natural gas exploration and development shall be pursued with the view to increasing their reserves base to the highest level possible. Lastly, the nation shall continue to engage extensively in the development of electric power with the view to making reliable electricity available to 75 % of the population by 2020; as well as to broaden the energy options for generating electricity.

The Nigerian Electricity Regulatory Commission and the Rural Electrification Agency were established in 2005 with in order to liberate the electricity sector. The Nigeria Renewable Energy Master Plan (REMP) is a policy aimed at making electricity more available through renewable energy. It envisions renewable energy providing a minimum of 10 % of total energy consumption in Nigeria by 2025 [63]. It was produced in 2006 with United Nations Development Programme support, and outlined the road map for more renewable energy usage in Nigeria's quest to meet her energy demands and improve grid reliability and security [64]. The policy hopes to meet this goal by providing an enabling platform for renewable energy, legal instruments, technical-know-how, manpower, infrastructure and the markets.

The objectives are; expanding access to energy services and raising the standard of living, especially in the rural areas; Stimulating economic growth, employment and empowerment; Increasing the scope and quality of rural services, including schools, health services, water supply, information, entertainment and stemming the migration to urban areas; Reducing environmental degradation and health risks, particularly to vulnerable groups such as women and children; Improving learning, capacity-building, research and development on various renewable energy technologies in the country; and Providing a road map for achieving a substantial share of the national energy supply mix through renewable energy.

4. Challenges

The high cost of implementation of renewable energy technologies, particularly solar, is the major impediment militating against their widespread use [65]. High cost is not unconnected to the fact that nearly all the parts are imported from overseas at a very high cost. Most of the personnel and technologies are sourced abroad [58]. The key challenges facing the successful deployment of solar energy technologies can be grouped into cost, policy,

technical, people and environment. Some of the key challenges of solar energy in Nigeria are discussed below. Firstly,cost plays a major role in the life of people and the success or failure of a technology. Nigeria is a developing country home to both rich and poor, living in rural and urban areas. Initial investment in the cost of solar energy infrastructure is one of those factors militating against penetration of solar energy in Nigeria. The lack of adequate funding for solar energy development poses a high risk to the success of solar energy in Nigeria. Also, the general absence of comprehensive national energy policy. Nigeria has never formulated a comprehensive energy policy; only sub-sectoral policies have been formulated. Since such a policy is pivotal to using energy efficiently and solar energy, the lack of such a policy has, to a large extent, contributed to the lack of attention to solar energy. Thirdly, lack of technological capability is an issue in penetration of solar energy in Nigeria. The bulk of the technologies for solar energy are imported thereby increasing the high investment cost of solar energy. Cultural and low level of public awareness is also another challenge. The cultural inclination in some parts of Nigeria coupled with public awareness of renewable energy sources and technologies in Nigeria and their benefits, both economically and environmentally, are generally low. Consequently, the public is not well-equipped to influence the government to begin to take more decisive initiatives in enhancing the development, application, dissemination and diffusion of renewable energy resources and technologies in the national energy market.

5. Prospects for solar energy in Nigeria

Geographically, Nigeria lies within a high sunshine belt on longitude 3º and 14º East of Greenwich and latitude 4º and 14° north of equator [66] and thus has enormous solar energy potential [67]. The country has an annual average daily solar radiation of about 5.535 KW/m^2 /day [68]. The minimum average is about 3.55 kW/m^2/day in Katsina in January. It is 3.4 kW/m^2/day for Calabar in August. And the maximum average is 8.0 kW/m^2/day for Nguru in May [69]. This puts the solar radiation figure at an average of 19.8 MJ/m^2/day and is fairly distributed.

The country's annual average daily sunshine is 6.25 hours per day, the coastal areas are 3.5 hours and 9.0 hours at the far northern boundary [70]. Nigeria receives about 4.851 x 10^{12} KWh of energy per day from the sun [71]. This is equivalent to about 1.082 million tons of oil equivalent (mtoe) per day, and is about 4 000 times the current daily crude oil reduction, and about 13 000 times that of natural gas daily production based on energy units. This huge energy resource from the sun is available for only about 26 % of the day. This data couple with the prevailing efficiencies of commercial solar-electric generators and if solar collectors or modules were used to cover 1% of Nigeria's land area of 923 773km^2, it is possible to generate 1.804 x 10^{15} kWh of solar electricity per year. This is over one hundred times the current grid electricity consumption level in the country [72]. The annual solar energy insolation is 27 times the nation total conventional energy resources in energy units. This is over 117 000 of the electric power generated in 1998 in Nigeria [40]. Only about 3.7 % of Nigeria's land area is required for solar energy to meet the electricity demand of the country.

5.1 Future prospects

Though the bulk of the prospects for solar energy in Nigeria are in the off-grid areas and rural electrification, some areas on the grid and in urban areas also hold some prospects. Areas that provide opportunities for application include, but are not limited to: power plants, non-thermal electricity generation, large scale and family scale cooking, heating, drying of farm produce, water purification, clean water provision for humans and animals, aerospace development of the country, provision of light arms and ammunition for the Nigeria Army especially as they combat Boko haram terrorism and militants in the Niger Delta of the country. The future prospects of solar PV are shown in Figures 5 and 6.

The major focus on renewable energy in Nigeria is on transportation and electricity generation. Electricity generation from renewable energy in Nigeria is estimated to be 9.74 % for 2015, 18 % for 2020 and 20 % for 2030. However, electricity generation using solar is projected to be 1.26 % for 2015, 6.92 % for 2020 and 15.27 % for 2030. The targets of renewable electricity from solar alone is projected to be 12.96 %, 38.43 % and 76.36 % for these years. This shows that solar progressively dominates in the long-term. Figure 6 shows the targets for solar PV application in Nigeria for year 2020 and 2030.

Figure 6 shows the targets for solar thermal energy application in Nigeria for year 2015, 2020 and 2030. This is too dismal to be commended even in the long-term.

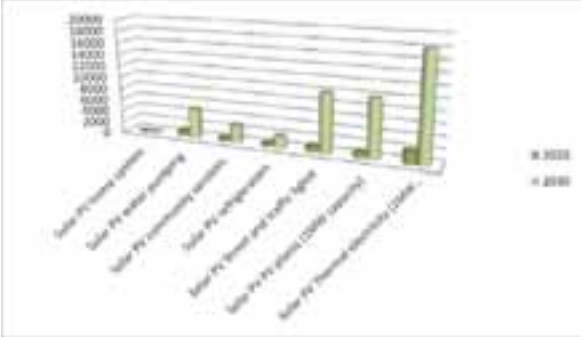

Fig. 5: Solar PV application in Nigeria for year 2020 and 2030

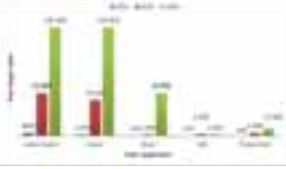

Fig. 6: Targets for solar thermal energy application in Nigeria for year 2015, 2020 and 2030

For example, consider the targets for solar cookers. Suppose each solar cooker is constructed to cook for five people as proposed by Saxena et al. [73]. With a population growth rate of 3.2 % per annum, the population in 2015, 2020 and 2030 population becomes 186 458 723, 218 263 539 and 299 073 660 respectively. The penetration level which represent the percentage of the population supplied with solar cooking energy becomes 0.0054 %, 0.1145 % and 0.2508 % respectively. Although this figure indicates a rising trend into the future, the penetration level is minor and does not reflect the energy crisis in Nigeria. This is because in 2014 about 80 % of the population were exposed to health issues. Many of these health issues arose from the heating and cooking used in the rural setting, using mainly biomass and waste resources. The maintenance-free and cheap nature of solar box cookers makes them well suited to developing countries.

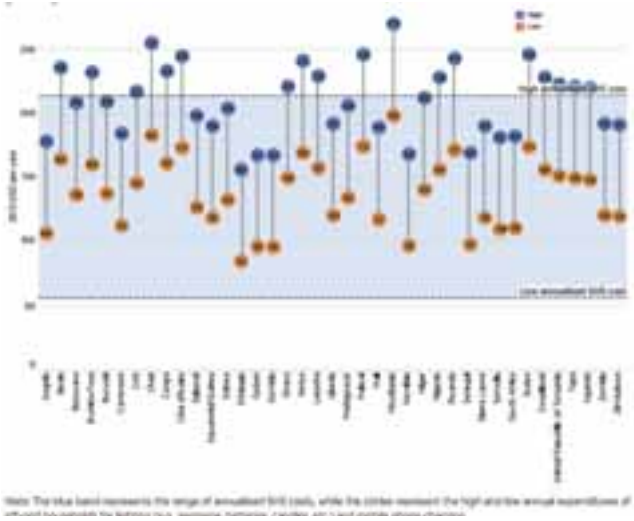

Fig. 2: Africa annual off-grid household expenditure on lighting and mobile phone charging compared to solar home system (< 1 kW) annualized costs, by country in 2015 [18]

Figure 8 gives the annual expenditure for off-grid lighting and mobile phone charging in Africa in 2015. The blue band represents the range of annualized solar system costs. Circles represent the high and low annual expenditures of off-grid households for lighting (e.g., kerosene, batteries, candles, etc.) and mobile phone charging. Expenditure in Nigeria is USD 140 per year. The lowest expenditure in Africa is in Ethiopia (USD 84) and the highest is

Mauritania (USD 270). Therefore, solar systems can be a very economical solution for powering homes in Africa

6. Conclusion

Nigeria has the capacity to use solar energy to end the problem of an erratic power supply facing her. This work has been able to shed light on solar energy domestication in Nigeria, reviewing work that has been done relating to solar energy in Nigeria, and the prospects and challenges of the technology. A lot of brilliant studies have been conducted. Well-articulated policies have been made and signed with memorandums of understanding on the part of the government but well monitored implementation seems to be an issue working against the full success story of solar energy utilization in Nigeria. Research into in-country fabrication of solar cells, thin films and solar panels is highly recommended for both public and private partnership in Nigeria. The windows of opportunities for solar energy inclusion in Nigeria are enormous. These are: solar power generation, increased internally generated revenue through manufacture of solar panels, capacity building in the field of solar energy technologies, supply of renewable energy equipment and accessories, and contracts in solar energy projects. The rest of Africa can benefit from the success story of Nigeria if well implemented.

7. Recommendation

More education should be conducted to sensitize the populace on the benefits of solar energy and the government should encourage more research on solar energy, especially the setting up of and/or funding of solar cells research centres.

Direct vaporization of an organic fluid in a parabolic trough solar collector

Simone Dugaria[1], Matteo Bortolato[1] and Davide Del Col[1]

[1] Department of Industrial Engineering (DII), University of Padova, Padova, Italy

Abstract

An innovative solar receiver for linear concentrating collectors is used for the direct vaporization of a low GWP halogenated fluid. Experiments have been conducted to determine the thermal performance of the collector during vaporization of an organic fluid that can be adopted for ORC cycle. The mass flow rate and the subcooling of the halogenated fluid entering the receiver have been varied, along with the outlet vapor quality and saturation pressure. The results of the experimental campaign reveal that the solar collector is able to vaporize this halogenated fluid at 85°C with 73% efficiency. A numerical model of the collector has been developed and validated against the experimental data. The estimated thermal performance of the collector is in good agreement with the experimental tests. The mean relative error in the prediction of the thermal efficiency of the collector results within 2%.

Key-words: HCFO-1233zd(E); solar direct vaporization; parabolic trough collector

Nomenclature

Symbols

A_a	Aperture area, m^2
c_{II}	Specific heat of the secondary fluid, J K^{-1} kg^{-1}
DNI	Direct Normal Irradiance, W m^{-2}
h	Specific enthalpy, J kg^{-1}
h_L	Specific enthalpy of the saturated liquid, J kg^{-1}
h_{LV}	Latent heat of vaporization, J kg^{-1}
$\dot{m}$	Mass flow rate, kg s^{-1}
p	Pressure, Pa
q	Heat flow rate, W
T	Temperature, °C
T_m^*	Reduced mean temperature, K m^2 W^{-1}
x	Vapor quality, -

Greek symbols

$\alpha_{r,coat}$	Absorbance of the coating layer, -
ρ_c	Reflectance of the collector's mirror, -
γ_r	Receiver intercept factor, -
η_{col}	Collector thermal efficiency, -

Subscripts

I	Primary fluid (HCFO-12333zd(E))
II	Secondary fluid (Cooling water)
HE	Heat Exchanger
in	Inlet
R	Receiver
out	Outlet

1. Introduction

Organic Rankine Cycle (ORC), unlike the traditional steam Rankine cycle, can work with low temperature heat sources, by using an organic fluid instead of water as working fluid (Peris et al., 2015). The selection of the organic working fluid (OWF) is a crucial choice in determining the performance and the cost of the system (Chen et al., 2010). For ORC systems coupled to low-grade heat sources, HFC-245fa has been considered by many authors the best choice (Cataldo et al., 2014, Quoilin et al., 2011). This is a common working fluid used in commercial ORCs generating mechanical power from low-temperature heat sources and for high-temperature heat pumps. Despite the excellent thermodynamic performance of HFC-245fa for the exploitation of low-grade heat source the growing sensitivity of the society on environmental issues will increasingly limit its use due to its high GWP (1030 according to Molés et al., 2015). Moles et al (2014) identified the halogenated fluid HCFO-1233zd(E) as valuable candidate for the future replacement of HFC-245fa in various applications. Despite the presence of the chlorine in its molecule, it presents an extremely small value (0.00034) of ODP (Patten and Wuebbles, 2010), due to its very short atmospheric lifetime. Its GWP value was recently reported to be lower than one (Myhre et al., 2014).

Besides the theoretical studies (Giuffrida, 2014, Heberle et al., 2016, Molés et al., 2014), very few experiments on the use of HCFO-1233zd(E) as HFC-245fa drop-in replacement for ORC have been presented in the literature. Eyerer et al. (2016) studied the applicability of HCFO-1233zd(E) as substitute for HFC-245fa in ORC system supplied by a heat source at 120 °C by comparing cycle efficiency and power output. The authors concluded that HCFO-1233zd(E) can be successfully used to replace HFC-245fa without major modifications in the system. It was found that the use of HCFO-1233zd(E) can lead to an increase of 6.92% in the thermal efficiency with

doi:10.18086/swc.2017.17.01 Available at http://proceedings.ises.org

constant condensation and evaporation temperatures and constant isoentropic expansion efficiency. However, the net electric power generated by the ORC was 12.17% lower due to the largest volumetric flow rates of the HCFO-1233zd(E) required for the use of the system designed for HFC-245fa. In the work of Molés et al. (2016), an experimental evaluation of the working fluid HCFO-1233zd(E) as HFC-245fa replacement in ORC systems for low-temperature heat sources at different operating conditions has been conducted. Thermal and electrical powers resulted lower for HCFO-1233zd(E) than those for HFC-245fa at the same volumetric flow rate, due to the fact that the different densities of the working fluids. However, the net electrical efficiency was similar for both working fluids, ranging from 5% to 10%.

The exploitation of solar radiation can significantly contribute to reduce the consumption of conventional (non-renewable) energy sources and relieving associated environmental problems. A solar thermal system can be combined with ORC system according to two configurations: coupling with direct vaporization of the OWF or by using an intermediate solar circuit to heat a heat transfer fluid and evaporate the OWF in a separate heat exchanger. In a solar powered ORC system with direct vaporization of the OWF, the solar receiver coincides with the evaporator. By adopting this configuration is possible to simplify the system layout as the intermediate loop for transferring the heat from the solar collector to the OWF is no longer needed. It is expected that the direct vaporization of the OWF in the solar receiver allows to convert the solar energy collected by the solar system into the thermal energy of the OWF with a higher efficiency. In fact, this process takes place without the irreversibility associated with the heat transfer occurring in the heat exchanger/evaporator of the indirect vaporization. This aspect is particularly important in ORC systems where the temperature differences between the heat source and environment are quite low (around 100 °C).

Although, the feasibility of conventional steam Rankine cycles with direct vaporization of water in parabolic trough collectors (PTCs) has been extensively demonstrated (Eck et al., 2003, 2007), it has not yet been proved with organic fluids. This paper presents the experimental and numerical results on the direct vaporization of the halogenated fluid HCFO-1233zd(E) in an innovative aluminum flat absorber for medium temperature linear concentrating solar collectors.

2. Experimental apparatus and campaign

The small parabolic trough concentrator considered in this work is asymmetrical since the reflective optics extends from the vertex line to the mirror rim (Figure 1). This concentrator has been installed at the Solar Energy Conversion Lab of the Industrial Engineering Department, University of Padova (45.416°N, 11.883°E). The present concentrator exhibits an aperture width of 2.9 m, a rim angle of 78°, a focal length of 1.81 m and a trough length of 2.4 m, resulting in an aperture area slightly lower than 7 m^2. The reflecting optical system is made up by four back silvered glass facets arranged in two rows, which have a nominal reflectance of 96%, as provided by the manufacturer. Due to the small dimensions of the prototype, it is equipped with a two-axes solar tracking system to have the beam radiation normal to the aperture area without any cosine loss. The motion is governed by a solar algorithm when approaching the sun and by a sun sensor to achieve the best alignment.

Figure 1. Asymmetrical parabolic trough linear solar concentrator installed in the Solar Energy Conversion Lab of the University of Padova.

Figure 2. Bar-and-plate flat receiver arranged on the support bar of the collector under concentrated solar radiation during a test run.

The particular geometry of the parabolic trough concentrator is suitable to be coupled with a receiver provided with a flat geometry absorber. The innovative receiver considered in this work has been manufactured with bar-and-plate technology and is provided with an internal offset strip turbulator (Bortolato et al., 2016). The combined use of a high thermal conductivity material and a passive heat transfer enhancement technique in the absorber is a promising solution for linear concentrating devices. In order to minimize the incidence angle of the concentrated beams on the flat receiver, the optimal concentration plane of this system is 45° tilted with respect to the plane containing the focal line and the normal to the aperture area. The receiver presents a length equal to 1.2 m, which corresponds to half of the total trough length, and a width of 70 mm, thus, the resulting geometrical concentration ratio of the concentrating collector is equal to 42 (Figure 2).

2.1 Test facility

The test facility has been designed in order to measure the thermal efficiency of the solar concentrating collector during the vaporization of the fluid. A primary loop, where the halogenated fluid flows, is arranged on board the concentrating collector (Figure 3). The heat provided by the concentrated solar irradiance is dissipated through a heat exchanger to a secondary loop with cooling water. Both the loops are thermally insulated to limit heat losses towards the surroundings. The laboratory is equipped with a measuring system of the solar irradiance including a first class pyrheliometer mounted on a high precision solar tracker that is used to measure the direct normal irradiance (DNI). An anemometer measures the wind speed on the horizontal plane and the ambient air temperature is gauged by a Pt100 resistance temperature detector (RTD).

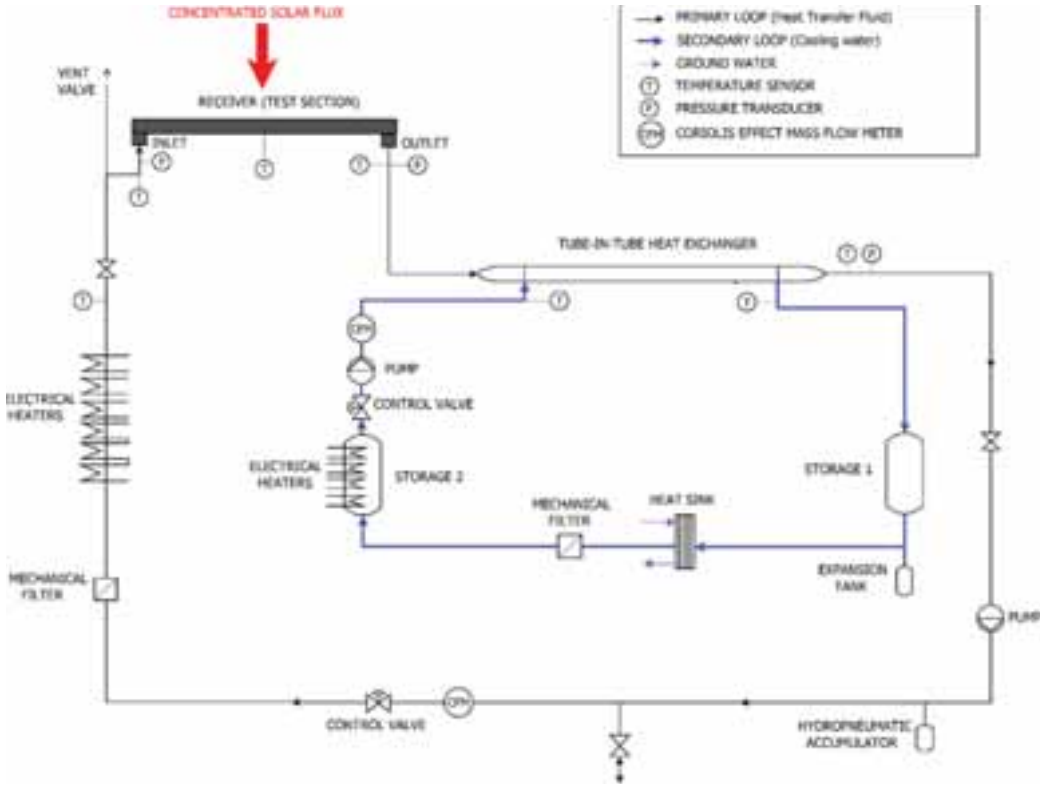

Figure 3. Sketch of the experimental test rig.

In the primary loop, after exiting the receiver, the heat transfer fluid (HCFO-1233zd(E)) enters a tube-in-tube heat exchanger, where the HCFO-1233zd(E) flows inside the inner tube, while the coolant (water) flows in the annulus. The pressure of the primary loop is regulated by a hydropneumatic accumulator with a fluoroelastomer diaphragm: this device plays an important role in direct vaporization tests as the working pressure determines the temperature of the generated vapor. Before entering the receiver, the halogenated fluid passes through a pre-heating section which consists of a electrical heater connected to a solid-state relay which is governed by a PID temperature controller. Temperatures and pressures of the organic fluid at inlet and outlet of the receiver and downstream of are measured by Pt100 RTDs and high precision absolute pressure transducers. Since the presence of a turbulator may penalize the hydraulic performance, accurate measurements of pressure drop have also to be carried out. In the

secondary loop, the controls on the cooling water mass flowrate and inlet temperature are useful to achieve constant conditions of the primary working fluid at the inlet of the receiver. The temperatures of the water at the inlet and at the outlet of the tube-in-tube heat exchanger are measured by Pt100 RTDs. All the measured quantities are recorded by a data logger with sampling rate of 3 s and the collected data are reduced in a MATLAB environment by calculating the fluid properties with NIST Refprop Version 9.0 (Lemmon et al., 2010).

2.2 Experimental technique and data reduction

The test methods to determine the thermal performance of solar concentrating collectors, namely the steady state method in the ASHRAE 93:2010 standard and the quasi dynamic method in EN ISO 8609:2013 standard, refer only to liquid or air heating devices. This means that the useful heat gained by the working fluid can be calculated considering its temperature increase inside the solar collector. There are no standard procedures to experimentally define the thermal efficiency of a solar concentrating collector performing direct steam generation, when a latent heat transfer is involved. The procedure proposed by Bortolato et al. (2016), has been adopted to evaluate the thermal performance of the concentrating solar collector during the vaporization of the halogenated fluid. During the test runs, the organic fluid enters the test section as subcooled liquid and its thermodynamic condition is completely determined by the temperature and pressure measurements at the inlet of the receiver. The fluid exits the receiver as saturated vapor and then it is condensed and subcooled in the tube-in-tube heat exchanger. The thermodynamic state of the halogenated fluid at the outlet of the receiver under saturated conditions can be experimentally defined by applying the energy balance to the heat exchanger, under the reasonable hypothesis of negligible heat losses towards the surroundings. The saturation temperature is assumed equal to the temperature measured at the outlet of the receiver because, during the two-phase test runs, the pressure drop across the receiver is very small.The specific enthalpy $h_{out,R,I}$ and of vapor quality $x_{out,R,I}$ of the saturated steam at the outlet of the receiver can be expressed as reported in the following expressions

$$h_{out,R,I} = h_{out,HE,I}\left(T_{out,HE,I}, p_{out,HE,I}\right) + \frac{\dot{m}_{II}\, c_{II}\left(T_{out,HE,II} - T_{in,HE,II}\right)}{\dot{m}_I} \qquad (2.1)$$

$$x_{out,R,I} = \frac{h_{out,R,I} - h_L\left(T_{out,R,I}\right)}{h_{LV}\left(T_{out,R,I}\right)} \qquad (2.2)$$

The experimental results are presented in a diagram plotting the experimental thermal efficiency η_{col}, as a function of the reduced mean temperature T_m^* along with the obtained efficiency curve of the collector.

$$\eta_{col} = \frac{q_I}{\mathrm{DNI}\, A_{ap}} = \frac{\dot{m}_I\left(h_{out\,R,I} - h_{in\,R,I}\right)}{\mathrm{DNI}\, A_{ap}} \qquad (2.3)$$

$$T_m^* = \frac{\frac{\left(T_{out\,R,I} + T_{in\,R,I}\right)}{2} - T_{amb}}{\mathrm{DNI}} = \frac{T_{m\,R,I} - T_{amb}}{\mathrm{DNI}} \qquad (2.4)$$

In order to express the reduced mean temperature under two-phase flow, it is required the introduction of the equivalent mean temperature of the fluid during direct vaporization of the fluid. Since the working fluid enters as subcooled liquid, both sensible and latent heat transfers occur inside the receiver of the solar concentrating collector. Hence, the equivalent mean temperature of the fluid shall be assumed as a weighted average temperature based on the enthalpy changes associated to the sensible and latent heat transfers (Equation 2.5).

$$T_{m\,eq,I} = \frac{\left(\frac{T_{out,R,I} + T_{in,R,I}}{2}\right)\left(h_L\left(T_{out,R,I}\right) - h_{in,R,I}\right) + T_{out,R,I}\left(h_{out,R,I} - h_L\left(T_{out,R,I}\right)\right)}{h_{out,R,I} - h_{in,R,I}} \qquad (2.5)$$

2.3 Experimental uncertainty analysis

Before the test campaign, the primary loop is evacuated and then filled with HCFO-1233zd(E). After a preconditioning period of 20 min, during each test sequence, that lasts for 3 hours minimum, the collected data are averaged every 10 min and the following criteria have been satisfied during tests:

- the inlet temperature of the subcooled liquid is kept stable within ±1 °C as compared to its mean value;
- the HCFO-1233zd(E) mass flow rate is kept stable within ±2% as compared to the mean value;
- the thermodynamic vapor quality at the outlet of the receiver must be higher than 0.1.

The uncertainty analysis has been performed in agreement with the guidelines provided by the “Guide to the

Expression of Uncertainty in Measurement" (International Organization for Standardization, 2008). Type B uncertainties of the measured parameters are reported in Table 1 with a level of confidence of 95%.

Table 1. Type B uncertainty of measured parameters during direct vaporization in bar-and-plate flat receiver under concentrated solar radiation.

Ambient air temperature	± 0.07°C
Fluid temperature in primary and secondary loops	± 0.035°C
Coriolis effect mass flow meters	± 0.3 kg h^{-1} (cooling water) ± 0.07 kg h^{-1} (HCFO-1233zd(E))
Pressure of the fluid in the primary loop	± 0.023 bar
Direct normal irradiance	± 3% of measured value
Wind speed	± (0.1 m/s + 1% of measured value)

With respect to the parameters which are not directly measured, their combined standard uncertainty can be calculated by applying the law of error propagation with level of confidence of 95%. Type A uncertainty is the standard deviation of the mean and, in the present tests, it comes out considering 200 readings collected over the averaging time period of 10 min.

2.4 Experimental results

The experimental tests have been carried out during the month of August 2016 at the average evaporation pressure of 7.5 bar corresponding to 85°C saturation temperature. During the tests, the ambient temperature was in the range 28 – 35°C and the values of the direct normal irradiance were between 700 W m^{-2} and 920 W m^{-2}. The mass flow rate of the halogenated fluid has been varied between 46 kg $h^{-1}$and 106 kg h^{-1}. The experimental results show that the collector thermal efficiency η_{col}, calculated according to Equation 2.3, was around 73%. Figure 4 reports the effects of the outlet vapor quality on the collector efficiency during the vaporization of the halogenated fluid Considering that the extended uncertainty of the collector efficiency is ±3%, it can be concluded that the outlet vapor quality has a negligible effect on the collector efficiency. This remarkable result suggest that it is possible to vaporize almost completely the halogenated fluid in the bar-and-plate receiver without any losses of efficiency. In Figure 5, where the thermal efficiency of the collector is plotted against the inlet subcooling, it can be noted that also the inlet subcooling did not significantly affect the efficiency of the solar collector.

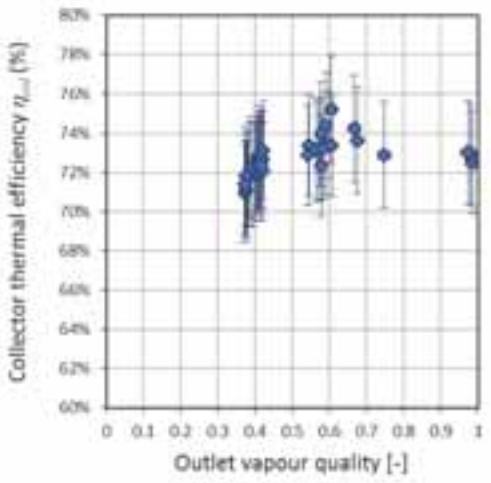

Figure 4. Experimental thermal efficiency of the solar collector as a function of the outlet vapor quality.

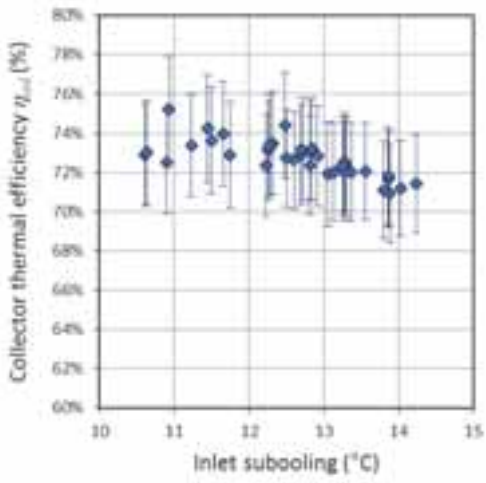

Figure 5. Experimental thermal efficiency of the solar collector as a function of the inlet subcooling.

Figure 6 reports the pressure drop through the bar-and-plate flat receiver as a function of the mass flow rate during the vaporization test runs of the halogenated fluid. This Figure provides only a general trend of the pressure drop, because the plotted values are lower than the experimental uncertainty of the pressure transducers. Anyway, the result shows that the designed absorber is capable of vaporize the fluid HCFO-1233zd(E) with a limited pressure drop, implying a low electrical consumption for the circulating pump.

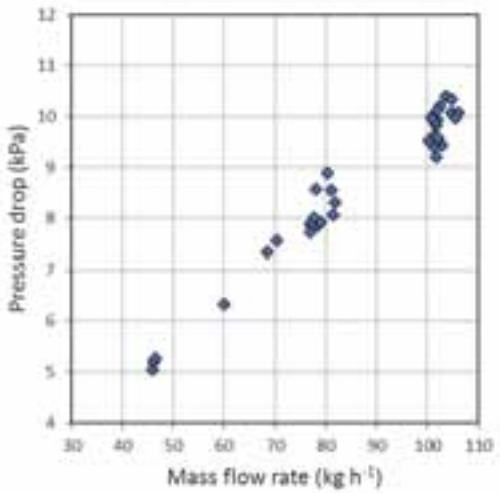

Figure 6. Pressure drop through the receiver as a function of the mass flow rate during vaporization.

3. Numerical model

A numerical model of the solar absorber system is developed in order to predict the performance of the receiver installed in a linear concentrating system. The receiver has been discretized along its length in several segments. Each segment constitutes a control volume where a zero-dimensional steady-state energy balance is applied. The zero-dimensional thermal resistance network is reported in Figure 7, where the external surfaces (front, back and lateral) of the absorber, the external surface of the insulation layer on the back of the receive, the internal surface of the absorber in contact with the fluid and the fluid itself constitute the thermal nodes of the model.

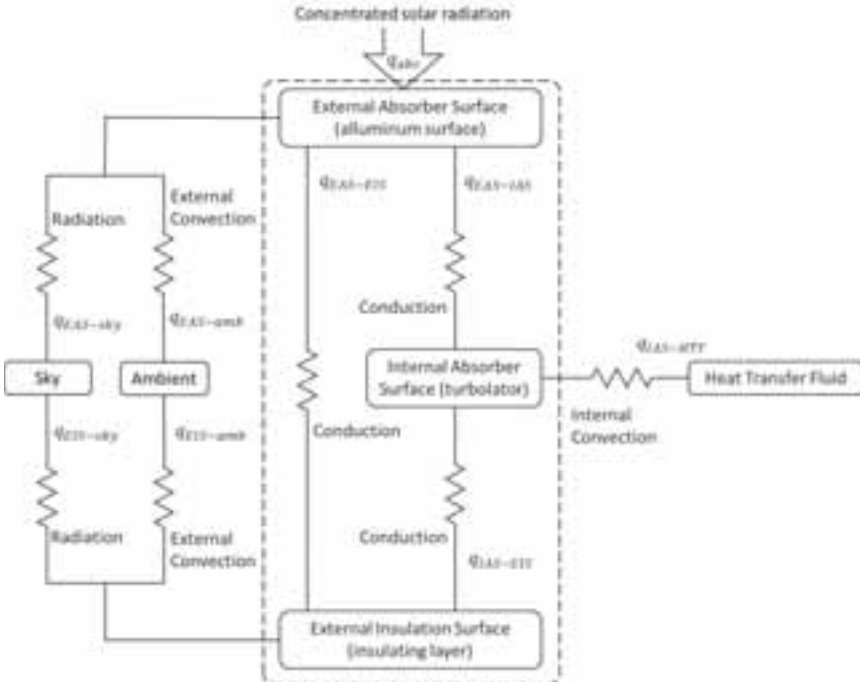

Figure 7. – Thermal resistance network representing the dimensionless model of the bar-and-plate flat receiver.

In the model, the effective incident concentrated solar radiation, net to the losses in the optical concentration, is mainly absorbed by the surface coating of the absorber and the absorbed heat flow rate q_{abs} has been considered as:

$$q_{abs} = DNI\ A_a \alpha_{r,coat} (\rho_c \gamma_r) \qquad (3.1)$$

Some energy absorbed into the coating is conducted through the absorber and transferred to the fluid $q_{EAS\text{-}HTF}$ by convection or by vaporization, while the rest is conducted through the insulating layer to the back surface $q_{EAS\text{-}EIS}$.

The remaining energy is lost directly to the environment by convection and radiation ($q_{EAS\text{-}amb}$, $q_{EIS\text{-}amb}$, $q_{EAS\text{-}sky}$, $q_{EIS\text{-}sky}$). The model assumes that all temperatures, heat flow rates and thermodynamic properties are uniform around the perimeter of the receiver. With reference to Figure 7, the energy balance equations are determined by conserving energy at each surface of the receiver cross-section:

$$q_{abs} = q_{EAS-amb} + q_{EAS-sky} + q_{EAS-IS} + q_{EAS-EBS} \quad (3.2)$$

$$q_{IAS-HTF} = q_{EAS-IS} - q_{IS-EIS} \quad (3.3)$$

$$q_{EAS-EIS} + q_{IAS-EIS} = q_{EBS-amb} + q_{EIS-sky} \quad (3.3)$$

Correlations for heat transfer in single- and two-phase flows are implemented in the energy balances depending on the flow conditions in each control volume. Convective losses from the outer surface of the absorber have been modelled considering a forced convection mechanism in which the wind speed plays the main role. Radiative heat losses to the environment depend on the difference between the temperature of the external surface of the receiver and the apparent temperature of the sky assumed 8 °C below the ambient air temperature (Forristall, 2003).

The heat transfer from the external to the internal (turbulator) surface of the absorber can be treated as heat conduction in a rectangular cross section hollow body with the inner and outer surfaces at constant temperatures. In the considered receiver, given the high conductivity of the aluminum, which the absorber is made, it is reasonable to assume that the internal surface temperature is fairly constant.

Finally, to calculate the heat flow rate gained by the heat transfer fluid in the absorber, two heat transfer mechanism have been considered. Convective liquid heating occurs when the fluid is subcooled or saturated liquid and the wall temperature of the inner surface is lower than the saturation temperature, while a two-phase heat transfer occurs when the temperature of the internal surface in contact with the fluid is above its saturation temperature. To calculate the convective heat transfer coefficient when the liquid is heated, the procedure proposed by Manglik and Bergles (1995) is adopted. In the two-phase heat transfer, vaporization of the fluid can occur already in the presence of undercooled liquid. The formulation proposed by Liu and Winterton (1991) at the average vapor quality between inlet and outlet conditions of the control volume is applied to calculate the heat transfer coefficient between the inner wall and the vaporizing fluid.

The numerical model is implemented in Matlab® in a block diagram Simulink® environment. The thermophysical properties of the fluids are calculated with NIST Refprop Version 9.0 (Lemmon et al., 2010). The model includes the parameters used to describe the concentrator's optical performance (i.e. the nominal reflectance of the mirrors, optical properties of the external surface of the receiver), the geometric properties of the receiver and of its internal turbulator. The inputs of the model are the direct normal irradiance, the temperature and the velocity (wind speed) of the ambient air, the inlet temperature and mass flow rate of the heat transfer fluid in the receiver, assuming that it is always in conditions of subcooled liquid and its saturation pressure. The model estimates the temperatures at each of the considered thermal nodes in each receiver's segment as long as the convergence criteria based on the local and global thermal balances are not satisfied. Once the convergence is reached, the model provides the useful heat flow rate gained by the fluid, the average fluid temperature, the outlet temperature and vapor quality for each segment of the receiver, and finally, the thermal efficiency of the solar thermal collector.

3.1 Model validation

The results of the numerical simulations are compared against experimental data to assess the accuracy of the model. The difference between the estimated value of the collector efficiency and the collect data are plotted as function of the mass flow rate of the halogenated fluid. Figure 8 shows that the estimated thermal performance of the collector is in good agreement with that determined through the experimental tests. The prediction of the thermal efficiency displays a prediction error within 2%.

The validated numeric model has been used to perform an estimation of thermal performance of the collector including vaporization of the halogenated fluid up to a saturation temperature of 120 °C. The result of these simulations is shown in Figure 13. For these simulations, the values of the mass flow rate are assumed according to the inlet subcooling, so that the outlet vapor quality resulted between 0.55 and 0.6. This is done to prevent the onset of dryout phenomenon and the use of the Liu and Winterton (1991) outside its validity range. The ambient temperature is considered equal to 30 °C. From the numerical predictions, it results that it is possible to vaporize

the halogenated fluid HCFO-1233zd(E) inside the modelled receiver at a saturation temperature of 130 °C with a thermal efficiency of solar collector higher than 65%. Even though, the experimental efficiency curve plotted in Figure 9 is extended from its original range of definition, it results in very good accordance with the simulated efficiency curve.

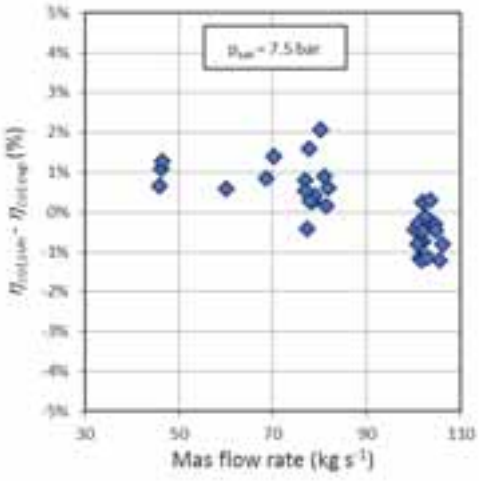

Figure 8 – Difference between simulated and measured values of the collector efficiency as a function mass flow rate.

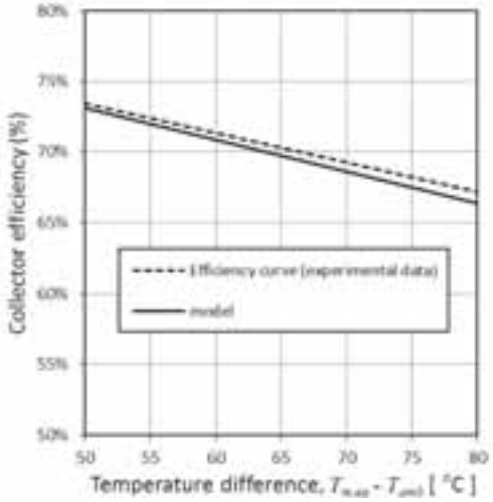

Figure 9. Simulated and experimental efficiency curves as a function of the temperature difference between the calculated mean condition of the fluid and the ambient.

4. Conclusions

An innovative solar receiver for linear concentrating collectors has been experimentally tested for the direct vaporization of a low-GWP halogenated fluid. The conducted experiments allow to determine the thermal performance of the collector composed by a parabolic trough concentrator and the flat solar receiver. During the tests the mass flow rate and the subcooling of the halogenated fluid entering the receiver have been varied to obtain different values of the outlet vapor quality.

The results of the experimental campaign reveal that the solar collector is able to vaporize the HCFO-1233zd(E) at 7.5 bar saturation and outlet vapor quality between 0.37 and 0.98 with a mean efficiency of 73%. In the present operating conditions, the mass flow rate and the subcooling of the halogenated fluid entering the receiver display a negligible influence on the performance of the collector.

A numerical model of the receiver has been developed in Matlab®. This model divides the receiver in several segments and is capable to estimate the temperatures at each thermal node in each receiver's segment providing the heat flow rate gained by the fluid, the average fluid temperature, the outlet temperature and vapor quality at each segment of the receiver, and finally, the thermal efficiency of the solar thermal collector. The results of the numerical simulations were compared against experimental data to validate the model. The estimated thermal performance of the collector is in good agreement with the experimental tests. The prediction of the thermal efficiency of the collector displays error within 2%. The model can be used to perform an estimation of thermal performance of the collector with vaporization of the halogenated fluid up to 120°C saturation temperature. It results that it is possible to vaporize the halogenated fluid HCFO-1233zd(E) at an outlet vapor quality between 0.55 and 0.6 with a thermal efficiency of the solar collector higher than 65%.

Abstract

Water scarcity is a severe problem that involves large areas of the World. The possibility to extract water from atmosphere is more and more investigated as a fascinating solution to face this problem in arid climates. A day-night thermodynamic cycle is here investigated to produce water from air using low temperature heat in an adsorption bed typically used for air dehumidification in DEC systems. The system can be easily integrated with a solar thermal collector and waste heat at 50-80 °C. The preliminary results of the experimental tests of a prototype that gives the possibility to simultaneously exchange heat and mass through the adsorbing mass are here presented.

Keywords: Atmospheric water harvesting, adsorption material, solar energy, water production,

1. The problem of access to water resources

Water scarcity is not a new problem, but the rise of the fresh water demand in the last years poses this issue as the critical challenge for the next 20 years. The OECD Environmental Outlook 2050 estimates that by 2050 water demand will increase by 55%, BRICS and developing countries plays a fundamental role in this scenario: respectively with an increase by 700% and 400%. Main actors of this increase are the domestic, manufacturing and power sector, driven by the increase of population, evaluated up to 33%, that will be concentrated in developing countries. (UNESCO, 2015). Cities are the areas in which the water challenge will most be played: in 2014 54% of the global population lived in cities and by 2050 it will be more than 65% (UNDESA, 2014). This water demand is mainly satisfied by the extraction from the available surface and groundwater source, that are yearly recharged by the hydrologic cycle. Figure 1 depicts the world condition in 2015 in terms of water withdrawal as a percentage of the renewable resources.

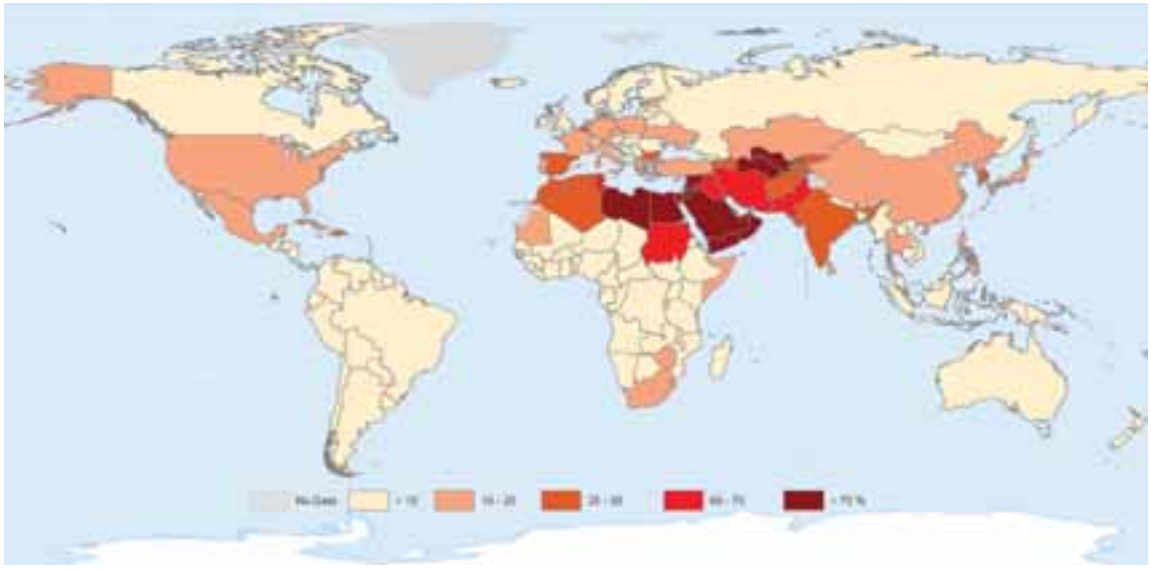

Figure 1. Percentage of withdrawal of renewable water resource in 2015

doi:10.18086/swc.2017.17.02 Available at http://proceedings.ises.org

The map shows clearly that the regions in which water issues presently are and will appear in the future more severe are North-Africa, Arabic peninsula, Middle East, and India in which there's a higher population density. In these regions water withdrawal overcomes 60% of the total renewable resource. Despite sub-Saharan region appears not involved in this issue, the uncontrolled rapid urbanization happened between 1990 and 2012 have reduced the percentage of population that have a direct access to piped water. In this case the problem of fresh water access is rather an infrastructure issue then a resource deficiency.

Up to now, the alternatives to satisfy the increase of water demand are to dig deeper to access available water resources or exploit other innovative solutions such as the use of reclaimed water or the reverse water osmosis process for sea-water desalination, that appears as the most promising solution for that problem (UNESCO, 2015). The use of technologies for wastewater treatment and water desalination are research object of many scientific research (Youssef et al., 2016; Siddiqui et al., 2016; Chiavazzo et al., 2017). The typical solutions become economically feasible for large plants only. Moreover, they are quite energy intensive, being based on the use of fossil fuels and, causing a large carbon footprint of the produced fresh water. Further on, it appears evident that persons that lack the access to water will also likely lack the access to electricity or other fuels to power decentralized solutions. There are a lot of countries nevertheless in which both the distance from brackish or polluted water resources is an obstacle for these alternatives, arid areas of inner region of North-Africa and the Arabic peninsula commonly face this problem. The atmosphere, containing 12,900 km^3 of fresh water in the form of water vapor, could be an alternative to this situation and should be considered as a valid renewable source of fresh water. Just for comparison, liquid fresh water at the earth surface is about 110,000 km^3 and superficial rivers, which represent the first source for human use, 2,107 km^3 (El-Ghonemy, 2012).

2. Water extraction from atmosphere

The possibility to use ambient air as water source has been already studied and tested in different research activities (El-Ghonemy, 2012). There are two main valid options:

- Use a refrigeration cycle based on vapor compression heat pumps or absorption chillers, to cool the air under dew point and condense the moisture (Margini et al., 2015)
- Use sorption materials to subtract the water vapor contained in the atmosphere. Afterwards the material is regenerated and the water is condensed at ambient temperature (William et al., 2015)

The system proposed in this paper is based on the second approach, a thermodynamic cycle is investigated as a feasible and practical solution driven by solar renewable energy, and experimental tests are carried out to investigate relative potentialities.

A fundamental role in this cycle is played by the heat provided at low temperature, 50-80°C, that can be easily and economically produced by low temperature solar technologies: flat-plate or evacuated tube solar collectors. This way of producing heat has high compatibility with such regions that are characterized by arid climate conditions, in which the problem of water scarcity is frequently coupled with a huge amount of solar radiation. Furthermore, the low level of temperature of the heat supply opens the access to a huge amount of *"alternative"* heat sources, such as waste heat or thermal cascade from other technological processes.

The cycle alternates two different successive phases as shown in Figure 2:

- *Adsorption*. Water vapor capture from the atmospheric air exploiting adsorption material such as silica gel, Zeolite, addicted clay, etc…
- *Desorption*. Very hot and humid air stream production by the regeneration of the adsorption material providing heat to the system.

The hot and humid flux is then condensed in a dry cooler at the outdoor ambient temperature. To have significant production of water during condensation it's necessary to produce an air stream reaching a sufficient level of temperature and humidity so that the environment might be accepted as an effective condenser. This consideration has to deal with the physics behind adsorption/desorption of water vapor in the material. Humid air when exposed to adsorption or desorption transformations moves along an isenthalpic line. This means that variation of air moisture content is always linked to a variation of air temperature: during adsorption, moisture content reduces and air temperature increases; conversely, during desorption moisture content increases and air temperature

reduces. For instance, if we want to have a condensing stream at the ambient temperature of 35°C, the saturation point corresponds to about 36.5 g kg^{-1} (point 3 in Figure 3). The only way to reach points on the saturation line above this reference point with an isenthalpic transformation is to have at the inlet of the desorption phase air at temperature around 50°C with the same moisture content (point 1). Anyhow, the moisture content at the saturation is very poor (point 2 iso-H) and just a reduced amount of water would be condensed (4-5 g/kg).

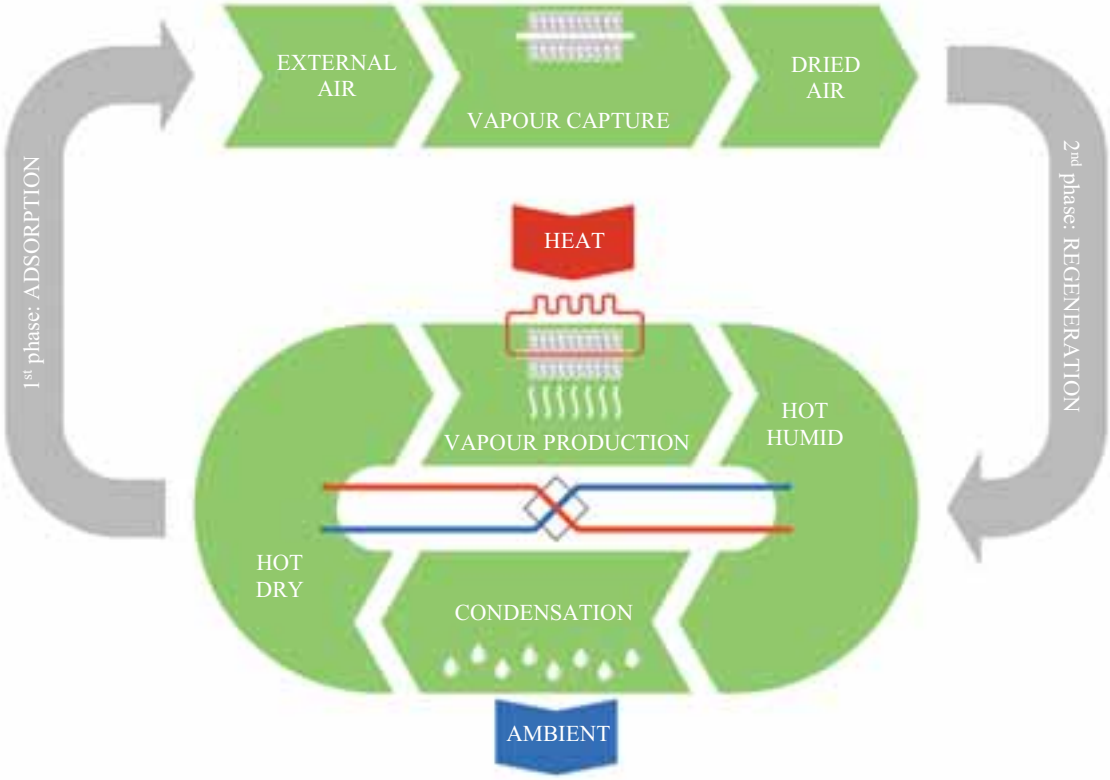

Figure 2. Conceptual scheme of the adsorption/desorption cycle

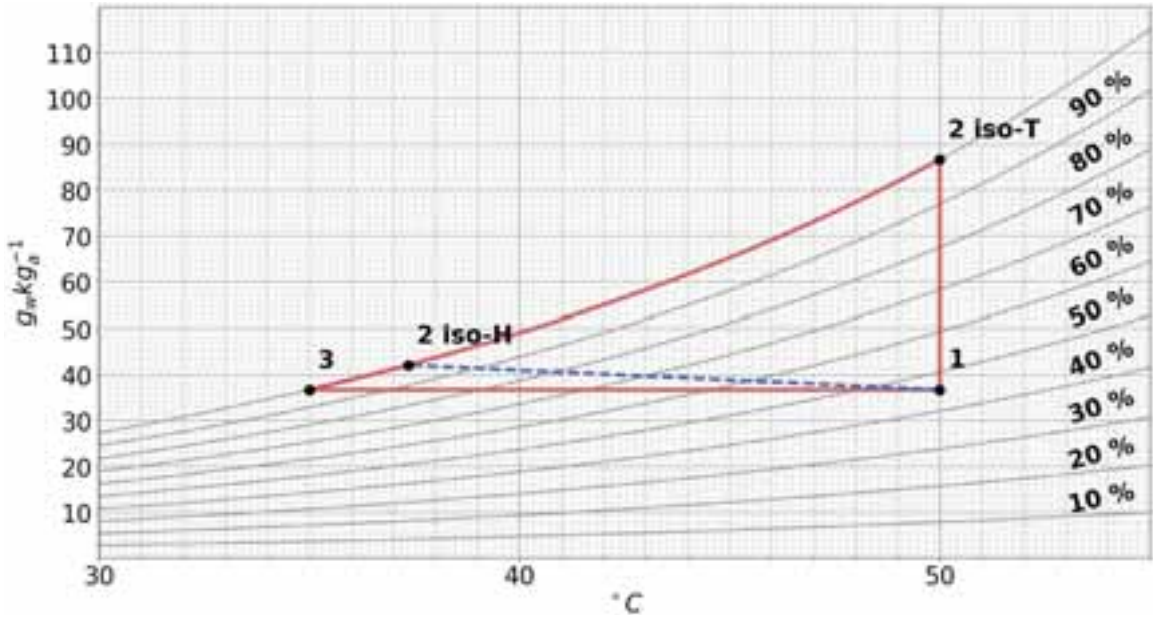

Figure 3. Comparison between a desorption with an isenthalpic (iso-H) or isothermal behavior (iso-T)

A different solution is when the sorption material follows a desorption transformation with an isothermal behavior

(2 iso-T). The specific humidity difference, starting from the same regeneration starting point (1), exceeds 40 g kg^{-1}, far more than the 5 g kg^{-1} given by the isenthalpic transformation. Obviously, this huge difference will require an equivalent amount of energy to allow the movement of water molecules from sorption material to the air. This amount of energy is slightly above the latent heat of water evaporation multiplied by moisture content difference. The point is that, to obtain the point 2 iso-T one has to supply an amount of heat equivalent to the latent heat, but always at the same temperature, 50°C. On the contrary, if point 2 iso-T had to be reached by an isenthalpic line the heat supply temperature would be above 70°C. This gives important advantages in terms of efficient utilization of solar thermal source at low temperature (flat plat or evacuated tubes), and limits the design problem only to the thermal requirement from the source.

To realize an isothermal transformation a system is required, that gives the possibility to exchange at the same time heat and mass. To do this, the sorption material such as Silica gel, Zeolite, etc. can be arranged in a finned heat exchanger (HX-ADS) (Finocchiaro et al., 2016; Simonetti et al., 2016). The heat to the adsorption heat exchanger is supplied by water circulation at 50-80°C, and a quasi-isothermal regeneration occurs. A fan circulates the air flow through the HX-ADS in a closed loop, thus permitting to continuously subtract water from the sorption material. The quasi-isothermal regeneration (line 1-2 iso T) is fundamental to obtain a hot and humid air stream from which water vapor can be easily condensed using ambient temperature in a dry cooler.

After this stage the air is cooled down by a double step thermal exchange: first by a heat recovery to reheat the regeneration stream and second by the condenser at the environment temperature. According to the thermodynamic cycle described in Figure 2 and Figure 3, around two liters of water can be collected from the treatment of an air volume of 100 m^3. In Table 1 different commercial solutions using vapor compression or absorption chillers are compared, in order to cool down the air to the dew point obtaining liquid water. Main differences of the proposed solution are the thermal supply at lower temperature, and lower specific consumption in terms of primary energy.

Table 1. Comparison of the proposed solution to existing commercial product and not.

3. Prototype

In the laboratory of the Energy Department (DENERG) of Politecnico di Torino a prototype has been assembled composed by and adsorption heat exchanger (Figure 4), and a condenser with a heat recovery system Figure 5. The adsorption system contains about 20.5 kg of silica gel grain with an average diameter of 3 mm. The heat is supplied to that system by a water circulation between 50-80 °C, produced by an electric resistance of 1.25 kW. The condenser is composed by an air to air heat recovery system and an air to water radiator which is used to condense the hot and humid stream, through cold water taken from water network, at around 20°C.

Integrated-Circuite temperature sensors LM35CAZ, with a precision of ± 0.2°C, monitor air and water temperature through the cycle. The RH sensor is a thermoset polymer capacitive type with on chip conditioning HIH4000-4 sensor monitors humidity at the inlet and outlet of the adsorption heat exchanger with

a precision of ± 3.5%. The air flow is driven by a centrifugal fan, at variable velocity with a maximum power consumption of 43 W, and an air flow rate range 0-100 $m^3 h^{-1}$. The two parts, adsorption/desorption packed bed and the condenser, are connected by a flexible duct: the outlet of the adsorption heat exchanger with condenser's inlet, and the condenser's outlet with the adsorption stage's inlet.

Figure 4. Adsorption heat exchanger

Figure 5. Condenser and heat recovery system

4. Experimental Tests

The testing procedure and preliminary results of the prototype operation are here presented.

Each test, as explained in the concept of the cycle, is composed by two successive phases. First the outdoor air circulates at the maximum flow in the adsorption bed, until equilibrium with adsorption material is reached with the air inlet condition, and the material can be considered as "quasi-saturated". Due to the prototype design this phase takes tens of hours, during which only the air at the inlet and outlet are monitored, in terms of temperature and humidity. After that, hot water starts to circulate through the coil of the adsorption heat exchanger and heats up the material. When the desired temperature is reached, flexible ducts are connected to the condenser and the fan is turned on. The regeneration starts, and humidity and temperature at each step of the cycle and the inlet/outlet water temperature are monitored. Finally, condensation starts, and water droplets are collected in a recipient, Figure 6. At the end of each test the water is discharged and the total amount is finally weighted with a high precision scale.

Figure 7 shows data monitored during the adsorption phase. This part of the test had a duration of more than 18 hours, with an average air inlet temperature of 22 °C and an average inlet air humidity of 8 g kg^{-1}. The outlet air from the adsorption bed reached a maximum temperature of 37.5 °C after around two hours from the start of the test, showing as the combination of a very high amount of sorption mass (20.5 kg) and a low air flow rate (100 $m^3 h^{-1}$) leads to a huge inertia of the system. In this phase outlet air moisture content drops down to 1 g kg^{-1} at the beginning of the test. The adsorption phase is stopped when outlet moisture content is around the inlet value. Figure 8 and Figure 9 shows data monitored during the desorption phase, that have a duration of about 6.5 hours. This phase has been divided in 5 successive intervals in which, between each other there isn't air flow but only hot water circulation. These intervals are visible in the graphs by the unshaded band, in this way at each interval the desorption starts at higher temperature. Condensation temperature is between 15 and 20°C depending on the

temperature of the water network. Air flow rate have changed from 50 to 100 $m^3\ h^{-1}$ during the desorption phase. The moisture content of the air had a big variation in each interval from 100 to 30 g kg^{-1}.

In Figure 10 to Figure 14 the cycle on the psychrometric chart is depicted for each interval of the desorption phase. It can be noticed that:

- Maximum moisture content at the outlet of the bed reduces progressively in each interval as consequence of the reduction of water contained in the adsorption material (red points)
- Air in the condenser always reaches the saturation condition, and all points fall on the 100% line of relative humidity (pale blue points)
- The temperature difference between the outlet of the bed and the outlet of the heat recovery system increases, following the increase of the sensible thermal exchange (red and yellow points)
- There's a big temperature difference between the inlet to the bed and the outlet of the heat recovery system caused by high thermal losses that occur in the path through the flexible duct that connect these two components. (blue points)

The total amount of water obtained from this test is equal to 2.318 kg. Starting from electrical power of the resistance (1.25 kW_{el}) and the total period of active desorption, 220 minutes, the thermal consumption is found to be 4.583 kWh_{th}. Then, the specific consumption results in 1.98 $kWh_{th}\ lt^{-1}$, that is 3.3 times the ideal value found through the thermodynamic analysis shown in Table 1. It has to be considered that numerous thermal losses occur in that system, the highest being in the duct between the condenser's outlet and the sorption bed's inlet, that can be estimated from the temperature difference between these two points, equal to 0,5 kWh lt^{-1}, or 25% of the total amount.

Another point is that the definition of the thermal specific consumption parameter in terms of total values, total thermal energy consumed and total water condensed, does not consider the transient behavior of the packed bed. In other terms, despite the thermal power provided to this system is always constant, the production of water decreases in time as the reduction of moisture content difference between inlet and outlet of the sorption bed. As a result of that, specific thermal consumption is not constant but an increasing function of the operating time. This behavior has been estimated in Figure 15, where positive difference of the air moisture content in the desorption phase is compared with a specific energy indicator, e_{th}, defined as follow:

$$e_{th} = \frac{P_{th}}{\dot{Q}_a * (X_{out} * \rho_{out} - X_{in} * \rho_{in})} = \left[\frac{Wh}{gr_{H_2O}}\right]$$

This function has two characteristic behaviors in time:

- *Continuous increase*. For each interval the increase is strictly correlated to the reduction of the outlet moisture content. This variation is very consistent such that at the end of each interval the final value is many times larger than the initial one.
- *Step behavior*. The reduction of internal moisture content of the sorption material amplifies the continuous increase between each interval. Instead the increase of the regeneration temperature between each interval shift down the initial value of the specific energy consumption. In this case the temperature and the duration of the hot water circulation period between each interval plays a fundamental role that is strictly related to the diffusive resistance of the water vapor in the micropore of the sorption material.

The correct management of heat in the regeneration phase has a large influence on the efficiency of the process, and thermal consumption can be reduced by an optimized control strategy.

5. Conclusion

The goal of this research is to demonstrate the feasibility of a system that catches the water vapor from air for many hours, such as a nocturnal period, and condenses this vapor using low temperature (50-80°C), solar heat. The prototype here presented has been tested in the laboratory of Energy Department (DENERG) of Politecnico di Torino. Preliminary results showed the capability to concentrate the water vapor contained in outdoor air for 18 of hours in the sorption material. Afterwards, with the use of heat under 80°C this vapor was released in about one fifth of the time to an air stream and condensed in order to obtain liquid water. A quantity of 2.318 lt of water has been obtained with an energy consumption of 4,625 kW_{th} of heat for an active period of operation around 3,7 hours.

Efficiency and performances of the process can be increased, and different strategies will be implemented to increase the efficiency of the system and reach values close to the theoretical value of 0,6 $kW_{th}\ lt^{-1}$, such as: the increase of ducts insulation; reduction of the length of air ducts; improvement of the regeneration strategy. New tests will be carried out with different outdoor temperatures and moisture contents, in order to simulate different climatic conditions such as in hot humid and arid countries. Also, the condensation temperature will be varied in a range of temperature between 15-35°C. Chemical test on water will be carried out in order to understand the best treatment needed to transform it in potable water.

Finally, we may say that the experiment has validated the concept on which this type of machine is based, and has shown an encouraging prospective.

All-weather snow machine driven by solar energy

Michael Joemann[1], René Völkel[1], Clemens Pollerberg[1], Lorenzo Podesta[2] and Francesco Besana[2]

[1] Fraunhofer UMSICHT, Oberhausen (Germany)

[2] NeveXN s.r.l., Rovereto (Italy)

Abstract

Technical snowmaking is the only solution to run ski slopes at the beginning and at the end of the winter season if natural snow is missing. However, technical snowmaking has several shortcomings e. g. high water and power consumption. Furthermore, with current snowmaking technology, snow can only be produced below wet-bulb temperatures of approx. -2.5 °C for compressed air and water guns or below approx. -4 °C for fan guns. This paper presents the concept of a snow machine which can be driven by renewable energy sources, able to produce high quality snow at temperatures above 0 °C, in all-weather conditions, and even in high summer season. The proprietary technology is based on a steam jet ejector chiller (SJEC) and uses the triple point of water. The thermal energy for the ejector can be provided by solar collectors or by a biomass steam boiler. Water is the only working fluid in the entire refrigeration system, which guarantees an ecologically friendly concept for the snow supply. Within the paper, the first operational experiences of the prototype as well as performance figures are presented. Furthermore, a concept for the solar circuit of a solar-assisted snow machine is presented. Subsequently, the system design and system performance of a solar-assisted machine will be evaluated for different scenarios. The evaluation is based on simulation results gathered with a model based on mass and energy balances.

Keywords: Technical snowmaking; steam jet ejector chiller; solar-assisted; all-weather conditions

1. Introduction

At the beginning and at the end of the winter season, natural snow is often missing and ski slopes are closed. The missing snow delays the opening of ski resorts, and represents a serious threat for the multibillion-dollar ski tourism industry, resulting in great losses for the economy of the mountain regions. Technical snowmaking is the only solution to run the ski slopes, but it has several shortcomings e. g. high water and energy consumption. Energy is consumed mainly to generate compressed air and to pump water. Typically, 67 % of all energy consumed in a ski resort is used for snowmaking (Smith 2010). A study, which evaluated the energy consumption of ski resorts in Finland, indicates that the average electricity consumption for slope services including lift operation, lighting and snowmaking amounts to approximately 34.6 MWh/a per hectare of snowed slope. The share of snowmaking is high with an average energy consumption of approximately 24.1 MWh/a (Timonen and Ikkunassa Oy 2010). Beside ski resorts, another sector which is dependent on technical snowmaking is indoor ski domes. The specific energy demand for snow production and air cooling in indoor ski domes is even higher as they are operated all year round even at high ambient temperatures.

1.1. Technical snow generation – State of the art

There are several physical processes to produce technical snow. The available processes split into nozzle atomization of water, cooling technology or cryotechnology (Fuhrmann 1996). Snowmaking via nozzles is the most common way. Snowmaking systems via nozzles can be divided into following subspecies: compressed air and water guns (internal and external mixing guns), and fan guns. Compressed air and water guns can be mounted on the ground or on a tower. These systems require pressurized water and compressed air from an external source which is usually supplied by a central facility via a piping network. In contrast, fan guns use electric driven axial fans to propel the water droplets to a huge distance and only require a small amount of compressed air which is nowadays usually provided by an on-board air compressor. Fan guns typically have one or more rings of nozzles which inject water into the fan air stream. Some separate nozzles are fed with a compressed air and water mixture and provide the nucleation points for the snow crystals. For both systems the production of snow works by the atomization of water into myriad water particles (droplets). A water-compressed air mixture is ejected from a

doi:10.18086/swc.2017.17.03 Available at http://proceedings.ises.org

nozzle at a pressure of 5 to 10 bar. During the expansion of the water-compressed air mixture the temperature decreases and the water droplets freeze. Aside from the cooling effect by expansion, the water droplets are also chilled by convection and evaporative cooling. The ice nucleation occurs on impurities in the water droplets. The ratio of water and compressed air has a significant influence on the consistency of the snow. By regulating this ratio, either a dry and powdery snow, a wet and heavy snow, or an ice glaze can be obtained (Pierce, JR. 1954). While a relatively low ambient temperature favors the snowmaking process and decreases the necessary compressed air volume flow, a higher snowmaking temperature increases the need for compressed air. A calm wind is advantageous in order to enable a rapid removal of the crystallization heat. The two main factors, which have influence on the effectiveness of snow production are air temperature and humidity, both combined in the wet bulb temperature. Higher air humidity results in a longer cooling time of water droplets to reach the nucleation temperature. With nozzle based systems snow can only be produced with low wet-bulb temperatures. The borderline temperature where compressed air and water guns (snow lances) can start operation is approx. -2.5 °C and the borderline temperature of fan guns is approx. -4 °C (Fuhrmann 1996). These requirements impede the use of traditional technical snowmakers in many critical situations. According to a study from 2011 assessing the energy use of mobile snowmaking at Swedish ski resorts, the energy demand to produce 1 m^3 of snow is 0.58 – 0.72 kWh_{el} for snow lances and 0.97 – 1.94 kWh_{el} for fan guns. The snow production capacity varies for the tested lances between 13 and 22 m^3/h and for the fan guns between 15 and 34 m^3/h. Thus fan guns are more energy demanding but reach a higher snow production capacity (Rogstam and Dahlberg 2011).

1.2. All-weather snow machines

At wet bulb temperatures above approx. 0 °C some kind of active cooling process is required to produce snow, either refrigeration technology or cryotechnology. Cryotechnology uses a cryogenic medium (e.g. liquid nitrogen (LN) or liquid air) which is mixed in the snow cannon with compressed air and water. The cryogen is required to cool the water droplets for snow generation at ambient temperatures above 0 °C. Alternatively, a room can be chilled with cryogen. Then ordinary snow guns can be used to generate the snow in the chilled room. Cryotechnology is complex and expensive, thus this type of snow production is only used for very special purposes (e. g. snow production in summer as part of events) and thus not suitable for large scale snow production.

In the last decades temperature independent snow machines, also called »all-weather snow machines«, based on different cooling technologies and processes have been developed. Compared to traditional snowmaking technology via nozzles, snow production at temperatures above °C is energy demanding and the systems are technologically more complex. These are the main reasons why all-weather snow machines are currently not widespread. Most of the available all-weather snow machines are electrically driven and produce ice in different forms (e.g. blocks, ice cubes, flake ice, plate ice) which is crushed afterwards to small flakes. However, the snow quality is not comparable with natural snow or snow from nozzle systems, because just big chunks of ice are crushed. The snow is not as fine as natural snow and has sharp edges. In contrast, snow machines based on ice slurry generators produce snow by separating ice crystals from an ice slurry. The snow quality of these machines is much closer to natural snow. At present several types of ice slurry generators exist (cf. (Kauffeld et al. 2005)):

- Mechanical-scraper type with rotating knifes, scrape blades, rotating brushes or screws
- Vortex-flow type with oscillatory moving cooled wall method
- Direct-injection or direct heat exchange type
- Fluidized-bed ice generator
- Vacuum freezing method
- Super-cooling water method

The main functionality of the different principles is described in (Kauffeld et al. 2005). Up to date mechanical-scraper method and vacuum freezing method are used for snow generation. Tab. 1 shows a comparison of market available all-weather snow machines.

The snow quality of snow machines based on ice slurry generators differs, too. With the mechanical-scraper method, the slurry has a slush consistence (cf. (Mogilevsky 2013)). Snow generated with the vacuum freezing method is smoother than ice, which is scraped from a surface, as the ice is generated by formation of crystals in water at the triple point conditions. However, for both technologies, main challenges are the ice separation from the slurry and to produce dry and groomable snow.

Fig. 1 illustrates a process scheme of an all-weather snow machine based on an ice slurry generator with vacuum freezing method. Such a system consists of an evaporator where the ice slurry is generated, a snow separator, a compressor, and a condenser. In the evaporator, water is taken to the triple point condition namely the point that occurs at 0 °C and 6.1 mbar by reducing the evaporator pressure with a compressor. In these conditions, the liquid, ice and vapor phases of water coexist in a stable equilibrium. The compressor feeds the water vapor against a higher pressure into the condenser where it is liquefied again. Some of the water in the evaporator freezes forming a water and ice mixture called ice slurry. The ice slurry is fed to the snow separator, where water and ice crystals are separated.

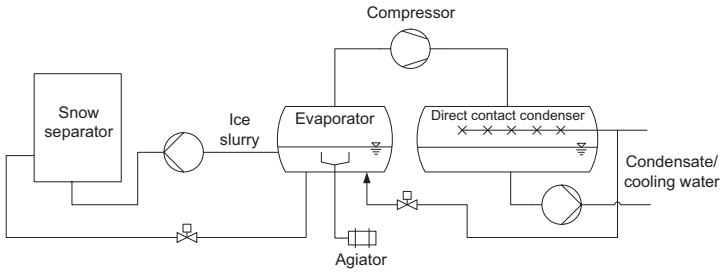

Fig. 1: Exemplary process scheme of an all-weather snow machine based on ice slurry generator with vacuum freezing method

Such a system has been realized by the company IDE Technologies Ltd. from Israel. The vacuum ice maker (VIM) of IDE uses an mechanical driven centrifugal compressor to create a vacuum in the evaporator where the ice slurry is generated. The suction vapor is fed to a direct contact condenser (mixing condenser). The direct contact condenser is cooled by a chilled water spray (coolant). The chilled water is produced by a conventional electric driven water chiller. A large surface area packing is installed in the condenser to increase the heat transfer between vapor and coolant. The liquid consisting of condensate and the sprayed coolant is fed via a coolant pump to the water chiller. The water vapor taken from the evaporator is replaced by chilled water. The ice slurry is pumped to the snow separator, where snow is separated from water. The water from the snow separator flows back to the evaporator. The IDE-system uses electricity as main driving energy to run the centrifugal compressor and the water chiller for condensation of the coolant. (IDE 2017), (Ophir et al. 2011)

1.3. All-weather snow machine based on steam jet ejector technology

An alternative concept for technical snow production based on an ice slurry generator with vacuum freezing method is presented in this paper. The system uses a thermally driven steam jet ejector to feed the water vapor from the evaporator to the condenser. The main components of an ejector are the motive nozzle, the mixing chamber and the diffuser. In the ejector an expansion of a motive steam takes place through a jet nozzle. Thereby the expansion of the motive steam is accompanied by a large increase in velocity up to Mach numbers of 3 to 4. The motive steam entrains the water vapor from the evaporator through momentum exchange. In a following diffuser, the kinetic energy of the mixed vapor streams consisting of motive steam and water vapor from the

evaporator is gradually transformed into potential energy respectively in pressure. Both vapor streams are liquefied in the condenser. The condenser pressure represents the back pressure of the ejector and is related to the cooling water temperature. If the temperature of the cooling water decreases the condenser pressure decreases, too. Lower condenser pressure leads to a lower necessary motive steam pressure, which reduce the motive steam consumption. This improves the thermal coefficient of performance (COP) of the refrigeration process. The steam to run the steam jet ejector can be generated by e. g. waste heat, renewable sources or be provided from district heating systems. Electric power is only used for auxiliary drives such as pumps, fans etc. Therefore the power consumption is reduced to a minimum and makes an all-weather snow machine without using an electric driven compressor an ecologically friendly concept of snow supply. The development of the snow machine started in 2012 thanks to a regional grant which financed the development of the first test rig. The snow machine was commissioned in October 2014 in Val di Fiemme at the Nordic Ski stadium. Within an EU-project, which started in 2017, a first prototype has been developed with a snow production capacity of approx. 2 m³/h. Furthermore, it is planned to realize two demonstration plants with a snow production capacity of 4 m³/h, one with biomass and one with solar energy as heat source. The foreseen location to erect the solar driven one is a ski dome in the Netherlands and the biomass driven one in a ski resort in Italy. This paper presents first operational experience as well as performance figures of the prototype, which is electric driven. The prototype has been presented on the Interalpin trade fair in 2017.

2. Design and test operation of the prototype

The prototype of the snow machine consists of a single-stage steam jet ejector chiller (SJEC) with a snow production rate of approx. 2 m³/h. The thermal power for the steam supply is nowadays provided by an electric boiler for testing the technology. The mass flow of the steam is approx. 240 kg/h and the steam is provided at a pressure of 4.5 bar(abs). A plate heat exchanger is used as condenser, which is cooled via a secondary cooling water loop connected to a wet cooling tower. Two pictures of the prototype are shown in Fig. 2. The left picture shows the installation at the Interalpin trade fair in Innsbruck in April 2017 and the right picture shows the installation at the test site in Bolbeno, Italy, in July 2017. The system is integrated into a 20 ft container. The hydraulic scheme of the snow machine with the main process data is depicted in Fig. 3. The steam jet ejector is designed for a back pressure of approx. 40 mbar. According to the design of the cooling water circuit, this design point corresponds to a maximum temperature of 20 °C (e.g. wet bulb temperature t_{WB} of 15 °C with 60 % rel. humidity).

Fig. 2: Pictures of the prototype (left: trade fair installation at Interalpin 2017; right: installation at test side in Bolbeno, Italy)

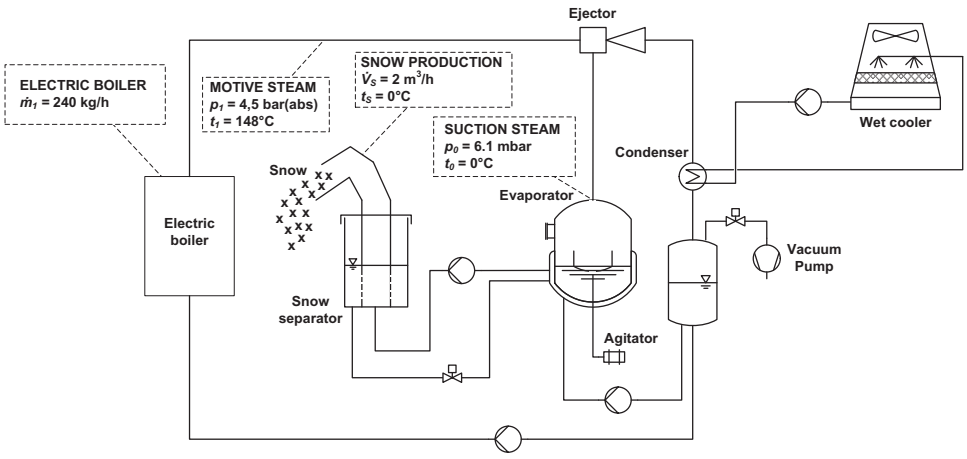

Fig. 3: Process scheme of the prototype

The prototype has been tested on 28. July 2017 in Bolbeno, Italy. At the test site well water with a constant supply temperature of approx. 10 °C was used for the heat rejection. Fig. 4 depicts the system temperatures and Fig. 5 the system pressures during the operation time from 16:10 – 17:40. The diagram in Fig. 6 depicts the heating and cooling capacity, the evaporator temperature and the thermal COP of the SJEC from 16:55 – 17:40. The SJEC was in operation from 16:22 – 16:40, from 16:43 – 17:08, from 17:15 – 17:31 and from 17:32 – 17:39. The evaporator temperature and pressure decreases during the SJEC operation. During the short operation breaks the evaporator was heated up with hot steam from the boiler (at 16:40 from 5 – 10 °C and at 17:07 from 0 – 15 °C).

The cooling water spreading was approx. 7.5 °C and larger than the designed 4 °C due to a lower flow rate of the cooling water pump. However, the SJEC was running close to the design point of the SJEC of 40 mbar back pressure. The condenser pressure was ranging between 32 – 41 mbar (see p_2 in Fig. 5). The cooling capacity plotted in Fig. 6 is calculated related to the evaporator water level and the temperature decrease of the evaporator during the operation of the SJEC. The cooling capacity is underestimated as no heat input from the ambience as well as from the ice slurry pump is considered. The heat consumption has been calculated to determine the thermal COP. The steam consumption was calculated according to (DIN 28430) and (GEA Wiegand 2017). The product of nozzle loss coefficient and outflow function is according to (Loschge 1914) constant for water vapor with a value of 0.459. The calculated value was crosschecked with the electricity consumption, which was measured by a current clamp.

$$\dot{m}_1 = \alpha \cdot \psi_{crit} \cdot A_1 \cdot \sqrt{2 \cdot p_1 \cdot \rho_1} \qquad \text{(eq. 1)}$$

with:

α	–	Nozzle loss coefficient [-]
ψ_{crit}	–	Outflow function [-]
A_1	–	Nozzle cross-section [m²]
p_1	–	Inlet pressure [Pa]
ρ_1	–	Density of water vapor [kg/m³]

In Fig. 6 the thermal COP ranges between 0.1 and 0.9 and is decreasing with declining evaporator temperature. At a temperature close to 0 °C (time span after 17:30) the thermal COP is between 0.1 and 0.4. The calculation of the cooling capacity does not consider the freezing of the water in the evaporator, so that the thermal COP is underestimated in the temperature range close to 0 °C. Actually there is no possibility to directly measure the cooling capacity while water freezes in the evaporator and thus to calculate a more accurate thermal COP value.

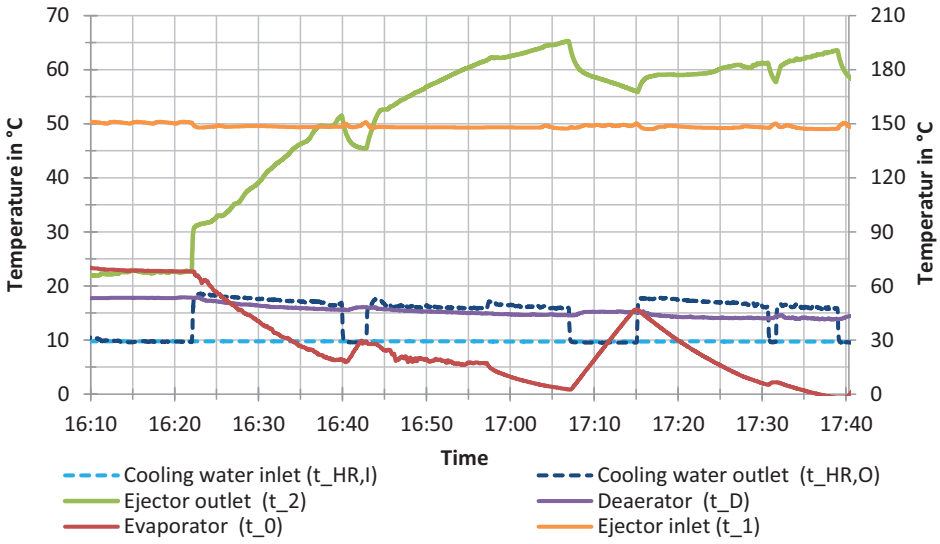

Fig. 4: Exemplary measurement data of the prototype: System temperatures (read ejector motive steam inlet temperature t_1 on right ordinate)

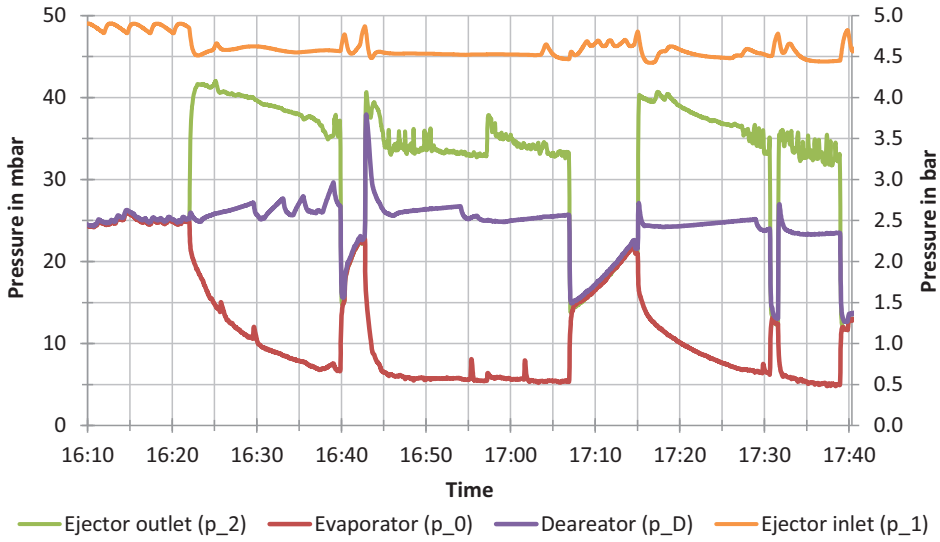

Fig. 5: Exemplary measurement data of the prototype: System pressures (read ejector motive steam inlet pressure p_1 on right ordinate)

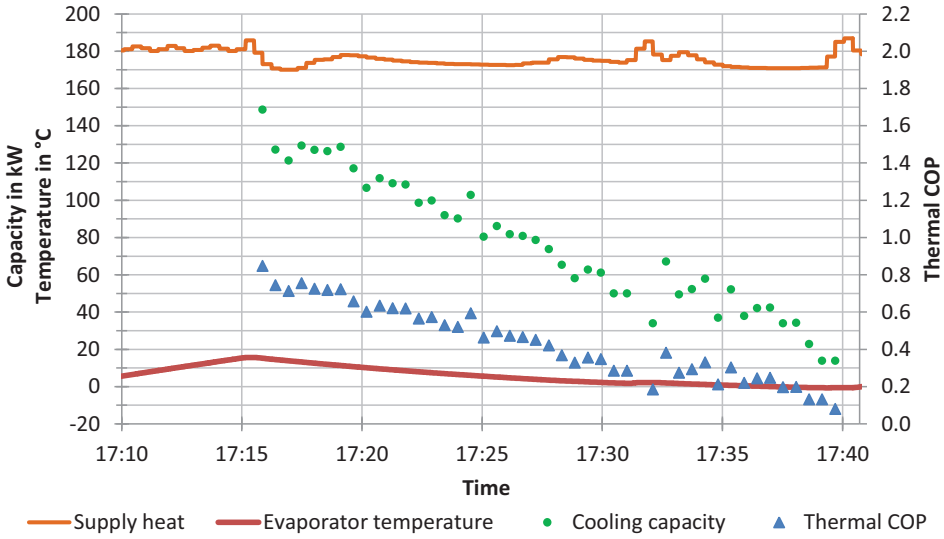

Fig. 6: Exemplary measurement data of the prototype: Heating and cooling capacity, evaporator temperature & thermal COP

3. Solar-assisted snow machine

3.1. Solar steam generation

There are parabolic troughs and Fresnel collectors, innovative evacuated tube and high-vacuum flat plate collectors available for the temperature range up to 250 °C. The collector types can be distinguished between concentrating and non-concentrating systems. The usable irradiation of concentrating collectors is often significantly lower compared to non-concentrating collectors. In case of 50 % lower irradiation the efficiency of the concentrating collector has to be twice as high to reach the same yield. Hence, important selection criteria for the choice of a suitable collector type are the solar profile at the system site and the required temperature.

Generally, there are two fundamental manners in which solar heat can be transferred to the ejector chiller system: direct steam generation (DSG) and indirect steam generation with pressurized water loop and steam drum. With DSG systems the motive steam is directly generated within the collector field and transported to the ejector. However, an intermediate steam drum, which can be bypassed, can be useful as an additional heat capacity to smooth the operation of the SJEC. In addition, it could also serve as droplet separator. The DSG technologies can be realized with parabolic trough collectors or linear Fresnel collectors. In case of a direct solar steam generation in the collector field, thermodynamic losses can be reduced. The control of the resulting two-phase flow has been extensively researched and has been already demonstrated in first commercial pilot plants. Alternatively to the line-focusing collector systems, evacuated tube collectors (ETC) can be used for DSG, too. This possibility has

been investigated within the research project ProSolarDSKM (Joemann et al. 2016). However, until now there is no commercial ETC available, which is designed for DSG.

The second technical solution for the solar thermal steam generation is a pressurized water loop. This means, that boiling in the collector is inhibited by increasing the pressure in the solar collector. The water boils in a steam drum subsequent to the collector field at lower pressure. The advantages of this technical solution are an easier controllability of the solar thermal system as well as a more reliable operation condition of the collector field. The pressurized hot water loop can be realized in different manners, either by hydraulic separation (heat exchanger between solar loop and steam drum) or by applying a specially designed solar pump which maintains an overpressure in the solar circuit in combination with a throttle valve before expanding into the steam drum. If there is no hydraulic separation with a heat exchanger and thus no water-glycol mixture is used as heat transfer medium one has to consider antifreeze protection if the ambient temperature can drop below 0°C.

Fig. 7 provides an exemplary hydraulic scheme for a solar loop of the presented all-weather snow machine. However, there is a variety of possibilities. The following requirements have been defined for the system:

- Indirect steam generation with pressurized water loop and steam drum: ✓
- Solar storage: ✓
- Short start-up time of the SJEC (→ small volume/capacity of the steam drum): ✓
- Operation of SJEC only with heat from storage: ✓
- Backup heating system: ✓
- Reheating of solar fluid with backup system (prior to the steam drum): ✓
- Operation of SJEC only with heat from backup system ✓

To meet the various requirements of the solar loop, the system needs two pumps. One pump to feed the collector field and a second pump to enable the operation of the SJEC with the backup system without solar energy. The control throttle valve VRM-S1 is used to maintain the required overpressure in the system to inhibit boiling in the solar loop. In case that the solar loop is not in operation, the valves VAM-S1 and VRM-S1 are closed. The main operation modes are: 1) solar heating of the steam drum, 2) charging of the solar heat storage (no operation of steam drum), 3) heating of the steam drum with heat from the storage (no operation of the solar field) and 4) backup heating mode.

1) In case of solar heating of the steam drum both pumps are in operation. The proportion of the flow rates of the pumps defines, whether the storage is simultaneously charged (P1>P2) or discharge (P1<P2). If both flow rates are equal, the storage is neither charged nor discharged. To disconnect the storage the valve VAM-S3 can also be closed. In this operation mode, the valve VAM-S4 is open and the valve VAM-S2 is closed. If the solar irradiance is not sufficient to reach the desired temperature, the backup system is used to heat the water up.
2) If solar heat is available, but not required from the SJEC, the heat can be used to heat up the solar storage. In that case, only P2 is in operation, VAM-S3 and S4 are open and VRM-S1, VAM-S1 and S2 are closed.
3) P1 is in operation, when heating the steam drum with heat from the storage. VAM-S3 is open and VAM-S2 and S4 are closed. The backup system can be used to increase the temperature level.
4) To heat up the steam drum with the backup system only P1 is in operation. The valve VAM-S2 in the bypass is open and the valves VAM-S3 to the solar storage and VAM-S4 to the solar field are closed.

3.2. Model of the snow machine

For the design of a solar-assisted snow machine, a calculation tool is required to evaluate different system designs and to investigate the operational behavior at varying climate conditions. Such a calculation tool has been developed based on a model of the system using mass and energy balances. The model describes the operational characteristic of the different components, e.g. solar collector, SJEC, pumps, fans, etc. It calculates the pumping power, pressure losses and flow rates of all hydraulic circuits for the determination of auxiliary power demand. Furthermore, the model enables to do year-round calculations on an hourly basis. Microsoft Excel with its spreadsheets in conjunction with VBA (Visual Basic for Applications) is used as software to compile parametric studies for different parameters such as solar field size, storage size or nominal motive steam temperature of the SJEC. Input data for the simulation are meteorological data, which are taken from Meteonorm database 4.0. Consumption and yield data for the components as well as various indicators, such as the solar fraction or the seasonal thermal and electrical efficiency of the system are calculated.

3.3. System design and system performance evaluation

In this chapter different aspects of the system design and system performance of a solar-assisted snow machine with SJEC will be discussed and evaluated. The application scenario is the snow production for an indoor ski dome. In order to assess the climatic influences on the system, three locations are considered (Doha in Qatar; Seville in Spain; Essen in Germany). Below, the reference scenario and design parameters are listed:

- Snow production rate: 4 m³/h (constant → additional heat provided by a backup system)
- Cooling capacity: 215.2 kW (snow density: 500 kg/m³)
- Operation time: 08:00 – 18:00; Season: all year round
- Condenser technology: mixing condenser; heat rejection: wet cooling tower
- Motive steam design temperature: optimized in dependence of system site (climatic conditions)
- Motive steam consumption at varying operating conditions:
  - Motive steam pressure p_1 increases/decreases by the ratio of the back pressure p_2 to nominal back pressure $p_{2,nom}$ (min: 80 % of $p_{1,nom}$; max: 115 % of $p_{1,nom}$)
- Nominal back pressure $p_{2,nom}$ of SJEC: selected in dependence of climatic conditions to be able to operate the SJEC ca. 95 % of the year (5 % no operation possible due to too high t_{WB})
  - Essen: $p_{2,nom}$ = 37.7 mbar (corresponds to t_{WB} of 15 °C + Δt 12 °C + $\Delta p_{Leakage\ Air}$ 2 mbar)
  - Seville: $p_{2,nom}$ = 48.3 mbar (corresponds to t_{WB} of 19.5 °C + Δt 12 °C + $\Delta p_{Leakage\ Air}$ 2 mbar)
  - Doha: $p_{2,nom}$ = 67.6 mbar (corresponds to t_{WB} of 25.8 °C + Δt 12 °C + $\Delta p_{Leakage\ Air}$ 2 mbar)
- Design of the internal and external cooling water loop and cooling tower
  - $\Delta t_{Cooling\ limit\ distance\ of\ wet\ cooler} = 3.0$ °C; $\Delta t_{Heat\ exchanger} = 5.0$ °C; $\Delta t_{Internal\ cooling\ water\ loop} = 4.0$ °C
- Collector field:
  - ETC (Paradigma AQUA PLASMA 15/27)
  - Fresnel (Industrial Solar LF-11)
  - Specific collector area: 7.5 m² per kW cooling capacity of SJEC (total collector area: ca. 1,600 m²)
  - Specific storage volume: 10 l per m² collector area (total storage volume: ca. 16 m³)
- Design data of auxiliaries
  - Nominal pump efficiency $\eta_P = 77.9$ % (efficiency varies with flow rate of the pump)
  - Nominal pump head H_P of the different pumps (pump head varies with flow rate of the pump):
    - Solar pump head $H_P = 6\ m$, storage pump head $H_P = 5\ m$, backup system pump $H_P = 5$ m, ice slurry pump $H_P = 15$ m, internal cooling water pump $H_P = 5$ m, external cooling water pump $H_P = 15$ m
      → to overcome pressure losses in the solar circuit a surcharge to avoid boiling in the collector has been considered for the solar pump, the storage pump and the backup system pump
- Nominal efficiency η_F and total pressure of the wet cooling tower fan p_F
  - Fan efficiency $\eta_F = 60$ %; total pressure p_F approx. 120 mbar

For the design of a solar-assisted snow machine based on SJEC technology, it is important to consider that the efficiency of the SJEC increases up to a certain level with increasing motive steam temperature, but contrary the solar collector efficiency decreases with increasing temperature, which governs the motive steam temperature. The design point is ought to be the optimum operation point taking both effects into account. Furthermore, each solar collector type has a specific decrease of the efficiency with temperature, thus the selection of the design point must be made in view of the selected solar collector type. Finally, it is an optimization problem, since both influence the system efficiency. In Fig. 8 (left part) the average annual thermal COP of the SJEC is plotted over the motive steam temperature for the three locations. For each location the respective dimensions of the SJEC (e. g. nozzle diameter) have been optimized for the motive steam temperature. The required motive steam temperature ranges between 140 and 160 °C to reach the highest possible efficiency. The comparison of the solar fraction for the different scenarios (see right diagram in Fig. 8) indicates that the highest solar fraction is reached at a lower temperature than the temperature level of the highest thermal COP. The reason for this is that the collector efficiency and hence the collector yield decreases with increasing temperature (see Fig. 9). Furthermore, the comparison points out that the ETC collector reaches the highest solar fraction (Essen ETC 100 °C; Seville ETC 120 °C; Doha ETC 140 °C).

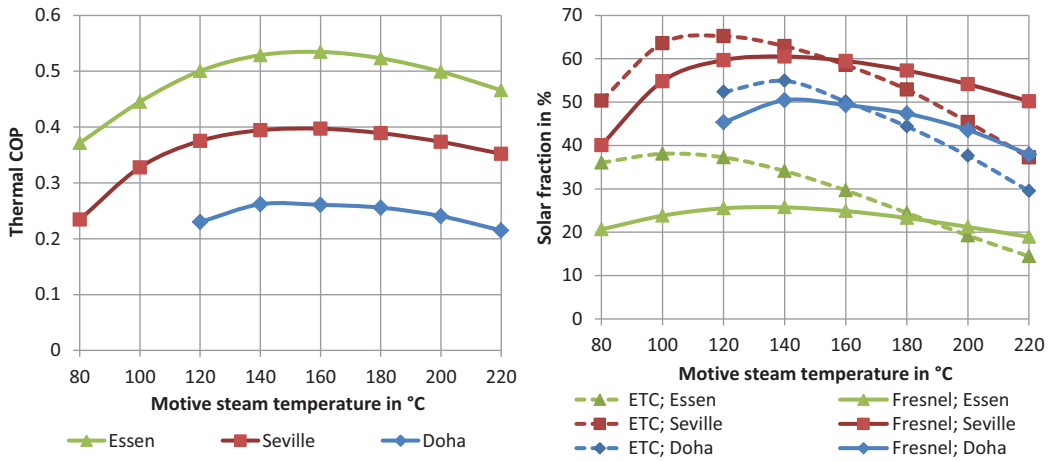

Fig. 8: Average annual thermal COP of the SJEC in dependence of motive steam temperature (left) and solar fraction (right) in dependence of motive steam temperature for ETC and Fresnel collector for the locations Essen, Seville and Doha

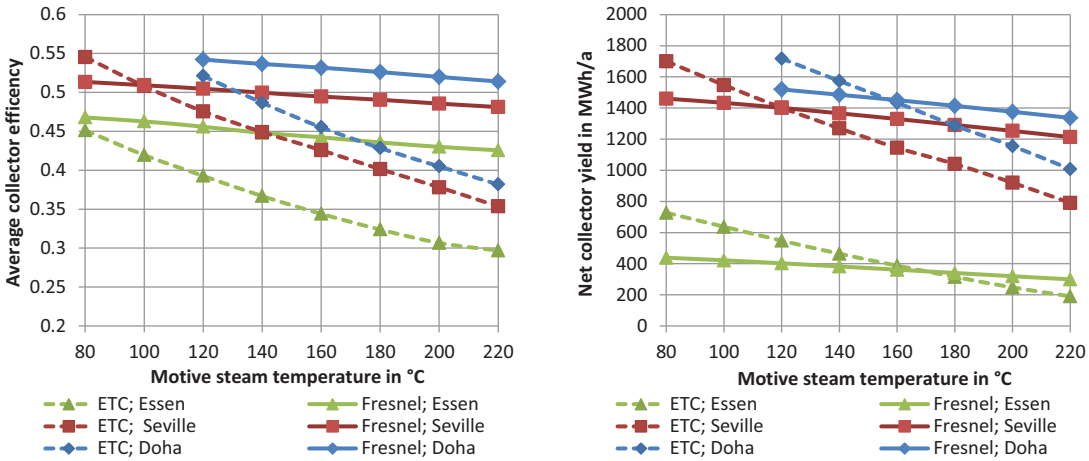

Fig. 9: Average collector efficiency (left) and net collector yield (right) in dependence of motive steam temperature for ETC and Fresnel collector for the locations Essen, Seville and Doha

The results of a parameter variation of the collector field and storage size for the location Seville are depicted in Fig. 10. For the reference scenario with a specific collector area of 7.5 m²/kW$_{Cooling}$ and a specific storage volume of 10 l/m² a solar fraction of approx. 67 % is reached. Small solar fields with a specific collector area of 2.5 – 5 m²/kW$_{Cooling}$ do not require heat storage. Larger solar fields require a storage size of 30 l/m², but not more. A further increase in storage volume would not result in a significant increase of the solar fraction. In comparison to solar driven cooling systems for comfort cooling, the required specific collector areas are significantly higher (cf. (Joemann 2015) page 118). This issue can be explained by different reasons. The cooling load profile of a

building is often dominated by the solar irradiation profile, thus the Solar-Load-Match is significantly higher. Another reason is that the thermal COP of the SJEC is much lower due to a lower evaporator temperature of 0 °C. Also the average solar field temperature to run the SJEC is higher than for a single stage absorption chiller which decreases the solar heat yield.

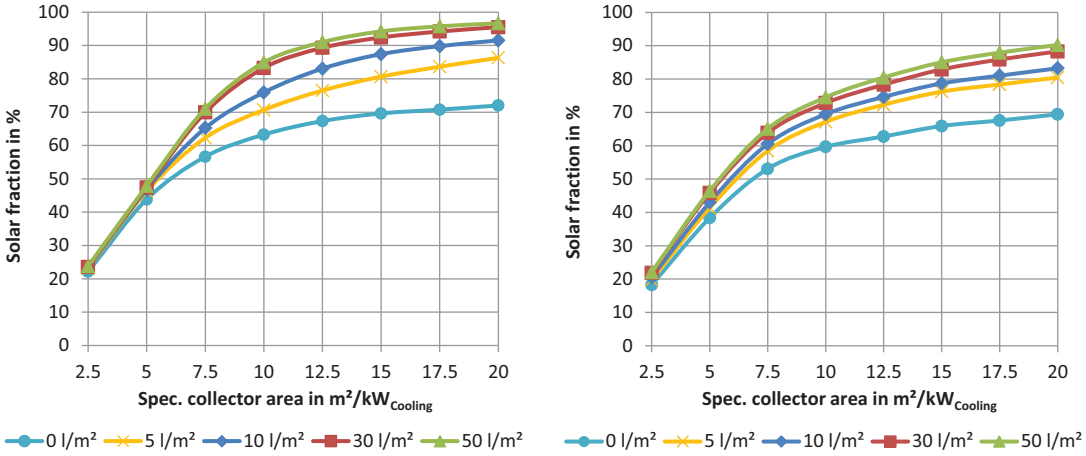

Fig. 10: Solar fraction in dependence of specific collector area and the specific heat storage volume for ETC (left) and Fresnel collector (right) for the location Seville; nominal system temperature: ETC = 120 °C, Fresnel = 140 °C

The annual sums of motive heat demand of the SJEC as well as gross and net heat supply are given by Fig. 11: monthly based (left diagram) and hourly based (right diagram) timeline. The data are given for ETC and Fresnel collector at the location Seville. The results prove that both collectors can provide the required motive heat to operate the SJEC in summer from May to August. The Fresnel collector even provides some surplus heat. From September to April, the backup heating system provides a significant amount of the heat to cover the demand. The data in the right diagram, which are the yield of heat energy and the demand of motive steam over the day, point out that the Fresnel collector provides the heat on a more constant level over daytime, whereby the solar heat provided by the ETC collector has a bell-shaped course so that some surplus heat is generated between 13:00 and 15:00.

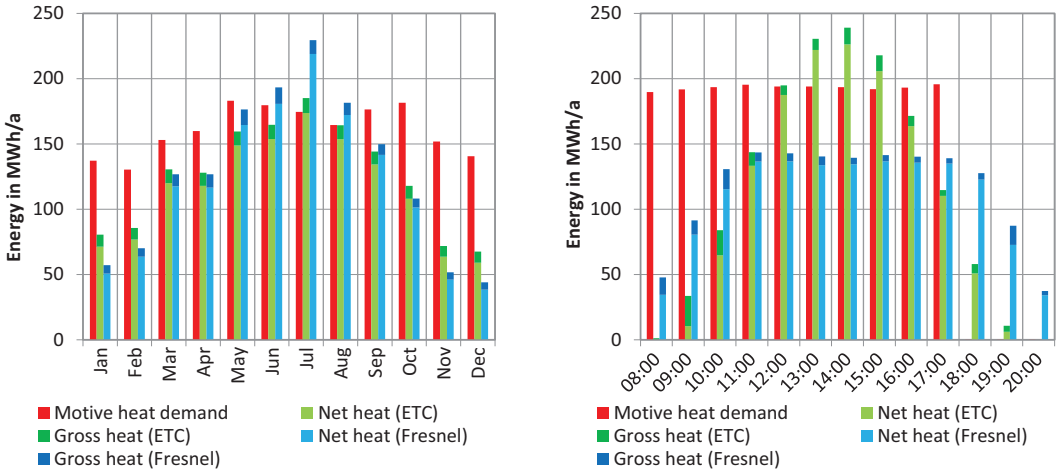

Fig. 11: Annual sums monthly for the year (left) and hourly for the day (right) of motive heat demand of the SJEC as well as gross and net heat supply of the ETC and Fresnel collector for the location Seville; nominal system temperature: ETC = 130 °C, Fresnel = 130 °C (same temperature to assure an identical motive heat demand of SJEC)

The electrical COP given in Fig. 12 is the ratio of the cooling capacity to the auxiliary power demand. The given data are average values for electrical COP monthly for the year (left) and hourly for the day (right) of systems with ETC collector. The nominal system temperature has been optimized to reach the highest possible solar fraction (see right diagram of Fig. 9). The values range between approx. 6 and 14. The annual average values are 10.5 for Essen, 8.8 for Seville and 7.1 for Doha. At the design point of the system, the nominal power consumption is 31.2 kW for Essen, 35.4 kW for Seville and 44.5 kW for Doha. At favorable ambient conditions, the power consumption is significantly lower due to the higher thermal COP of the SJEC. Thus the annual average values

for power consumption are 20.6 kW for Essen, 24.3 kW for Seville and 30.2 kW for Doha. However, it has to be mentioned that the power consumption of the control cabinet, of the drives of valves and of the vacuum pump is not considered, thus the electrical COP is slightly overestimated.

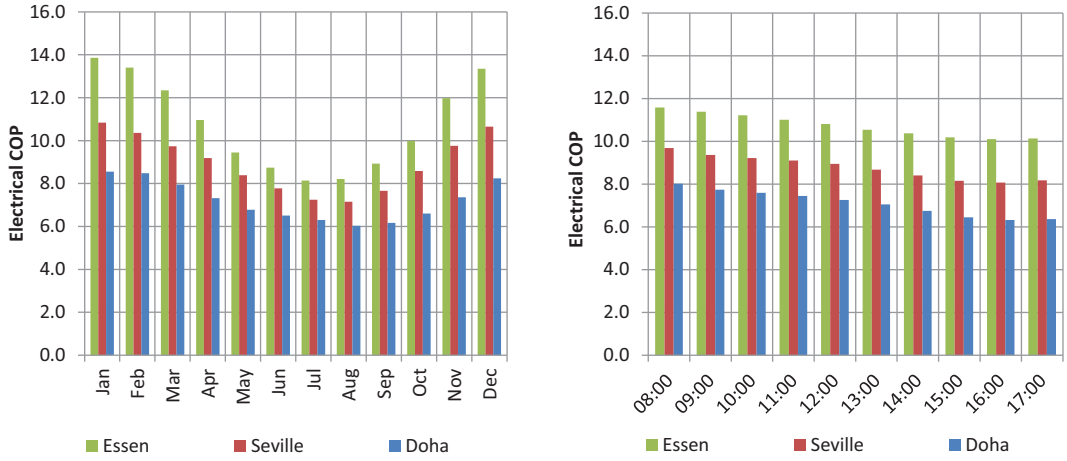

Fig. 12: Average electrical COP monthly for the year (left) and hourly for the day (right) for ETC and for the locations Essen, Seville and Doha; nominal system temperature: Essen = 100 °C, Seville = 120 °C, Doha = 140 °C

The average electrical energy consumption is depicted in Fig. 13 monthly for the year (left part) and hourly for the day (right part) of a system with ETC collector. The electrical energy consumption ranges between approx. 4 and 9 kWh/m³ depending on the climatic conditions. The annual average values are 5.1 kWh/m³ for Essen, 6.1 kWh/m³ for Seville and 7.6 kWh/m³ for Doha. In hot ambient climatic conditions the motive steam consumption of the SJEC increases and thus the power consumption increases, too. The reason is that higher amounts of heat have to be transported, mainly in the internal and external cooling water circuit. That also explains the higher values for electrical energy consumption in the summer time (compare for Essen) and for warmer regions like Doha. There is also a slight increase in power consumption throughout the day as the temperature increases over the day. Summarizing, a contrary behavior of the electrical COP (see Fig. 12) can be seen, which decreases while ambient temperature increases.

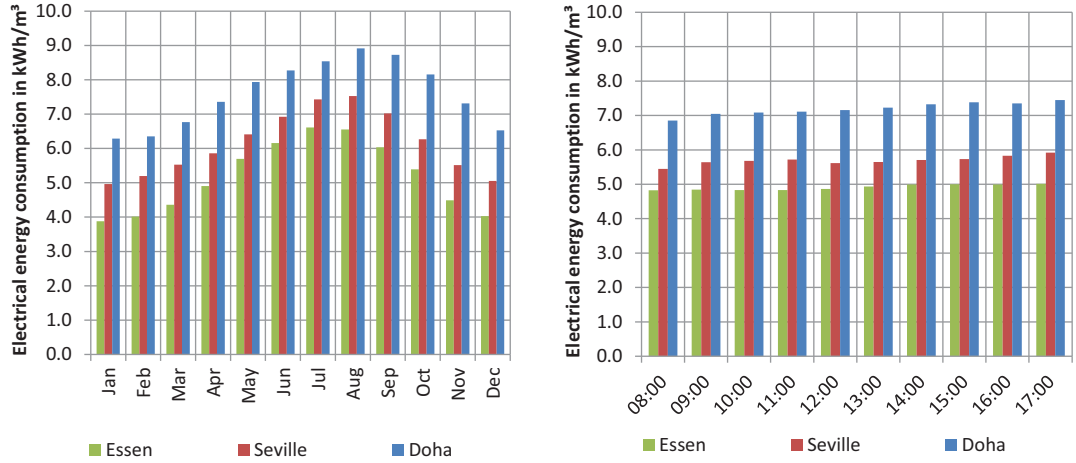

Fig. 13: Average electrical energy consumption monthly for the year (left) and hourly for the day (right) for ETC and for the locations Essen, Seville and Doha; nominal system temperature: Essen = 100 °C, Seville = 120 °C, Doha = 140 °C

The electrical energy consumption of the presented technology for snow production is about 2.7 to 6 times lower compared to other all-weather snow machines (cf. Tab. 1). Furthermore, it has to be highlighted that the presented values are seasonal values. The consumption data for all-weather snow machines from Tab. 1 are only given for the design point and are expected to be worse at a seasonal contemplation. Nevertheless, the snow machine based on SJEC technology needs thermal energy, too. This should come from renewable energy source to assure a sustainable system operation.

4. Conclusion

The developed pilot plant of the all-weather snow machine represents an innovative system for high quality snow generation at temperatures above 0 °C. The system is based on an ice slurry generator with vacuum freezing method and uses a steam jet ejector as thermal compressor for the refrigerant. Water is used as refrigerant in the process. The system can be operated with heat from renewable sources which enables a sustainable system operation. With the aid of the pilot plant it was possible to examine the performance system. The functionality of the system has been proven and the first measurement data of the pilot plant are giving a promising outlook.

Based on the experiences of the pilot plant, a concept for a solar-assisted snow machine has been developed. The development of the concept includes the determination of the design points and the evaluation of the system performance. Both have been realized by year-round calculation and simulating the operation of the system. The simulation proves that the electrical energy consumption of the presented technology for snow production is about 2.7 to 6 times lower compared to other all-weather snow machines, which are currently available.

Infrared optical properties of doped and pure thermochromic coatings for solar thermal absorbers

Anna Krammer[1], Fabrice T. Demière[1] and Andreas Schüler[1]

[1] Solar Energy and Building Physics Laboratory, École Polytechnique Fédérale de Lausanne (EPFL), Lausanne (Switzerland)

Abstract

A new generation of solar collectors is based on thermochromic thin film technology, where the remarkable optical changes of vanadium dioxide, through its reversible semiconductor-to-metal phase transition, are exploited. This study reports on the infrared optical properties of VO_2 based coatings deposited on Al substrates by reactive magnetron sputtering. Fourier transform infrared (FTIR) spectroscopy is used to determine the emittance of a VO_2 coated sample before (ε = ~6%) and after (ε = ~33%) the phase transition. The angular dependence of the thermal emittance for such coating is investigated. It is found that the emittance increases with increasing the angle from normal incidence. In literature it is widely reported that the transition temperature of vanadium dioxide can be tuned by doping with different elements. An increase in the transition temperature is desired for solar thermal applications and it is reached with the addition of Ge into the VO_2 matrix. Here we show that through Ge doping, the emittance switch, especially the emittance in the high temperature state, can be optimized as well. An increase of ~10% in emittance is recorded.

Keywords: Solar thermal, thermochromic absorber coating, doped vanadium dioxide, overheating protection

1. Introduction

Due to their simple design and operation, solar thermal collectors for domestic hot water generation and space heating are one of the most common solar energy harvesting systems in use today. Such collectors are typically designed to cover between 50-80% of the annual domestic hot water demand. During cold periods all the absorbed energy is useful. During hot periods, however, when solar radiation is abundant and demand is low, stagnation occurs. Storage is limited and excess heat cannot be diverted. The heat transfer fluid evaporates and temperature of the solar absorber can exceed 200°C. A self-draining system and special valves are then necessary. At such temperatures, glycol degradation and further damage of the collector occurs. Frame, thermal insulation, selective absorber coating deteriorate and become less efficient.

A novel type of thermochromic solar collector has been proposed [1, 2, 3]. Recently, industry has demonstrated functional collectors on the real scale [4]. These new collectors are based on switchable selective absorber coatings that can change their optical properties in the infrared spectral region so that they can absorb and repel heat in a controlled manner. Thus, the stagnation temperature is limited and overheating of the system is avoided. Until recently, this was one of the main drawbacks of thermal collectors.

The “smart” thermochromic absorber coating exhibits good selectivity (high absorptance, low emittance) up to a given temperature and bad selectivity (high absorptance, high emittance) above that temperature in order to prevent overheating. Here the material of choice is vanadium dioxide.

It undergoes a reversible thermochromic transition, during which its switch in thermal emittance and subsequent heat dissipation to the surroundings at high temperatures is sufficient to limit the stagnation temperature. Evaporation of the transfer fluid is avoided and thermal charges on the system reduced.

1.1 Vanadium dioxide

Vanadium dioxide is an emblematic thermochromic material. It undergoes an ultrafast and fully reversible first order semiconductor-to-metal (SMT) transition at 67°C.[5] Through the transition the crystal structure changes from the low temperature monoclinic (P21/c) to tetragonal rutile (P42/mnm) at high temperature and is accompanied by abrupt changes in electrical and optical properties.[6] A resistivity change of several orders of magnitude and significant changes in the optical constants – especially in the infrared range – occur at the transition. Due to these remarkable changes occurring close to room-temperature, vanadium dioxide has been the object of overwhelming fundamental and applied research. Vanadium dioxide shows potential in a wide range of applications ranging from smart windows[7] and radiators for space applications[8] to microelectronic and device applications such as steep-slope switches[9], tunable capacitors[10] etc. Meanwhile, the underlying mechanism – structural or charge driven transition – is still open to debate with recent studies [11] suggesting a correlation-assisted Peierls transition, stressing the joint effect of lattice symmetry breaking and Coulomb interactions. Additionally, discoveries of exotic VO_2 behaviors, such as the very recently reported one order-of magnitude breakdown of the Wiedermann-Franz law in the vicinity of the semiconductor-to-metal transition[12], push the fundamental research of VO_2 even further.

Through doping with different elements, the optical and electrical properties of vanadium dioxide can be tuned and, most importantly, its transition temperature can be tailored to suit various applications. W^{6+}, Mo^{6+} Ta^{5+} and Nb^{5+} have been widely reported as dopants decreasing the transition temperature[6]. Tungsten has been regarded as one of the most efficient in doing so, enabling a reduction of 49-55°C per at.% dopant[13]. Therefore, for room temperature applications such as smart windows, tungsten doping is well-established. On the other hand, increasing the transition temperature through doping has been less studied and the identified dopants proved less efficient. Aluminium doping has been reported as both increasing and decreasing the transition temperature. In [13], authors show that Al^{3+} induces gradual amorphization of the thin films without significant effect on the transition temperature. Cr^{3+} and Fe^{3+} were reported to increase the transition temperature with no more than 3°C [14]. Thermochromic VO_2 based solar absorber coatings, as discussed in the present work, or the recent developments at microelectronic device level (where the required switching temperatures are higher than the normal operating temperatures of the device), underline the importance of an efficient and reliable doping which allows for a range of elevated transition temperatures to be achieved.

Authors have recently showed that Ge doping is successful in increasing the transition temperature of vanadium dioxide sputtered thin films and a transition temperature of ~95°C has been reached [15]. In comparison, the currently available commercial products, based on Al doped (4 – 12 at.%) vanadium oxide films, transition at 70° - 75°C. Therefore, the above 20°C temperature rise constitutes a significant increase and an important step in establishing efficient vanadium dioxide based absorber coatings. In the present work, authors determine the effect of Ge addition to the vanadium dioxide lattice from the thermal emissivity point of view. First, the spectral reflectance and emissivity of a pure VO_2 film in the mid-infrared range (2-15μm) is measured. The sample is measured both below and above the switching temperature. Then, the angular dependence of the thermal emittance is discussed. Finally, the spectral emissivity in two differently doped samples is measured and compared with that of a pure VO_2 film. Thus, the influence of Ge doping on the IR optical properties of the coatings - specifically their thermal emissivity - is determined.

2. Experimental

Pure and doped vanadium dioxide thin films have been deposited by reactive magnetron co-sputtering in sputter-up configuration. A schema of the deposition chamber and the process is shown in Fig. 1.

The base pressure of the chamber was below $5 \cdot 10^{-8}$ mbar. The process gas is Ar (purity 99.999%) and O_2 (purity 99.995%) is the reactive gas for oxide formation. A mass flow controller regulates the Ar gas feed to the chamber and the Ar flow is set to 17.4 sccm. Inside the chamber, a lambda-probe (Zirox XS22) oxygen sensor is installed. Based on the pressure readings, a Proportional Integral Derivative (PID) feedback control regulates the oxygen flow such that a constant oxygen pressure is maintained. The oxygen partial pressure during depositions is $5.25 \pm 0.25 \cdot 10^{-4}$ mbar, while the working pressure is $\sim 7.1 \pm 0.1 \cdot 10^{-3}$ mbar.

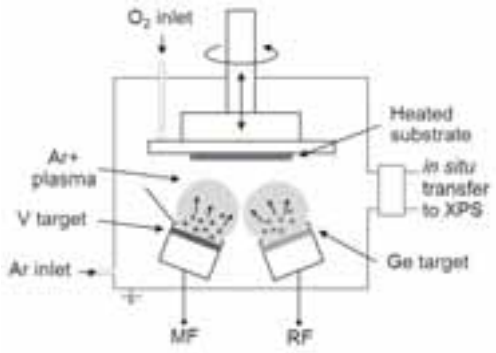

Fig. 1: Schematic representation of the sputtering chamber with targets, plasma glow and adjustable substrate holder

The magnetrons are run by DC power (MKS) for the vanadium target and radio frequency (RF) AC power (Advanced Energy) for the germanium target. The metallic target discs are provided by Testbourne Ltd. The purity of the 2" targets is guaranteed at 99.95% for the V and 99.999% for the Ge target. The power on the V target is set to 150 W, whereas for the Ge source, RF power (13.56 Mhz) of 8W and 12W are applied. To limit doping, magnets are removed from the magnetron, thus reducing the magnetic field and, subsequently, the plasma density.

The films are deposited on 0.5 mm thick, 50 mm x 50 mm sized Al foil (Goodfellow) for the Fourier transform infrared (FTIR) spectrometry, on stainless steel for the thermal imaging and on Si wafer for the angular dependence determination. The deposition takes place at high temperature – 600°C is measured by a stationary thermocouple above the rotating substrate holder. The thickness of the deposited films is estimated at ~320 – 340 nm.

A commercial thermographic camera (FLIR Systems, Inc.) is used to visualize the optical switch of VO_2 based coatings over the transition and to determine the angular dependence of the emissivity of these samples. The camera detects infrared radiation in the range of 7.5 - 13 μm.

The spectral reflectance is measured with a Bio-Rad FTS-175C Fourier transform infrared spectrometer equipped with a 3" golden integrating sphere and a high performance nitrogen-cooled MCT detector for the Mid-IR range (2-20 μm).

3. Results and discussion

3.1. Switching emittance

The optical switch of the thermochromic film in the infrared spectral region has been captured by thermal imaging (Fig.2). A VO_2 based coating has been deposited on reflecting stainless steel (SS) substrate. Below the transition temperature, the semiconducting VO_2 coating is transparent to the IR radiation and only the substrate is seen on the thermal image. However, above the transition temperature, the film - deposited in the middle of the SS sheet - appears on the thermal image as the VO_2 becomes opaque to the infrared radiation in its metallic state. Therefore, when deposited on a reflecting substrate such as stainless steel, copper or aluminium, the thermochromic coating has a low thermal emittance below and a high emittance above the transition temperature.

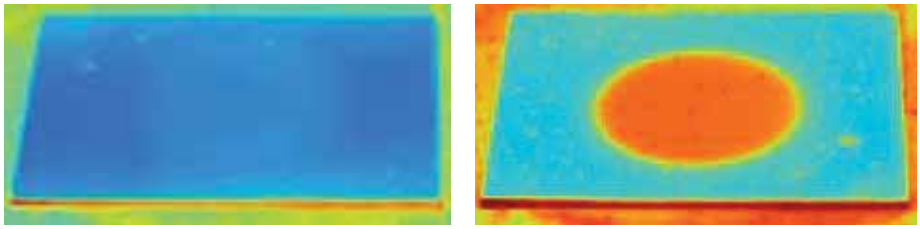

Fig. 2: Thermal image of the thermochromic absorber coating in the cold state with low emittance (left) and in the hot state with high emittance (right)

Then, with an FTIR spectrometer coupled with an integrating sphere and a Mid-IR MCT detector, the total reflectance spectra of a VO_2 coated aluminium sheet is determined. The measurement is done both below and above the transition temperature (T_C) of vanadium dioxide. Since the considered sample is opaque, from the measured reflectance spectra, the spectral emissivity can be determined and the results are displayed in Fig. 3. The thermal emittance of the thermochromic absorber in its two states considerably differs.

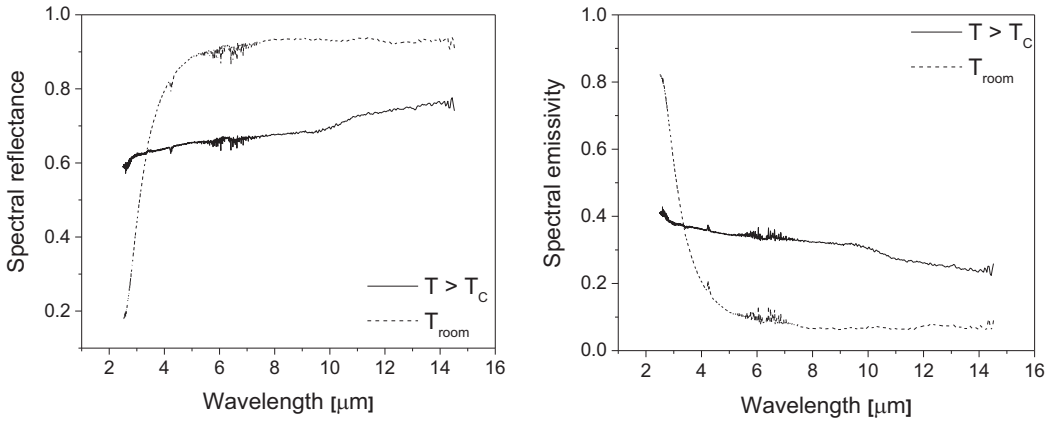

Fig. 3: Spectral reflectance and corresponding spectral emissivity of the thermochromic absorber both below and above the transition temperature of vanadium dioxide.

Above 100°C collector temperature, the operating temperature should be limited to avoid thermal stresses on the system. The spectral emittance of a blackbody at 100°C peaks at around 8 μm wavelength. Therefore, the emittance change in this spectral region is of special interest. In Fig. 3, at 8 μm, the emissivity changes markedly from ~6% below T_C to ~33% above T_C.

3.2. Angular dependence

The angular dependence of the emittance of a thermochromic VO_2 film deposited on Si wafer, above its critical transition temperature was determined. Since the coating is supposed to show metallic properties, the emittance versus angle for a rough oxidized aluminum plate was measured for comparison. The measurements were performed at 100°C for the VO_2 and aluminium samples. The results are shown in Fig. 4a. The curves are similar. The VO_2 coating in the metallic state follows the same trend of directional emissivity as the Al plate, whose values are similar to those given in tables. They are roughly constant from normal angles to about 60 degrees from the normal. At angles higher than 60 degrees the thermal emittance rises and reaches a maximum at grazing angles. The thermal emittance is expected to drop to 0 when parallel to the surface, but this measurement could not be made precisely with the experimental setup. This behavior is well described by the Fresnel's equation and typical results for metals are illustrated in Fig. 4b.

The emittance being higher at greater angles is beneficial as most thermal emittance measurements are done at normal angles. Therefore the thermochromic coating will be more efficient at dissipating heat via radiation than what normal measurements would predict.

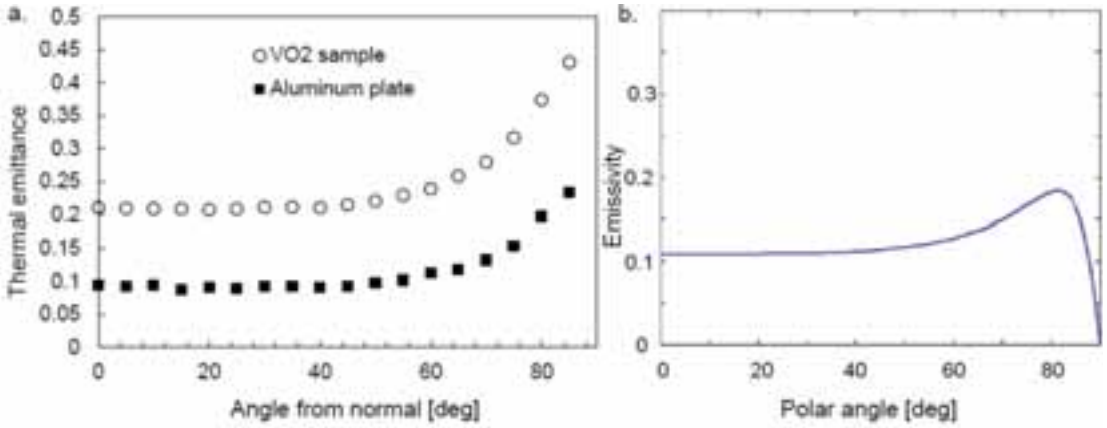

Fig. 4: a) Angular dependence of the thermal emittance of VO_2 and Al plate. b) Typical directional emissivity of a metal according to Fresnel's relation with n=1.5 and k=7 [16].

3.3. Thermal emittance of doped thermochromic samples

The transition from low to high emittance of the thermochromic absorber at a temperature of 67°C might be too low for solar thermal applications. Several elements have been reported to alter the phase transition temperature of vanadium dioxide. The authors have long studied dopants capable of increasing T_C to around 100°C. Recently [15], we have reported on the successful increase of the transition temperature to ~95°C. This has been reached with 5.9 at.% Ge doping. In the next step, our aim is to measure the effect of such doping on the thermal emittance of the samples. A pure and two Ge doped thermochromic coatings have been deposited on Al sheet. The Ge content in the doped samples has been varied by applying different power on the Ge target during deposition – 8W and 12W. This is calculated to correspond to 1.1 and 2.6 at.% Ge in the samples, leading to transition temperatures of ~75°C and ~77°C respectively. The three different samples have been compared and it is found that the emittance, notably in the hot state, is gradually increasing with doping. Roughly 10% increase in emittance between the pure and the strongly doped sample (with 12W applied on the Ge target) at 8 μm, is recorded. The results are shown in Fig. 5.

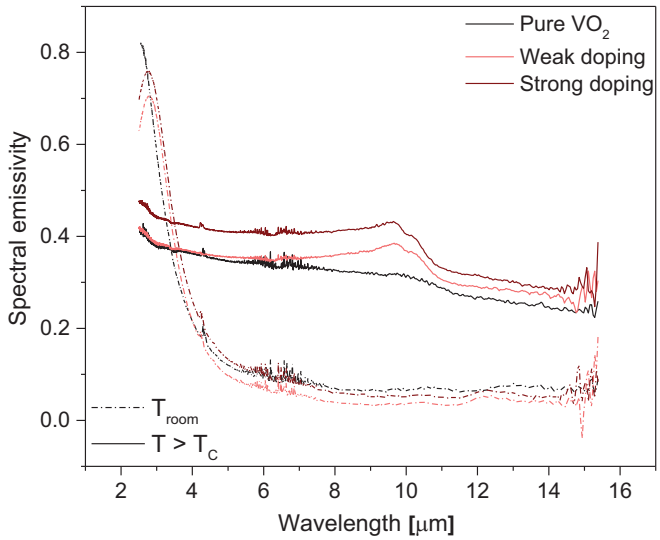

Fig. 5: Spectral emissivity change between the low (dashed line) and high temperature state (solid line) of three samples with different composition: pure VO_2, weakly doped and strongly doped coatings.

Using a simple model collector consisting of a glass cover, an air gap and a switchable absorber in thermal contact with the water pipes, *Baldi et al.*[17] calculated the stagnation temperature map plotted as a function of solar absorptance and thermal emittance. Based on this work and with the assumption that the switch only impacts the absorber emittance, while the solar absorptance remains relatively unchanged, the stagnation temperature is estimated to be lowered from ~195°C to ~150°C using pure VO_2 based absorbers and from ~185°C to ~140°C for Ge doped VO_2 based absorbers. At these reduced stagnation temperatures, the degradation of glycols is mostly prevented and, at the typical pressures present in the collector (3 bars), the evaporation of the heat transfer fluid is overcome.

4. Conclusions

Adding a thermochromic function to the currently available selective solar absorber coatings could bring forward a new generation of smart solar thermal collectors where the stagnation temperature is limited and overheating prevented. In this work, pure and Ge doped vanadium dioxide based thermochromic coatings have been deposited by reactive magnetron co-sputtering on highly reflective substrates. Their optical properties in the Mid-IR range have been determined. Pure VO_2 films show high potential as their emissivity changes significantly from 0.06 to 0.33 at the wavelength of interest of 8 μm. Moreover, the angular dependent emittance measurements show that the emittance of the coatings in the hot state (above the transition temperature of the thermochromic layer) is increasing with the angles from the normal. This suggests that normal emittance measurements underestimate the total emittance of the coatings. Finally, it is shown that, besides raising the phase transition temperature to 95°C, Ge doping has the additional advantage of increasing the emissivity of the thermochromic coating above T_C and, therefore, decreasing the stagnation temperature of the collector.

Abstract

Spectrally selective materials show high technical potential for use as radiative cooling heat exchangers for buildings. Recent work by Stanford University has applied a photonic approach to tailor the optical properties of a coating material. In a prototype test, a radiative cooler based on that photonic material has demonstrated the ability to maintain radiator surfaces at below-ambient temperatures in the presence of intense, direct sunlight. This paper presents the simulation and parametric analysis of photonic radiative cooling system that integrates the use of the photonic radiative cooler and radiant floor cooling via the whole energy simulation program EnergyPlus. The simulation was made for a medium office building with three floors and a total floor area of 5,000 m^2. Three key design parameters including the radiator area, the storage tank volume to radiator area ratio, and the water flow rate to radiator area ratio, which are expected to have a large impact on system performance, were investigated in this paper. The results show that the percentage of cooling electricity savings from the photonic radiative cooling system relative to a reference variable-air-volume system has a linear relationship with the radiator area, and a quadratic correlation with the other two variables. The findings from this parametric analysis are valuable to understand how component sizing affects system performance.

Keywords: radiative cooling, parametric analysis, building simulation, nanomaterial

1. Introduction

Space cooling accounts for about 15% of the total primary energy consumed by all commercial buildings in the U.S. (DOE 2011). In the current practice, electricity-driven equipment such as room air conditioners, packaged air conditioners, and chillers are usually the source of mechanical cooling. Although the mechanical cooling equipment can operate reliably to maintain space thermal comfort, they are major energy consumers in buildings. To reduce energy consumption for space cooling, more efforts are needed to utilize passive cooling techniques to replace at least partially the mechanical cooling energy requirement. Possible passive cooling techniques fall into three broad categories (Geetha and Velraj 2012): 1) solar and heat protection techniques to reduce heat gains; 2) heat modulation or amortization techniques to modify heat gains; and 3) heat dissipation techniques to remove heat gains. Radiative cooling belongs to the third category because it uses natural heat sinks (the sky) for heat dissipation.

Radiative cooling refers to the physical process by which a body loses heat to another body of lower temperature via long-wave radiation. In the case of buildings, radiative cooling results from the thermal radiative heat transfer between building surfaces and the colder atmospheric layers in the sky. For a surface with high thermal emittance, the maximum radiative cooling power is about 100 W/m^2 for clear night sky and low ambient relative humidity (Meir et al. 2002). Because of the significant potential of radiative cooling, many studies have been conducted to design suitable materials and systems to make use of radiative exchange with the sky to condition buildings. In general, there are two methods of applying radiative cooling in buildings (Argiriou 2013): passive radiative cooling and active radiative cooling. With passive radiative cooling, the building roof radiates towards the sky and the cooled roof surface temperature then contributes to decreasing the conductive heat gains from the exterior. Representative design strategies of passive radiative cooling include moveable insulation and cool roofs (Al-Obaidi et al. 2014). With active radiative cooling, a heat carrier (air or water) is circulated between the interior spaces and radiative panels on the roof. Example studies on active radiative cooling can be found in (Eicker and

doi:10.18086/swc.2017.17.05 Available at http://proceedings.ises.org

Dalibard 2011, Mihalakakou et al. 1998, Parker 2005). These studies vary with respect to the characteristics of radiative panels, the heat transfer medium used, and the system design.

2. Photonic Radiative cooling

Spectrally selective materials have high technical potential for radiative cooling applications by tailoring the spectral optical properties (e.g., emissivity and reflectivity) of the surface in order to maximize thermal heat losses and minimize absorbed solar radiation. In the context of radiative cooling, heat losses occur in the infrared (IR) wavelength range, for which a 300 K blackbody radiation peaks at approximately 10 microns. The blackbody radiation peak shifts to shorter wavelengths with higher temperatures, but is still in this approximate range for most buildings applications. Spectrally selective materials can potentially offer the capability of daytime radiative cooling, which is highly sought after because of its potential to offset peak cooling loads. However, realizing daytime radiative cooling is severely complicated by both solar irradiance, which peaks at approximately 1,000 W/m^2 between 0.25 and 3 microns (Granqvist 2003), and atmospheric absorption. Without an effective solar irradiation heat shield in place, solar irradiance will easily swamp any radiative cooling effect during most of the day. Atmospheric absorption is problematic in that at many infrared wavelengths, the heat transfer phenomena at a conventional building surface or from radiative panels are closely coupled with the surrounding air (atmosphere is opaque to thermal radiation) and can be further complicated by sky conditions. There is however, a range between 8 to 14 microns where atmospheric absorption is negligible and the buildings thermal radiation can effectively be exchanged with the coldness of outer space. Thus, for optimal cooling, the spectral reflectivity of a building envelope coating would then be (Granqvist 2003):

- $R(\lambda) = 1$ for $0.3\ \mu m < \lambda < 3\ \mu m$ (Daytime radiation shield)
- $R(\lambda) = 0$ for $8\ \mu m < \lambda < 14\ \mu m$ (Thermal emission)

Much of the initial work [e.g., Eriksson and Granqvist 1986, Niklasson and Nilsson 1995) on spectrally selective materials focused on pigments (e.g., ZnS, and ZnO) and sputtered multilayer dielectric films (e.g., MgO, LiF, and oxynitride) on Aluminum backing (infrared reflective). Although such materials are relatively easy to fabricate and deposit, their solar reflectivity is only approximately 80-85%, which means that daytime radiative cooling is not possible, with the exception of early morning or late evening when the solar irradiance is low. Because of the inability of standard materials to meet the strict requirements for daytime radiative cooling, there has been recent research into advanced materials with tailored optical properties to fill the need. These advanced materials are primarily featured of nanomaterials or nanostructured and microstructured thin films (Gentle and Smith 2015, Raman et al. 2014).

The work presented in this paper is based on the nanostructured coatings developed by a research team at Stanford University (Raman et al. 2014). The advanced coatings are made up of seven one-dimensional photonic layers. The incorporation of the micro or nano photonic layers allows the tailoring of the optical properties of the coating in ways not possible with bulk materials. Such a photonic structure has achieved spectrally selective emittance: strongly reflective over visible and near-infrared wavelengths but strongly emissive between 8 and 14 μ (Fig. 1). When exposed to direct sunlight exceeding 850 W/m^2, the photonic radiative cooler maintained its surface temperature 4.9°C below the ambient air.

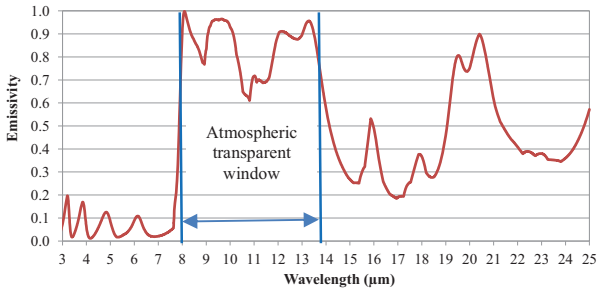

Fig. 1: Photonic material emissivity in the infrared range

3. Photonic radiative cooling System design

It must be noted that the nanostructured coating material studied in this paper is still at the very early research stages. No commercial photonic radiative cooling panels are available, let alone the application of photonic radiative cooling systems in buildings. Many materials presented in the following are more on the conceptual design than the real application design because the focus is to estimate the potential of energy savings from photonic radiative cooling and the associated impact of key design variables.

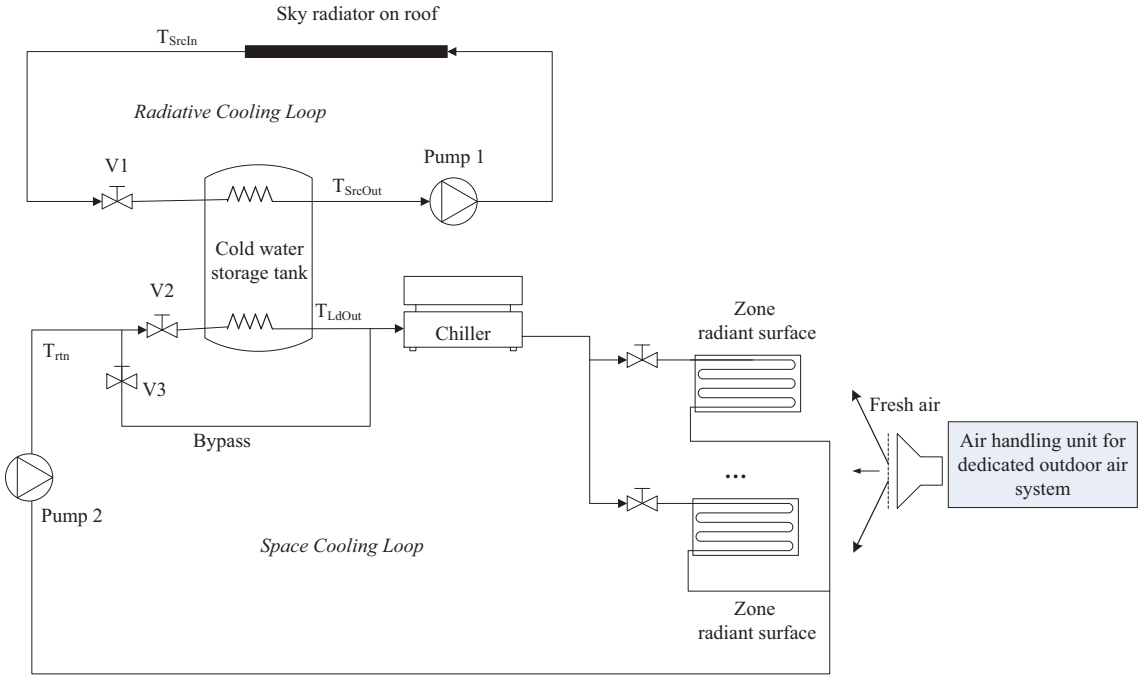

Fig. 2: Schematic diagram of the photonic radiative cooling system

Fig. 2 shows the schematic of the proposed radiative cooling system, which consists of two hydronic loops: a radiative cooling loop and a space-cooling loop. These two loops are coupled via a cold-water storage tank. The radiative cooling loop circulates water through a roof-mounted radiator via a constant-speed pump (Pump 1 in Fig. 2), which draws water from the storage tank and delivers cold water back to the tank. The pump is controlled to run whenever the temperature at the outlet of the radiator (T_{SrcIn}) is lower than the temperature of water at the outlet node of the tank (T_{SrcOut}), subject to the constraint that the loop will not run when the radiator temperature falls below 1°C. The space-cooling loop uses the water storage tank and a supplementary air-cooled chiller to provide cooling. A variable-speed pump (Pump 2 in Fig. 2) serves the space-cooling loop and adjusts the flow as necessary to provide sufficient cooling water to the space. If the outlet tank water temperature for the space cooling loop (T_{LdOut}) is colder than the chilled water temperature set point ($T_{chw,sp}$), i.e., $T_{LdOut} < T_{chw,sp}$, both valves V2 and V3 modulate open, mixing bypassed return water with cold water from the storage tank such that the desired water temperature set point is achieved. Under this scenario, the chiller is not used. If T_{LdOut} is higher than the chilled water return temperature (T_{rtn}), valve V2 closes, the water tank is bypassed, and only the chiller operates to address the cooling load. If $T_{chw,sp} < T_{LdOut} < T_{rtn}$, valve V3 closes and the chiller operates to address the remaining cooling load unmet by the tank.

Because radiative cooling generates cool water at a relatively higher temperature than the chilled water from conventional hydronic systems, it is favorable to employ a zone-level system design that makes use of high-temperature water for cooling. Therefore, as Fig. 2 shows, hydronic radiant floors are used to address the space sensible loads. In the radiant floor design, water tubes spaced at 150 mm are embedded in cement screed for sensible heat exchange with the space. The water tubes are separated from the concrete thermal mass by a 25-mm thick insulation layer (Raman et al. 2014).

To maximize the contribution of radiative cooling, the cold water supplied from the system should be controlled

to run at the highest possible temperature. This minimizes the use of the chiller by bringing the supply-water temperature set point closer to the tank water temperature. To achieve a balance between meeting the space cooling demand and maximizing radiative cooling, the supply-water temperature set point is reset according to the following strategy. If the average temperature for all thermal zones is above the space cooling set point more than 0.27°C, the supply-water temperature set point is decreased at a rate of 2°C per hour. On the other hand, if the average temperature is below the cooling set point more than 0.13°C, the supply-water temperature set point is increased at a rate of 2°C per hour. The supply-water temperature set point is limited to the range between 12.8°C and 18.3°C. Note that the above strategy supply-water temperature reset is based on our engineering experience for this simulation study oriented towards the dry climate in Las Vegas. Refinement and modifications may be needed for real implementations and for different climates.

As mentioned earlier, an air-cooled chiller is used in the photonic radiative cooling system to provide auxiliary cooling whenever the tank water temperature is higher than the supply-water temperature set point. Because of the high supply water temperature, it is desirable to use a low-lift chiller for supplemental cooling, such as that from Katipamula et al. (2010) to achieve superior performance at part load and "low lift" conditions (reduced difference between the entering condenser air temperature and the leaving chilled water temperature). These conditions are representative characteristics of hydronic radiant systems, which use much warmer chilled water temperatures (e.g. ~15°C) than conventional hydronic cooling systems.

A dedicated outdoor air system (DOAS) is used to provide ventilation air to the building in the absence of conventional air-handlers. The DOAS contains a constant volume fan, a hydronic heating coil and a direct-expansion cooling coil for air conditioning. The supply-air temperature set point of the DOAS is set at 12.8°C when the outdoor-air temperature is higher than 16°C, 18°C when the outdoor-air temperature is lower than 10°C, and linearly between the above boundary set points when the outdoor-air temperature lies in the range between 10°C and 16°C.

Regarding the sky radiator on roof (Fig. 3), it is conceptualized as a flat, metallic plate with its surface covered with the nanostructured, spectrally selective coating material as described in the previous section. Underlying the surface layer is an array of metallic piping, welded to the underside of the top plate. Each pipe runs parallel from an inlet manifold on one side of the radiator and returns to an outlet manifold on the other side of the radiator. The spacing between pipes is 150 mm (6 in.) and the pipe diameter is 19 mm (0.75 in.). Water pipes are located in-between the radiative cooler and a thin thermal conductive layer (e.g., aluminum plate). The sky radiator is integrated with the roof construction. To mitigate the convective heat gains from the surrounding, the photonic radiative cooler (Fig. 3) is covered with a 25-μm low-density polyethylene film and there is a 25 mm air space in between them. The use of polyethylene film follows the prototype design by the photonic radiative cooling material developer (Raman et al. 2014).

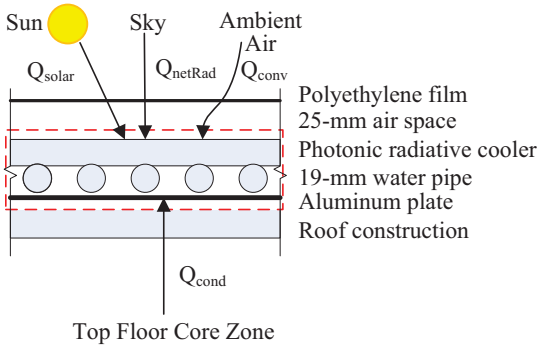

Fig. 3: Roof-integrated photonic radiator design

4. Building Model and Reference System

The building model originated from the Building Energy Codes Program (DOE 2015), which maintains a series of EnergyPlus models in compliance with different versions of commercial codes. A prototype medium-sized office building was used for the parametric analysis. The building (Fig. 4) has three floors and a total floor area of about 5000 m^2. The building has a rectangular shape with an aspect ratio of 1.5. Windows are distributed evenly

in continuous ribbons around the perimeter of the building. The window fraction of the overall façade area is 33%. The building construction includes steel-framed walls, a flat roof with insulation above the deck, and a slab-on-grade concrete floor. The performance values of the exterior envelope meet the minimum requirement of ASHRAE Standard 90.1-2013 (ASHRAE 2013). More detailed description about the building model including thermal zoning and internal loads can be referred to Thornton et al. (2011).

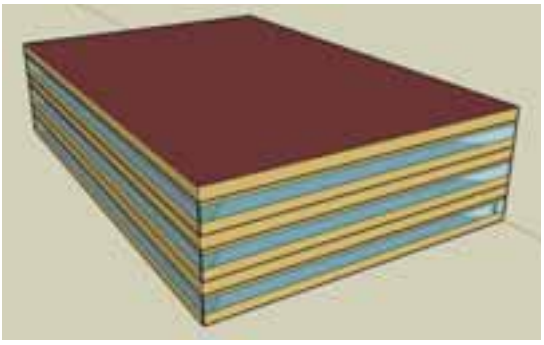

Fig. 4: Axonometric view of the medium office building

To investigate the impact of different design parameters of the photonic radiative cooling system on building energy consumption, we defined a reference system to represent the prevailing technology used to condition medium-sized office buildings. With a reference system, the potential of energy savings from different design scenarios of the photonic radiative cooling system can be conveniently derived and compared in a straightforward manner. The reference has an individual variable-air-volume (VAV) system for each floor (Fig. 5). All equipment types, efficiency, and system design features followed Standard ASHRAE 90.1-2013. The building model is essentially the same as the original source (DOE 2015) except for one change. The original source used the mean air temperature to define the heating and cooling set points at 21°C and 24°C, respectively. They were changed to use operative temperature for thermal comfort, with heating set point at 21.6°C and cooling set point at 25.7°C. Such a change is necessary to make a fair comparison between the VAV system and the photonic radiative cooling system. The use of hydronic radiant floors is favorable for occupant thermal comfort because of its higher floor temperature for heating and lower floor temperature for cooling relative to the VAV system.

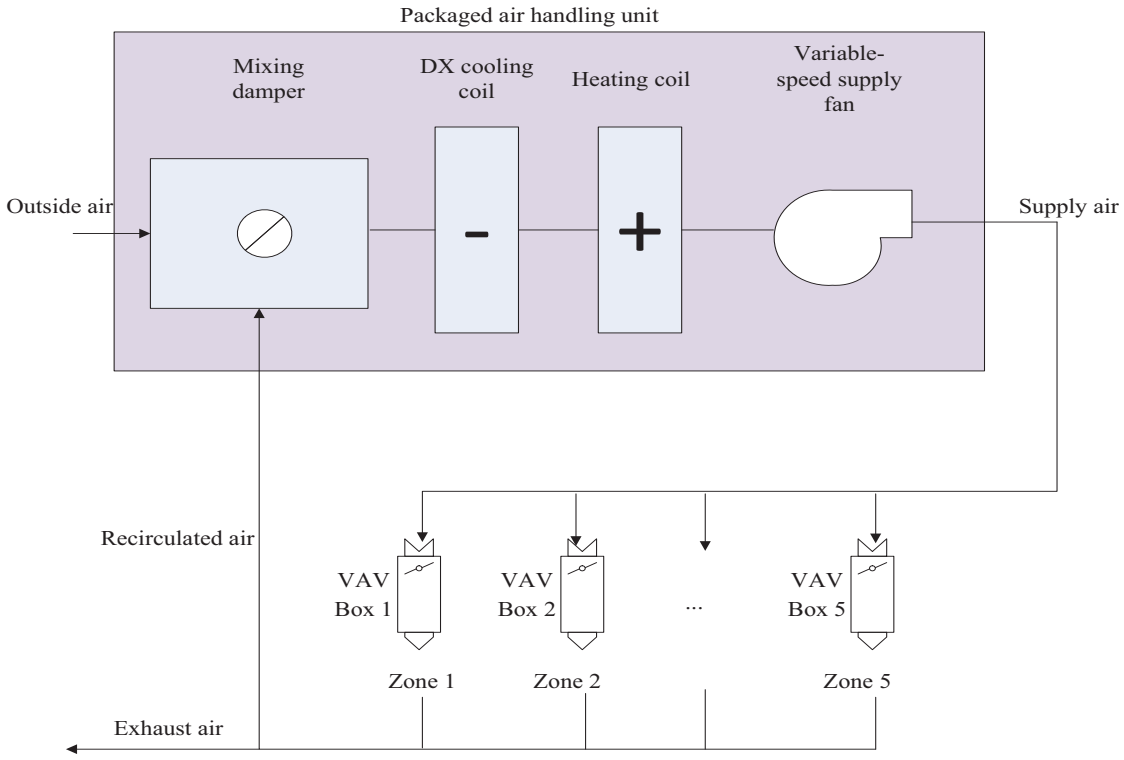

Fig. 5: Schematic diagram of the reference VAV system for each floor

5. System Modeling and Simulation Matrix

The photonic radiative cooling system, the reference VAV system, and the building were all simulated with EnergyPlus, a dynamic, whole building simulation program that supports a large variety of mechanical systems and components. Because there is no existing object in EnergyPlus for the novel photonic radiator, the energy management system (EMS) module in EnergyPlus was used to create a user-defined model of the radiator that is directly interfaced with the rest of the hydronic system specified in EnergyPlus. The EMS supports a simple programming language through which the user can construct new models and customize control sequences. To calculate the expected outlet temperature from the rooftop radiator and the average temperature of the radiator, the rooftop radiator was modeled in the EMS as a discretized heat exchanger by dividing the radiator into a discrete number of segments (Fig. 3 shows on segment as enclosed in the dashed lines). Heat transfer processes involved in the modeling of the photonic radiator includes the following:

- Absorbed solar radiation (Q_{solar}, W/m^2);
- Conduction (Q_{cond}, W/m^2) heat transfer between the underside of the radiator and the underlying building roof;
- Convection (Q_{conv}, W/m^2) heat transfer between the upper radiator surface and the ambient air; and
- Net longwave radiation (Q_{rad}, W/m^2) heat transfer between the upper radiator surface and the sky, which combines the outgoing longwave radiation emitted from the radiator minus the downward radiation from the sky absorbed by the radiator.

Detailed modeling of the photonic radiative cooler and the strategies used for the system simulation were reported in a previous paper (Wang et al. 2016) and are no longer repeated here.

Many design variables potentially affect the performance of the photonic radiative cooling system. Examples of those design variables include the sky radiator area, the tank size, the water flow rate in the radiative cooling loop, the system control variables (e.g., the supply water temperature), and building design variables (e.g., building location, area, and envelope thermal resistance). Recognizing that performing an exhaustive parametric analysis is resource-prohibitive, we decided to select the following three variables for further parametric analysis: the sky radiator area, the cold-water storage tank size, and the cold-water flow rate in the radiative cooling loop. These

three variables were thus selected because they are usually regarded as the key variables to be considered for a radiative cooling system design. Both the baseline values and the perturbed values of these three variables are discussed below.

The sky radiator area directly affects the amount of free cooling that the system can provide. A larger radiator area can generate more cooling but also implies a higher initial cost. In addition, practical constraints may apply for the area of roof-integrated radiators because the existence of mechanical equipment, ventilation and roof access infrastructure makes it unrealistic to cover the entire roof with the radiative panels. In the baseline mode, the sky radiator is assumed to occupy 50% (i.e., 830 m^2) of the roof area. Additional values studied for the parametric analysis include 30% (498 m^2), 40% (664 m^2), 60% (996 m^2), and 70% (1163 m^2) of the roof area.

The cold-water storage tank plays an important role in the system as the mismatch (temporal or magnitude) between radiative cooling capacity and space cooling load is common throughout the whole year. However, no practical design guide was found to determine the optimal size of tank storage. Eicker and Dalibard (2011) used a 1.2 m^3 storage tank for a net-zero home with a radiator area of 38 m^2. We simply scaled up the tank size following the same storage tank volume to radiator area ratio (i.e., 1200 L/38 m^2 = 31.6 L/m^2), which ends up with a tank volume of 26.2 m^3 in the baseline model. In the parametric analysis, the tank size was perturbed to take 50%, 75%, 125%, and 150% of the baseline value, which has the storage tank volume to radiator area ratio of 15.8 L/m^2, 23.7 L/m^2, 39.4 L/m^2, and 47.3 L/m^2, respectively.

The cold-water flow rate was also explored in the parametric analysis to investigate its impact on system performance. The baseline model had a cold-water flow rate at 26 kg/h per m^2 of radiator area. In the parametric analysis, the cold-water flow rate was perturbed to take 50%, 75%, 125%, and 150% of the baseline value, which respectively corresponds to 13.0 kg/h, 19.5 kg/h, 32.5 kg/h, and 39.0 kg/h per m^2 of the radiator area.

Tab. 1 summarizes the parameter values used in the baseline design as well as 12 other parametric models. It needs to be noted that in each run, a single variable was perturbed in the parametric analysis, relative to the baseline. Multi-variable parametric analysis is left for future work.

Tab. 1: Simulation runs for parametric analysis

Run	% of roof area used for radiator	Storage tank volume to radiator area ratio (L/m^2)	Water flow rate to radiator area ratio (kg/h/m^2)
1 (baseline)	50%	31.6	26.0
2	60%	31.6	26.0
3	70%	31.6	26.0
4	40%	31.6	26.0
5	30%	31.6	26.0
6	50%	15.8	26.0
7	50%	23.7	26.0
8	50%	39.4	26.0
9	50%	47.3	26.0
10	50%	31.6	13.0
11	50%	31.6	19.5
12	50%	31.6	32.5
13	50%	31.6	39.0

6. Simulation Results and discussion

All simulation runs shown in Table 1 were made for the location of Las Vegas, NV. Simulation results are discussed below.

As Fig. 2 shows, the sky radiator provides cooling and thereby reduces the time needed to run the electric chiller. Therefore, in comparison with the reference VAV system, the photonic radiative cooling system saves the

electricity for cooling, saves the fan energy, but also introduces additional pump energy as needed by the hydronic system. We will focus on the cooling electricity savings only because 1) fan energy savings is mainly due to the use of DOAS, which is not exclusive to photonic radiative cooling; and 2) the pump energy is negligible in comparison with cooling energy.

Fig. 6 shows the impact of sky radiator area on cooling electricity savings. The following can be seen from this figure:

- Relative to the reference VAV system, the photonic radiative cooling system saved 42% cooling electricity for the case of sky radiator occupying 50% of the roof area. The percentage of savings increased by 2% as the roof area used for the sky radiator increased by every 10%.
- There is a linear relationship between the percentage of cooling electricity savings and the percentage of roof area for radiative panels. Eq. 1 is the linear regression derived from the five sets of data with different radiator areas.

$$PerClgElec=0.204*PerRA+0.317 \quad \text{(eq. 1)}$$

where, $PerClgElec$ is the percentage of cooling electricity savings of the photonic radiative cooling system, and $PerRA$ is the percentage of roof area used for radiative panels.

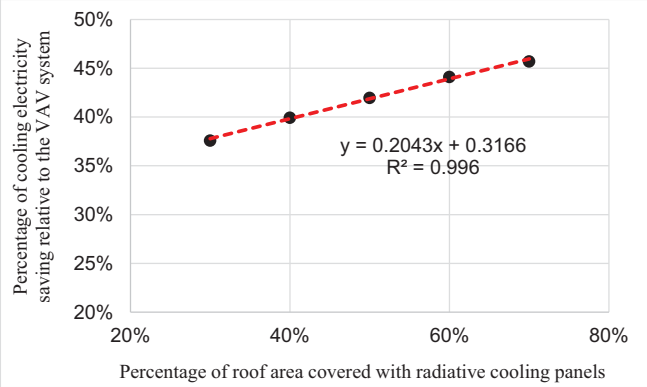

Fig. 6: Impact of radiator area on cooling electricity savings

Fig. 7 shows the impact of tank size on cooling electricity savings. This figure indicates that:

- Relative to the reference VAV system, the photonic radiative cooling system saved 42% cooling electricity for the case of baseline design of the cold-water storage tank size. The percentage of savings increased to 42.7% and 43.3% if the tank volume to radiator area ratio (VAR, L/m^2) was increased to 39.4 L/m^2 and 47.3 L/m^2. The percentage of savings decreased to 38.8% and 40.7% if the VAR was decreased to 15.8 L/m^2 and 23.7 L/m^2.
- The marginal benefit decreases with the increase of tank size. It is reasonable to expect that the cooling electricity savings will reach to a peak at certain value of VAR, beyond which no marginal benefit can be achieved.
- A quadratic correlation exists between the percentage of cooling electricity savings and the tank volume to radiator area ratio. Eq. 2 is the regression derived from the five sets of data with different values of VAR.

$$PerClgElec=-0.00004*VAR^2+0.0037*VAR+0.3394 \quad \textit{(eq. 2)}$$

Fig. 8 shows the impact of the water flow rate to radiator area ratio on cooling electricity savings. This figure shows that:

- The percentage of cooling electricity savings increased from 42% to 44% if the water flow rate to radiator area (FAR, kg/h/m^2) was decreased from 26 kg/h/m^2 for the baseline by half to 13 kg/h/m^2. No evident change of cooling electricity savings was observed if the FAR was increased from the baseline.

- A quadratic correlation also exists between the percentage of cooling electricity savings and the water flow rate to radiator area ratio. Eq. 3 is the regression derived from the five sets of data with different values of FAR.

$$PerClgElec=0.000005*FAR^2 - 0.0036*FAR+0.4753 \quad \text{(eq. 3)}$$

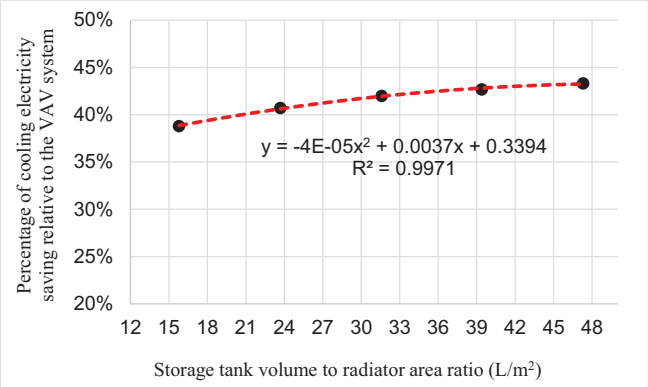

Fig. 7: Impact of storage tank volume to radiator area ratio on cooling electricity savings

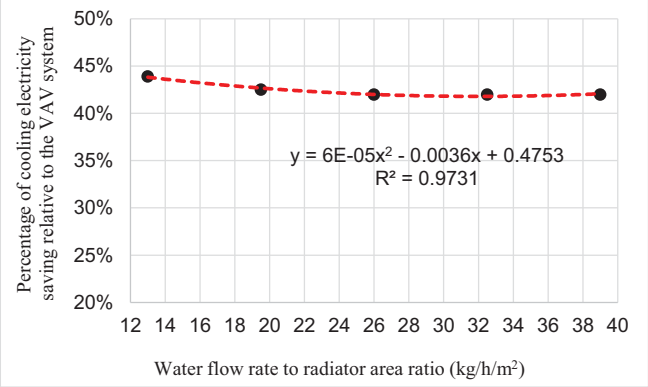

Fig. 8: Impact of water flow rate to radiator area ratio on cooling electricity savings

The difference of cooling electricity savings is attributable to the capacity of radiative cooling relative to the system cooling demand. As Fig. 2 shows, the water returned from radiant floors is cooled by the storage tank or the air-cooled chiller. The tank cooling energy is from the radiative cooler, so it can be regarded as "free" energy. For the photonic radiative cooling system, the percentage of free energy used to address the cooling load for each month is illustrated in Fig. 9 and Fig. 10, respectively illustrating the impact of radiator area and storage tank volume to radiator area ratio. The results for flow rate to radiator area ratio is not shown because of its minor impact on cooling electricity.

Fig. 9 and Fig. 10 show the following:

- For both cases, the percentage of "free" cooling from the sky radiator was the lowest in the summer months when there was a higher cooling load and a lower radiative cooling potential.
- As expected, the percentage of free radiative cooling increased with the sky radiator area (Fig. 9) and the tank size (Fig. 10).
- The percentage of free radiative cooling is less sensitive to the tank size than to the radiator area. Over all 12 months, the average difference of cooling electricity savings is 14% by changing the sky radiator area from 30% to 70% of roof area, while it is about 9% by changing the storage tank volume from 50% to 150% of its baseline design.

- For the baseline model, the free cooling from the sky radiator is can satisfy more than 90% of the entire building cooling load in January, February, March, November, and December. Such observation still holds true when the sky radiator area is reduced down to 30% of the roof area.

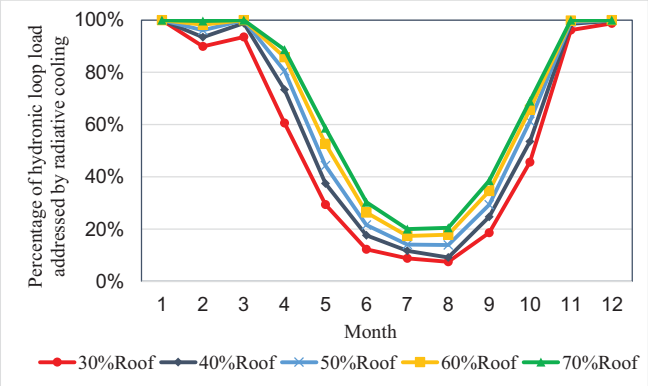

Fig. 9: Percentage of free cooling relative to radiator area

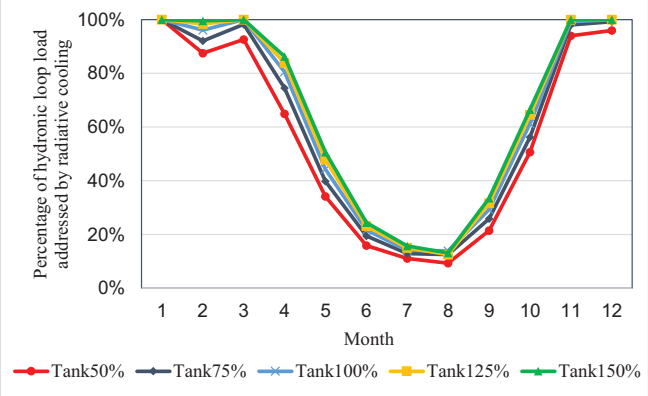

Fig. 10: Percentage of free cooling relative to tank volume to radiator area ratio

It needs to be noted that the electricity savings presented in this section should be interpreted as the outcome of system change, instead of the photonic radiative cooler only. The technical report (Fernandez et al. 2015) can be referred to for the benefits of the photonic radiative cooling system in comparison with other alternative systems (e.g., hydronic radiant systems and nighttime radiative cooling systems). In addition, using the regression equations to extrapolate results beyond the ranges investigated in this work may be questionable.

7. Conclusions

The photonic radiative cooling system has a great potential in building applications to save cooling electricity, compared to typical VAV systems for office buildings. The detailed energy simulation showed that for a three-floor medium office building located in Las Vegas, a baseline design of the photonic radiative cooling system with 50% of the roof area used for radiator and cold water storage tank sized at 31.6 L per m^2 of radiator area saved 42% cooling electricity relative to the reference VAV system. Based on a parametric analysis for three key design parameters, namely the radiator area, the storage tank volume to radiator area ratio (VAR), and the water flow rate to radiator area ratio (FAR), the simulation results revealed that the percentage of cooling electricity savings had a linear relationship with the radiator area, and a quadratic relationship with both VAR and FAR. The percentage of savings increased by 2% as the roof area used for the sky radiator increased every 10%. The marginal benefit decreased with the increase of storage tank volume to radiator area ratio. The cooling electricity savings decreased by if the flow rate to radiator area ratio was increased from 13 kg/h/m^2 to 26 kg/h/m^2, beyond which there is no change of electricity savings. The percentage of free radiative cooling increased with the sky radiator area and the tank size. The percentage of free radiative cooling is more sensitive to the radiator area than to the

storage tank volume to radiator area.

Further investigation can be made for other variables such as the radiator orientation if standalone sky radiator is used. Design optimization of multiple variables is also worth considering in future work.

Abstract

In order to realize Nearly Zero Energy Buildings and make the existing building stock energy efficient, the energy demand for heating and cooling and the electrical energy consumption needs to be reduced drastically. The next step in the so-called Trias Energetica is the local production of renewable energy, both electricity and thermal energy. A large (growing) part of the energy demand is related to hot water consumption. Here thermal solar energy can play an important role. Therefore, development of easy to integrate and install, efficient thermal solar systems is essential. Moreover, the main disadvantage of thermal solar energy systems, i.e. the required south orientation on z tilted roof and the competition with PV systems needs to be tackled to increase the applicability of such systems. In this paper the development of the Sunridge® system, a ridge integrated solar domestic hot water system, is described. A tube in tube concept as SDHW is developed and is placed on the ridge of the roof. The outer tube contains the spectral selective layer and the inner tube is the storage volume, a transparent cover is placed as outer layer. Heat is transferred from the outer tube to the inner tube by means of the effective boiling and condensation of water under low pressure between the two cylinders. The system will be inherent safe for overheating and freezing. The performance and end user price target is to be in the order of the price /performance of a standard SDHW system, nowadays on the market. The final design for the system is ready and pre-production takes place. In 2018 the first systems will go to the market.

Keywords: Integrated collector system, Solar domestic hot water, system, ridge integrated solar energy system,

1. Introduction

In order to realize Nearly Zero Energy buildings not only renewable electricity has to be produced, but also energy consumption needs to be reduced as well as renewable heat needs to be generated and used effectively. The heat demand of existing and new buildings is about 1.5 to 3 times higher than the electricity demand. A large part of the energy consumption in buildings is for space heating, space cooling and hot tap water production. The yearly energy needed for hot tap water is about the same as the yearly electricity demand for a household. In the next years the demand for electricity will increase, the demand for house heating will decrease but the energy needed for hot tap water will increase (comfort!). Better insulation of the buildings, energy efficient windows, and heat recovery results in a lower space heating demand in the building. For the reduction of the energy consumption for hot tap water production, new high efficient equipment such as HE gas burners and heat pumps offers possibilities, but still fossil energy is needed. For hot tap water production, the solar domestic hot water system is a good alternative. Thermal solar energy systems can reduce the heat demand and especially the heat demand for hot water production. However, thermal solar energy systems have some draw backs. These are among others:

- a required south orientation on z tilted roofs,
- competition for suited roofs space with PV systems,
- competition with windows in the roof

doi:10.18086/swc.2017.17.06 Available at http://proceedings.ises.org

- the space needed in the house for the water tank.
- an easy to integrate and install, efficient thermal solar system is under development.
- aesthetics

These main disadvantages are tackled through the development of the Sunridge® system. This development of a ridge integrated solar domestic hot water system, is in this paper further described. As ridge integrated system, the Sunridge® system is truly orientation independent. The system under development is a tube in tube concept placed on the ridge of the roof (see fig 1) . The ridge integrated solar energy system offers the integration of a solar product at a place of the building (the ridge) which has a low attention factor (aesthetics), is not in competition with other energy systems at that place, integrates also the water tank (no extra space in the building needed), is scalable to fit the ridge length and the Sunridge® product deviates not too much from ridge caps or upper roof tiles. From street level the system is almost invisible. For safety and health reasons the hot water temperature should be higher than ca. 60 °C. So the energy consumption in the built environment will be more and more dominated by the energy needed for the hot water production, at relative high temperature. A typical SDHW system reduces the conventional energy consumption by about 50%. Since the Sunridge® product will be very well suited for especially the existing one family buildings the market potential is huge (approx. 120 million existing dwellings across Europe are suited). The product is orientation independent, suited for both tilted roofs and flat roofs and modular adaptive to the length of the ridge. The calculated energy performance for 3 modules is that more than 50% of the energy consumption needed for hot water will be produced by the Sunridge® system. This performance will, of course, vary according to the climate, the number of modules and the hot water consumption. Higher contribution (>75%) in the South of Europe and lower contribution in the Northern countries of Europe (approx. 40%).

Fig 1 Artist impression of the. Sunridge® system on the ridge of a dwelling.

2. Technology of the Sunridge® system.

The Sunridge® product is a solar system in which the absorber for solar energy and the storage tank, for the hot water, have been merged into one unit.(see figure 2). The product consists of two tubes whereby one tube is assembled into the other. The inner tube is the container for (hot) tap water. The outer tube (copper) will be provided with a special layer with which the absorbed solar energy is efficiently transferred into heat. Water is placed in the space under low pressure between the inner and outer tube in order to transport the solar heat form the outer tube to the inner tube. When the outer tube is heated by solar energy, the water evaporates. The evaporated water condenses at the inner tube and transfers in this way the heat from the outer tube

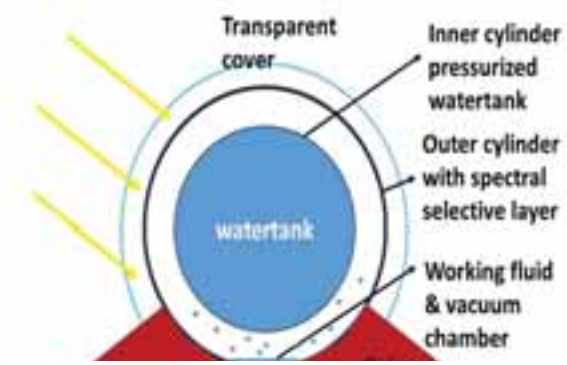

Fig 2. Scheme of the Sunridge® system.

to the inner tube. The condensed water drips of the inner tube and the whole process of evaporation and condensing starts again. In case of absence of solar energy, the heat transfer from the inner tube to the outer tube is only possible through radiation because the inner tube does not come direct into contact with water.

The inner tube serves as storage tank for the hot water. When the outer tube is heated, this water evaporates and consequently condenses on the colder side of the inner tube. In this way the solar heat is efficiently transported to the storage tank. Because the space between the inner and the outer tube is vacuumed, as a result of which the storage tank works as a thermos flask.

In figure 3 the physical process, used in the modelling are shown. The solar irradiation passes the outer transparent cover. For the largest part of the solar radiation passes heats the first copper cylinder. heats the outer surface of the outer tube. Heat losses are occurring due to re-radiation and convection. The first cylinder is equipped with the spectral selective layer. The radiation losses are low due to the low emissivity of the layer. The space between the tubes is under very low pressure enabling the water to evaporate and condensate to the inner tube, filled with tap water. In this way the solar heat is transferred to the inner tube and heats the tap water storage tank.

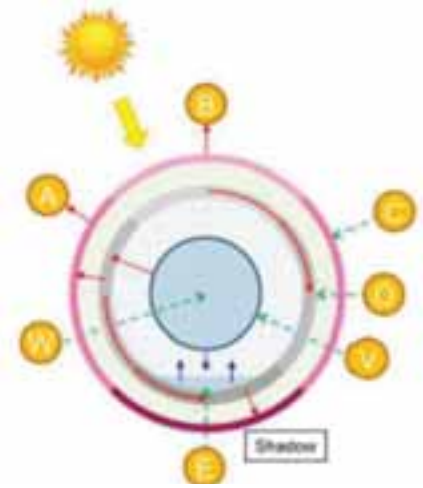

Fig. 3 Energy flows in the Sunridge® System

The Sunridge® product is placed on the ridge of the dwelling and placed in series of modules in order to reach the required volume for storing the hot water. Dependent on the number of modules connected the volume can go up to 130 liters, for a typical Dutch one family house. Due to the characteristic of the tubular SUnridge® system and the placement of the system at the ridge of the roof, the system performance is now almost independent of the orientation of the dwelling. Another advantage of the integrated system is the fact that in this concept an extra storage tank for hot water is not needed inside the dwelling, but is integrated at the roof. In this way a large market for SDHW systems now becomes available especially in refurbishment sector.

3. Experience with previous system

The first development of the Sunridge® system (Ekonok system) started some years ago. The manufacturing of tube in tube construction with vacuum has been carried out successfully. The principle of heat transport and diode function through the water/vapor under low pressure was tested and the performance is designed. The long-term performance and durability of the system was demonstrated in a field test over more than 10 years. After first market introduction, the market development stagnated at that time. The overall system concept had some drawbacks. These were:

- Installing the system on the roof and the connection to the tap water circuits was too complex, due to the connection of the modules connection under the roof.
- Deterioration of the transparent polymeric cover was going too quick
- The heat losses were high, for reasons of not having a spectral selective layer
- Industrial redesign of the system and production process was delayed

The system concept has been proven over the years. Therefor the redevelopment of the Sunridge system started with the help of the InnoEnergy innovation project. In order to get a good starting point for this development a module of the old system was tested at IREC.

In Figure 4 the calculated output of the DST test is presented. Under Dutch conditions the Sunridge system (consisting of 3 elements) had a performance of 2.6 GJ based on 100 L/day from 10°C to 65°C, preheated by the system, tested outdoors according to the DST test method in 2002. Since than the DST method is using other climatic conditions and is using other testing parameters. Nowadays the performance would be in the order of about 2.75 GJ.

A module of the old system has been tested at IREC. In figure 4 is shown that the module produced in 2015 without spectral selective layer gives the performance comparable to the old system.

The new design of the Sunridge system is based on spectral selective layer and new other materials is opting for 3. GJ for the Dutch conditions.

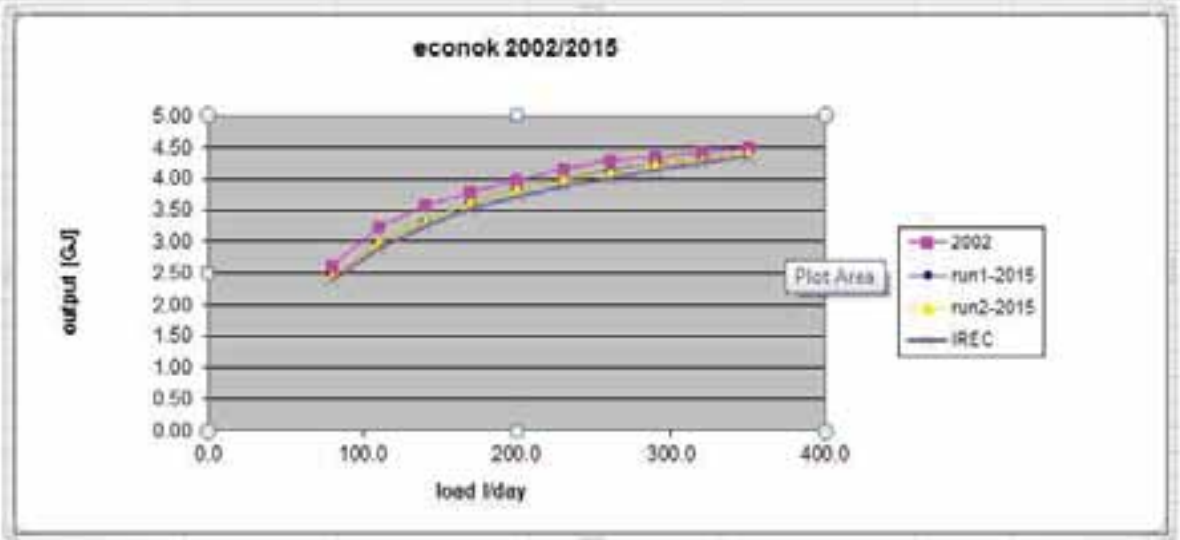

Fig 4. The output of the old Sunridge® system based on the DST test.

4. The Industrial Design.

As described in chapter 3 the old system had some drawbacks, reasons why parties in the market could not enter the market well enough. Some developments were needed and at that point of time this investment could not be made.

Since InnoEnergy (Knowledge Innovation Community of European Institute of Technology) started in 2010, a new vehicle became available supporting the further developments of products with a relative high TRL(technology readiness level) level from about TRL=6. This opportunity was used to develop a KIC InnoEnergy innovation project [1]. The Sunridge® product is since end 2014 under development to realize a competitive product for the market by 2018. The following aspects are under development:

- improve the performance of the systems (higher solar absorption and lower heat losses);
- make an inherent safe product for overheating and freezing;
- an esthetic, simple and scalable ridge integration for new and existing dwellings;
- Easy to be installed by roofers and installers
- Robust and quick connection for the modules;

Furthermore, the goal of the development in this InnoEnergy innovation project is to develop the pilot prototype production line, showing the manufacturing process at small scale, proving the realistic end price of the system and showing the high performance under realistic conditions.

The program of requirements was made with the following main aspects:

- The product has to withstand all the tests according to the standard and internal Monier standards for roofing product, such as wind, ventilation, hail, durability and safety.
- The product must be easy adaptable to different widths of the roof.
- Product should be easy to install by roofing companies
- Installation connections: only at one place of the roof connection through the roof for connection the water pipes to the aux and mains water supply.
- Inherent safe overheating and freezing protection.

Based on these requirements the industrial design of the Sunridge system was made, leading to the following important systems parts to be further developed and tested. These are

- The transparent outer cover. The choice has been made to use glass tubes.
- Stainless steel as the material for the inner tank containing the drinking water. Copper as material for the outer tank with water under very low pressure for the heat transfer between the outer and the inner tube.
- Spectral selective layer applied on the outer copper tank.
- Supporting construction for quick installation between the ridge and the system, in the form of dedicated aluminum profiles.

In the following figures 5 to 9 the results of the industrial design are showed.

Besides the solar and thermal performance, the durability, safety and ecological performance must be excellent. And of course, last but not least the price performance ratio must be competing with normal solar domestic hot water system.

The roofing company Monier is participant in this project and has the rights for the first market introduction. For this reason, the systems overall performance and the integration in the roof should fulfill all the requirement of the quality of products which are standard at Monier. For this reason, the durability and safety tests will be performed by Monier in their roof testing Centre in Heusenstamm, Germany.

5. Testing the new Sunrise system

In the spring 2017 one module for the Sunridge system consisting of the spectral selective layer and glass transparent layer was delivered at IREC, for outdoor performance testing. In figure 12 the system placed at the testing roof at IREC is shown.

Fig. 12. The Sunrise system at test facility at IREC(Taragona Spain)

During summer 2017 one module of the Sunridge system was tested. This module was 1.4 m long and had a tap water content of 35 l.

5.1 Performance testing

The system was tested according to the DST test method described in the EN 12976. The performance of the new Sunridge module is compared to the old Econok system. Based on the test results obtained in summer 2017 the DST parameters were established. These parameters are used for the long term performance calculations for various climatic conditions and tap water consumptions. In figure 13 the outcome of the new module is presented and compared to the old module. The results shown are for one module. For typical one family conditions about 3-4 modules will be used.

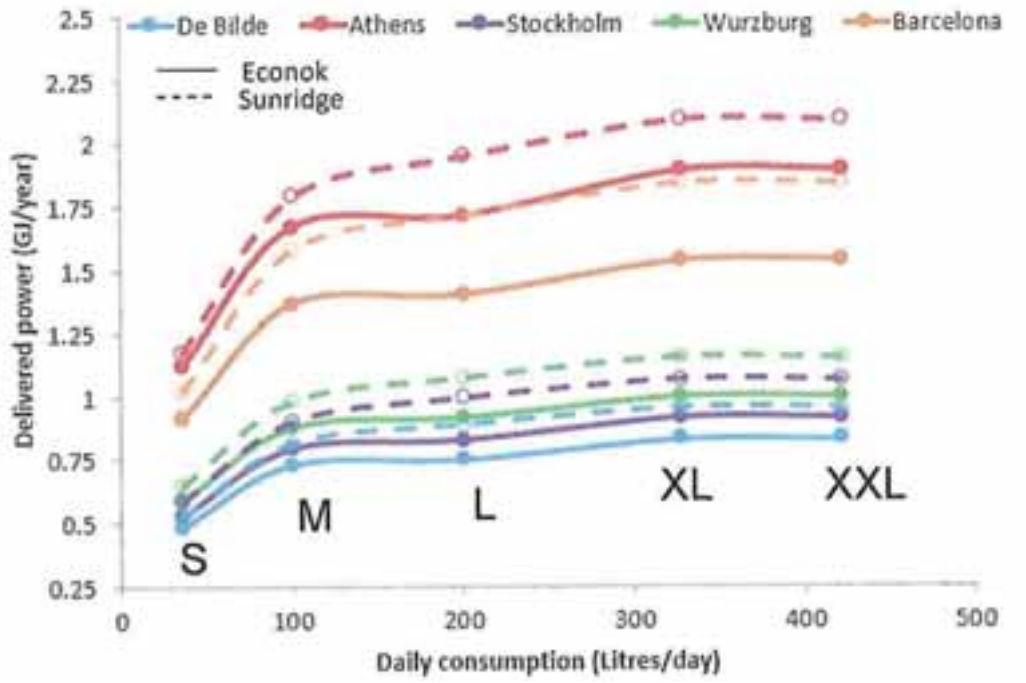

Fig. 13. Results from the DST test. Yearly energy output for one module for various climatic zones and different daily hot water consumptions. Comparison between the old Eocnok module and the new Sunrise module

From the testing the following conclusions for the Sunridge system under development were drawn, incomparison to the previous (Ekonk) system:

- The DST model parameters points at lower storage losses
- The DST parameters point sat significant mixing during draw-off
- The performance increase is in the order of 10 to 25%

Based on the test results for only one module it is shown that the goal set for the performance improvement of at least 10% for Dutch conditions is clearly met. Complete Sunrise® system, consisting of 3 modules, will be demonstrated end 2017 and beginning 2018 in The Netherlands. Moreover, in April 2018 the solar key mark testing for the complete system will start.
Based on the tests at IREC summer 2017 the design model of the system is validated. This design model is a dedicated TRNSYS model for the Sunrise system. Moreover, a detailed model for the Sunrise system has been developed at TNO. With this model the effective collector efficiency curve can be calculated. This effective collector curve is used in the design model. W
With the design model the lay-out of the system can be calculated based on the climate and predicted hot water consumption. The result is a predicted performance, energy savings and number of modules needed.

5.2 Outdoor Shock test

As part of the testing at IREC, internal and external shock test have taken place and the stagnation temperature has been characterized. These tests have been performed according to the EN12975-2 standards.

Fig. 14. Condensation after the first external shock test.

The stagnation temperature measured for the system fully filled with tap water reached a value of 63,4 °C. using the standard conditions of the EN 12975-2 means that this a value is 67,7 °C.

The internal and external thermal shock tests were performed and the results showed no damages or leakage. Moreover, the vapor pressure of the vacuum space between the tubes showed no significant changes. At the first external shock test significant condensation at the glass tube was detected visually (see fig 14).

5.3 Overheating and freezing test

As discussed in 5.2 the stagnation temperature of the system has been measured. In the case of long period of absence (holiday) and high solar radiation the temperature in the tank of the Sunridge system can be very high, even higher than 100 ℃. for this reason a well-known safety control will always be a part of the installed installation.

Since the complete system is place outside freezing during winter conditions can occur. For this reason, the Sunridge will be equipped with an electrical tracer. The typical vulnerable aspects in the design are in the inlet and outlet tap water piping and the connecting pipes between the modules (see fig 14 and 15).

Fig. 15. Tracer on the connection pipe between the modules

Fig. 16. Electrical tracer to the inlet and outlet pipe of the module.

In a freezing cabinet at TNO the Sunridge system including the installed electrical tracers were tested according the requirements of EN 12976-2. The complete system has to withstand an outdoor temperature of -20°C during a period of 12 hours with a start temperature of the tap water of 5 °C In fig. 17 the test results are shown.

The system was tested under -20°C for more than 30 hours. The temperatures of T203, T204 and T205 are around 0°C, but the more critical temperatures of the connecting pipes are above 15°C. The temperatures T deep and T shallow drop to a still safe level of slightly below 3°C.

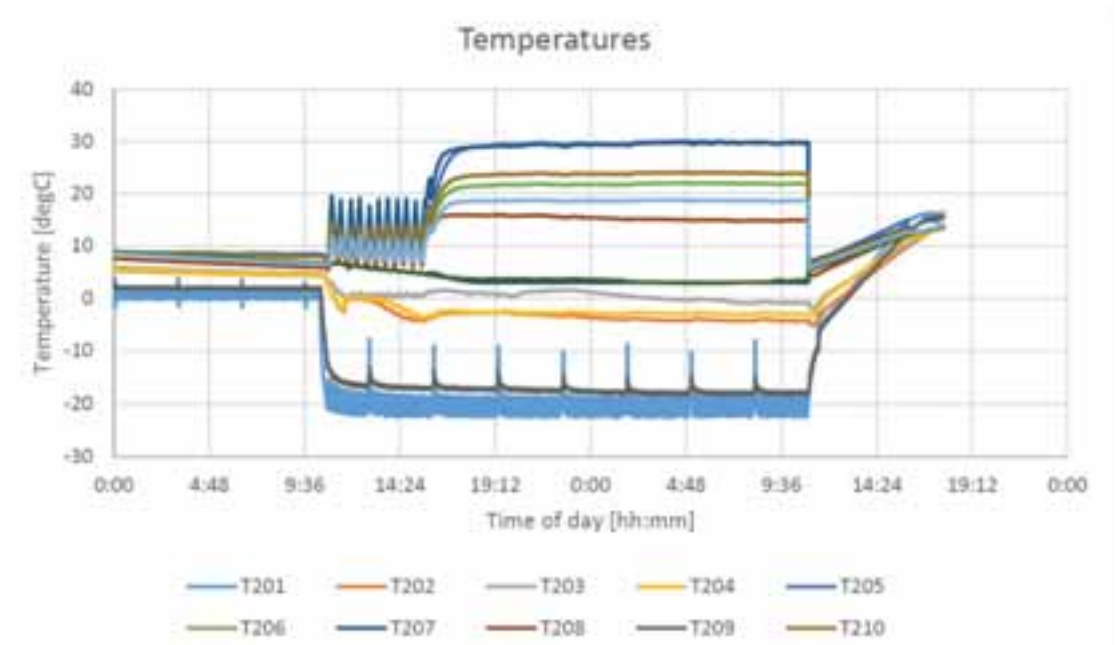

Fig. 17. Temperatures in the and around the Sunridge®water tank during the freeze testing

The conclusion from the test was that the Sunridge® system equipped with the electrical traces and the clckon sensor placed on the right position, fulfills the EN12975-2 requirements with respect to withstanding freezing.

5.4 Wind load design

Fig 18. The aluminum profile connected to the beam and the clamp for holding the wooden beam for connection to the roof plates.

The Sunridge® system is mounted on an aluminum profile. This profile clicks in to a profile that is connected to the ridge. The wooden beam for the ridge is connected to the roof plates by means of a number of clamps. Wind loads will come on the glass tube of the Sunridge® system. These forces will generate momentum to the roof. The connection from the system to the roof plates have to withstand severe wind loads. For this the most severe conditions from the standards are taken. In this case that is the British Standard for wind loads on roofs. The glass tube is mounted on the aluminum support profile. The profile is screwed on the beam of the ridge. This is a new wooden beam mounted with ridge batten holders on the roof plates. A dedicated design has been made for the ridge batten because they form a constructive unit with profiles. In order to with stand the wind load, the place and thickness of the screws was calculated. Moreover, this was also carried out for the clamps and ridge batten holder. Hereafter this was manually tested at the test roof set-up at Monier. A first quite simple tests showed that the steel support for the beam were not strong enough. Redesign was carried out and this ended up with thicker clamps. In figure 19 the testing of the system and forces are shown.

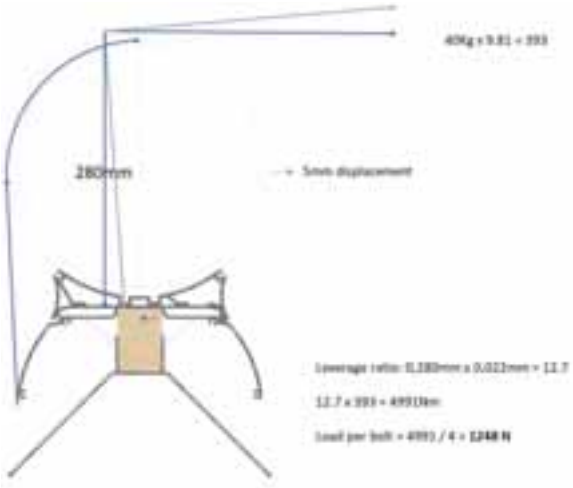

Fig. 19 Forces on the Sunridge system

6. .Production

An important aspect of the project is the cost price of the Sunrise® product. The cost price is among others determined by the bill of materials, bill of labor and the production process.
The flow chart for the production process is developed. A very import step in the production is the welding process of the end caps for the tubes with the tap water connections. Since the pressure between the copper outer and stainless steel inner tube is very low, leakage can occur. For the welding process an excellent supplier has been selected. The welding of the copper tube and the stainless steel tube is performed at a manufacturing plant with an automated rolling and welding process. The next step is the welding of the end caps first to the stainless-steel tanks. Here the connecting pipes for inlet and outlet tap water are welded to the caps.
Then stainless-steel end caps are welded to the copper tube with connecting water pipes through this end caps. This welding of the end caps is a very critical production step. The welding has to be airtight since a very low pressure between the tubes is needed for the working of the Sunridge® system.

Fig. 20: Industrially designed module complete with caps and the tap water connections between the modules.

Fig. 21 Welding of the copper tube.

In figure 20 the industrial design of a module is presented. In the figures 21-24 the welding process is shown.
The field demo modules are produced in March 2017. About 25 modules will be produced. From this demo modules a number of about 15 modules will be used for performance testing and testing as demo in the field. Other modules will be used for risk assessment test at Monier test Center in Heusenstamm.
Based on the test results for the performance, installing in the demo, risk assessment testing and other new information the final design will be made during 2017/2018. This also will lead to a final production plan with bill of materials and bill of labor. In the end the cost price will be determined. During 2018 first modules will be sold to the market through the channels of Monier.

Fig.22. The end cap with tap water connection. Welding of copper tube, stainless steel cap and copper water tube.

Fig.22. The longitudinal automatic welding machine.

7. Conclusions

In this paper the development of the ridge integrated solar water heating system, Sunridge® is described. The Sunridge system consist of a number of modules coupled and placed on the ridge of the roof. With this flexible design for the system, the solar energy contribution to the hot tap water can be tuned to the demand, the climate and the dwelling. The energy performance of the ridge integrated system can be about 50% of the energy demand for hot tap water and most important this is orientation independent. Moreover, the ridge integration enables the roof of the dwelling being used for other purposes, such as photo voltaic panels and/or roof windows.

The Sunridge system is a preheater for hot tap water with the tap water storage tank placed outside the dwelling, on the roof. The design of the system enables an inherent safe product, easy to install and to connect to the hot water system in the dwelling.

The industrial production process is designed in order to produce the system at high quality in a professional way. The overall cost price including installing the system is expected to be competitive the standard solar thermal domestic hot water systems. The production process can be up scaled to large numbers in a due time, due to the modular set-up of the system and production. In 2018 the Sunridge® product will be introduced in the market in The Netherlands.

Abstract

High temperature is a challenging problem with all solar collectors that are using PV panels for electricity production. Cooling of PV panels using traditional fluids become not effective as for the poor thermal properties of these fluids. Dispersion of nanoparticles with different liquid was found to enhance the thermal properties of these liquids. Nanofluids and Nano-Phase Change Materials (Nano-PCMs) were considered as promising solutions to enhance the performance of PV/Thermal (PV/T) systems. Nanofluids can be used beneath the PV for cooling or above it for optical filtration. In addition, Nano-PCM can be used beneath the PV for cooling and storage. In this study, an analytical solution was developed to evaluate the effect of using nanofluid filtration and nano-PCM on the overall performance of the PV/T solar collector. Four models were examined alternating between the presence and absence of optical filtration and lower nano-PCM layer. Neglecting the storage side, it was found that without optical filtration, presence of nano-PCM below the PV module decreases the overall efficiency (thermal + electrical) by around 6.7%. In contrast, presence of optical filtration decreases this percentage to be less than 1%. Moreover, using the optical filtration alone improves the overall efficiency by 6-12%.

Keywords: Nanofluid, PCM, PV/Thermal, PV cooling, Optical filteration

1. Introduction

Solar energy is considered one of the most promising sources of renewable energies that should be used efficiently to be able to completely replace the fossil fuel energy very soon. Many devices are used for the collection process of solar radiation. Hybrid Photovoltaic/Thermal collectors are found to combine the advantages of electrical and thermal energy generation as well as solving the problem of performance degradation of PV cells because of high temperature by cooling the PV panels. In this demand, many researches had been made alternating from changing the design of the collector to using different cooling fluids to attain the highest possible overall efficiency.

Hussain et al. (2013) studied the efficiency of using honeycomb channels beneath the PV in enhancing the thermal efficiency of hybrid PV/T collector cooled by air. They examined the enhancement under different flow rates. It was found the thermal efficiency enhanced from 27% to 87% when using honeycomb channels with air mass flow rate of 0.11 kg/s. Fudholi et al. (2014) investigated a study for different configurations of water cooled PV/T under different mass flow rates and solar irradiation levels. Three different new absorber channels were proposed; web flow absorber, direct flow absorber, and spiral flow absorber. They found that as the mass flow rate increases, the PV temperature decreases and the electrical efficiency increases. Also, increasing the solar radiation level increases the PV temperature and the generated electrical efficiency. They ended up with that the spiral flow absorber presented

doi:10.18086/swc.2017.18.01 Available at http://proceedings.ises.org

the highest overall performance at solar incident radiation of 800 W/m2, with overall, thermal, and electrical efficiencies of 68.4, 54.6, and 13.8% respectively.

Nanofluids, which was first proposed by Choi and Eastman (1995), for enhancing the thermal properties of different fluids were used for the cooling purposes of the PV module as well as collecting the large possible amount of heat from solar radiation. Nanofluids were used in channels below the PV module (H Zhu and C Zhang, 2006; A Kasaeian et al., 2015; W I.A.Aly, 2014) and were recently used to flow in the front of the PV module for optical filtration (N. E. Hjerrild et al., 2016) beside the cooling objective. Vakili et al. (2016) examined the effect of using graphene nanoplatelets in enhancing the heat transfer in solar collectors as it is dispersed in a deionized water as a base fluid. The authors tried different concentration in weight fractions of 0.0005, 0.001, and 0.005, and different mass flow rates of 0.0075, 0.015, and 0.225 kg/s. Maximum efficiency was obtained at mass flow rate of 0.015 kg/s and there was an enhancement in the thermal efficiency with increasing the concentration of the nanoparticles. Hajjar et al. (2014) proposed a study on the thermal conductivity enhancement as a result of using graphene oxide nanofluids. Through all types of GO/water nanofluids, GO 5 had the best enhancement in thermal conductivity relative to that of water (about 47.54% more than water at 40°C). In addition, regarding its optical properties, they examined high absorptance for the graphene oxide nanofluid in the spectral range of solar radiation. Hassani et al. (2016a, 2016b) used nanofluid as spectrally-selective material for the solar irradiation. They found that the nanofluid-optical filter did not prevent solar radiation from reaching the PV panels, and at the same time, it gets the most benefit from the solar thermal energy. Moreover, silver/water nanofluid was found to be better than only water, as water alone is not capable of absorbing except the IR spectra.

As the solar radiation is not constant throughout the day and the need for the availability of energy in the night time, it became necessary to have storage for the absorbed solar radiation. Phase Change Materials (PCMs) were found to be the best storage idea with solar collectors, as it has very high capacity and it makes cooling as well. In contrast, low thermal conductivity of PCM causes a resistance for heat transfer so dispersing some nanoparticles for enhancement of thermal conductivity was proposed reaching the Nano-PCMs concept. Colla et al. (2017) discussed the feasibility of using alumina and carbon black nanoparticles with pure paraffin waxes PCM. Two PCM materials were examined (RT20 and RT25) with the addition of nanoparticles (Carbon black and Aluminum oxide). They ended up with that the addition of alumina can make an enhancement in the latent heat while CB will be able to make an enhancement in the thermal conductivity that is required. Su et al. (2017) investigated a comparative study on the benefits behind using PCM in cooling the hybrid PV/T solar collectors. The effect of PCM position relative to the cooling channels on the surface temperature, outlet temperature and the efficiencies were studied as well as the effect of the thickness of the PCM layer. It was found that putting the PCM on the upper side of the duct with 3 cm thickness gives higher overall efficiency.

The current paper studies the effect of existence of optical filtration above the PV and PCM beneath the PV in enhancing the overall efficiency of the PV/T solar collector by studying four different models alternating between existence and absence of optical filtration and PCM layer. It was found that existence of optical filtration above the PV and absence of PCM layer beneath the PV will result in the best performance.

2. Method:

The analytical equations governing the energy transfer through the PV/T were developed. These equations included all the physical, optical, thermal, and electrical contributions of the system. A systematic study for the governing equations was studied under reasonable assumptions to examine the thermal and electrical performance of the PV/T under different configurations.

2.1. The physical model:

In this part, the physical descriptions of the different provided configurations (M-1 to M-4) are discussed. Model-1 consists of one PV module, one thermal unit below the PV for the cooling purposes at which water/graphene nanofluid is used, and one thermal above the PV for the optical filtration purposes at which water/silver is used. Also, single PCM layer under the PV with graphene nanoparticles for storage and cooling as well. Model-2 is the same as Model-1 but without nano-PCM layer at the bottom of PV. Model-3 is slightly different from Model-1 that the optical filtration was removed and a vacuum channel was added at the bottom of the cooling channels. Model-4 is exactly like Model-3 but also without using nano-PCM layer at the bottom of the PV panels. Figure 1 shows schematic

diagrams for the proposed designs for the PV/T solar collector.

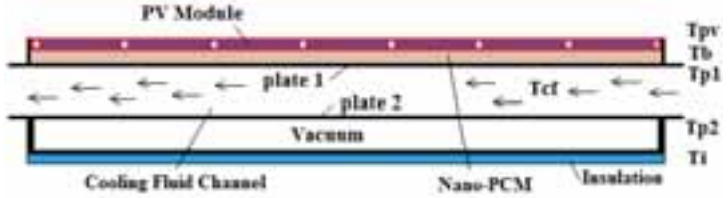
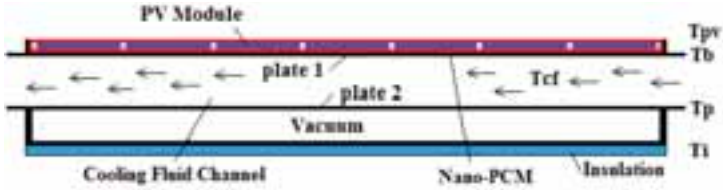
(b) M-2



(c) M-3



(d) M-4

Figure 1 Numerical solution models

2.2. *Working principles of PV/T configurations:*

Figure 1-(a) shows the configuration of the first model M-1. In M-1, the incident solar radiation reaches the PV cells after passing through the first cover glass, then through the optical filtration fluid channel through. The optical filtration fluid is responsible for allowing the solar radiation within the useful spectral range for electricity production only to pass through. The nano-PCM layer at the bottom of the PV is responsible for storing heat as well as transferring heat to the cooling fluid beneath the PV module. Nanoparticles were added to the PCM layer to enhance its thermal conductivity. It was guessed that the nano-PCM layer may resist the heat transfer to the cooling fluid and that's why it was removed in M-2. In Model-3, the optical filtration was removed totally and the solar radiation reached the PV cells directly. In M-4 the nano-PCM layer was also removed.

2.3. *Mathematical model:*

The simple general numerical models presented later were used to evaluate the performance of the PV/T collector through the calculation of the different temperatures, thermal, and electrical efficiencies using previously calculated optical and thermal properties. Table 1 shows the governing equations for the four proposed models. The assumptions that were used in this study are listed in Table 2. In addition, the technical data of the proposed models are available

at Table 3. The optical properties for the optical filter were taken from literature [10,11]. Table 4 summarize the thermal and rheological properties of the main substances used in the models.

Table 1 Governing equations for the proposed Models

M- #	Balance	Governing Equations	Equation no.
1	Glass cover	$\alpha_g G = h_{g-am}(T_g - T_{am}) + h_{g-of}(T_g - \bar{T}_{of})$	(eq. 1)

	Efficiency	$\eta_c = \eta_{ref}[1 - \beta_{ref}(T_c - T_{ref})]$	(eq. 28)

Table 2 Assumptions considered in the present study

	Assumptions
1	Steady state
2	Normal incident radiation
3	Radiation losses from glass cover or insulation to atmosphere were neglected
4	Very thin glass covers, plates, and insulation so conduction was neglected
5	Working fluid is flowing through a rectangular channel
6	Heat transfer was only considered in one dimension
7	All fluids remain liquids through the operation of the system
8	Thermal properties were calculated at an average temperature of 30°C
9	Negligible pumping power due to very low mass flow rate
10	Reference electrical efficiency of 12%

Table 3 Technical design data of the different solar collectors investigated in the present study

Item	Specifications	M-1	M-2	M-3	M-4

Table 4 Thermal and rheological properties

Substance/Property	k	μ	ρ	C_p
Air	0.026424	18.718×10^{-6}	1.165285	1007.22
Water	0.615504	0.000797345	995.65	4180.02
PCM	0.195	0.01145	820	2500
Graphene	5000	-	1000	15
Silver	429	-	10500	235

2.4. Thermal and rheological properties of nanofluids and nano-PCM:

The equivalent thermal properties for the nanofluids and nano-PCM were calculated based on the formulas that are available in the literature.

Thermal conductivity:

$$k_{nf} = \left[\frac{k_p+2k_f-2\emptyset(k_f-k_p)}{k_p+2k_f+\emptyset(k_f-k_p)}\right] k_f \qquad \text{(eq. 29)}$$

Dynamic viscosity:

$$\mu_{nf} = \frac{1}{(1-\emptyset)^{2.5}}\mu_f \qquad \text{(eq. 30)}$$

Density:

$$\rho_{nf} = \emptyset\rho_p + (1-\emptyset)\rho_f \qquad \text{(eq. 31)}$$

Specific heat:

$$(\rho c_p)_{nf} = \emptyset(\rho c_p)_p + (1-\emptyset)(\rho c_p)_f \qquad \text{(eq. 32)}$$

Table 5 shows the thermal and rheological properties of the nanofluids and nano-PCM used in the present study.

Table 5 Properties of Nanofluids and nano-PCM

	∅	μ	ρ	c_p	k
Optical filter	0.001	0.0008	1005.1543	4138.8	0.61734
Working fluid	0.001	0.0008	995.65	4175.855	0.61735
Nano-PCM	0.001	-	820.18	-	0.19558

2.5. Temperature distribution::

In the current section, the equations describing the temperature distribution throughout the optical filtration and cooling nanofluids used with M-1 were formulated. The energy equations that communicate between the fluids temperatures and its surroundings were used.

The working fluid:

From eq. 6:

$$h_{p-cf}(T_p - \bar{T}_{cf}) = h_{cf-I}(\bar{T}_{cf} - T_I) + \frac{m^o{}_{cf} cp_{cf}}{L}\frac{dT_{cf}}{dx_2}$$

By rearranging,

$$\therefore \frac{dT_{cf}}{dx_2} = \frac{L}{m^o{}_{cf} cp_{cf}}\left[h_{p-cf}(T_p - T_{cf}) - h_{cf-I}(T_{cf} - T_I)\right]$$

$$\therefore \frac{dT_{cf}}{dx_2} = \frac{L}{m^o{}_{cf} cp_{cf}}\left[h_{p-cf}T_p + h_{cf-I}T_I - T_{cf}(h_{p-cf} + h_{cf-I})\right]$$

Take $A = \frac{L}{m^o{}_{cf} cp_{cf}}(h_{p-cf}T_p + h_{cf-I}T_I)$, $B = \frac{L}{m^o{}_{cf} cp_{cf}}(h_{p-cf} + h_{cf-I})$

$$\therefore \frac{dT_{cf}}{dx_2} = A - BT_{cf}$$

$$\int_{T_{cf,in}}^{T_{cf,x2}} \frac{dT_{cf}}{A - BT_{cf}} = \int_0^{x_2} dx_2$$

$$\therefore T_{cf}(x_2) = \frac{A}{B} - \left[\frac{A}{B} - T_{cf,in}\right] exp(-Bx_2) \quad \text{(eq. 33)}$$

$$T_{cf}(W) = \frac{A}{B} - \left[\frac{A}{B} - T_{cf,in}\right] exp(-BW) \quad \text{(eq. 34)}$$

$$\bar{T}_{cf} = \frac{1}{W}\int_0^W T_{cf}(x_2)dx_2 = \frac{1}{W}\int_0^W \left[\frac{A}{B} - \left[\frac{A}{B} - T_{cf,in}\right] exp(-Bx_2)\right] dx_2$$

$$\therefore \bar{T}_{cf} = \frac{A}{B} - \frac{1}{B^2W}\left[A - BT_{cf,in}\right][exp(-BW) - 1] \quad \text{(eq. 35)}$$

The optical filter channel:

From eq. 2:

$$\tau_g \alpha_{of} G = h_{of-g}\left(\bar{T}_{of} - T_g\right) + h_{of-pv}\left(\bar{T}_{of} - T_{pv}\right) + \frac{m^o{}_{of} cp_{of}}{W} \frac{dT_{of}}{dx_1}$$

By rearranging,

$$\therefore \frac{dT_{of}}{dx_1} = \frac{W}{m^o{}_{of} cp_{of}}\left[\tau_g \alpha_{of} G - h_{of-g}\left(T_{of} - T_g\right) - h_{of-pv}\left(T_{of} - T_{pv}\right)\right]$$

$$\therefore \frac{dT_{of}}{dx_1} = \frac{W}{m^o{}_{of} cp_{of}}\left[\tau_g \alpha_{of} G + h_{of-g} T_g + h_{of-pv} T_{pv} - T_{of}\left(h_{of-g} + h_{of-pv}\right)\right]$$

Take $C = \frac{W}{m^o{}_{of} cp_{of}}\left[\tau_g \alpha_{of} G + h_{of-g} T_g + h_{of-pv} T_{pv}\right]$, $D = \frac{W}{m^o{}_{of} cp_{of}}\left(h_{of-g} + h_{of-pv}\right)$

$$\therefore \frac{dT_{of}}{dx_1} = C - DT_{of}$$

$$\int_{T_{of,in}}^{T_{of,x1}} \frac{dT_{of}}{C - DT_{of}} = \int_0^{x_1} dx_1$$

$$\therefore T_{of}(x_1) = \frac{C}{D} - \left[\frac{C}{D} - T_{of,in}\right] exp(-Dx_1) \quad \text{(eq. 36)}$$

$$T_{of}(L) = \frac{C}{D} - \left[\frac{C}{D} - T_{of,in}\right] exp(-DL) \quad \text{(eq. 37)}$$

$$\bar{T}_{of} = \frac{1}{L}\int_0^L T_{of}(x_1)dx_1 = \frac{1}{L}\int_0^L \left[\frac{C}{D} - \left[\frac{C}{D} - T_{of,in}\right] exp(-Dx_1)\right] dx_1$$

$$\therefore \bar{T}_{of} = \frac{C}{D} - \frac{1}{D^2L}\left[C - DT_{of,in}\right][exp(-DL) - 1] \quad \text{(eq. 38)}$$

Table 6 Reference values used

L (cm)	103.5	**$T_{wf,\,in}$ (K)**	298
W (cm)	100	**$T_{of,\,in}$ (K)**	298
L_c (cm)	100	**V_{am} (m/s)**	1
Δt_{PCM} (cm)	0.5	**m^o (kg/s)**	0.0104
Working fluid channel width (cm)	4	**η_{ref} (%)**	12
Optical filter channel width (cm)	2	**β**	0.0045
T_{am} (K)	298		

2.6. Calculation of heat transfer coefficients for M-1:

For flow over flat plate surfaces, $Nu = 0.86Re^{1/3}Pr^{1/2}$, $Re = \frac{\rho v L_c}{\mu}\Big|_{am}$, $Pr = \frac{\mu c_p}{k}\Big|_{am}$

Using the properties of air mentioned before and that $h = \frac{Nuk_{am}}{L_c}$

$$h_{g-am} = h_{l-am} = 5.065\ W/m.K$$

For internal laminar flow with constant heat flux inside rectangular channels, and with height to width>8, Nu=8.24,

Then for the optical filter fluid, $h = \frac{Nuk_{of}}{D_{h,of}}$

With $D_{h,\,of}$ = 3.92 cm, and the properties of the optical filter nanofluid,

$$h_{g1-of} = h_{g2-of} = h_{p2-of'} = h_{l-of'} = 129.715\ W/m.K$$

And for the working fluid, $h = \frac{Nuk_{wf}}{D_{h,wf}}$

With $D_{h,\,wf}$ = 7.69 cm, and the properties of the working fluid nanofluid,

$$h_{p1-wf} = h_{p2-wf} = 66.13\ W/m.K$$

3. Analytical results and discussion

The governing equations were solved separately for each model and the results are shown in Figure 2, Figure 3, Figure 4, and Figure 5. In addition, the results for solving the governing equations for conventional PV module were also discussed.

Studying the effect of existence of optical filtration, a comparison were held between the performance of models 1 and 2 versus that for models 3 and 4, it can be seen clearly that the existence of the optical filtration helped in enhancing the overall performance of the PV/T system. Comparing the models with optical filtration to the models without optical filtration, it was found that the PV temperature has decreased by 16-27.6 ˚C (Figure 2), electrical efficiency increased by 0.87-1.49% (Figure 3), and thermal efficiency increased by 11.7-17.4% (Figure 4).

The effect of the existence of the nano-PCM layer below the PV module can be distinguished by comparing the performance of M-1 with M-2 and M-3 with M-4. It was found that treating the nano-PCM on its thermal conductivity and neglecting its storage effects will end up with the result that existence of nano-PCM will decrease the performance due to low thermal conductivity and as a result resistance to heat transfer from the bottom side of the PV to the cooling fluid. Figure 2 to Figure 5 show that the effect of nano-PCM existence is not significant in the models that deal with optical filtration fluid; M-1 and M-2, M-3. In contrast, the effect of existence of nano-PCM layer in resisting the heat flow is very clear when comparing the performance of M-3 to M-4.

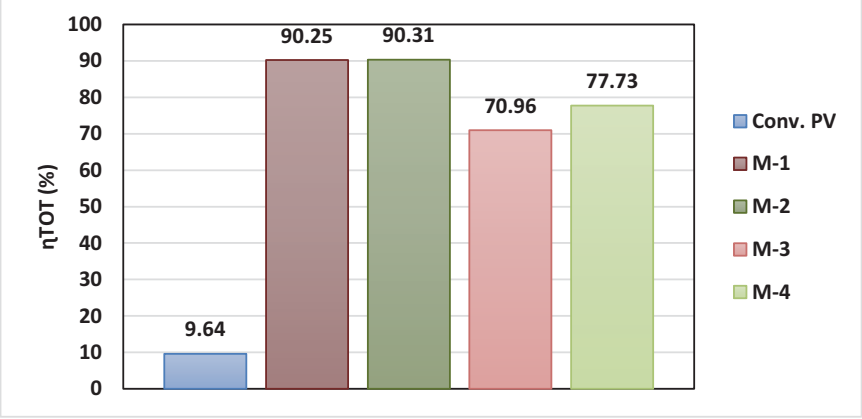

Figure 5 Total efficiency for different configurations

4. Conclusions

In the current paper, an analytical solution based on steady state assumption was developed. Four different models of hybrid PV/T solar systems studying the effect of optical filtration and nano-PCM technologies were studied. The governing energy equations for the heat transfer throughout the four models were solved to evaluate the solar utilization performance. From the discussion of the results, different conclusions were attained and can be summarized in:

- Using optical filtration is highly beneficial in enhancing the overall performance of PV/T systems.
- Neglecting the storage effect of the nano-PCM, existence of nano-PCM layer below the PV cells resists heat transfer to working fluid and thus increase the temperature of PV cells and decrease the performance of PV/T.

5. Additional work:

- Considering the honeycomb channels during analysis should end up with more enhancement in the performance of the PV/T.
- Using only one channel for optical filtration may increase or decrease the performance, so it needs to be studied.

Abstract

Photovoltaic Thermal (PVT) collector is a type of solar collector that produces electricity and uses heat from the backside of PV simultaneously for space heating. In particular, air type PVT has the benefit of being easily managed and can be used directly for heating in buildings. Baffle is installed in the heat-collecting layer of the PVT collector to increase the velocity and flow path of air inside the collector. As a result, it can be used to improve the performance of the PVT collector. In this study, effect of different baffle types on thermal performance of air type PVT collector was analyzed using NX simulation program. The design variables used for analysis were square, triangle, and bent (using absorb plate) type of baffles of collector. The outlet temperature rose by 3-6^{o}C when the shape of the baffles changed from square to triangular to bent type. Also, the thermal efficiency of the collector with the absorber plate increased by 11.3% compared to the collector without baffle..

Keywords: Air-type PVT Collector, Thermal efficiency, Baffle design, CFD analysis

1. Introduction

Photovoltaic Thermal (PVT) collector is a type of solar collector that produces electricity and uses heat from the backside of PV for space heating simultaneously. In particular, air type PVT has the benefit of being easily managed and can be used directly for heating in buildings as compared to water-type PVT collector. Baffle is installed in the heat-collecting layer of the PVT collector to increase the velocity and flow path of air inside the collector. As a result, it can be used to improve the performance of the PVT collector.

In this study, effect of baffle on thermal performance of air type PVT collector was analyzed. For this purpose, collectors with different types of baffles were designed and analyzed using NX simulation program.

2. Air-type PVT Collector with Baffles

2.1. Air-type PVT collector with various baffle types

Air-type PVT Collector has been developed with lots of space types, materials, and flow path to improve thermal efficiency. The space consists of various types of air space layer such as applying fins, aluminum sheet and steel absorber. Inside structure of air-type PVT collector can highly affect the thermal efficiency and electrical efficiency as well. Especially, Baffles which is installed in surface on air space have merits for air uniformity and heat absorption. Currently, many type of baffles has been developed and analyzed (Fig. 1) [2]. Square baffle design is a basic type and other shapes are analyzed with different baffle sizes and installation positions. Particularly, minimizing vortices and dead zone has been more important and focused on the research field (Fig. 2).

doi:10.18086/swc.2017.18.02 Available at http://proceedings.ises.org

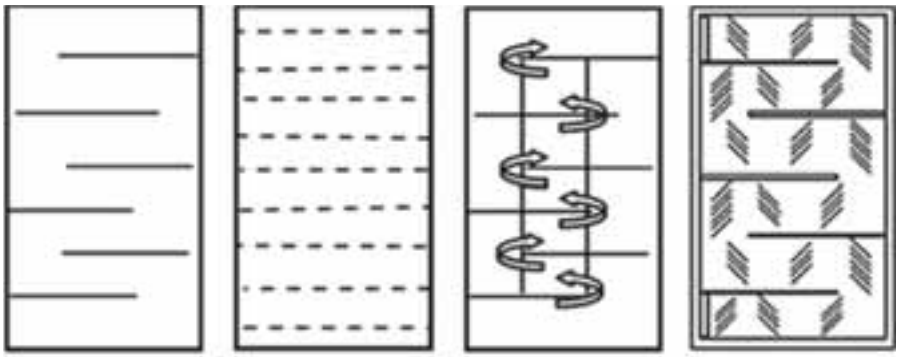

Fig. 1: Various baffle designs inside collector

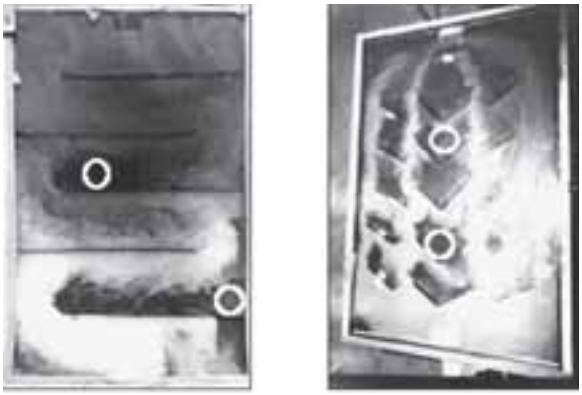

Fig. 2: Vortices and Dead zone inside collector

3. Methodology

3.1. Modelling of Air-type PVT collector with baffle designs

In this study, general PVT collector without baffle and with different shape of baffles were designed. The shapes of baffle used were square, triangle and bent (using absorber plate) type as shown in Fig. 3. For comparison, a collector without baffle was added, and other variables such as the shape and size of inlet/outlet for each condition were set to be same. The square baffle type was designed in an intercrossed placement with spacing between the baffles to increase the flow rate of the air. The top surface of triangle baffle was made streamlined so that the air passes smoothly through the PV back surface to improve thermal absorption. The bent type baffle was designed with different PV arrangement so that solar radiation directly reaches the absorber plate inside the collector. And the plate was designed to receive more solar radiation with the form of curves. The 3 types of air-type PVT collectors with different baffles were modeled with NX simulation program.

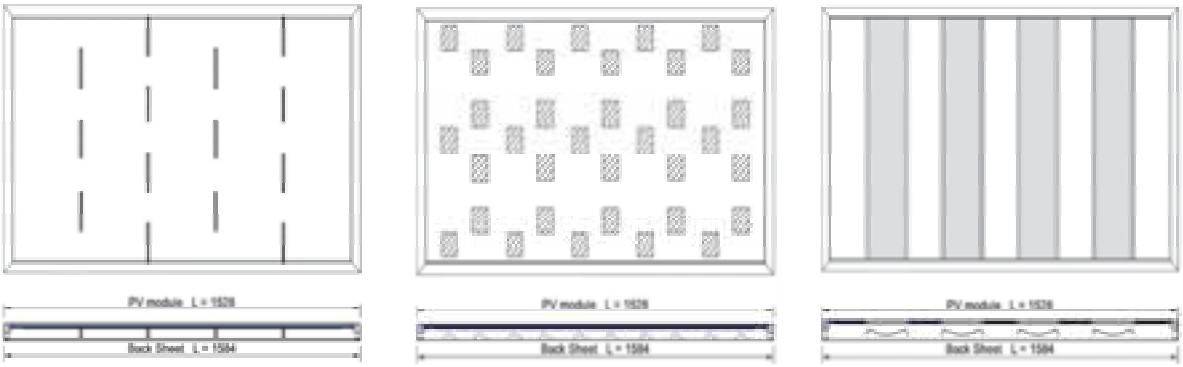

Fig. 3: Baffle designs inside of the collectors(from left; square, triangle bent types)

3.2. Simulation Properties

Modelled Air-type PVT collector size is 1.63m^2 (height 42.5mm), and supplied thermal energy 780W/m^2 that is supposing 15% of solar radiation reached the PV surface. Ambient temperature was 20^{o}C for heat loss calculation, and the air density was decided by each air temperature value such as 1.225kg/m^3 when the air temperature was 25^{o}C. K-epsilon model was applied for turbulence expectation, and inlet, outlet and heat flux area of all collector types were equivalent for comparison. Input difference was air flow rate (30, 60, 100 CMH) and baffle designs. The parameters are summarized Table 1.

Table 1: CFD Simulation parameters

Input	Elements	Unit
Collector size	1.6	m^2
Collector height	42.5	mm
Supplied thermal energy	780	w/m^2
Ambient temperature	25	^{o}C
Air density	1.225(25^{o}C)	kg/m^3
Air flow rate	30, 60, 100	m^3/h(CMH)
Turbulence model	K-epsilon	-

4. Results and Discussion

4.1. Air uniformity distribution

As a result, partial congestion of temperature was observed inside the collector depending on the shape of the baffles. Turbulence and dead zone was found in Square type, on back side surface of the installed baffles against air flow pathway (Fig 4). Triangle type was improved compared with square type. However, lots of Dead zone were caused. Unlike the triangle and square baffles, air uniformity and collector temperature of the bent baffle was uniformly distributed. The average flow rate of collector increased to 19% with square baffle. Also, the temperature distribution in the collector was relatively uniform according to the installation of the baffles.

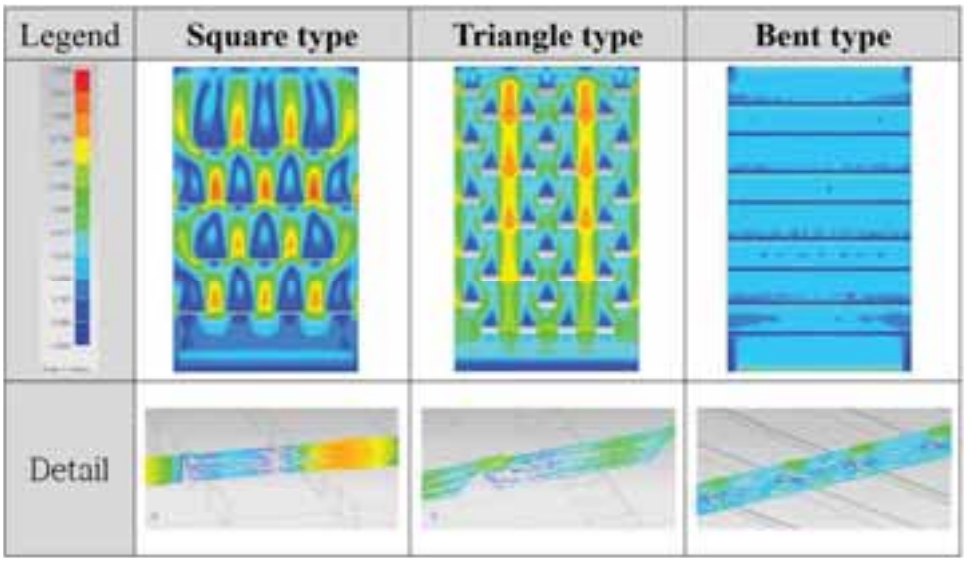

Fig. 4: air flow pathway with velocity in different baffle types of the collector

4.2. Temperature characterization of the Air-type PVT collector

Fig. 5 displays the air temperature inside collector according to different baffles. Square type had lots of air stagnant behind baffles against air movement. Triangle type improved the uniformity of the air and velocity especially between baffles. Bent type showed better air uniformity and movement. The air moved to whole surface of the collector and efficiently took heat from the space.

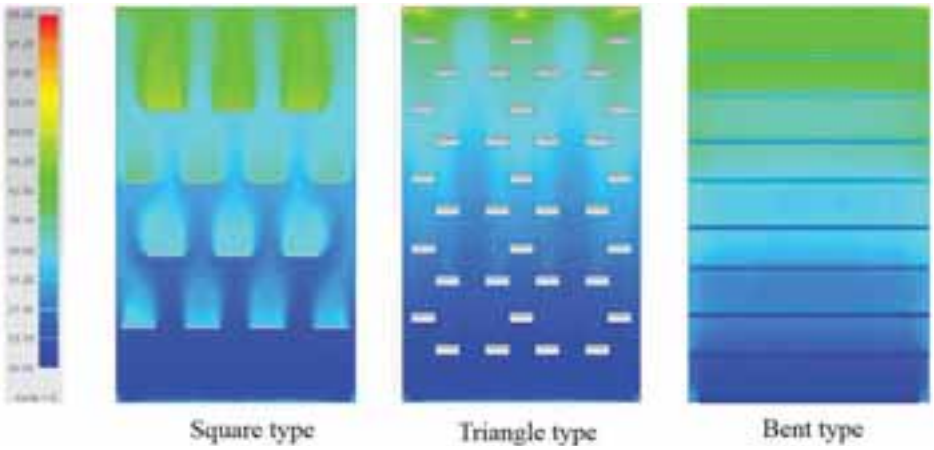

Fig. 5: air flow pathway with velocity in different baffle types of the collector

4.3. Thermal performance

Thermal efficiency are presented in Fig. 6. The results were calculated by equation 1.

$$\eta_{th} = \frac{\dot{m} C_p (T_o - T_i)}{A_{pvt} G} \qquad \text{(equation. 1)}$$

η_{th} thermal efficiency [-]
A_{pvt} collector area [m^2]
T_o collector outlet air temperature [$^{\circ}C$]
T_i collector inlet air temperature [$^{\circ}C$]
$\dot{m}$ air flow rate [$m^3 h^{-1}$]
C_p specific heat [$J kg^{-1} K^{-1}$]
G irradiance on the collector surface [$W m^{-2}$]

According to the shape of the baffle, the outlet temperatures were varied by 3-6 degrees. With the outlet temperature difference, thermal efficiency of the air-type PVT collector without baffles was 31.3%. The collector with square and triangle type showed improved thermal efficiency of 32.5% and 33.1% respectably. Bent type had 35.3% with minimized turbulence and dead zone inside collector. Consequently the thermal efficiency of PVT collector with baffle increased by 11.3% than the collector without baffle.

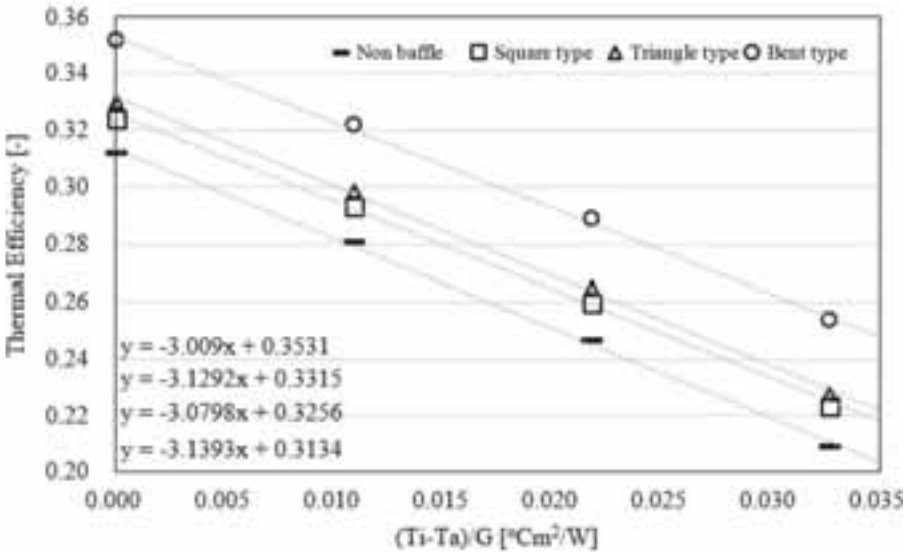

Fig. 6: Thermal efficiency graph of the different baffle type collectors

5. Conclusion

In this research, Air-type PVT Collector with various baffle types was analyzed with CFD simulation. Results showed that partial air statement was caused with baffle types except for bent type. Also, air uniformity of bent type was improved compared with square and triangular baffles. Outlet air temperature varied by 3-6°C according to baffle type. Air flow velocity of square type baffle improved 19% compared with basic baffle type. Dead zone was minimized for bent baffle type than square and triangular types by baffle shapes. Furthermore, thermal efficiency of the air-type PVT Collector with bent type improved 11.3% compared with basic (Non baffle) type.

Abstract

This work, performed in the context of the LowUP H2020 European project, presents a modelling approach for innovative renewable technology consisting of a hybrid solar photovoltaic-thermal (PV/T) collector system that includes Phase Change Material in its back layer. The whole model is described focusing on the mathematical representation of the PCM layer and its associated non-linear behaviour. Main modelling assumptions are based on an energy balance for the PCM and a simple representation of the phase change process through the parametrization of the h-T curve. The thermal resistance between the absorber and the PCM layer is identified as a key model parameter, and its influence is demonstrated in a preliminary simulation analysis of different designs. Thus, the model developed within this work provides interesting for integration into energy simulations, enabling contributions to the design and smart operation of sustainable heating and power systems.

Keywords: PV/T solar panels, Phase Change Materials (PCM), mathematical model, TRNSYS

1. Introduction

Hybrid PV/T solar collectors have been widely studied and developed in the past years (Chow 2010, IEA-SHC 2005). They increase global system's efficiency and enables that the amount of low-grade heat dissipated by PV cells (that will be otherwise rejected to the ambient) can be used to meet thermal energy demands (DHW or space heating) through the application of low exergy concepts in heating facilities. Indeed, this idea is being investigated within the LowUP European project (LowUP 2017), aimed at integrating different low-grade energy sources for innovative, efficient heating solutions.

LowUP works to improve the design and operating performance of this technology, particularly addressing the demonstration of a novel PV/T system that includes a Phase Change Material (PCM) in the back layer of the panels. Positive effects of the hybrid PV/T concept are expected to be enhanced. PCM will act as a thermal storage able to limit the operating cell temperature (increasing the electrical efficiency). Besides, it can be able to extend the availability of the thermal resource beyond the periods of relevant solar radiation at the end of the day.

The particular purpose of this work is to present a mathematical model for this PV/T-PCM innovative configuration. So far, some references from literature address the use of PCM to cool down PV cells and improve their efficiency (Smith et al. 2014). However, very little experience on the proposed hybrid PV/T-PCM concept has been previously reported (Browne et al. 2015) and no existing specific models are known. The proposed model will facilitate the estimation of systems' behaviour and help the design process for later implementation.

2. Description of the modelling approach

The selected modelling approach for the PV/T-PCM panel intends to account for the original PV/T geometry together with those modifications involved by the PCM layer. To this end, TRNSYS Type560 (TESS 2012) was used as the basis to account for hybrid PV/T characteristics and a self-developed PCM layer model was integrated with consistent modifications on several parameters and the original back insulation.

2.1 PV/T reference model

Type560 PV/T thermal model relies on algorithms from the classic work by Duffie and Beckmann (2013)

doi:10.18086/swc.2017.18.03 Available at http://proceedings.ises.org

and is based on the following main considerations:

- Linear relation between PV efficiency (η_{PV}), cell temperature (T_{PV}) and incident solar radiation (G_T)
  $\eta_{PV} = \eta_{nom}\chi_T\chi_G = \eta_{nom}\left(1 + eff_T\left(T_{PV} - T_{ref}\right)\right)\left(1 + eff_G\left(G_T - G_{ref}\right)\right)$ (eq.1)
  where eff_T and eff_G are constant factors.
- PV cells are assumed to be operating at their maximum power condition.
- Energy balance equation for the PV cell surface neglecting conduction effects along the surface
- Classical considerations on absorbed solar radiation based on transmittance, absorptance and incident angles.
- Energy balance equation for the absorber surface, which is addressed as a classical fin problem to derive absorber plate temperature distribution
- Energy balance equation to the base area of the absorber in contact with the fluid tubes (see Figure 1)

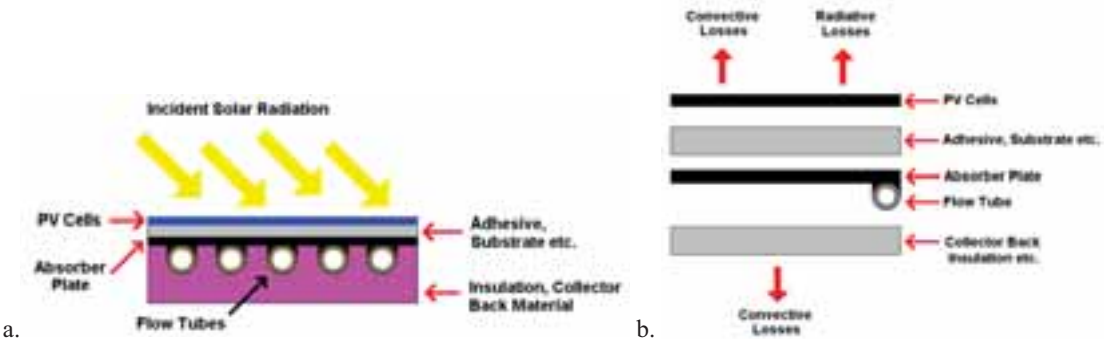

Figure 1. . (a) Schematic solar panel configuration and (b) relevant component definitions for TRNSYS Type560 PV/T model Source: (TESS 2012)

This mathematical representation allows deriving the temperature values of the different PV/T components as well as relevant output variables (both thermal and electrical). Yet, the current model does not account for the possibility of including the PCM, which requires the integration of a completely new layer with non-linear behaviour.

2.2 PCM modelling and integration

The novel PV/T-PCM system implies that the back layer (adjacent to the absorber plate) is now able to store the dissipated heat while keeping constant temperature along the phase change process. Back surface is still considered to be in contact with ambient temperature. The existence of this PCM layer involves a non-linear behaviour that cannot be modelled with a simple additional thermal resistance. Therefore, this work proposes a simple model that treats the PCM layer as a thermal storage with homogeneous temperature and is based on the energy balance equation and a simple parametrization of the enthalpy-temperature (h-T) behaviour of the Phase Change Material.

PCM temperature is affected by the heat transfer received from the collector, and simultaneously this temperature (as a boundary condition for the PV/T collector) influences the aforementioned heat transfer. Based on this, the energy balance to the PCM 'storage' layer provides its energy content at every timestep.

$$E_{i+1} = E_i + \Delta t \cdot \left(\dot{Q}_{PV/T,i} - \dot{Q}_{loss,i}\right) \qquad \text{(eq.2)}$$

Then, from the h-T curve of the material and the energy content, the PCM layer temperature is obtained. The parametrization of this h-T behaviour is described next. Figure 2 represents the h-T curves corresponding to different real heating and cooling processes of a given PCM (Belmonte et al. 2016). Although an idealized thermal behaviour with constant melting temperature is often considered when analysing Phase Change Materials, deviations associated to three main different effects can be observed:

- Variable temperature along the phase change process (temperature range)
- Different h-T curves (within the phase change range) for cooling and heating evolutions (i.e. hysteresis effects)
- Sub-cooling effects that makes the PCM requiring to achieve colder temperatures than the 'normal'

melting temperature range in order to start solidification (therefore, once the freezing process starts, the temperature increases slightly).

The present PCM model defines 3 parameters: melting temperature (T_{melt}), melting range ($range_{PCM}$) and melting hysteresis ($hyst_{PCM}$), which allows accounting for most of common h-T behaviours with reasonable accuracy (see Figure 2). Sub-cooling effects are neglected by this model.

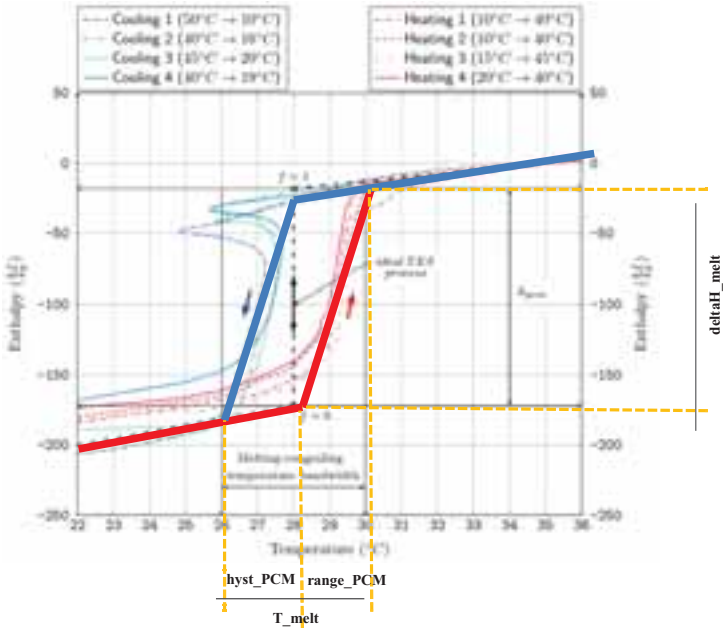

Figure 2. h-T behaviour of a particular PCM (Source: Belmonte et al. 2016) and definition of related model parameters

The PCM layer model was developed in C++ and integrated in the corresponding new TRNSYS type (Type261). Model inputs and outputs (required to connect the new type to other modelling components) as well as internal model parameters are collected in Table 1.

Table 1. Inputs, outputs and internal parameters for the PCM layer model

Model Inputs	
T_ini_PCM	Initial temperature of the PCM
A_coll	Area of collector surface
ePCM	Thickness of the PCM layer
Q_PVT	Heat transfer from the absorber to the PCM layer
T_ext	External (ambient) temperature
Model Outputs	
T_PCM	Temperature of the PCM layer
E_PCM	Energy level of the PCM layer
Q_loss	Heat transfer losses from the back surface of the PCM layer
f	Melted fraction of PCM (0 = completely solid; 1 = completely liquid)
Internal Parameters	
U_loss	Overall heat transfer coefficient from the PCM layer to the ambient temperature (including insulation and convective/radiant external thermal resistance)
Rho_PCM_liq	Density of the PCM liquid phase
Rho_PCM_sol	Density of the PCM solid phase
Cp_PCM_liq	Specific heat capacity of the PCM liquid phase
Cp_PCM_sol	Specific heat capacity of the PCM solid phase
T_melt	Melting temperature of the PCM
deltaH_melt	Specific enthalpy
Range_PCM	Characteristic temperature range for the phase change process (see Figure 2)
Hyst_PCM	Characteristic temperature hysteresis for the phase change process (see Figure 2)

Finally, in order to enable the integration of the proposed model, the thermal resistance of the Type560's back layer was modified and new connections between both TRNSYS components (560 for PV/T and 261 for PCM) were defined:

- PCM temperature is given to the PV/T model as the back surface environment boundary condition.
- Heat transfer through the PV/T back surface is given to the PCM model as an input.

It should be remarked that the thermal resistance between the absorber and the PCM layer is one of the key parameters of the proposed model. Theoretical derivation of this parameter is not evident, so its value should be calibrated with experimental data from manufacturer tests or real operation monitoring data.

3. Results and discussion

To explore the behaviour of the proposed modelling approach and demonstrate the influence of the above-mentioned thermal resistance some simulations were conducted for the first week of January in Seville (Spain). The TRNSYS simulation setup showed in Figure 3 was devised based on the following conditions and simulation hypotheses:

- Two solar systems with the same dimensions and configuration, except the back layer : PV/T panel with conventional back insulation, and PV/T panel with integrated PCM layer (3 cm-thick)
- PCM melting temperature of 30 ºC.
- Ideal energy demands able to return 25 ºC to the panels.
- Simple control strategy with pump operation turned on if minimum solar radiation is available or if outlet water temperature above 25 ºC can be achieved (even without solar radiation).

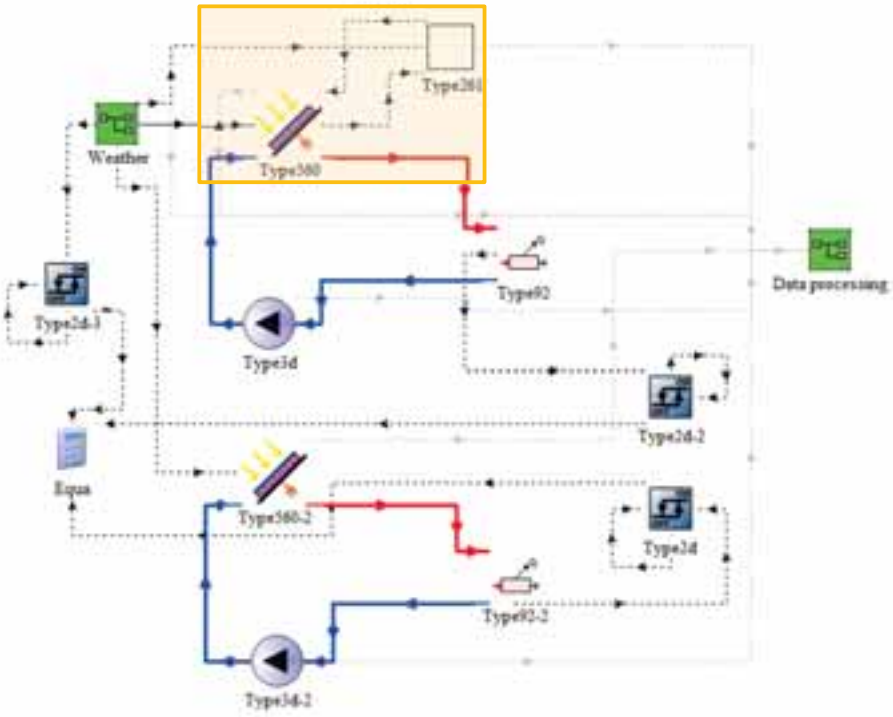

Figure 3. TRNSYS simulation setup for PV/T-PCM model analysis

A preliminary sensitivity analysis was done by modifying the thermal resistance (R) between the absorber and the PCM layer in the PV/T-PCM system: a) R = 0.07 $m^2 \cdot K \cdot W^{-1}$, b) R= 0.0007 $m^2 \cdot K \cdot W^{-1}$ and c) R= 0.00007 $m^2 \cdot K \cdot W^{-1}$. Figure 4 shows the obtained results.

m_woPCM (dark green), m_wPCM (purple)

Figure 4. Temperature evolutions for PV/T system with and without PCM considering different values of the characteristic thermal resistance between the absorber and PCM layer (R in m2·K·W-1): (a) R = 0.07, (b) R= 0.0007, (c) R= 0.00007

One can observe clearly different behaviours of the PCM and fluid outlet temperatures depending on the R-values. If the R-value is high enough, the model reflects a decoupling effect between the thermal responses of the fluid and the PCM layer. In such case, the PV/T-PCM behaviour is very similar to the original PV/T system.

However, as the considered R-value is reduced, the PCM layer plays a relevant role in the overall thermal behaviour of the panel. The PCM layer absorbs enough heat from the PV/T configuration to reach its melting point. Then, less heat transfer to the fluid takes place and the outlet fluid temperature is clearly lower than that from the PV/T system.

Additionally, at the end of the day that heat stored into the PCM layer enables panel temperatures to decrease slowly and daily system operation to be extended beyond the solar radiation availability schedule. It is difficult to say how close to the first or the second option will be. Then, within the proposed model, the R-value will be a characteristic parameter of a given PV/T-PCM panel product that requires to be calibrated with experimental data.

4. Conclusions

This work presented the development of a mathematical model for innovative renewable technology consisting of a hybrid photovoltaic-thermal (PV/T) solar panel integrating a PCM-based thermal storage in its rear side. This simple approach, with a few input parameters, provides interesting potential for integration into energy simulations, enabling contributions to the design and smart operation of sustainable heating and power systems.

The key point of the proposed model is the definition of a simple representation for the h-T behavior of the PCM in the phase change temperature range. Then, a reasoned integration of the PCM behavior together with heat transfer from the PV/T system was analyzed in terms of a characteristic thermal resistance.

Moreover, a calibration procedure was envisaged focusing on the adjustment of this thermal resistance allowing to model different PV/T-PCM systems with different designs of the coupling between the absorber (heat recovery component) and the PCM layer.

Finally, it should be noted that this model is the result of tasks developed within the LowUP European project and detailed validation of the obtained results will be accomplished in the very next steps of the project based on actual monitoring data.

Abstract

To understand specific performance characteristics of a flat photovoltaic thermal (PV/T) module, a general simplified model (1D) has been performed, leading to an exponential equation for output temperature when weather and input fluid characteristics are known. To validate the model, a unique parametrical experimental validation was performed and is the focus of this paper. The present work includes nine prototypes built and monitored with the normative Solar Keymark approach.

The model exhibit a good fit with the experimental results. This conclusion has to be confirmed for future prototypes based on a polymeric heat exchanger.

Keywords: Photovoltaic thermal (PV/T) collector; Experimental validation; Energy performance

1. PV/T context and propose of the work

Since 2015, solar power is the number one energy source in terms of new capacities of electricity production ahead of coal, and the IEA published in Renewable 2017 (Renewable 2017, IEA) that the share of renewables for electrical needs will be 30% in 2022.

UNEP estimates that the buildings sector represent 30% of total energy consumption in the world (Global Status Report 2016, UNEP). Photovoltaics (PV) on buildings is ineluctable and the European Energy Performance of Buildings Directive requires all new buildings to be Nearly Zero-Energy (NZEBs) by the end of 2020. This directive is one of the political initiatives that gives a frame for its massive development.

But heat will certainly be the issue of the 21st century for Buildings. Almost 80% of energy demand in the buildings sector is for heat according to the IEA's article (Renewable energy's next frontier: heat, 6/12/2016).

Even with a strongly insulated building, the need for domestic hot water (DHW) is still here, and the space on the buildings' rooftops is not infinite. That is why the "2-in-1" PV/T technology a key solution to meeting energy needs of highly energy-efficient buildings. PV/T modules enable to produce DHW and photovoltaic with the same module, and make buildings more and more autonomous in heat and electricity using solar power.

Additionally, building-integrated PV (BIPV) may lead to a decrease in electrical performance of photovoltaic cells due to an increase in operating cell temperature (0.5%/K for mono-crystalline technology). In this context, the design of hybrid Photovoltaic-Thermal (PV-T) collectors, which recover wasted heat from the photovoltaic panel and in effect reduce cell temperature, offer an innovative solution for BIPV.

A review of PV/T technologies has been done by Zhang *et al.* (2012) and Good *et al.* (2015). The DualSun PV/T module in the study (Fig. 1) is based on the unglazed flat-plate liquid design described in these reviews. It has 60 monocrystalline cells for a nominal power of 250 Wp (PV) and 912Wth (Thermal).

doi:10.18086/swc.2017.18.04 Available at http://proceedings.ises.org

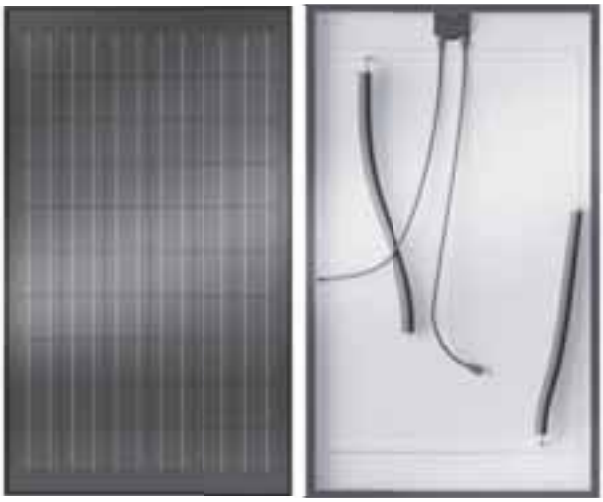

Fig. 1: DualSun PV/T module, 60 cells 250Wp, direct lamination of a stainless steel heat exchanger 912Wth

As reported by Zondag, H.A., 2008 in his review on flat-plate PV-T collectors, one key point for the development of PV-T collectors concerns the heat transfer between PV cells and fluid. That is why DualSun focused during their PV/T module developments on heat transfer between PV cells and fluid. Thermal resistance has been minimized by direct lamination of the specific heat exchanger. Direct lamination is possible due to a pertinent material choice, which prevents delamination due to differential dilatation in the long term.

As Dupeyrat, P., et al., 2009 pointed out, glazed PV-T modules lead to a better overall energy conversion. But DualSun has made the choice of an unglazed collector to keep a low stagnation temperature, and thus prevent overheating. The PV encapsulant is very sensitive to high temperature, which could irreversibly destruct the laminate. Furthermore, the residential sector, stagnation will often occur during summer months when families have left on vacation, and thus when solar irradiation is important.

The original concept of the DualSun module is different from what can be observed in existing literature. In order to simulate the energetic performances of the DualSun module, a numerical 1D model was developed. To validate the 1D model, the layers of the module have been changed in this study and tested.

2. Numerical model

An energy balance of the module leads to a quasi 1D simplified model, a methodology which has been previously used by many authors (Chow et al. 2008, Duffie and Beckman 1991, Fraisse et al. 2017, Tess library). The model input values include weather entries (ambient temperature T_A, insulation, wind velocity V_{WIND}) and solar domestic hot water load parameters (stock bottom temperature $T_{F,IN}$, flow rate $\dot{m}$). Thanks to an energy balance (Fig.2) on photovoltaic cells and on a fluid slice (eq. 1), we deduce an exponential behavior of fluid temperature along the path (eq. 2).

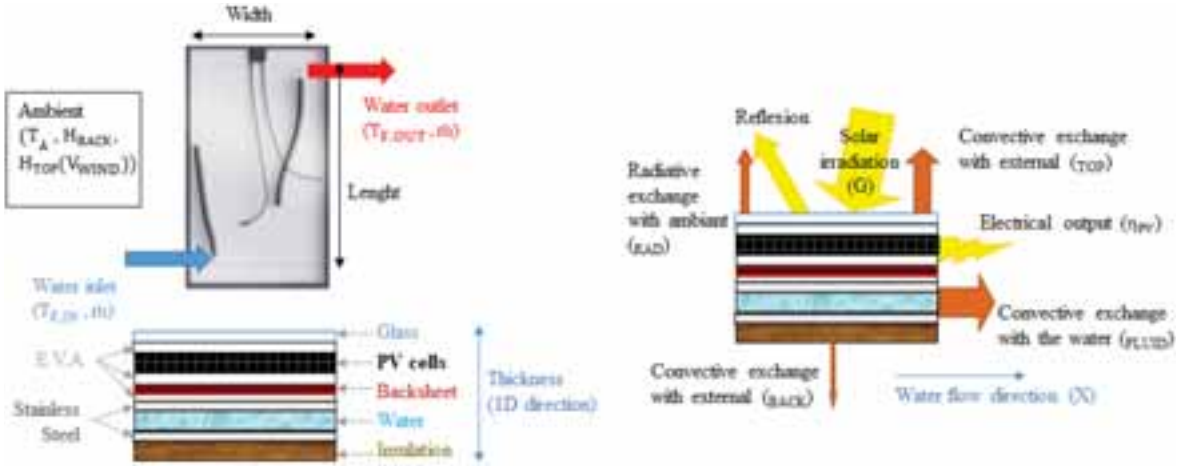

Fig. 2: Description of the studied system

Module output temperature and electrical power are then deduced thanks to an iterative approach on photovoltaic temperature (T_{PV}). The definitions of the symbols are given in Tab. 1 and subscript in Tab. 2.

$$\underbrace{(\tau_\alpha).G.\left(1-\eta_{PV}(G,T_{PV})\right)}_{\textit{Solar Recovered energy}} = \underbrace{h_{RAD}(T_{PV}).(T_{PV}(x)-T_{SKY})}_{\textit{Radiative exchange with ambiant}} + \underbrace{H_{TOP}(V_{WIND}).(T_{PV}(x)-T_A)}_{\textit{Convective exchange with external}} + \underbrace{H_{FLUID}.\left(T_{PV}(x)-T_F(x)\right)}_{\textit{Convective exchange with the water}} \quad \text{(eq.1)}$$

$$\underbrace{H_{FLUID}.\left(T_{PV}(x)-T_F(x)\right)}_{\textit{Convective exchange with the water}} = \underbrace{H_{BACK}.(T_F(x)-T_{BACK})}_{\textit{Convective exchange with external}} + \dot{m}.Cp.\frac{dT_F}{dx} \quad \text{(eq.2)}$$

Module outlet temperature and electrical power are then deduced thanks to an iterative approach on photovoltaic temperature (T_{PV}).

$$T_{F,OUT} = \left(T_{F,IN} - C\right).\, e^{-D.Width} + C \quad \text{(eq.3)}$$

$$T_{PV} = A\,.\,T_{F,MEAN} + B \quad \text{(eq.4)}$$

In non-null flow rate cases, equations were simplified to follow Solar Keymark standard directives (eq. 5).

$$\eta_{TH} = a_0 - a_1\,.\left(\frac{T_{F,MEAN}-T_A}{G}\right) \quad \text{(eq.5)}$$

Relations between the 1D-model and the linear formula are given by Eqs. 6 and 7.

$$a_0 = \frac{\dot{m}\cdot Cp\cdot D\cdot Width\cdot(C-T_A)}{G\cdot Area} \quad \text{(eq. 6)}$$

$$a_1 = \frac{\dot{m}\cdot Cp\cdot D\cdot Width}{Area} \quad \text{(eq. 7)}$$

Tab. 1: Meaning and units for symbols

Symbol	Meaning	Units
A,B,C and D	Coefficients depending on module characteristics	
Cp	Heat capacity	W/kg/K
G	Solar irradiation	W/m²
H	Global coefficient	W/m²/K
h_{RAD}	Radiative coefficient	W/m²/K
H_{WIND}	Convective coefficient on top plate due to the wind	W/m²/K
H_{FLUID}	Convective coefficient on the plate due to the water	W/m²/K
$\dot{m}$	Water Flow rate	L/s
T	Temperature	K
V_{WIND}	Wind velocity	m/s
Width	Width of solar collector	m
X	Water flow direction	
Tα	Transmitto-absorption depending on diffuse, direct and horizontal irradiation	-
η_{PV}	Electrical efficiency	-
η_{TH}	Thermal efficiency	-

Tab. 2: Meaning for subscripts

Subscript	Meaning
A	Ambient
BACK	Between fluid and back ambient
F	Fluid
FLUID	Between PV cells and fluid
PV	Photovoltaic cells
TOP	Between cells and ambient

3. Prototypes and testing

Some experimental validations at the module level were proposed but only with specific heat exchanger (Ben Cheikh et al. 2015, Rejeb et al. 2016). The aim of this paper is to do a complete parametric validation with a basic shape for the integrated heat exchanger with a full water slice (no tubes).

In order to validate the proposed simplified model, 9 prototypes were build and monitored according to the Solar Keymark approach in a sunlight test bench. All prototypes size 1669 x 982mm², except n°8 and 9, which were smaller (1365 x 886mm²). All integrated heat exchangers are directly laminated with the cells with an Ethylene Vinyl Acetate layer (EVA) under the BackSheet (BS) during a unique lamination step. Such manufactured heat exchanger (0.6mm stainless steel plates) allow a 2mm water gap to cool the photovoltaic part and have a 15mm non-irrigated border.

The description of the constitutive layers for the 9 prototypes tested are summarized in Tab. 3.

Tab. 3: description of the 9 prototypes tested

	Glass (mm)	EVA (mm)	Cells	EVA (mm)	BS (mm)	Fixation (mm)	Stainless Steel Heat exchanger / PV surface	Insulation equivalent thickness (k=0.033 W/(m.K))

The bench of artificial sunlight consists of two independent parts: the lamp holder and the sensor holder. The simulator is class BBB (Fig. 2). For the characterization of the PV/T module, an irradiant flux of 1000W / m² is adjusted at the level of the lamps.

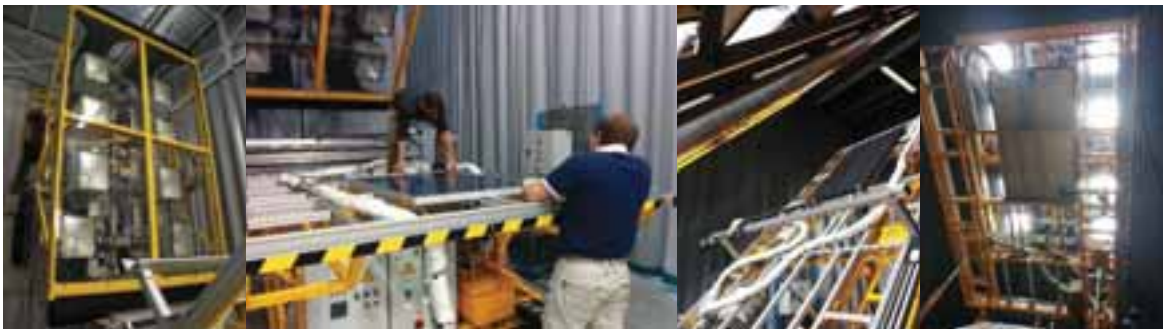

Fig. 2: Pictures of the artificial sunlight test bench

A mapping of the flux measurements is carried out in order to check a homogeneity on the surface of the sensor of plus or minus 5% on the mean value of the flux (Fig. 3). This mapping is carried out with each new characterization and it is obvious that the flux homogeneity is within ±1.5%.

Fig. 4: Mapping measurements of the wind speed [m/s]

A thermal regulation ensures the conditioning of the fluid (water), in order to generate a regulated inlet temperature in the module and to ensure good circulation in the exchanger. Six input temperature steps from 20 ° C to 70 ° C are programmed to scan the operating range of the module.

Local input / output temperature measurements and fluid flow measurements make it possible to draw up the appropriate thermal balances and determine the powers involved for each thermally stabilized operating point.

The measuring instrument I (V) plots the curves and extracts the important photovoltaic values. The red rectangle shows the location of the reference cell for the instrument which plots the I (V) curves, and the blue rectangle the module location (Fig. 3). The power of the module is limited by the current of the least photo-generating cell, which depends mainly on the minimum irradiance that the surface of the module receives (the limiting cell). In practice, the power value "equivalent to 1000 W / m²" is obtained from the reference cell (approx. -5% deviation).

Results are given in Tab.4.

4. Model validation

Two parameters were introduced to take better into account for the specific behavior of the Dualsun stainless steel heat exchanger. The first was the ratio Stainless Steel Heat exchanger over PV surface for the effect of the fin. Additionally, the heat exchange between the fluid and the stainless steel was supposed fixed at 800 W/(m².K) but is unknown. The second parameter was length of exchange.

Both parameter have been deduced from numerical optimization. The ratio Stainless Steel Heat exchanger over PV surface has been raised from a numerical optimization to 82% instead of 74%. The length of exchange has been optimized to fit with the experimental results to 770mm instead of 856mm.The model fit the experimental data very well as shown in Tab. 5 and Fig. 5 with a maximum root-mean-square error (RMSE) inferior of 67 to compare with the 1000Wth. The quality of the direct lamination for the 9th prototype was harder to achieve with the unusual size, which certainly explains the higher error with the theory.

These results seems to confirm that the 3D design could be neglect to predict performances, but this analyze could not be directly use for non-conductive material for the heat exchanger, as it could be an effect of the high homogenization of the temperature in the heat exchanger due to the relatively high conduction in the stainless steel. So it would be interested to continue this study with a polymeric heat exchanger.

Tab. 5: Root-mean-square error for each model/ test fitting

Test	1	2	3	4	5	6	7	8	9
RMSE	8.74	17.14	26.39	15.09	29.98	20.33	28.35	25.42	66.98

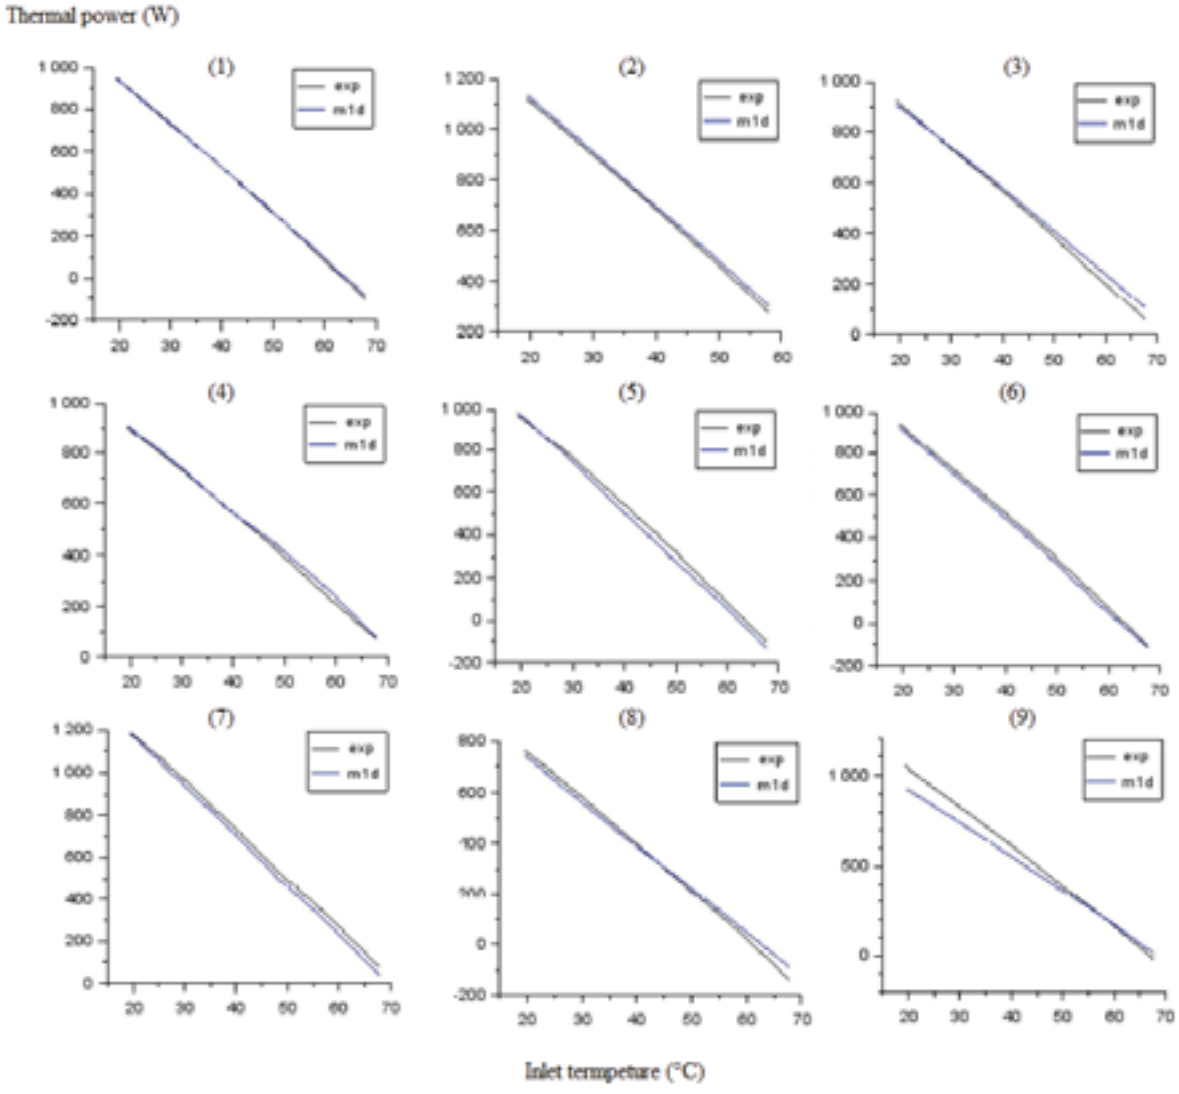

Fig. 5: Experimental and theorical thermal performance curves for the 9 prototypes

5. Conclusion

In this study, a general simplified model (1D) of PV/T module was proposed leading to an exponential equation for output temperature when weather and input fluid characteristics are known.

To challenge this model, the layers properties have been changed in 9 prototypes. The electrical and thermal performances of these 9 prototypes has been experimentally monitored with the normative Solar Keymark approach, and then compared with the performance outputs of the model.

The 9 first prototypes performance results have a good fit with the 1D model. These encouraging results must be confirmed with further tests with a polymeric heat exchanger.

Abstract

One way to reduce solar collector's production costs is to use concentrators that increase the output per photovoltaic cell. Concentrating collectors re-direct solar radiation that passes through an aperture into an absorber. The current study evaluates electrical performance of symmetric C-PVT solar collectors with a vertical bifacial receiver, through a numerical ray tracing model software, Tonatiuh. Several designs have been analysed, such as the Pure Parabola (PP) and MaReCo CPC geometries, both symmetric. Parameters such as concentration factor, electrical performance, transversal and longitudinal IAM (Incidence Angle Modifier), the influence of optical elements and influence of the length of the reflector in the shadow effect have been studied for different geometries. The simulations were performed for Mogadishu, Somalia and showed good results for the Pure Parabola collector (PPc) annual received energy, 379 and 317 kWh/m^2/year for a focal length of 15 e 30 mm, respectively. A symmetrical double MaReCo CPC collector has been simulated with the annual received energy of 315 kWh/m^2/year. The addition of the optical elements will decrease the annual received energy of the PPc by around 11.5%, where the optical properties (7.1%) and glass (4.1%) have the biggest impact in the annual received energy. Overall, symmetric geometries proved to be the most suitable geometries for low latitudes applications, being the geometry *f1* (focal length of 15 mm) the best one.

Keywords: Symmetric C-PVT, Pure Parabola collector, MaReCo CPC geometry, Tonatiuh.

1. Introduction

PVT systems can be based on Compound Parabolic Collector (CPC) (C-PVT) or on flat plate solar thermal collectors (PVT's) [1]. PVT collectors are hybrid solar collectors that simultaneously generate electrical (through PV cells) and thermal energy (through the solar radiation absorbed by the PV cells that is not converted into electricity). Since the efficiency of PV cells is temperature dependent, it is necessary to remove the excess heat. Previous studies showed that for every degree increase in temperature, the PV cell decreases around 0.45% [2]. This leads to a significant efficiency drop since PV cells can reach very high temperatures in summer [3], [4].

In order to carry the excess thermal energy generated by the PV cells, a cooling fluid is used (generally water), which leads to a decrease of the temperature of the solar cells, 'increasing' their overall efficiency. The waste heat harvested by the cooling fluid can be used as a cogenerated product and for heating applications [3]. This study will address different sets of simulations on symmetric low concentrator PVT geometries (with a vertical bifacial receiver), namely Pure Parabola (*f1* and *f2* geometry) and MaReCo CPC. Table 1.1 shows the main characteristics of the simulated reflector geometries, where the concentration factor, reflector height and focal length are shown.

doi:10.18086/swc.2017.18.05 Available at http://proceedings.ises.org

Table 1.1. Geometry characteristics.

		Concentration factor (C_i)	Reflector height (z) [mm]	Focal length (f) [mm]
f1		1.2	75	15
f2		1.7	75	30
MaReCo CPC[1]		1.6	75	30

[1]The MaReCo CPC geometry has an arc circle angle of 20° and a parabolic section with a focal length of 30 mm.

1.1 Concentrator Solar Panels

Solar energy technologies, just like any energy technologies, aim at providing energy at the lowest possible cost. This can be reached by increasing the efficiency or decreasing the investment cost. Concentrating collectors re-direct solar radiation that passes through an aperture into the receiver or absorber. These type of systems usually have a tracking system in order to maximize the energy yield [5]. Concentrating collectors are normally categorized on the field technology used, high or low concentration. The low concentration is categorized in three different categories such as (i) Booster reflector; (ii) Compound Parabolic Concentrator; (iii) Luminescent Concentrator. The high concentration technologies currently available are (i) parabolic trough collector; (ii) Linear Fresnel reflector; (iii) Central receiver (Tower); (iv) Parabolic Dish [6]-[8].

1.2 Compound Parabolic Collectors

CPC (Compound Parabolic Collectors) are non-imaging concentrators that do not require tracking system due to the ability to reflect all available beam radiation to the receiver. The incidence angle for these concentrators makes them very attractive from the point of view of system simplicity, flexibility and cost-effectiveness [9]. CPCs combine two parabolic reflectors (symmetric or asymmetric), each one of them with its own focus length (F, the focus of the right-hand parabola in Figure 1.1) at the lower edge of the other parabola [10], shown in Figure 1.1. The angle between the axis of the collector and the line connecting the focus of one of the parabolas with the opposite edge of the aperture is called acceptance half-angle (θ_c) [14].

The relationship between the size of the aperture (2a), the size of the receiver (2a') and the acceptance half-angle is expressed through the following Equation 1.1 [10]:

$$2a' = 2a \sin\theta_c \qquad \text{(eq. 1.1)}$$

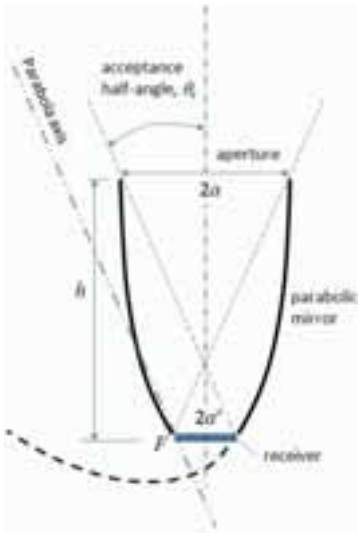

Figure 1.1. Cross section of a symmetrical non-truncated CPC [10].

Knowing the concentration ratio is possible to obtain the relationship between the concentration ratio and the acceptance angle [10]:

$$C_i = \frac{2a}{2a'} = \frac{1}{\sin\theta_c} \qquad \text{(eq. 1.2)}$$

Other useful equations that describe the design of CPC concentrators are shown below. The following equations relate the focal distance of the side parabola to the acceptance half-angle (θ_c), receiver size, and height of the collector (h) [10]:

$$f = a'(1 + \sin\theta_c) \qquad \text{(eq. 1.3)}$$

$$h = \frac{f\cos\theta_c}{\sin^2\theta_c} \qquad \text{(eq. 1.4)}$$

These types of concentrators are made for each ray with an angle θ that comes into the CPC aperture with an angle smaller than θ_c to be reflected to the receiver at the base of the collector. The ray will be reflected back to the atmosphere, if the angle θ is greater than θ_c, as shown in Figure 1.2 [10].

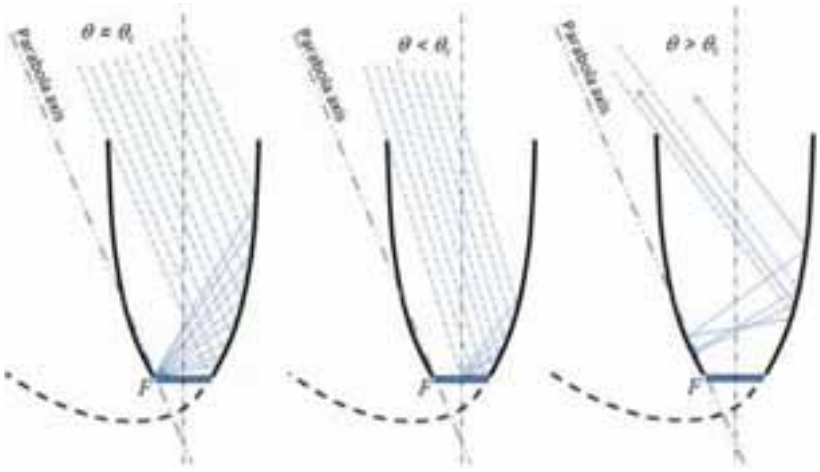

Figure 1.2. Reflection of the light rays directed to the CPC concentrator, at different angles [10].

1.3 Concentration with parabolic reflector

Different reflector geometries (symmetric) have been simulated in a ray tracing software, Tonatiuh. The simulated geometries are composed of either a full parabolic section or an arc circle with a parabolic section, thus, the importance of analysing the geometrical shape of these reflectors. For each point of the parabola, the distance between DR and RF is the same. Figure 1.3 shows the distance (VF) between the vertex and the focus of the parabola, known as focal length (*f*). The parabola axis intercepts the directrix and the focus, dividing the parabola into two symmetrical parts.

The following Equation 1.5 allows the calculation of the half aperture (x) in function of the reflector height (z) and the focal length (f) [4], [13].

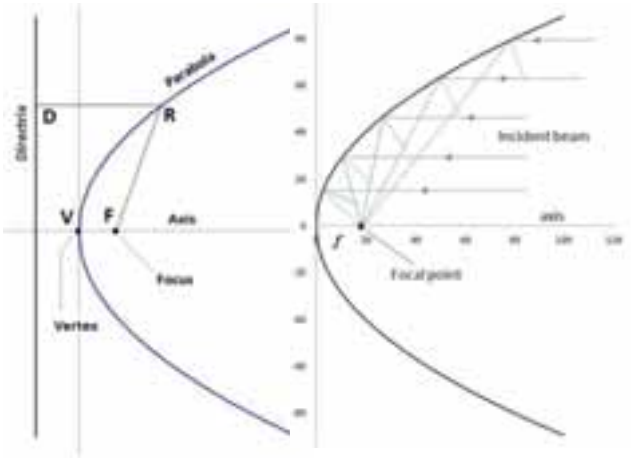

Figure 1.3. Parabola's geometry shape (left) and parallel incident beam rays (right) [11].

$$x = \sqrt{f \times 4 \times z} \qquad \text{(eq. 1.5)}$$

All incoming light rays parallel to the axis of the parabola will be reflected the focus area, by definition of the focal point of the parabola. The ideal location of the receiver can be given as the focal point position, assuming that the light rays that arrive at the reflector surface are essentially parallel light rays, as shown previously in Figure 1.3.

2. Methods

A thorough literature review in the field on reflector geometries and PVT technologies was carried out. Several sets of ray tracing simulations have been performed and posteriorly analyzed in Matlab. Below a short description of the procedure is presented.

- Literature review on symmetric and asymmetric reflector geometries and PVT technologies.
- Based on the literature review, two symmetric reflector geometries, Pure Parabola (PP) and MaReCo CPC geometries with a vertical bifacial receiver were selected:
  - Pure Parabola *f1* [focal length of 15 mm].
  - Pure Parabola *f2* [focal length of 30 mm].
  - MaReCo CPC [arc angle: 20°; focal length of 30 mm].
- Ray tracing simulations were performed for Mogadishu, Somalia (Latitude 2.04°, Longitude 45.31°) using a ray tracing software called Tonatiuh. The goal was to obtain the concentration factor, annual energy output, IAM (both transversal and longitudinal), the influence of optical elements (geometry *f2*), shadow effect (geometry *f1* and *f2*) and non-electrical area of the receiver.
- Analysis of the results was performed in a multi-paradigm numerical computing environment software, called Matlab.
- A comparison between the different geometries was established.

The ray tracing simulations were set for a location near the equator (low latitudes), Mogadishu, Somalia (Latitude 2.04°, Longitude 45.31°) in order to study different geometries that work at these latitudes. No meteorological files or historical years were used during the simulations.

2.1 Tonatiuh

For the analysis and design of solar concentrating systems, a Monte Carlo ray tracer software was used. Principles of geometrical optics are used as a statistical method to get a complete and statistically analysis of an optical system, studying the route of a ray of light as it passes through the optical system. It creates an accurate and easy use of Monte Carlo ray tracer, simplifying the optical simulation of almost any type of solar reflector system. The rays are generated in a light source that simulates the sun and then these ray's intersections with system surfaces are calculated. The sunlight is defined by the sun position, i.e. the elevation and the azimuth. These two parameters can also be calculated as a function of the day, the hour, the latitude and the longitude. In order to simulate an entire year, the program has the possibility to input a script for parametrical simulations allowing to launch several simulations by means of a few loops in a script file that was created in Matlab (a multi-paradigm numerical computing environment software). After the simulations, the data is exported to Matlab in order to analyze the data.
The optical properties of the different collector elements were considered non-ideal (losses were taken into account), that is, the different characteristics of the materials, such as reflector reflectivity (92%), glass and gable transmittance (96% and 90%, respectively) were introduced in the software. Each simulation had 10 000 rays and the direct irradiation set as 1 000 W/m².

2.2 Software and simulation limitations

Regarding the software used for the sets of simulations, some limitations were found while the simulations were being performed, such as:

- Tonatiuh simulates the rotation of the 'sun' around the collector as 360° in longitudinal and transversal directions over a day. This meant that is needed to set the sunrise and sunset to 6 am to 6 pm, respectively in order not to have night output. The sunset and sunrise differ from day to day around 30 minutes throughout the year in Mogadishu. Tonatiuh can only store 24 cells (corresponding to 24 hours per day), therefore it was necessary to select by hours, leading to a slight inaccuracy. The error is not relevant since the annual received energy at low angles is significantly lower.
- No meteorological data has been inserted in the ray tracing simulation tool.
- The software does not take into account the cooling factor of solar cells from the working fluid (PV cell temperature dependence).
- PVT system losses and cell efficiency are not taken into account in Tonatiuh.

2.3 Reflector shape selection

Regarding the Pure Parabola geometries, each set of simulations, the reflector height (z) was fixed at 75 mm and the focus length (f) varied between 15 and 30 mm. After the first set of simulations (with a focal length of 15 mm and reflector height of 75 mm), the focus length was increased to 30 mm and fixed (being the reflector height constant during the whole simulation). This procedure was made for reflector height of 75 mm, and for a focal length of 15 and 30 mm [12]. The simulations were performed for Mogadishu, Somalia (Latitude 2.04°, Longitude 45.31°). The geometry (*f1*) is composed of a focal length (f) of 15 mm, reflector height (z) of 75 mm and a low concentration factor (C_i= 1.2). The additional geometry (*f2*) has a C_i= 1.7, f = 30 mm and z = 75 mm.

In order to get a good perspective of how the PPg (Pure Parabola geometry) performs, a different geometry has been simulated. The simulation was performed for a symmetrical MaReCo CPC with a concentration factor of 1.6, an arc circle angle of 20° and a reflector height of 75 mm. The focal length of the parabola section and the reflector height were set in line with the *f2* geometry. Figure 2.1 shows a symmetrical MaReCo CPC geometry based on the MaReCo geometry. The receiver dimensions were set to fit this geometry (QQ'). The section of the concentrator between P_O and P'_O (red section in Figure 2.1) is an arc of a circle centred on Q. Section $A'P'_O$ and AP_O (green section in Figure 2.1) is a parabola with focus at Q and axis QP'_O. θ_i is the half-acceptance angle and θ_c is the arc circle angle.

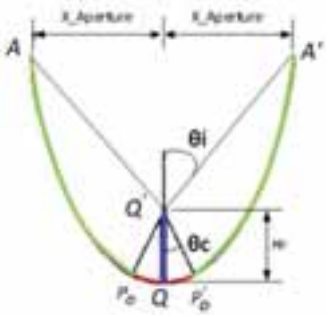

Figure 2.1. The optimum symmetrical MaReCo CPC.

2.4 IAM

The Incidence Angle Modifier (IAM) is the variance in output performance of a solar collector as the angle of the sun changes in relation to the surface of the collector. The longitudinal and transversal IAM can be obtained through the overall and optical efficiency, and aperture area (Apt_{area}). These values were collected from a Matlab script. The aperture area for receiver side is given by the following Equation 2.1.

$$\mathrm{Apt_{area}} = \left(\sqrt{z \times 4 \times f} - \frac{\mathrm{thickness_{receiver}}}{2}\right) \times \mathrm{Length_{receiver}} \qquad \text{(eq. 2.1)}$$

The aperture area allows the calculation of the overall efficiency of the collector [4].

$$\mathrm{Eff}(\theta_i) = \frac{\mathrm{Power}\ (\theta_i)\ [\mathrm{W}]}{\mathrm{I_a}\ [\mathrm{W/m^2}] \times Apt_{area}\ [\mathrm{m^2}]} \qquad \text{(eq. 2.2)}$$

Where the Power (θ_i) is given by Tonatiuh and I_a is the solar irradiance that passes through the collector aperture, with a value of 1 000 [W/m²].

The optical efficiency (η_{opt}) is given by the maximum value of Equation 2.3.

$$\eta_{opt} = \max(\mathrm{Eff}(\theta_i)) \qquad \text{(eq. 2.3)}$$

With all the parameters obtained, the transversal and longitudinal IAM is obtained using Equation 2.4.

$$\mathrm{IAM}(\theta_i) = \frac{\mathrm{Eff}\ (\theta_i)}{\cos(\theta_i) \times \eta_{opt}} \qquad \text{(eq. 2.4)}$$

Where θ_i are the angles [-90°, -89°, -88°, -87°, -86°, 85°, .. 0 .. , 85°, 86°, 87°, 88°, 89°, 90°]. The interval between angles was set in order to achieve a more accurate data.

2.5 Influence of the optical elements

In order to get a more precise knowledge of how the different elements affect the annual received energy of these kind of collectors, the influence of the optical elements such as (i) frame; (ii) glass; (iii) gables; (iv) receiver thickness; (v) optical properties were studied. The simulations consisted by adding the different elements to geometry *f2* and visualize their influence in the annual received energy.

2.6 Shadow effect

The effect of the shadow in the annual received energy was studied, by increasing the reflector length. Consisted by adding progressively length to the reflector, in order to reduce the shadow on the receiver. The receiver length was set as constant and the reflector area was gradually increased by 0.02, 0.04 and 0.06 m^2.

2.7 Electrical non-active area

The electrical non-active area gives the percentage of receiver area that does not produce electricity. In order to improve the performance of the collector, it is necessary to improve the performance of the receiver, by reducing the electrical non-active area. A study has been conducted in order to find the electrical non-active area of the selected receiver. The electrical non-active area was removed and after the annual received energy has been updated.

3. Results

3.1 Maximum efficiency and yearly energy output

This section presents the main results for an annual receive energy and a 3D view of the maximum efficiency at each angle. The vertical bifacial receiver is composed of side A (receiver side facing north) and side B (receiver side facing south).

3.1.1 Pure Parabola f1 collector

From the ray-tracing software, it was possible to extract the data to a Matlab script and run it, in order to get the annual received energy from both receivers A and B. This geometry receives an annual received energy of 2 186 kWh/m^2/year. The presented value is obtained by using a scale factor of 3.2, due to the fact that the simulated collector has 0.31 m^2.

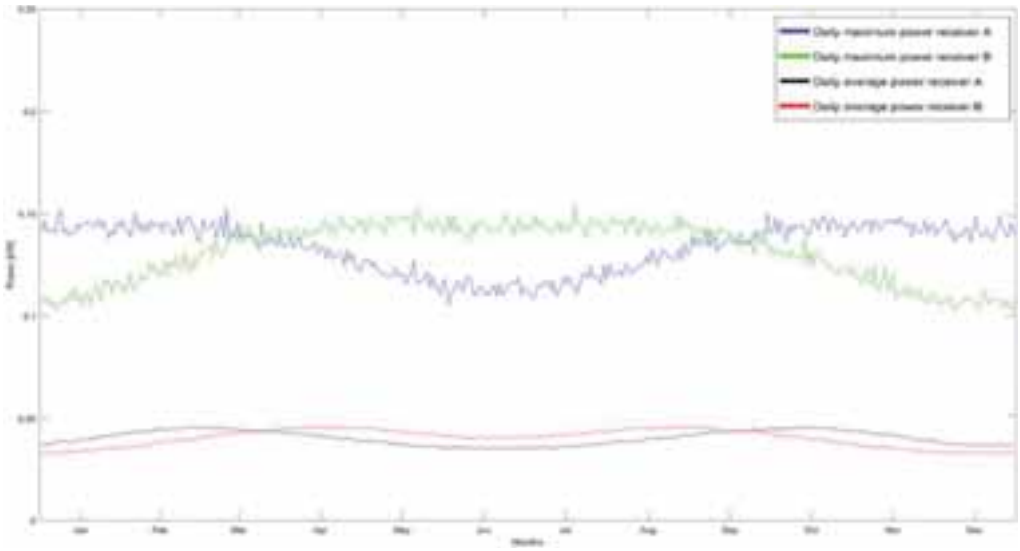

Figure 3.1. Daily maximum and average power output for the *f1* collector.

The receiver B will have higher annual received energy during the months of March-September, due to the fact that the sun will be on the north side of the collector. On the remaining months, the receiver A will have a higher annual received energy from September-March, when the sun is on the south side of the collector.

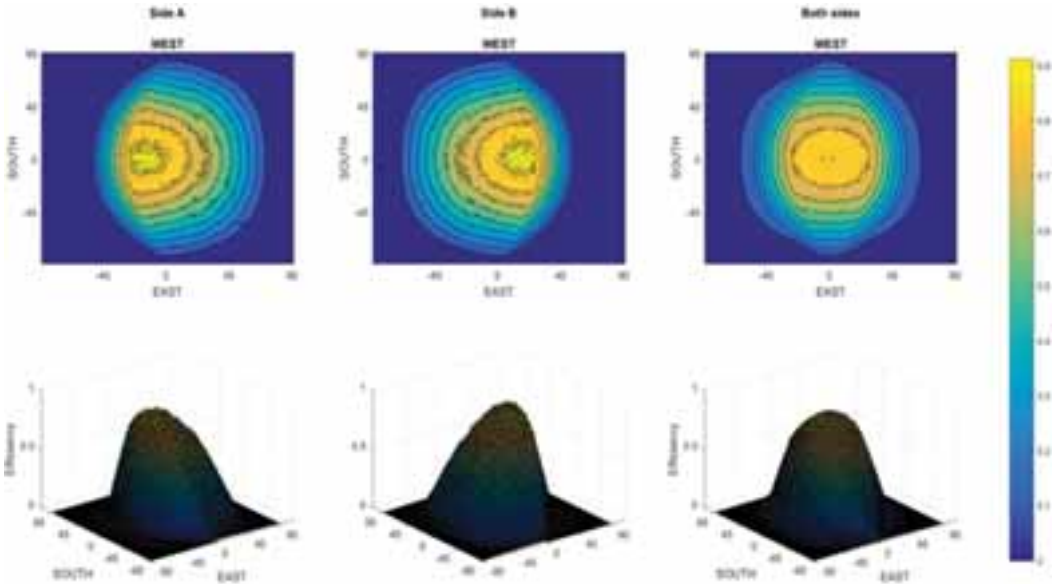

Figure 3.2. 3D view of the maximum efficiency at each angle (transversal and longitudinal) for the *f1* collector.

The distribution of the solar radiation is more evenly distributed across both receivers since they produce around the same. The maximum efficiency value is slightly above 90%. The collector performance (daily average power) throughout the year is in line with the average seasonal variation of the daily extra-terrestrial solar radiation for horizontal surfaces at low latitudes.

3.1.2 Pure Parabola f2 collector

This geometry receives an annual received energy of 1 831 kWh/m^2/year, with a scale factor of 2.3, for a simulated collector area of 0.44 m^2. Due to its concentration factor (bigger aperture), this geometry does not have the same properties as the one described above, since it has a different capacity to reflect the rays with the same accuracy as the geometry presented previously (*f1* geometry).

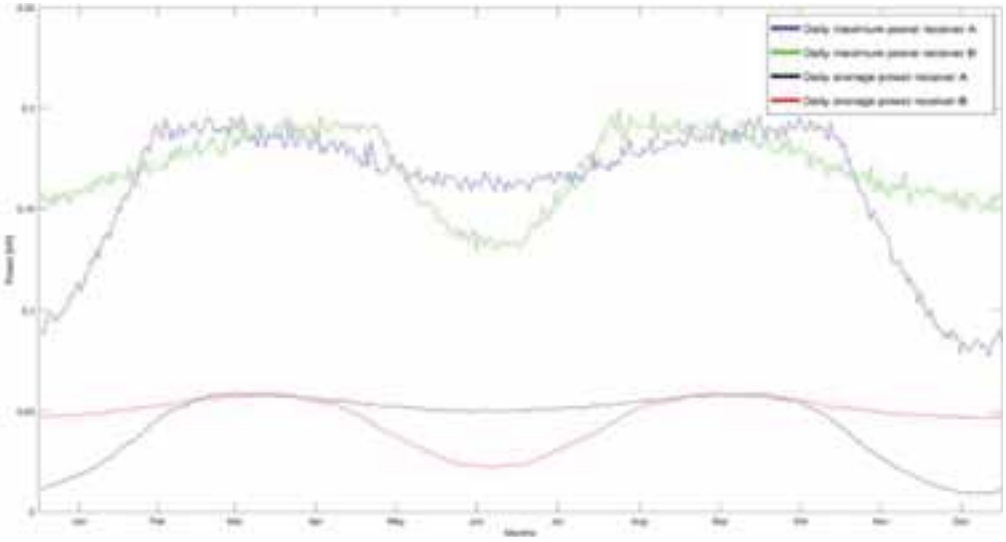

Figure 3.3. Daily maximum and average power output for the *f2* collector.

The receiver B has a higher annual received energy during the months of November-February, March-May and July-September, due to the fact that the sun is on the north side of the collector. On the other hand, the receiver A has a higher annual received energy during the months of February-March, May-July and September-November when the sun is on the south side of the collector.

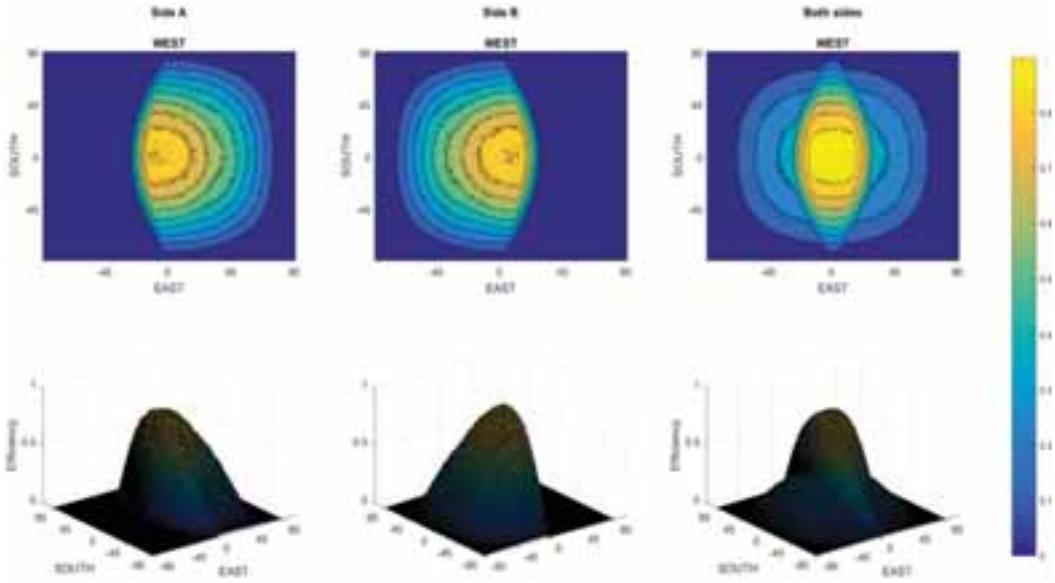

Figure 3.4. 3D view of the maximum efficiency at each angle (transversal and longitudinal) for the *f2* collector.

The maximum efficiency value is slightly below 90%. As *f1* geometry, this collector performance (daily average power) throughout the year is in line with the average seasonal variation of the daily extra-terrestrial solar radiation for horizontal surfaces at low latitudes.

3.1.3 MaReCo CPC geometry

A value of 1 819 kWh/m^2/year was obtained for this reflector shape, by using a scale factor of 2.4, due to the fact that the simulated collector has 0.42 m^2.

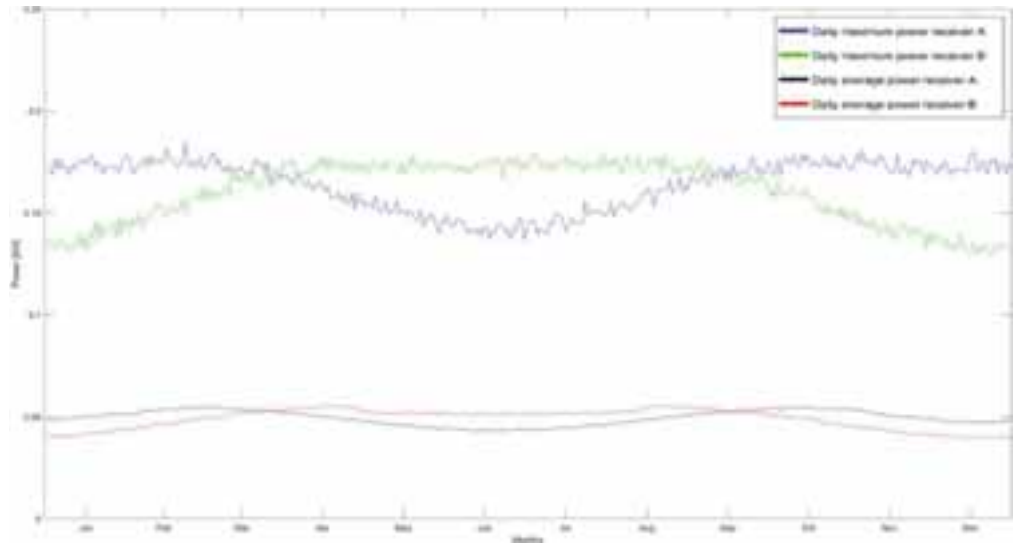

Figure 3.5. Daily maximum and average power output for the MaReCo CPC geometry.

The receiver B will have higher annual received energy during the months of March-September, due to the fact that the sun will be on the north side of the collector. On the remaining months, the receiver A will have a higher annual received energy from September-March, when the sun is on the south side of the collector.

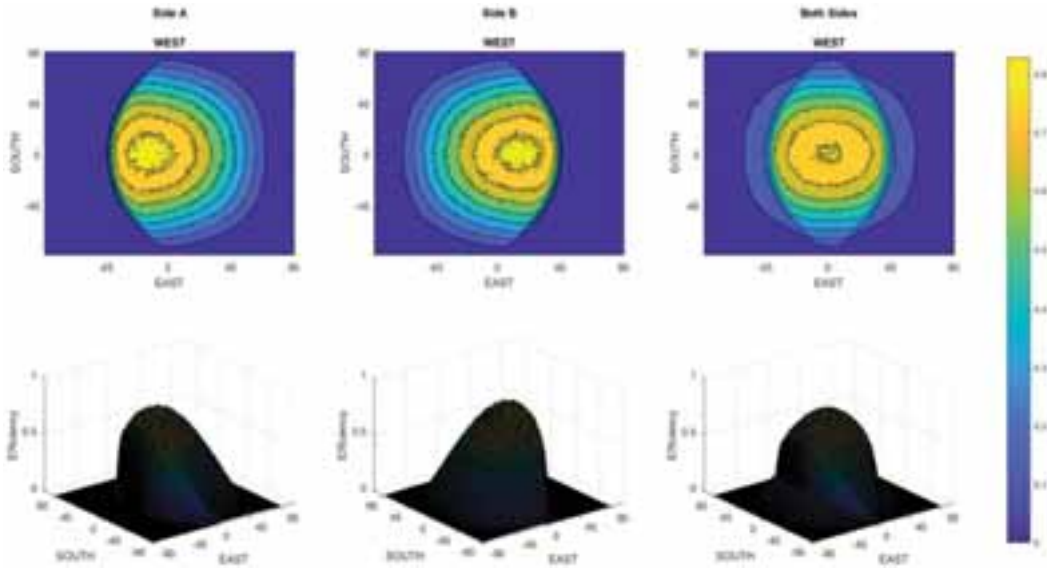

Figure 3.6. 3D view of the maximum efficiency at each angle (transversal and longitudinal) for the MaReCo CPC geometry.

Despite having a similar annual received energy as geometry *f2*, the maximum efficiency range of this geometry is bigger than in geometry *f2,* with a value slightly above 80%.

3.2 IAM

3.2.1 Pure Parabola f1 collector

Figure 3.7 shows the normalized maximum efficiency working range for the PPc *f1*, around [-30°S, 30°N].

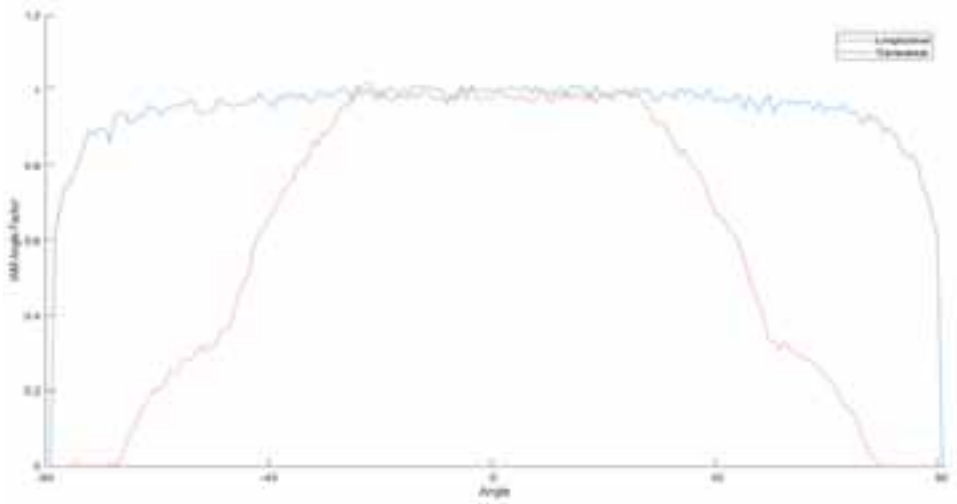

Figure 3.7. IAM transversal and longitudinal for both receiver sides, *f1* collector.

This geometry has the ability to re-direct efficiently the sun rays towards the receiver, due to the fact that the angles θ that comes into the CPC aperture with an angle smaller than θ_c (acceptance half-angle) will be reflected more efficiently into the receiver.

3.2.2 Pure Parabola f2 collector

Figure 3.8 shows the normalized maximum efficiency working range for the PPc *f2*, around [-15°S, 15°N].

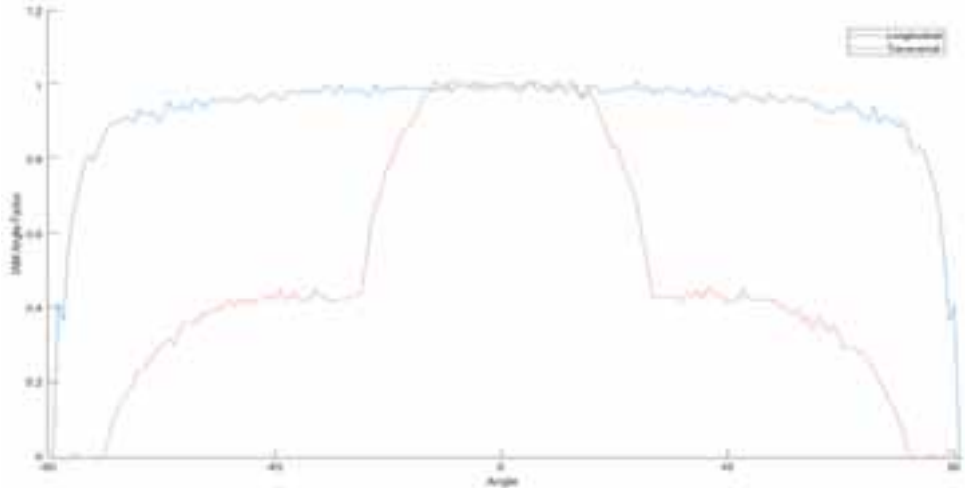

Figure 3.8. IAM transversal and longitudinal for both receiver sides, *f2* collector.

Comparing geometry *f2* with *f1*, it is possible to verify that at some angles, geometry *f2* has no ability to re-direct the incident rays to the receiver efficiently (steeper curve from [-30°S, -15°N] and [15°S, 30°N]), since the angle θ is bigger (for a longer period than for geometry *f1*) than θ_c, thus lowering the maximum efficiency range. A narrower maximum efficiency range and lower maximum efficiency led to a lower annual received energy when compared with geometry *f1*.

3.2.3 MaReCo CPC collector

Figure 3.9 shows the normalized maximum efficiency working range for the symmetrical MaReCo CPC collector, around [-40°S, 40°N].

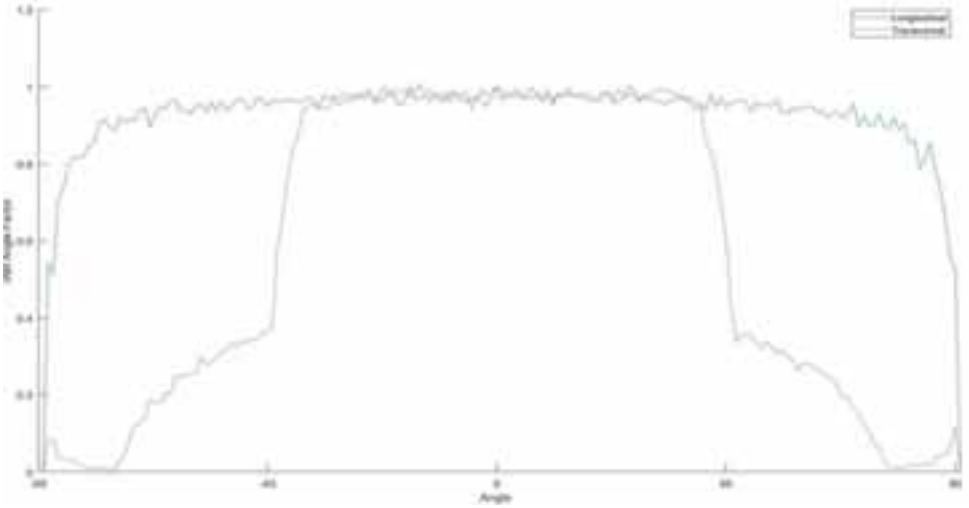

Figure 3.9. IAM transversal and longitudinal for both receiver sides, MaReCo CPC geometry.

The lower maximum efficiency value of this geometry is compensated by a wider maximum efficiency working range, when compared with geometry *f2*.

3.3 Influence of the optical elements in geometry f2

The PPg corresponds to the PPc without a frame, gable, glass, optical properties and a 2 mm receiver thickness.

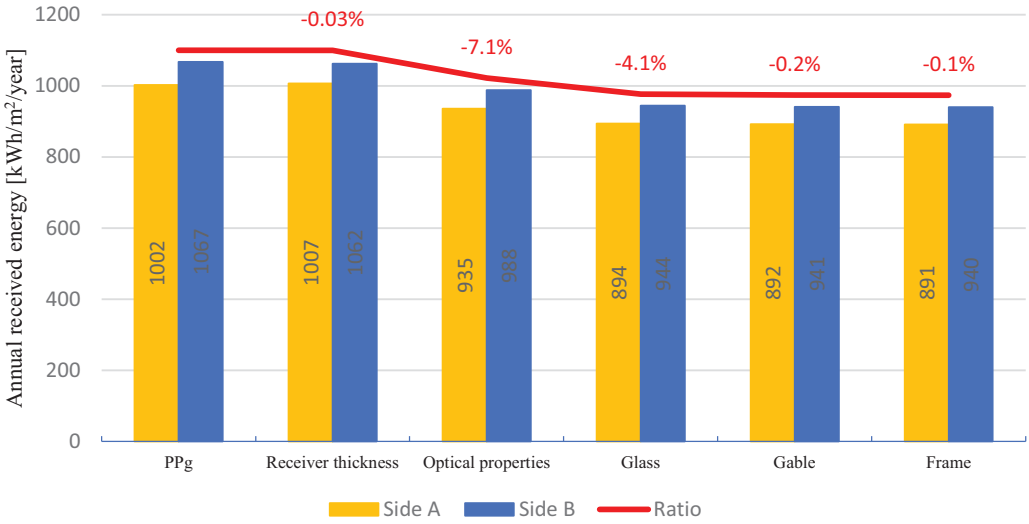

Figure 3.10. Results of the influence of the optical elements and properties in the geometry *f2*.

Figure 3.10 shows that the optical properties and glass have the biggest impact on the electrical performance of the collector. On the other hand the receiver thickness, gable and frame almost have no influence in the results, accounting for 0.3%. Overall, the difference between the geometry and the collector is around 11.5%. The energy production ratio between receiver sides decreases with the influence of the optical properties of the materials. Since the value of reflectivity was considered constant (normal to the collector) regardless the suns' altitude, the influence of the glass is lower. It is expected that the glass will have a bigger influence if this parameter is taken into account.

3.4 Shadow effect (Pure Parabola f1 collector)

Electricity costs were set as 0.211 €/kWh for households [12] and the reflector price was taken from a standard reflector with reflectivity of 98%. Table 3.1 shows the payback time for an increased reflector length.

Table 3.1. Payback time for an increased reflector length, geometry *f1*.

Additional area [m²]	Additional reflector price [€]	Production surplus [kWh/m²]	Payback [years]
+ 0.02	0.7	18	9.2
+ 0.04	1.5	20	8.9
+ 0.06	2.2	22	7.9

The payback time goes from 7.9 up to 9.2 years to start to pay off (breakeven point), showing that is not effective since the payback time is too big for such a small area. The presented values show that a longer reflector reduces the shadow effect, increasing the annual received energy.

3.5 Electrical non-active area

The electrical non-active area accounts for 12.1 % and the cell efficiency for 19.7%. The updated values for each collector are given in the following Table 3.2.

Table 3.2. Updated annual received energy per collector.

Annual received energy [kWh/m²/year]		
	Tonatiuh	**Updated**
PP *f1*	2 186	379
PP *f2*	1 831	317
MaReCo CPC	1 819	315

4. Discussion

As expected, the *f1* geometry has a wider transversal maximum efficiency working range as a result of its narrow aperture, when compared with *f2* geometry. This geometry has the ability to re-direct more efficiently the sun rays towards the receiver. The transversal maximum efficiency working range of the PPc is around [-30°, 30°] and [-15°, 15°] for a focal length of 15 and 30 mm, respectively. On the other hand, the MaReCo CPC collector has a maximum efficiency working range around [-40°S, 40°N].

The values for the annual received energy are, as expected, higher for the *f1* collector (2 186 kWh/m^2/year) than for the *f2* collector (1 831 kWh/m^2/year), especially as a result of its geometrical characteristics (lower concentration factor). Regarding the symmetric MaReCo CPC collector, the results show that this geometry has a slightly lower annual received energy than the *f2* geometry. It was expected that this geometry would perform better than the *f2* geometry, due to its lower concentration factor (fewer reflection losses). The MaReCo CPC collector has an annual received energy around 1 819 kWh/m^2/year. Lower concentration means higher annual received energy, due to lower reflection losses.

Figure 3.10 shows that the glass and the optical properties have the biggest impact in the annual received energy of the *f2* collector. The annual received energy for the symmetrical geometries can go up to 11.5%, showing that the optical properties of the different elements affect significantly the performance of these geometries.

Table 3.2 shows the annual received energy, considering a non-electrical area of 12.1% and a cell efficiency of 19.7%. The addition of these parameter led to an annual received energy of 379, 317 and 315 kWh/m^2/year for the collector *f1*, *f2* and MaReCo CPC, respectively.

Regarding the shadow effect, it is possible to acknowledge that increasing the reflector length is not effective, not only because at low angles (sunrise and sunset) the reflected sun rays will be reflected back to the atmosphere (the receiver is not long enough to collect the sun rays), but also due to the fact that the payback time for such small area can go from 8 to 9 years for such small area.

Overall, the simulated geometries showed potential for low latitudes applications, being the geometry *f1* the best one. A way to validate the simulations would be the construction of a prototype and to perform CFD simulations in order to study the thermal potential of a C-PVT with these geometries.

Abstract

The advantage of this laboratory optical characterization is to reproduce under controlled conditions an existing solar plant of Fresnel mirror type. The plant has 20 identical plane mirrors that concentrate the sunlight toward the secondary optics, which focuses it on the receiver. The procedure consists in performing the tests separately simulating the illumination of each plane mirror, finally combining the measured results to obtain collection efficiency and concentration factor of the entire solar plant. Two alternative secondary optics, a prismatic lens and a reflective concentrator, were optically tested to compare their behaviour. The total collection efficiency is similar, while the concentration factor is higher for the prismatic lens. Since the receiver is a photovoltaic device, a key aspect to be studied is the uniformity of receiver lighting: the power density measured in the image plane of the secondary optics evidences lateral zones of uneven lighting.

Keywords: secondary optics, Fresnel mirror, optical measurement, solar concentration

1. Analysis of the system

Two secondary concentrators were designed and realized for an actual solar concentration plant based on the principle of the Fresnel mirror [Abbas et al. 2012a, 2012b; El Gharbi et al. 2011; Fernandez-Garcıa et al. 2010; Kalogirou, 2004; Mills and Morrison, 2000; Singh et al. 1999; Winston et al. 2005]. The optical component is illuminated by 20 plane mirrors of equal size (50 mm x 1000 mm) that reflect the solar rays under various angles depending on the sunrays' inclination and on the relative positions of mirror and receiver [Fontani et al. 2015]. The secondary collector should then concentrate the solar light on a rectangular receiver of dimensions 50 mm x 10 mm [Fontani et al. 2015]. The secondary optics is placed as near as possible to the receiver to improve the collection efficiency, reduce the dimensions and avoid undesired shadow effects.

Several optical measurements and tests were effectuated on the implemented secondary concentrators. The tested optical components are a prismatic lens and a reflective concentrator [Abbas et al. 2012a, 2012b; El Gharbi et al. 2011; Fernandez-Garcıa et al. 2010; Kalogirou, 2004; Mills and Morrison, 2000; Singh et al. 1999]. The two elements are quite different because the working principle of the prismatic lens is based on refraction, while the other optics is based on reflection. The purpose of the laboratory tests is to study and characterize the optical properties and behaviour of the secondary optics in order to decide which is more suitable for improving the performance of the system. The two optical systems are compared in terms of collection efficiency and concentration factor, simulating the illumination arriving from the 20 mirrors at noon. In addition some image acquisitions are effectuated on the plane where the receiver will be placed, for a qualitative analysis of the illumination produced by the secondary optics on the receiver.

Tests and measurements are performed separately simulating the illumination of each plane mirror, being impossible to illuminate the samples in laboratory utilising 20 sources from different directions. The next phase is the data elaboration, for which it was chosen to perform the analysis at noon (as representative position, but the mirrors constantly move during the day). At noon the study can consider only 10 mirrors, exploiting the symmetry of the plant, and at noon there should be the maximum output of the solar plant. Hence it is interesting to compare the secondary optics behaviour in this particular moment of the day.

Angular aperture and incidence angle of the beam are the main factors that influence the collection efficiency of the secondary concentrator [Fontani et al. 2015]. Referring to Fig. 1, for the i-th mirror, the relevant parameters

doi:10.18086/swc.2017.18.06 Available at http://proceedings.ises.org

are:

- d: distance between mirrors line and receiver input (1000 mm).
- x_i: mirror position relative to the origin (fixed at the junction between the receiver normal passing through its centre and the mirrors line); measured positive to the right and negative to the left.
- D_i: distance between receiver centre and mirror centre.
- $\theta(t)$: sunlight incidence angle; measured from the normal to the mirrors line.
- $i_i(t)$: incidence angle of sunlight on the mirror; measured from the normal to the mirror.
- $\beta_i(t)$: tilt of the mirror; measured relative to the mirrors line.
- α_i: angle of the reflected beam; measured from the line of the mirrors.
- α'_i: incidence angle of the beam reflected on the receiver.

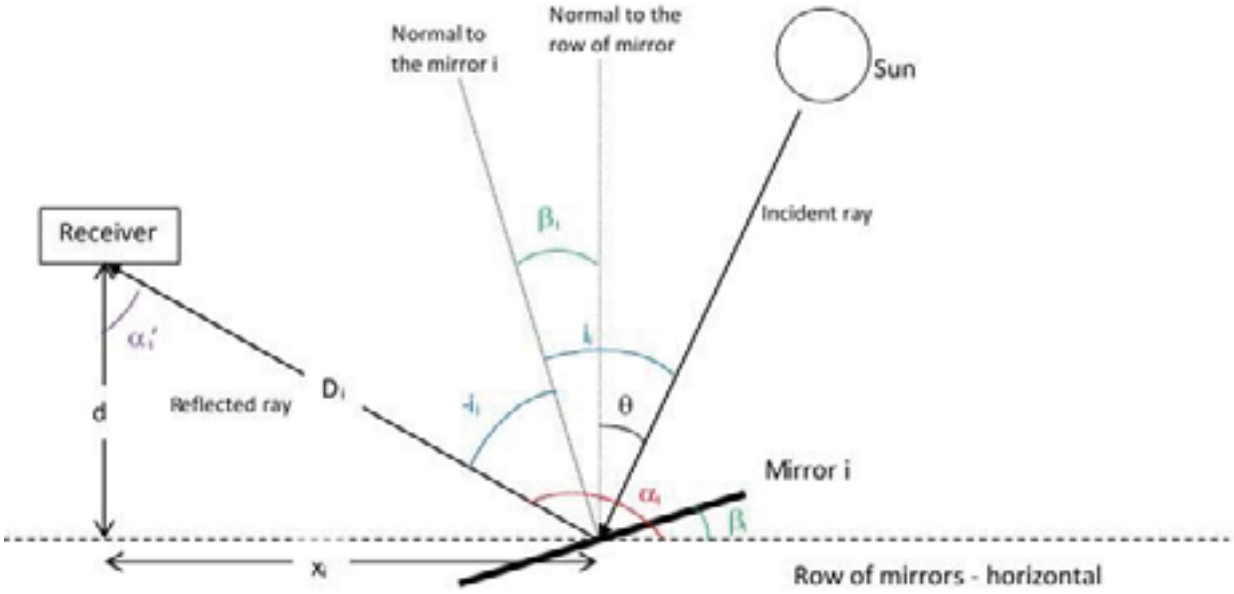

Fig. 1 – How the sunray is reflected by the primary system.

The sign of the angles is positive measuring counter-clockwise and negative measuring them clockwise.

For a given mirror, the angles i, β_i and θ are time dependent, while α_i must be constant to direct the beam toward the receiver. Referring to Fig. 1, the angles $i_i(t)$, $\theta(t)$, $\beta_i(t)$ and α_i are linked by 4 equations; so knowing α'_i (from the system geometry) and $\theta(t)$ (from the time of the day) α_i, $i_i(t)$, $\beta_i(t)$ can be derived [Fontani et al. 2015].

The collection efficiency of the receiver depends on how it is illuminated. For a single mirror the collection efficiency is defined as:

$$\eta_i\left(\alpha'_i, A_{eff,i}\right) = \frac{P_{out,i}(t)}{P_{in,i}(t)} \quad (1)$$

where $P_{out,i}(t)$ is the output power exiting from the receiver, and $P_{in,i}(t)$ the input power; α'_i is the entrance angle and $A_{eff,i}$ is the effective area of the beam entering into it. The input power is given by

$$P_{in,i}(t) = \bar{p}_i(t) \cdot A_{eff,i}(t) \quad (2)$$

where $\bar{p}_i(t)$ is the average power density of the beam at the receiver input.

The total collection efficiency (considering the contributions of all the mirrors) is

$$\eta = \frac{\sum_{i=1}^{20} P_{out,i}(t)}{\sum_{i=1}^{20} P_{in,i}(t)} \quad (3)$$

The concentration factor C_i for the i-th mirror is defined as:

$$C_i = \eta_i \frac{A_{in}^R}{A_{out}^R} \quad (4)$$

where A_{in}^{R} and A_{out}^{R} are respectively the physical area of receiver input and of receiver output.

Finally the total concentration factor C is given by:

$$C = \eta \frac{A_{in}^{R}}{A_{out}^{R}} \quad (5)$$

2. Measurement setup and procedure

The optical measurements are performed in a laboratory setup based on a solar divergence collimator, which produces a beam with solar divergence [Fontani et al. 2013]. Source, test sample and sensor are the principal components of the measurement system employed to optically characterize the samples of secondary collector. The scheme of the measurement set-up is reported in Fig. 2, with the pictures of the actual components as they are mounted on the optical table in laboratory.

The white beam emitted by the illuminator is angularly homogenized in the integrating sphere and comes out from the exit aperture of the sphere. Then the light is reflected by the collimation mirror, which generates a solar divergence beam. Suitable screens, to obtain a beam with dimensions adapted to illuminate the sample under test, finally cut this beam. The combination of the size of the sphere aperture with the focal length of the spherical mirror (collimation mirror) produces a uniform beam with solar divergence [Fontani et al. 2013].

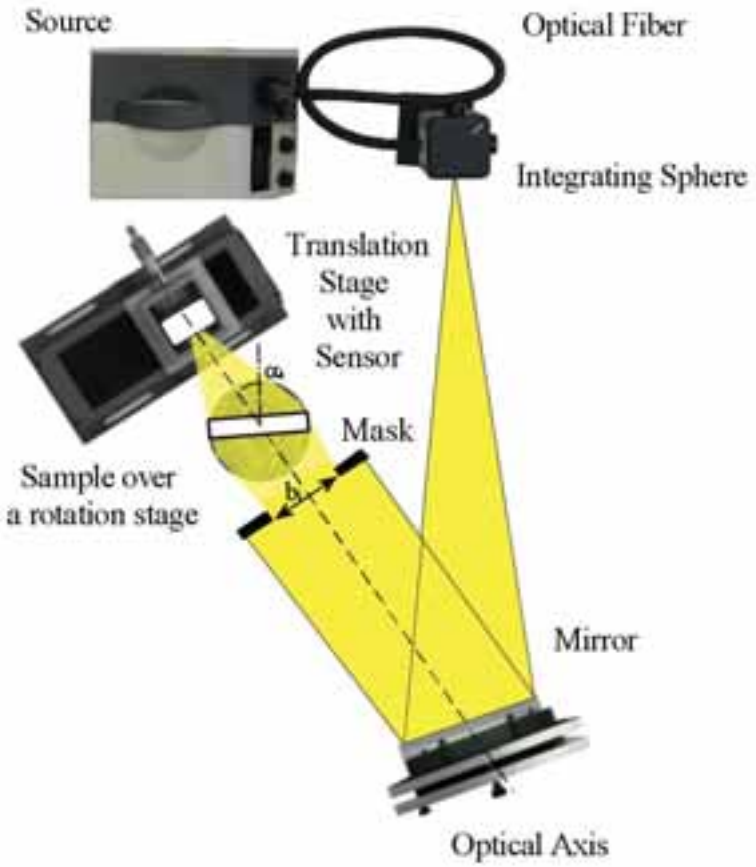

Fig. 2 – The optical system to test the secondary collectors.

The two secondary collectors examined are a prismatic lens and a reflective concentrator, specifically designed for the solar collection system of Fresnel mirror type.

The optical tests are executed with a reproducible procedure, identical for the two types of secondary optics. The final aim of this procedure of sample alignment and displacements is to reproduce the working conditions at noon

of the actual solar plant for which the secondary optics was developed.

Each examined sample is placed on a platform allowing rotation and translation with elevated precision and stability. The rotator has sensitivity of 0.025° and it permits to vary the incidence angle of the beam coming from the mirror. The micrometric translator allows to correct for the small difference between the rotation axis and the entrance of the secondary optics, so that the latter is always at the centre of the beam.

The acquisitions are of two types: photodiode measurements to obtain the collection efficiency or image acquisitions with a CMOS camera to know the light distribution in the image plane. The photodiode scan is a quantitative assessment, while the CMOS camera acquisition gives only qualitative information.

The main sensor is a photodiode with squared sensitive area of sizes 1 mm x 1 mm. The detector is mounted on a micrometric XY translating system, which allows to perform two-dimensional scans in a vertical plane (perpendicular to the optical axis, indicated in Fig. 2). Typically the examined vertical plane is the image plane of the secondary optics, where the optical design foresees that the collector creates its image. For these concentrators the photovoltaic (PV) receiver is placed in this plane and obviously the region of interest corresponds to the area of the receiver. The photodiode is connected to an amplifier, and the total amount of focused light, obtained by photodiode measurements, is used to calculate collection efficiency and concentration factor.

In addition to the photodiode scans, some image acquisitions are performed using a CMOS camera to know the light distribution in the image plane examined by the photodiode scans. The CMOS camera has sensitive area of size 7.74 mm x 10.51 mm. The camera is displaced with the same translation system used with the photodiode. The purpose is to assess the power density of the light focused on the receiver plane. This measurement gives information about uniformity of receiver illumination, which is a key parameter for obtaining the maximum conversion by the PV receiver.

A devoted LabVIEW program manages scansion and elaboration of measured signals for both sensors, allowing to select area and pitch of the scan. The mapping of the region of interest is automatically handled by this LabVIEW program that provides to move the shifters and to acquire the signal of the used sensor.

For the collection efficiency assessment with photodiode the procedure steps are listed below.

1) For a given time *t* the mirrors inclinations β_i for $\theta(t) = 0$ are known, consequently are obtained the angles α'_i of beam incidence on the receiver (10 in total, the other 10 correspond to $-\alpha'_i$), and the beam limiter widths.

2) Firstly a reference measurement is executed: the photodiode axis is aligned with the direction of the incident beam. It is performed a mapping of the beam incident on the receiver. The scanning is made on a plane perpendicular to the beam direction without the secondary optics.

3) The secondary optics is mounted, it is rotated up to the angle α'_i and the limiter opening is regulated.

4) Placing the photodiode in the measurement plane, the illuminated area is scanned to obtain a map, aligning the scan plane with the hypothetical plane of the PV cell. For the reflection concentrator, the detector is placed in the vicinity of the exit aperture. For the lenses, the detector is placed on the working plane, 50 mm from the rear surface of the lens. The shifters are moved with steps of 1 mm x 1 mm, in this way a direct and complete mapping of the image, with resolution limited by the detector size, is obtained.

5) steps 3) and 4) of the measurement procedure are repeated for all α'_i.

For the acquisition of images with CMOS camera the procedure is identical to the previous one, with the exclusion of the reference measurement, which is not needed in this type of acquisition since it is not a quantitative measurement. The scanning steps are in agreement with the CMOS sensor dimensions.

3. Data elaboration and results

The photodiode acquisitions are elaborated to calculate collection efficiency and concentration factor of the examined optical component.

The result of a scan with the photodiode is a two-dimensional matrix with dimension corresponding to the number of sampled points, and whose elements are the photodiode output current, which is proportional to the incident power. Since the sensitive area of the photodiode is 1 mm^2, these values can be considered as the power density

per mm^2.

The collection efficiency of the receiver is calculated using equations Eq. (1), Eq. (2) and Eq. (3). $P_{in,i}$ is given by Eq. (2), in which $\bar{p}$ is calculated by averaging the values of the scan on the incident beam. The effective area is rectangular: $A_{eff,i} = a \cdot b_i$. The receiver is always fully illuminated in the vertical direction, so a is constant for each measurement. The horizontal dimension (b_i) must be accurately calculated considering the projection (of length $l_{eff,i}$) of the receiver side (of length L_R) on the plane orthogonal to the beam axis [Fontani et al. 2015]. Each plane mirror (of length L_M) in the horizontal direction is seen with a length $L'_{eff,i}$, obtainable considering the projection effect and the beam divergence enlargement [Fontani et al. 2015].

Hence there are different situations of illumination. The receiver is fully illuminated (b_i data in bold in Tables 1-2) or it is partially illumined (b_i data in italics in Table 1). When it is entirely lighted $L'_{eff,i} > l_{eff,i}$ and $b_i = l_{eff,i}$, while in case of partial illumination $L'_{eff,i} < l_{eff,i}$ and $b_i = L'_{eff,i}$ [Fontani et al. 2015]. These quantities are visualized in Fig. 3.

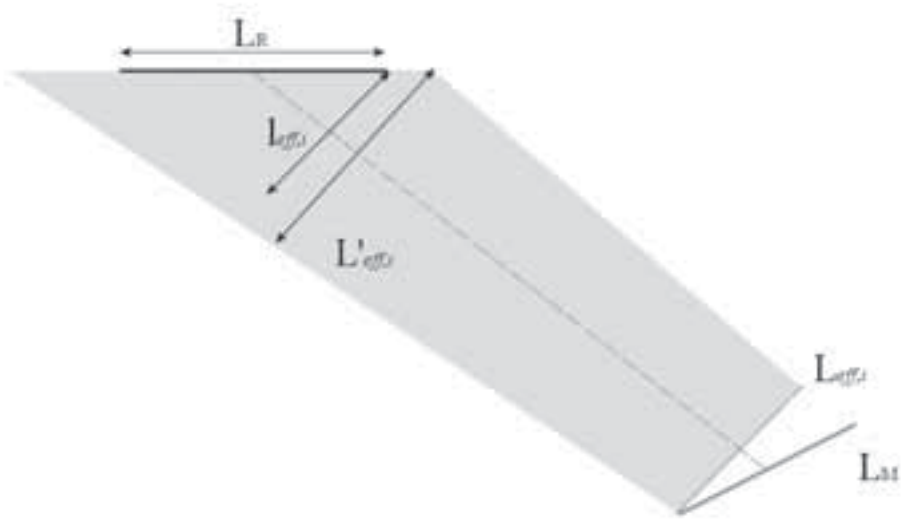

Fig. 3 – Effects on the beam.

Table 1 presents the measurement results for a reflection concentrator; whilst Table 2 reports the results measured on two samples of prismatic lens (denominated Lens1 and Lens2). The columns refer to: mirror tilt with respect to the mirrors line (β_i), incidence angle of the beam reflected on the receiver (α_i'), horizontal size of the effective area (b_i), and effective area ($A_{eff,i}$). The vertical size of the effective area is a.

From Table 1 it is clear that for the reflection concentrator there are some angles for which the beam does not completely enter in the receiver; in these cases the light collection is limited by the size of the receiver and not by the beam itself.

β_i (°)	α_i' (°)	b_i (mm)	$A_{eff,i}$ (mm^2)
0.759	1.518	**58.72**	2819
2.273	4.546	**58.69**	2817

Table 2 – Effective area of the beam entering in the prismatic lens as a function of the entrance angle, with a = 50 mm.

For the determination of P_{out} it is necessary to distinguish the two types of secondary optics.

For the reflection concentrator, the PV receiver is placed on the exit aperture and it collects all the light coming from it. Therefore, in this case P_{out} is obtained by integrating all the radiation collected in the scan.

For the lens, the PV receiver is placed at 5 cm distance. It will collect the light that falls directly on it and that is reflected from the lateral flaps. P_{out} is then obtained as the sum of these two contributions. The situation is illustrated in Figures 5 and 6. The radiation within the red rectangle is coming directly from the lens, while the radiation inside the yellow rectangles is reflected by the flaps. In any case, from the pictures of focused beam it can be noted that the light falls predominantly within the central band.

It is interesting to examine the values of efficiency and concentration obtained for the individual angles. The collection efficiency η_i is calculated using Eq. (1) while the concentration factor C_i is obtained from Eq. (4). Tables 3, 4 and 5 illustrate the results corresponding to each angle β_i (mirror tilt from the mirrors line); the columns report entrance angle α_i', collection efficiency η_i and concentration factor C_i.

Finally the total values are obtained by summing the contributions of all the examined angles, as Eq. (3) and Eq. (5) indicate.

Tables 6 summarizes the values of total collection efficiency and total concentration factor for all the examined samples of secondary optics designed for the solar plant with Fresnel mirror configuration. For the prismatic lenses two situations are considered, assuming that the reflectance of the lateral flaps could be equal to 90% or 75%, for helping to understand the influence of the flaps in the resulting performance of the component.

Secondary collector	Reflection of the flaps R (%)	total collection efficiency η	total concentration factor C
Reflection concentrator		0.656	3.43
Lens1	90	0.695	4.87
Lens1	75	0.663	4.64
Lens2	90	0.696	4.87
Lens2	75	0.664	4.65

Table 6 – Total values of collection efficiency and concentration factor for all the examined secondary optics.

1. Analysis in the image plane

The distribution of the radiation concentrated on the image plane of the secondary collector is accurately analysed to assess the level of uniformity of receiver illumination. The images in Figures 4-6 are obtained elaborating the measurements with the photodiode, and provide a schematic representation of the illumination produced by the 20 mirrors. The contributions of the various mirrors are calculated by summing the acquired maps and their specular copies (added in the elaboration phase).

The image of the reflection concentrator (Fig. 4) is simply obtained by summing the contributions of the various angles, given that it was possible to align the photodiode with the exit aperture of the reflection concentrator, and thus the analysed area was always the same.

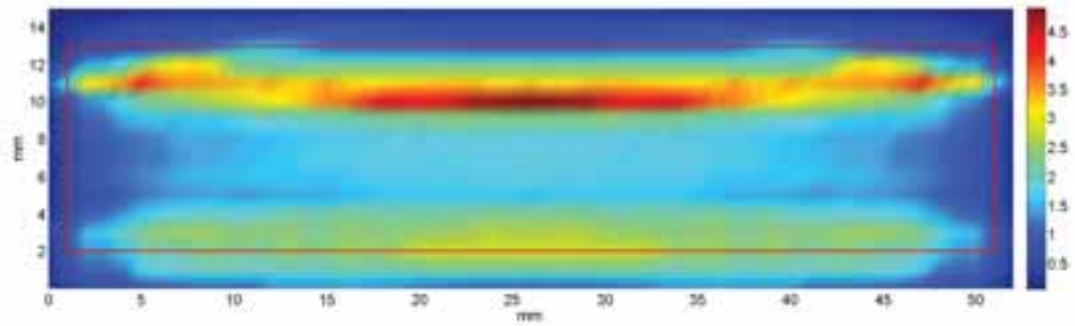

Fig. 4 – Elaboration in false colour of the power density (arbitrary units) on the image plane for the reflection concentrator.

The red rectangle in Fig. 4 denotes the area covered by the PV cell. It must be noted that this is not exactly the map of power density on the cell plane, because the measurement plane for Fig. 4 is about 2 mm behind it. Even

the light external to the rectangle is actually captured by the cell and contributes to the collection efficiency. The difference in intensity of the two horizontal bands at the edges of the rectangle can be attributed to a small vertical misalignment.

In Figures 5 and 6, in addition to the red rectangle of the cell, two side areas bounded by yellow lines are highlighted. The light that falls within these zones interacts with the lateral flaps of the collector and falls (attenuated) within the cell. For the evaluation of the collection efficiency it has been considered the contribution of the entire central band (with red zone and yellow zones). How the yellow zones contribute to the uniformity of illumination, however, depends on the interaction of the radiation with the flaps.

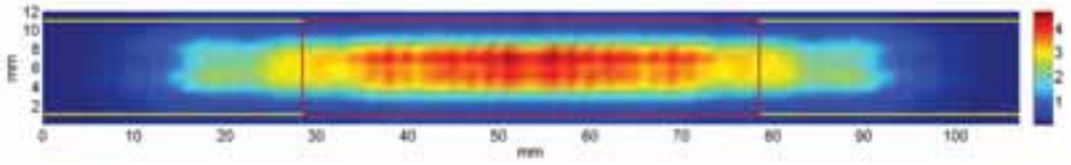

Fig. 5 – Elaboration in false colour of the power density (arbitrary units) on the image plane for Lens1.

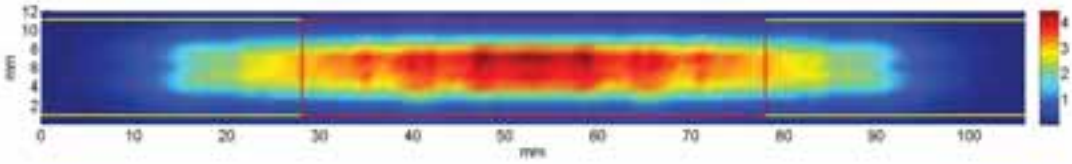

Fig. 6 – Elaboration in false colour of the power density (arbitrary units) on the image plane for Lens2.

The analysis is completed by the elaboration of the CMOS camera acquisitions. Due to the large size, the acquired images must be numerous and they must be accurately combined in order to obtain a final view of the illumination distribution.

As qualitative estimation, Figures 7 and 8 show the reconstructed images for reflection concentrator and prismatic lenses, respectively. Since fundamentally both lenses generate similar images, Fig. 8 shows only one image. It can be noted that the obtained images are in agreement with the results found with the photodiode.

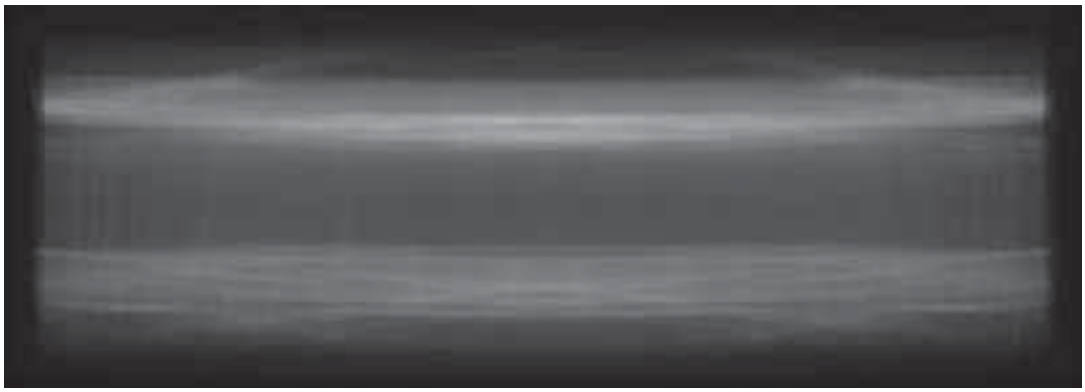

Fig. 7 – Image reconstructed for the reflection concentrator.

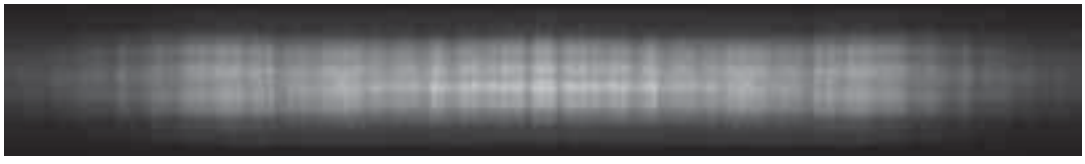

Fig. 8 – Image reconstructed for the prismatic lenses.

These reconstructed images serve only to have an idea of the distribution of the concentrated beam, which as it

can be seen in both cases is not homogeneous.

2. Conclusion

The purpose of this experimental work is to analyse the behaviour of two different secondary optics mounted near the focus of a solar collection system with a Fresnel mirror. An accurate analysis of the concentration layout and of the behaviour of the components inside the plant offered the possibility of performing in laboratory all the measurements simulating the behaviour of the single parts of the system. The contributions are then suitably combined to obtain collection efficiency and concentration factor of the entire solar plant.

The examined secondary optics are a prismatic lens and a reflection concentrator. These two types of secondary collector were optically designed for this solar plant, and samples of them were implemented. The tested secondary collectors are compared on the basis of their optical characteristics. The entrance area of the prismatic lens is larger than that of the reflective concentrator. The main comparison concerns total collection efficiency and total concentration factor of the secondary collector. These quantities are fundamental to understand the operation of the optical component and of the whole system for sunlight collection. The collection configuration is quite complicated and contains a large number of optical elements; therefore it was necessary to develop a special system for the calculation of collection efficiency and concentration factor. Another essential quantity to be analysed is the light distribution in the image plane of the secondary optics, because the level of uniformity of receiver illumination influences the photovoltaic conversion.

A specific experimental set-up was optically designed, implemented and aligned to perform the optical tests simulating the collection geometry of the existent plant. Having chosen to study the system at noon, there is symmetry with respect to the central axis of the system, so only half of the 20 mirrors were reproduced in laboratory. The procedure consists in performing the tests separately simulating the illumination of each mirror, finally combining the measured results. It was decided to perform the analysis at noon, considering that this hour usually corresponds to the maximum solar irradiation. In the actual plant the mirrors move during the day, thus for examining other day times 20 measurements are required and the inclination angles must be properly selected.

Two samples of prismatic lens and one sample of reflection concentrator are compared with an optical characterisation considering the inclinations of the mirrors at noon. The values of total collection efficiency (η) are very similar for all examined samples and they are around 0.66 – 0.69. The total concentration factor (C) is 4.6 – 4.9 for the prismatic lenses and 3.4 for the reflection concentrator. The higher value of C measured on the lenses is probably due to a larger entrance area of the prismatic lens with respect the other optics. In particular, specific tests verified that for some angles the beam does not completely enter into the reflective concentrator. To study the lighting distribution in the image plane of the secondary collector, the power density was computed from the photodiode measurements and some image reconstructions were obtained from the CMOS acquisitions. All these pictures evidence a quite uniform illumination of the receiver; only the two horizontal extremes show lower illumination levels.

The final results of this optical comparison are that the collection efficiency is comparable among all examined samples, while the concentration factor is higher for the prismatic lenses. Therefore, taking into account also that the entrance aperture of the prismatic lenses is larger with respect to the other, it can be concluded that the prismatic lens is a better performing secondary optics than the reflective concentrator. The characteristics of receiver illumination uniformity are analogous for both secondary collectors, which provide a focused image with elevated uniformity in the centre and some inferior light levels towards the right and left extremes.

Reminding that the presented study was carried out at noon, a more complete analysis should examine other hours of the day. Another interesting investigation could consider the angular limitations in order to control the losses, because the experimentation evidenced that there are some cases in which the reflection concentrator is not entirely illuminated.

Abstract

The overall aim of this work is to assess the performance of high-efficiency solar trigeneration systems based on a novel hybrid photovoltaic-thermal (PVT) collector for the provision of domestic hot water (DHW), space heating (SH), cooling and electricity to residential single-family households. To this end, a TRNSYS model is developed featuring a novel hybrid PVT panel based on a new absorber-exchanger configuration coupled via a thermal store to two alternative small-scale solar heating and cooling configurations, one based on an electrically-driven vapour-compression heat pump (PVT+HP) and one on a thermally-driven absorption refrigeration unit (PVT+AR). The energy demands of a single-family house located in three different climates, namely Seville (Spain), Rome (Italy) and Paris (France), are estimated using EnergyPlus. Hourly transient simulations of the complete systems considering real weather data and reasonable areas for collector installation (< 30 m^2) are conducted over a year. The household energy demands covered by the two systems indicate that the PVT+HP configuration is the most promising for the locations of Rome and Paris, covering more than 74% the DHW demand, 100% of the space heating and cooling demands, as well as an important share of the electricity demand. Meanwhile, for Seville, the PVT+AR configuration appears as a promising alternative, covering more than 80% of the DHW, around 70% of the cooling and electricity, and 54% of the space heating demands.

Keywords: solar energy, hybrid PVT, heat pump, absorption cooling, residential energy, energy modelling

1. Introduction

The EU low-carbon economy roadmap (European Commission, 2011) concludes that it is possible to reduce the emissions in the build environment by around 90%, and that this would be a significant contribution towards achieving the 80% total emissions reductions relative to 1990 levels by 2050 without disrupting energy supplies. Meeting this commitment requires an increased generation of renewable energy in the built environment by clean and affordable technologies. Solar energy has the potential to play a leading role in delivering such a high-efficiency sustainable energy future, and is quickly approaching grid parity in high-irradiation regions. In addition, it is capable of satisfying both the electrical and thermal needs of buildings, by means of photovoltaic (PV) and solar thermal (ST) technologies, respectively. Especially where there are space constraints, hybrid photovoltaic-thermal (PVT) panels appear as highly suitable solutions, as these units combine the advantages of PV and ST systems while generating both electricity and a useful thermal output simultaneously from the same aperture area, and with a higher overall efficiency than separate stand-alone systems (Guarracino et al., 2016). Nevertheless, the wider use of PVT technology currently remains limited (Herrando et al., 2014), and it is of interest to consider and to improve aspects of this technology that would enable its further deployment.

Interestingly, PVT-water systems can have higher efficiencies by up to ~15% compared to PV while generating hot water suitable for domestic use (DHW) or for space heating (SH), and it is believed that this technology has an important potential in the residential sector (Affolter et al., 2005) that accounts for 25% of the total electricity and 30% of the total final energy consumption in the EU (Antonanzas et al., 2015), and where the heat demand accounts for 60-90% of the energy demand in buildings in cold climates, and 30-40% in warmer climates (Kempener et al., 2015). However, despite its potential, there are still very few companies worldwide commercialising this technology (Herrando and Markides, 2016), with most of the products available on the market not having optimised designs for PVT applications. In an attempt to overcome this barrier, previous work

doi:10.18086/swc.2017.18.07 Available at http://proceedings.ises.org

focused on the design and characterisation of novel absorber-exchanger configurations for flat-plate PVT collectors based on a flat-box structure (Herrando et al., 2016, 2017), which demonstrated promising results, specifically a ~4% higher optical efficiency and a ~16% lower heat-loss coefficient than an equivalent commercial sheet-and-tube PVT panel, also with a lower weight (close to 10%) and capital cost (about 20%). This novel PVT panel configuration is the one selected in the present work for further research.

One of the limitations of the integration of hybrid PVT systems in buildings for power and heating provision, especially in the residential sector, arises from the annual heat demand variations of these buildings, which in temperate climates such as in Mediterranean countries splits into an 75-80% demand for space heating and a remaining 20-25% for DHW, with the minimum demand being in summertime when the irradiation levels are high. To avoid oversizing/generation, an installation is typically sized to cover about 50% of the DHW load, such that the generated solar-thermal energy can only cover 10% of the total heating load of the building (del Amo, 2015). To avoid this limitation and use the surplus heat provided by the PVT panels for other building energy needs, the present work proposes integrating PVT panels with thermal storage and heat pumps (HPs) or absorption refrigeration (ARs) units, thereby allowing the generation of heating (SH and DHW), cooling and electricity from a single, affordable solar-energy system (IEA, 2012).

Solar cooling, in particular in domestic applications, is considered attractive because high solar irradiance levels are typically in phase with high building cooling demands, which have been and are projected to continue growing on a worldwide basis (Montagnino, 2017). Previous research has highlighted the fact that the relationship between the solar resource availability and the cooling demand is of key importance in obtaining accurate estimations of the potential of solar-cooling technologies (Mokhtar et al., 2010). At the same time, other recent studies have indicated that suitable solar-cooling technologies are currently associated with noteworthy challenges, including their limited performance and high cost (Bataineh and Taamneh, 2016). Ongoing research on a range of solar-cooling technologies has focussed on overcome these challenges.

Most studies found in literature propose the integration of heating/cooling technologies with concentrated PVT (Mittelman et al., 2007), or PVT-air systems (Eicker and Dalibard, 2011; Kamel and Fung, 2014). Instead, in the few studies found to date on PVT-water panels integrated thermally with AR units, the hot water generated by flat-plate PVT-water collector designs (which can reach around 80-90 °C), can be utilized as a heat source for the generator of the absorption unit, thus providing cooling to the household. Recent studies have shown that coefficients of performance (COPs) of up to 0.8 can be achieved by solar-driven single-stage LiBr-water absorption chillers (Bellos et al., 2016). Some authors (e.g., Calise et al., 2012; del Amo, 2014; Ramos et al., 2017) considered the integration of PVT-water collectors with AR units, and concluded that this combination has an important potential for energy savings owing to the generated heating, cooling and electricity.

Alternatively, vapour-compression heat pumps (HP) driven by the electrical output of PVT-water collectors can also be integrated with the thermal output of the same collectors, increasing the COP of this configuration in winter “heating mode”, while in summer the electrical output generated by PVT units can be used to run the HP unit to provide cooling. Most of the approaches for the hybridisation of HPs with solar collectors involve a simple combination of ST and PV conventional systems. The ST+HP combination was the first the concept developed as a parallel source for minimising the HP operation or with more complex architectures in order to take advantage of higher source temperatures for enhancing the HP performance. Examples are solar air heaters coupled with air-air HP or ST collectors coupled with water-water HPs. The higher potential of heat source side solutions requires sophisticated, robust and well-tuned control systems to achieve high solar fraction for annual basis figures (Drosou et al., 2014). Further, Xu et al. (2009) developed a photovoltaic-thermal heat pump (PVT-HP) system model, from which they concluded that almost all of the required heating load in winter months in Nanjing and Hong Kong (China) can be covered by using a variable compressor for the HP. Similarly, Kamel and Fung (2014) studied an air-PVT collector integrated in a roof and coupled with air source HP, where the warm air generated in the air-PVT acted as the source for heat production. These authors concluded that an important reduction in electricity costs to run the HP can be achieved when it is connected with PVT systems. The economic performance of a solar photovoltaic/loop-heat-pipe (PV/LHP) and HP system for domestic heating applications has also been studied, e.g., by Zhang et al. (2014), who identified local utility prices and renewable incentives to be critical for the implementation of these systems.

The interest in the PV+HP combination is a more recent development, mainly driven by the cost reduction of PV modules in the last years; boosted also by the power-to-heat trends, the combination of these electricity-based

technologies seems promising. A theoretical and experimental study of PV modules coupled with a solar assisted HP (SAHP) showed higher values of the HP COP as well as higher averaged PV efficiencies than separated units (Ji et al., 2008). However, the weakly coupled profiles of PV generation and HP consumption lead to an important distribution grid impact if they are not properly managed (i.e., through electrical storage), and thus in a high penetration scenario the ideal grid storage solution is not feasible (Protopapadaki and Saelens, 2017) due to grid operation and infrastructure oversizing needs.

This research aims to investigate the potential of domestic solar trigeneration systems based on hybrid PVT-water collectors for the provision of DHW, SH, cooling and electricity in residential single-family households.

2. Methodology

The most promising PVT panel identified in previous research (Herrando et al., 2016), based on a polycarbonate flat-box structure design, is connected to a HP or AR unit and a suitable thermal store, within a combined heating-cooling-electricity (trigeneration) system model in TRNSYS (Klein, 2016) (see Fig. 1). Two alternative system configurations are considered: 1) PVT integrated with a water-to-water reversible heat-pump/refrigeration unit fed by the electrical and/or thermal output of the PVT panel to provide heating/cooling; and 2) PVT integrated with a thermal absorption refrigeration unit (single-stage LiBr-water) fed by the thermal output of the PVT panel to satisfy the cooling demand in summer, plus a suitable thermal store. Innovative approaches in the PVT+HP configuration are studied such as the integration of the PVT thermal output with a water-to-water HP unit to increase its COP (see Fig. 1 left), and the optimisation of the tank size.

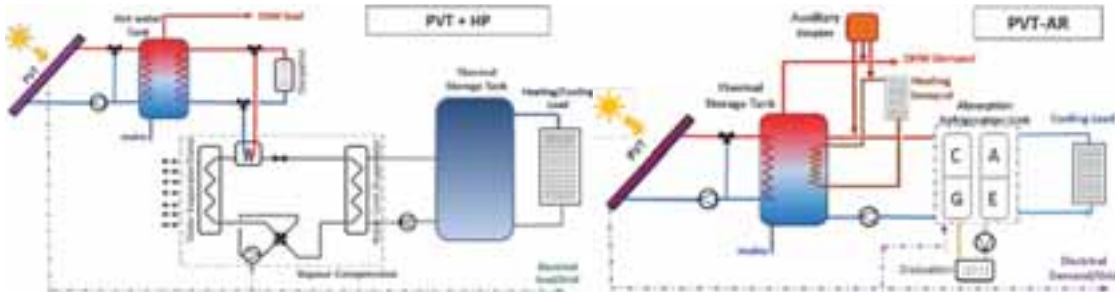

Fig. 1: Schematic diagrams of solar PVT panels integrated with (left) heat pumps, Configuration 1, and (right) absorption refrigeration units, Configuration 2.

2.1. Solar trigeneration system models

The core components of the solar trigeneration systems studied and modelled in this work are: i) the PVT collector, ii) a stratified water storage tank, iii) a closed loop with a water circulator pump that connects the PVT collector with the storage tank through an internal heat exchanger, iv) a HP unit (Configuration 1), v) an auxiliary heater, and vi) an AR unit (Configuration 2). The PVT collector, the stratified water storage tank, the HP and the AR unit models are described in detail below.

PVT collector

The novel PVT collector proposed and investigated in this work is based on a polycarbonate flat-box structure, which improves the heat transfer from the absorber to the fluid by means of 2×3 mm channels (Herrando et al., 2016). This main design features of this PVT collector are presented in Fig. 2.

Fig. 2: Schematic diagram of the novel PVT collector proposed in this work, based on a polycarbonate flat-box structure.

In order to model the proposed PVT collector, an existing PVT unit in TRNSYS (Type 560) is modified accordingly and the adjusted PVT model is validated against experimental data (Herrando, 2017). The PVT

collector has a nominal electrical power of 240 W_p and an aperture area of 1.55 m^2. The nominal electrical efficiency (η_{el}) of the PVT collector is 14.7%, and the temperature coefficient of the PV cells is 0.45 %/K. The thermal performance (η_{th}) of the collector is described by Eqs. 1 and 2 as follows,

$$\eta_{th} = 0.726 - 3.325 \cdot T_r - 0.0176 \cdot G \cdot {T_r}^2 \quad \text{(eq. 1)}$$

$$T_r = \frac{(T_{fm} - T_a)}{G} \quad \text{(eq. 2)}$$

where G is the total global solar irradiance on the surface at tilted angle (in W/m^2), T_{fm} is the mean fluid temperature and T_a is the ambient temperature.

Stratified water storage tank

A one-dimensional (1-D) model is used for the hot water storage tank (Type 534). The tank is assumed to consist of 6 fully mixed equal-volume segments that divide the cylinder along its vertical axis. The total mass of fluid in the tank is assumed constant, therefore the total mass flow-rate entering the tank through the inlet port must equal the total mass exiting the tank from the outlet port. For the stratification, a temperature gradient is preserved in the tank by ensuring that the hot water for DHW demand is supplied via a port at the top of the tank (at node n = 1), while replacement cold water from mains is introduced at the bottom (n = 6). The tank also has two immersed heat exchangers (HX): one connected to the PVT collector and another one to provide hot water to satisfy the SH demand (via radiant underfloor heating, UFH) to the household. In this second HX, water flowing in a separate closed loop circuit enters the heat exchanger coil (at node n = 4) at the UFH return temperature of 35 °C and is heated to a target supply temperature of 45 °C. This closed loop exits the tank at node n = 2. A bypass is included, to avoid sending fluid to the heat exchanger when the tank temperature is lower than 35 °C. In Configuration 1, the outlet of this second HX is connected to the HP to provide the target supply temperature when it is not reached within the tank, while in Configuration 2, a (gas-fired) auxiliary heater (nominal efficiency of 90.1% (BRE, 2014) is used. To satisfy the cooling demand, the reversible HP is used in Configuration 1, whereas in Configuration 2 the AR unit generator is connected to a second port leaving the tank at the top (n = 1) and entering at the bottom node (n = 6).

The storage tank volume is varied through the variation of the V_t/A_{cT} ratio, where V_t is the tank volume in litres and A_{cT} is the total PVT collector area in square meters. According to the Ministry of Housing of the Spanish Government (Gobierno de España, 2013), for solar thermal installations in households this range should be kept between $50 < V_t/A_{cT} < 180$. In this work, this recommendation has been considered for the 3 different locations under study. The size of the solar immersed heat exchanger coil also varies with the tank size, through the variation of the tank height, such that the ratio between the coil heat transfer area, and the total PVT collector area, is not lower than 0.15 (IDAE and CENSOLAR, 2009) to ensure adequate heat transfer. This HX enters the tank at the top (n = 1) and exits it at the bottom (n = 6).

Heat pump unit

In Configuration 1 (PVT-HP system), the PVT collector and the water storage tank are coupled with a single-stage water-to-water heat pump (HP) unit (Type 927). The heat pump conditions a liquid stream by rejecting energy to (cooling mode) or absorbing energy from a second liquid stream (heating mode). In heating mode, as detailed above, the inlet of the hot side of the HP is connected to the HX outlet of the water storage tank to raise the water temperature up to 45 ºC when required, while the inlet of the cold side of the HP is fed with water from mains, which is cooled down to absorb the energy required and transfer it to the hot side. In cooling mode, the cold side is cooling water from the mains to serve the cooling demand, while the hot side heats up the water from the bottom part of the tank to compensate the heat rejection on the cooling side; then the warm water is returned to the tank. Performance modelling of this HP unit is based on user-supplied data files containing catalogue-data for the normalised capacity and power draw, based on the entering load and source temperatures and the normalized source and load flow-rates (Klein, 2016).

Absorption refrigeration unit

In Configuration 2 (PVT-AR system), the PVT collector and the water storage tank are coupled with a single-effect absorption refrigeration (AR) unit (Type 107). The refrigeration cycle starts with LiBr-water pumped to the generator to be heated (using hot water from the top of the storage tank), as a result water is desorbed from this solution to vapour form as it is heated. Water vapour then flows to the condenser (cooling tower) where it is

condensed and rejects heat to the ambient. Condensed fluid then flows through an expansion device where the pressure is reduced and evaporated for the cooling effect (refrigeration or space cooling). The evaporated water is then absorbed into a strong LiBr solution in the absorber and the cycle is repeated. When the water exiting the top of the storage tank is lower than 65 ºC, an auxiliary (gas-fired) heater heats it up to ensure that it enters the AR unit at a temperature above 60 ºC (minimum temperature to start the cycle). Performance data of a commercial AR unit, Sonnen Klima-10 kW, is considered for the modelling of this unit (Mugnier and Sire, 2009). In addition, the data files are normalised so different AR unit sizes can be modelled.

2.2. Reference family house

To simulate the performance of the solar trigeneration system for domestic applications, a reference house is modelled in EnergyPlus (EnergyPlus, 2017) using real hourly weather data to estimate the energy demand in different months, including the thermal energy for space heating and DHW, the cooling demand, and electricity for lighting and other household appliances. The reference house is a semi-detached household with 2 floors with an area of ~58 m^2 each, a façade U-value of 0.26 W/(m^2·K), a roof U-value of 0.18 W/(m^2·K), and double-glazed windows. Typical occupancy profiles of a 4-inhabitant house (2 adults, 2 children) are considered, following the guidelines provided in the Spanish Building Code (Código Técnico de la Edificación) (Gobierno de España, 2013), which differentiates between working and non-working day, and provides loads and schedules for lighting and home appliances, as well as for occupancy, and the air renovations in the different months. Based on the aforementioned normative, the following temperature set-points are set: 20 °C primary and 17 °C secondary for space heating (January to May and October to December) and 25 °C primary and 27 °C secondary for air conditioning (June to September). As shown in Table 1, even though the same set-points and occupancy profiles are considered, due to the different weather conditions of the locations under analysis, considerably different space heating and cooling demands are estimated. The electricity demand (lighting and other household appliances) is relative similar between these three locations, and the small differences found are due to the lower lighting necessities while moving towards southern latitudes.

Tab. 1: Annual energy demand breakdown of the reference single-family house in the three different locations under analysis.

Location	DHW		Space Heating		Cooling		Electricity	
	kWh/year	kWh/m^2-year	kWh/year	kWh/m^2-year	kWh/year	kWh/m^2-year	kWh/year	kWh/m^2-year
Seville	942	8.19	668	5.81	2762	24.02	2603	22.63
Rome	942	8.19	2527	21.97	1327	11.54	2669	23.21
Paris	942	8.19	5373	46.72	529	4.60	2659	23.12

2.3. Methodology approach

The objective of the work presented in this paper is to analyse the performance of a solar trigeneration system based on the novel hybrid PVT panel described above. Two different configurations (PVT-HP and PVT-AR) are studied in three different climates: Seville (Spain), Rome (Italy) and Paris (France). For each of the former locations and for each different configuration, the sizing of the systems is undertaken as follows: i) the number of PVT collectors is selected after a parametric analysis to cover as much energy demand as possible (including DHW, SH, cooling and electricity), while minimising the excess of thermal energy and using reasonable areas (up to 29 m^2 area is considered available for the PVT collectors, which is half of the floor area of the reference house); ii) the tank size is selected as a trade-off to minimise the thermal energy excess while maintaining appropriate temperatures through the different nodes to satisfy the demand; iii) the PVT collector flow-rate selected for each location is that resulting in the highest percentage of the domestic energy demand covered from a previous parametric analysis, and in this analysis is kept constant over the year following previous conclusions (Herrando, 2017); iv) for the PVT-HP configuration, the size (nominal power) of the HP unit corresponds to maximum peak power required over the year (for both heating and cooling modes); this varies for each studied location; and v) and for the PVT-AR system the size of the AR unit corresponds to the peak cooling power required instantaneously, which also varies depending on the location.

The model for the PVT+AR configuration built in TRNSYS environment is presented in Fig. 3, with the element types indicated. The diagram presented in this figure has been simplified for clarity purposes. The main elements are the PVT panel, the water tank (thermal storage), the pumping system, the controller, the auxiliary heater and the AR unit. As it can be observed, DHW, SH, cooling and electricity demands are inputs to the model, as well as

the weather data. The main outputs are the electricity and thermal energy generated by the PVT panels, and the percentages of the household energy demands covered. The equivalent model built for the PVT+HP configuration is not presented here due to space constraints. Briefly, the PVT+HP model is built removing the AR unit, and its corresponding connections from the TRNSYS model presented in Fig. 3, and connecting the outlets of the two tee piece units in Fig. 3 with a new element, the HP unit (Type 927), which also needs a second controller unit (Type 2b) and second water tank (Type 4b), as indicated in Fig. 1.

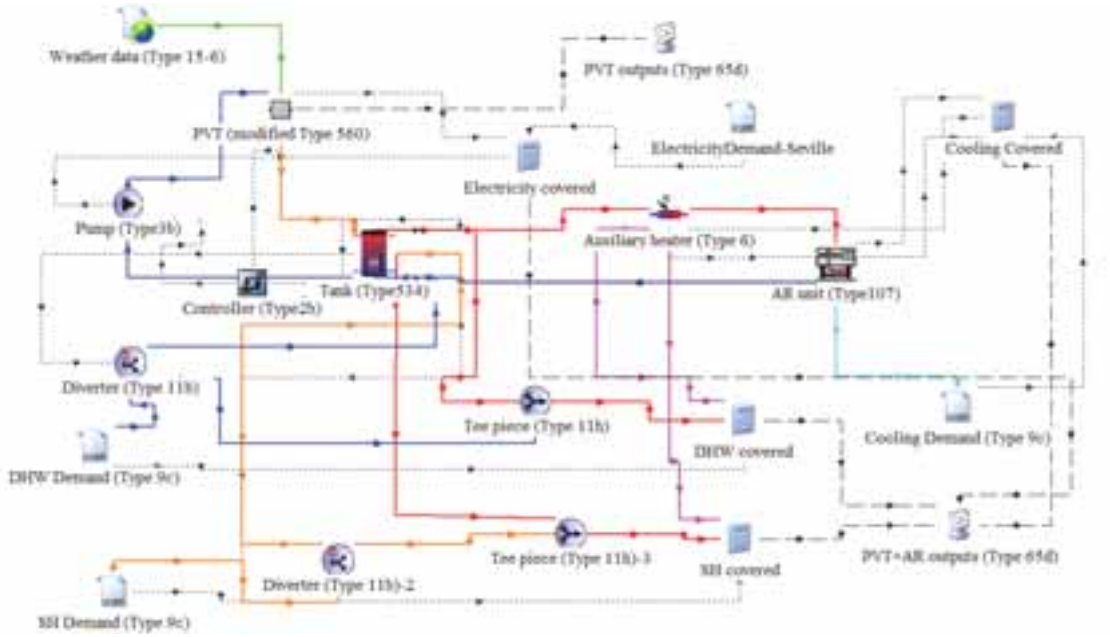

Fig. 3: Simplified model of the PVT+AR configuration built in TRNSYS environment.

Once each solar trigeneration system is sized for each of the aforementioned locations, an hourly transient simulation considering real weather data (Meteonorm Data Base, 2017) is conducted over a year, and the percentages of DHW, space heating, cooling and electricity demands covered are estimated. The modelled system, in all the locations and for both configurations, prioritises first of all DHW and SH demand, then cooling demand, and finally the electricity demand (corresponding to lighting and home appliances). For the results presented below, the family house is assumed to be connected to the electricity grid allowing the continuous exchange of electricity: i.e., electricity generation surplus is fed to the grid and when the PVT electricity generation is not enough to cover the instantaneous demand (deficit), this can be taken from the grid. However, this electricity exchange is only allowed until the electricity balance over a year is reached, that is, when the total annual electricity exported equals the total annual electricity imported to/from the grid.

3. Results and discussion

3.1 Solar trigeneration system configurations

For each of the selected locations and the two different configurations considered (PVT+HP and PVT+AR) a preliminary analysis is conducted, as indicated in the Methodology section, to size each system. In Table 2, the selected size of the storage tank together with the corresponding number of PVT collectors for each solar trigeneration system, based on an innovative polycarbonate flat-box PVT panel, are presented for Seville (Spain), Rome (Italy) and Paris (France). In addition, within the ranges of inlet and outlet temperatures considered for the HP and AR units, in the PVT+HP configuration an annual averaged COP of 4/5 is obtained in heating/cooling modes respectively; while for the PVT+AR configuration the annual averaged COP is 0.78.

On the basis of the solar trigeneration systems size presented in Tab. 2, hourly transient simulations over a year are conducted in TRNSYS software, and results and percentages of the energy demand (DHW, space heating, cooling and electricity) covered are discussed in the following subsections.

Tab. 2: Solar trigeneration systems size based on an innovative PVT collector for each particular location under analysis.

Location	Total PVT collector number / area	PVT collector flow-rate	Water storage tank volume	Peak heating/cooling power
Seville	6 / 9.3 m^2	50 L/h	0.54 m^3	3.9 kW/ 11.9 kW
Rome	12 / 18.6 m^2	50 L/h	1.08 m^3	4.6 kW/ 7.3 kW
Paris	18 / 27.9 m^2	30 L/h	1.08 m^3	5.2 kW/ 5.8 kW

3.2 Annually-integrated results in the selected locations

Annual results for the two solar trigeneration configurations, including the single-family house DHW, space heating (SH), cooling and electricity demand fractions covered in Seville, Rome and Paris are presented in Table 3. It is worth mentioning that the breakdown of the energy demand varies significantly from one location to another, as previously shown in Table 1; i.e., while the DHW demand is virtually the same in all the selected locations, it represents 1.4, 0.37 and 0.17 of the annual SH demand in Seville, Rome and Paris, respectively. Significant differences can also be found in the annual cooling/SH demand ratios between the mentioned locations, which take values of 4.13, 0.53 and 0.10, for Seville, Rome and Paris, respectively.

Tab. 3: Annual results for the two different solar trigeneration configurations, including percentages of DHW, space heating (SH), cooling and electricity demands covered of a reference single family house in three different locations.

Location	Configurations	DHW covered	SH covered		Cooling covered	Electricity Covered	
			PVT	HP$^+$		Inst.*	with excess$^+$
Seville	PVT+HP	90.0%	53.7%	100%	100%$^+$	24.5%	35%
	PVT+AR	81.9%	53.7%	-	71.4%	29.8%	70%
Rome	PVT+HP	87.7%	44.1%	100%	100%$^+$	27.2%	81%
	PVT+AR	86.9%	44.1%	-	96.9%	30.9%	126%
Paris	PVT+HP	74.3%	18.7%	100%	100%$^+$	25.1%	37%
	PVT+AR	73.4%	18.7%	-	85.8%	31.6%	124%

**Percentage of demand covered instantaneously at each time step, without grid interaction.*

$^+$*Percentage of demand covered considering that instantaneous surpluses of electricity exported to the grid can be used at other time step to cover a deficit of electricity.*

From the results summarised in Table 3, Configuration 1 (PVT+HP) appears as the most promising alternative in two of the locations (Rome and Paris), since percentages above 74% of DHW and 100% of the SH and cooling demand are covered; while with Configuration 2 (PVT+AR), similar percentages for DHW and slightly lower for cooling demand are covered, but instead less than 45% and 20% of the SH demand are covered in Rome and Paris, respectively. The case of Seville is significantly different, mainly due to the higher solar irradiance levels, thus the household has very small SH demand and quite high cooling demand. Therefore, in this location, the integration of the PVT collectors with an AR unit appears as a promising alternative because, although only around 54% of the SH demand is covered, the remaining percentage corresponds to a small amount of energy in absolute numbers (332 kWh/year), while the electricity covered with the PVT+AR is twice than the one covered with the PVT+HP configuration (1826 kWh/year *vs*. 915 kWh/year respectively).

3.2 Time-resolved weekly analysis of the systems in the selected locations

In this section, detailed results (weekly results on an hourly basis) are presented with the aim of understanding of the annual data presented in Table 3. A more detailed description of the energy performance of the most promising solar configuration at each of the selected locations is also included.

Solar trigeneration (PVT+AR) system integrated in the household located in Seville (Spain)

As shown in Table 3, the integration of the PVT collectors with an AR unit appears to be a promising alternative in Seville (Spain), as the AR unit uses the hot water generated by the PVT collectors in the summer months to satisfy the cooling demand, leaving a significant amount of electricity generated by the PVT collectors to satisfy the rest of the household's electricity demand. The later observation may seem not clear from the annual results presented in Table 3, where higher percentages of space heating and cooling are covered with the PVT+HP configuration. However, the PVT+AR configuration presents the additional advantage of covering double of the electricity domestic demand, since most of the cooling demand is covered by means of the PVT thermal output, thus avoiding excess of thermal energy that would be otherwise dumped to the ambient.

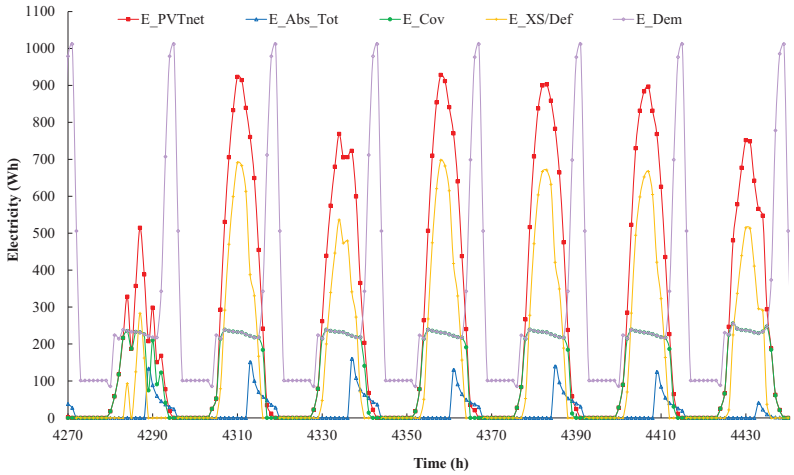

Fig. 4: Electricity generated by the PVT collectors (E_{PVTnet}), electricity consumed by the AR unit ($E_{Abs,Tot}$), electricity demand covered (E_{Cov}), electricity demand (E_{Dem}) and electricity excess/deficit ($E_{XS/Def}$) for the PVT+AR system located in Seville (Spain) during a summer week (28th June - 4th July).

Figures 4 and 5 show the hourly results of the PVT+AR system located in Seville detailed in Table 3 during a representative summer week (28th June - 4th July). It is observed that there is a clear mismatch between the profile of electricity generation (E_{PVTnet}) and that of the electricity demand (E_{Dem}), which implies that during the day all or most of the electricity demand is covered by the PVT+AR system (green circles in Fig. 4), with also an important excess of electricity (yellow pluses) that is exported to the grid. Meanwhile, at night the peak electricity demand (purple diamonds) is not covered. This gives rise to the difference in the percentage of electricity covered in Table 3, depending on whether only the electricity generated at each time step is considered ('Inst.' Column in Table 3) or whether it is assumed that the electricity exported to the grid at any time step can be used at other time step to satisfy the demand ('with excess' Column in Table 3).

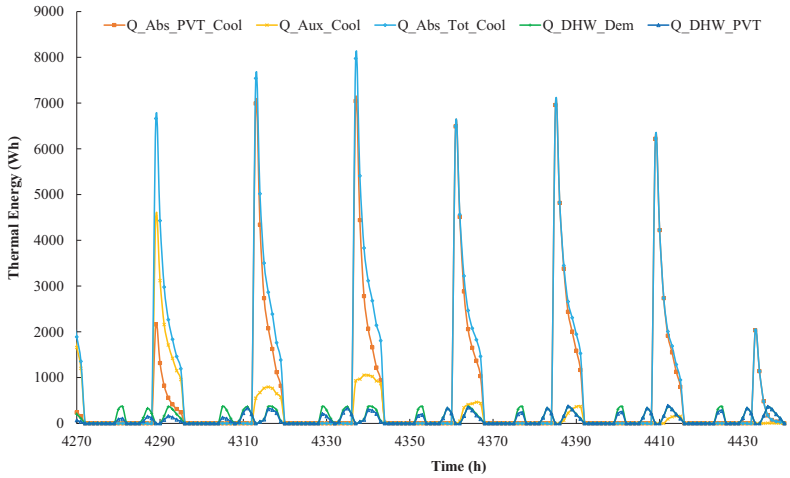

Fig. 5: DHW demand ($Q_{DHW,Dem}$), DHW demand covered by the proposed PVT+AR system ($Q_{DHW,PVT}$), thermal energy required by the AR unit to satisfy the cooling demand ($Q_{Abs,Tot,Cool}$), thermal energy provided by the proposed PVT+AR system to satisfy the cooling demand ($Q_{Abs,PVT,Cool}$) and auxiliary energy required to satisfy the cooling demand ($Q_{Aux,Cool}$) for the PVT+AR system located in Seville (Spain) over a summer week (28th June - 4th July).

In Fig. 5 we consider the thermal energy generation/consumption. From this figure, it can be seen that in the selected summer week most of the DHW demand can be covered by the proposed PVT+AR system (dark blue triangles and green pluses), as well as a significant part of the cooling demand (light blue diamonds and orange squares). It is observed that on the first day, due to the lower solar irradiance (which can be inferred from the electricity generated by the PVT panels in Fig. 4), the temperature reached at the top of the tank is not enough to feed the AR unit and to satisfy the cooling demand, so an important amount of auxiliary heat is need (yellow crosses). Conversely, later in the week, thanks to the increase in solar irradiance, more thermal energy is collected by the PVT collector array, leading to an increase in the storage tank temperature and thus a reduction in the

auxiliary energy required to heat the water that feeds the AR unit.

Solar trigeneration (PVT+HP) system integrated in the household located in Rome (Italy)

In the case of the household located in Rome (Italy), the results indicate that it is more appropriate to integrate the PVT collectors with a HP instead of with an AR unit, as this allows the system to cover all the space heating and cooling demands while also covering most of the DHW and an important fraction of the electricity demands, when the electricity excess at different time steps is considered ('with excess' Column in Table 3).

To compare the energy performance of the PVT+HP system with the PVT+AR system, the same summer week as in the case of Seville is shown in Fig. 6 below. In this case, only the electrical results are shown as the thermal outputs are the ones corresponding to the DHW demand and are very similar to those shown in Fig. 5. As before (in Seville, Fig. 5), a mismatch is observed between the electricity generated by the PVT panels and the household electricity demand. However, here, the cooling demand is satisfied by the HP, consuming electricity (see dark blue triangles), so there is less excess of electricity during the main cooling hours (early afternoon), while when the electricity generation decreases later in the day (red squares), there is a deficit of electricity (yellow crosses) that should be bought from the grid to cover the HP electricity consumption.

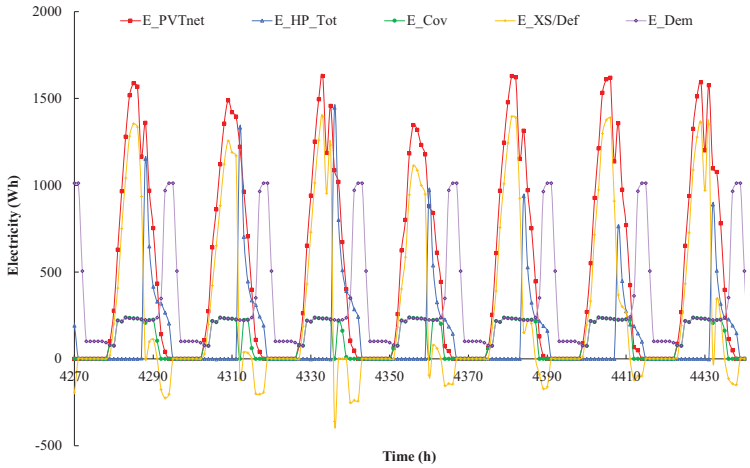

Fig. 6: Electricity generated by the PVT collectors (E_{PVTnet}), electricity consumed by the HP unit ($E_{HP,Tot}$), electricity demand covered (E_{Cov}), electricity demand (E_{Dem}) and electricity excess/deficit ($E_{XS/Def}$) for the PVT+HP system located in Rome (Italy) over a summer week (28 June - 4 July).

Solar trigeneration (PVT+HP) system integrated in the household located in Paris (France)

For the case of the household located in Paris (France), the results show once again that the most appropriate system configuration is the one that integrates the PVT collectors with a HP instead of an AR unit, which in this case allows the system to cover up to 100% of the space heating and cooling demands, while also covering most of the DHW demand; on the other hand, only 37% of the electricity demand is covered (see Table 3).

In this case, it is considered more relevant to show a representative winter week (27th January to 2nd February) since the cooling demand in Paris is small compared to that for space heating. In Fig. 7 one can clearly observe the mismatch between the profiles of the electricity generated by the PVT panels and that of the household electricity demand, while it can also be seen that the electricity demand (purple diamonds) is lower than the electricity needed by the HP to cover the SH demand (blue triangles) from morning to evening. In addition, despite the fact that the amount of electricity covered seems quite small (green circles), on an annual basis the instantaneous energy covered is around 668 kWh/year which, together with the annual excess of electricity (310 kWh/year), allows the system to cover 37% of the total domestic electricity need (assuming that the electricity exported to the grid at any time step can be used at other time step to satisfy the electricity demand).

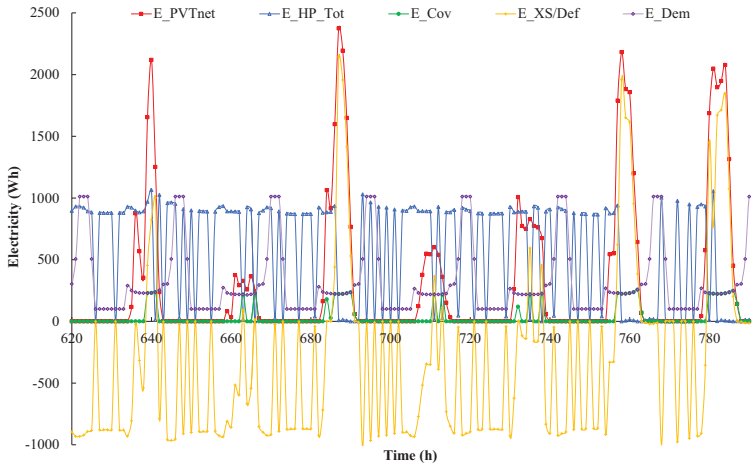

Fig. 7: Electricity generated by the PVT collectors (E_{PVTnet}), electricity consumed by the HP unit ($E_{HP,Tot}$), electricity demand covered (E_{Cov}), electricity demand (E_{Dem}) and electricity excess/deficit ($E_{XS/Def}$) for the PVT+HP system located in Paris (France) during a winter week (27 Jan. - 2 Feb.).

The total heating demand, including both DHW and SH, is presented in Fig. 8, together with the part of these demands covered directly by the PVT thermal-energy generation. From Fig. 7, the 4 days of the selected week that have relevant irradiance levels can be inferred (red squares), which allows the system to cover some percentage of the SH demand with the thermal PVT output on those days, especially in the evening (red squares on Fig 8). However, when the electricity generated by the PVT is used by the HP to cover the remaining SH needs (blue triangles in Fig. 7), 100% of the SH demand is covered (see Table 3).

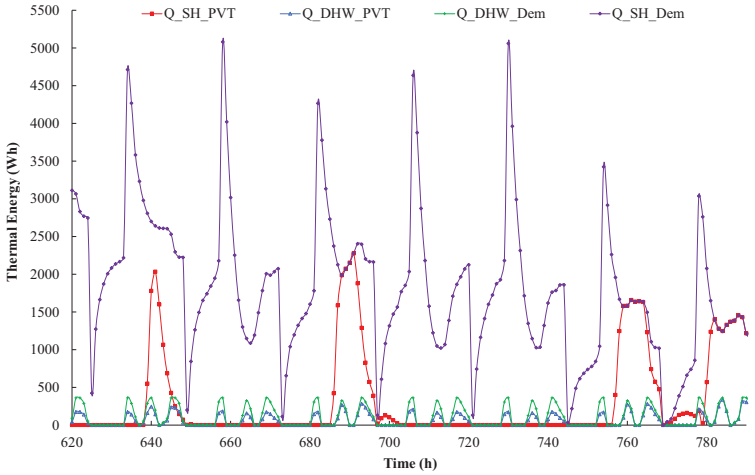

Fig. 8: Space heating demand ($Q_{SH,Dem}$), Space heating demand covered by the thermal output (hot water) of the proposed PVT+HP system ($Q_{SH,PVT}$), DHW demand ($Q_{DHW,Dem}$), DHW demand covered by the thermal output (hot water) of the proposed PVT+HP system ($Q_{H,PVT}$) for the PVT+HP system located in Paris (France) over a winter week (27 Jan. - 2 Feb.).

4. Conclusions

In this paper, the performance of high-efficiency solar trigeneration systems based on a novel hybrid photovoltaic-thermal (PVT) collector based on a flat-box structure for the provision of domestic how water (DHW), space heating (SH), cooling and electricity to residential single-family households is assessed. To this end, the energy demands of single-family houses located in three different climates, namely Seville (Spain), Rome (Italy) and Paris (France), are estimated using the engine tool EnergyPlus, and a TRNSYS model is developed featuring the hybrid PVT panel coupled via a thermal store in two alternative small-scale solar heating and cooling configurations to: 1) an electrically-driven vapour-compression heat pump (PVT+HP), or 2) a thermally-driven absorption refrigeration unit (PVT+AR).

Based on transient simulations over a full year on an hourly basis, it can be concluded that the proposed solar

configurations, PVT+HP or PVT+AR depending on the location, appear as an interesting solutions for the provision of solar DHW, SH, cooling, and electricity in residential buildings. Significant fractions of domestic energy demands can be covered with reasonable PVT collector-array areas. It is also concluded that the most promising solar trigeneration configuration for each location depends on the weather conditions (in particular solar irradiance levels) and the household energy demand profiles. The percentages of the different energy demands covered indicate that the PVT+HP configuration is the most promising alternative for the locations of Rome and Paris, covering 87.7% and 74.3% of the DHW respectively, 100% of the space heating and cooling demands in both locations, as well as 81% and 37% of the electricity demand, respectively. This is achieved with a PVT panels installed area of 18.6 m^2 in Rome and 28.9 m^2 in Paris. For the case of Seville, due to the higher solar irradiance levels and the significant cooling demand, the PVT+AR configuration arises as a promising alternative, with which it is possible to cover 81.9% of the DHW, 53.8% of the space heating, 71.4% of the cooling and 70% of the electricity demands, with a PVT panels installed area of 9.3 m^2. In this case, the PVT+AR configuration presents the advantage of covering double of the domestic electricity demand compared to the PVT+HP system, since most of the cooling demand is covered by means of the PVT thermal output, thus making more electricity available for other purposes that would otherwise have been required to run the HP. Furthermore, the use of the PVT thermal output in summer helps reducing the high temperatures that would be otherwise reached in the storage tank and would lead to heat being dumped to the ambient.

This work suggests that PVT trigeneration systems have an important potential in domestic applications, in particular in urban areas where space is at a premium, since both electrical and thermal outputs are generated from the same area. Still, for the benefits of this technology to be realised and for it to contribute meaningfully towards the envisaged renewable energy generation in the built environment, additional research on solar heating and cooling technologies is required into enhancing efficiency, solar resource use, and reducing costs.

Abstract

Integrating photovoltaic (PV) cells with the solar thermal collector is found beneficial and attractive in the context of the simultaneous production of electricity and heat. Using nanofluid and air as the coolants, a transient mathematical model of a bi-fluid photovoltaic/thermal (PV/T) is developed. Experimental validation of the mathematical model is performed using results from the published work. For nanofluid, aluminum oxide (Al_2O_3) nanoparticles with different concentrations of 0.15 wt%, 0.3 wt%, 0.45 wt%, and 0.6 wt% were dispersed in a base fluid (pure water). The interdependence transient temperature responses of the PV/T collector components are simulated using MATLAB® software. The overall collector performance is predicted and compared when both fluids are to be operated independently and simultaneously. The simulation results indicate that when the fluids are operated simultaneously, the collector performance is better than the independent mode. It is observed that nanofluid & air based PV/T collector provides a higher performance in comparison with conventional heat exchanger systems used in this study.

Keywords: *Mathematical model, Bi-fluid PV/T, Nano-engineered, Model validation*

1. Introduction

A photovoltaic/thermal (PV/T) system possesses better solar harvesting ability in comparison with an individual solar thermal collector or Photovoltaic (PV) system (Hussain and Lee, 2015). Therefore, the PV/T collectors can generate more energy per unit surface area than that of conventional collectors. In a hybrid-PV system, the PV cells performance can be further improved by circulating appropriate heat transfer fluid across its surface. By considering this fact various types of heat transfer fluids having different thermophysical properties have been studied for the PV/T systems (Bhattarai et al., 2012; Rejeb et al., 2016). Water and air among them were the most frequently used cooling fluids (Imtiaz Hussain et al., 2015; Kim et al., 2014). Furthermore, the literature review shows that the rate of heat transfer between the absorber and circulating fluid can be enhanced by increasing the thermal conductivity of the base fluid. The thermal conductivity of the coolant is improved by dispersing nano-sized metallic, metal oxides and nanotube particles in the base fluid. Therefore, application of nanofluid as a coolant for the PV/T system seems to be more promising.

Since the mid-1970s, when the research on the PV/T system started many researchers focused their efforts to improve its performance to get maximum possible thermal and overall efficiency. Chow (2003) proposed an explicit dynamic model that can predict the PV module and circulating fluid temperatures even under rapidly fluctuating solar radiation. Rejeb et al. (2016) evaluated the effect of nanofluid as a heat transfer fluid on the performance of the PV/T system. Among various colloidal solutions, the suspension of copper nanoparticles in pure water provided higher overall energy efficiency compared to alumina. Simultaneous application of two fluids as the heat transfer fluids for the PV/T system offer a great range of benefits in terms of a higher thermal and electrical output. As mentioned by Abu Bakar et al. (2014), the dual fluids based PV/T system was first built and tested by Tripanagnostopoulos (2007). For the purpose of heat extraction improvement, the PV module was integrated with water or air heat extraction elements. Thenceforward, further studies on the effectiveness of the bi-fluid PV/T design was carried out by applying low cost modifications such as introducing serpentine-shaped copper tube as the water heat extraction element transverse to the air flow and fins in the air channel parallel to the air flow direction (Abu Bakar et al., 2014; Jarimi et al., 2016). According to published literature, no previous study using nanofluid and air as the heat extraction fluids for PV/T system has been reported.

doi:10.18086/swc.2017.18.08 Available at http://proceedings.ises.org

This study suggests a transient mathematical model of a bi-fluid PV/T system with the novelty lies in design and the heat extraction components in which nanofluid along with air is introduced. This research seeks to overcome the challenges and gaps to develop a bi-fluid based PV/T system which can significantly decrease PV cells temperature and increase the overall performance of the system.

2. Design concept

A novel bi-fluid PV/T system mainly consisted of standard off the shelf mono-crystalline PV module, copper pipes as the nanofluid heating component, and a single pass air duct as the air heating component. Schematic diagram of the nano-engineered bi-fluid PV/T system is shown in Fig. 1. The flow paths for the nanofluid and air are designed in such a way that there is no physical interaction between two fluids. However, interdependence heat exchange occurs across both heat exchanger components. In order to improve heat transfer rate to the flowing air, the surfaces of the nanofluid carrier pipe and the PV panel are taken as matt black. To heat transfer improvement, a set of baffles is introduced transverse to the direction of airflow. The parallel-arranged fluid carrier pipes are attached directly to the PV module back surface instead of using absorber plate. This direct coupling of PV module with nanofluid heating component results in a decrease of thermal resistance and an increase of heat transfer rate between the PV surface and circulating fluids.

Pipe inner diameter	D_i	0.008 m	Al_2O_3 Thermal conductivity	-	30 W/m K
Pipe thickness	δ_t	0.0012 m	Al_2O_3 Specific heat	-	773 J/kg K
Pipe Specific heat	C_t	903 J/kgK	Al_2O_3 Density	-	3890 kg/m^3

3. Mathematical model

A model based on conservation of energy of bi-fluid PV/T system components is developed and analyzed in transient conditions using ODE solver in MATLAB®. Details of simulation parameters and thermo-physical properties are presented in Table 1. To evaluate the electrical and thermal performances of a bi-fluid PV/T system, heat balance equations for different components such as PV module, copper pipes, nanofluid, circulating air, and back panel are presented as follows:

For PV

$$M_pC_p(dT_p/dt) = G\alpha_p - E - h_{wind}A_{p\infty}(T_p - T_\infty) - h_{p\infty}A_{p\infty}(T_p - T_\infty) - h_{pt}A_{pt}(T_p - T_t) - A_{pa}\,h_{pa}(T_p - T_a) - h_{pb}A_{pb}(T_p - T_b) \quad \text{(eq. 1)}$$

$$E = GP\eta_e \quad \text{(eq. 2)}$$

For copper pipe

$$M_tC_t(dT_t/dt) = h_{pt}A_{pt}(T_p - T_t) - A_{tn}\,h_{tn}(T_t - T_n) - A_{ta}\,h_{ta}(T_t - T_a) - h_{tb}A_{tb}(T_t - T_b) \quad \text{(eq. 3)}$$

For nanofluid in pipe

$$M_nC_n(dT_n/dt) = \dot{m}_nC_n\,(T_{n,o} - T_{n,in}) + A_{tn}\,h_{tn}(T_t - T_n) \quad \text{(eq. 4)}$$

For inside air

$$M_aC_a(dT_a/dt) = \dot{m}_aC_a\,(T_{a,o} - T_{a,in}) + A_{pa}\,h_{pa}(T_p - T_a) + A_{ta}\,h_{ta}(T_t - T_a) + h_{ab}A_{ab}(T_a - T_b) \quad \text{(eq. 5)}$$

For back panel

$$M_bC_b(\partial T_b/\partial t) = h_{tb}A_{tb}(T_t - T_b) + h_{pb}A_{pb}(T_p - T_b) + h_{ab}A_{ab}(T_a - T_b) - h_{b\infty}A_{b\infty}(T_b - T_\infty) \quad \text{(eq. 6)}$$

where, G, α_p, E, and P are the solar radiation, the absorptivity of PV cells, electrical power and packing factor, respectively. M, C, T, A, $\dot{m}$, and h are the mass, specific heat, temperature, surface area, mass flow rate and heat transfer coefficient, respectively. The subscripts p, t, n, a, b, and ∞ are denoted the PV, copper pipe, nanofluid, inside air, back panel insulation and ambient air, respectively. The subscripts p∞, pt, pa, tn, ta, ab, tb, pb, and b∞ are denoted the heat transfer contacts between the PV and ambient air, PV and pipe, PV and inside air, pipe and nanofluid, pipe and inside air, back panel and inside air, back panel and pipe, back panel and PV, and back panel and ambient air, respectively. The subscripts in and o are denoted fluid inlet and outlet, respectively. The electrical, thermal and primary energy saving efficiencies of dual-fluid PV/T systems are calculated using following expressions (Baljit et al., 2017):

$$\eta_e = \eta_r[1 - \beta_r(T_p - T_r)] \quad \text{(eq. 7)}$$

$$\eta_{th} = \frac{\dot{m}_nC_n\,(T_{n,o} - T_{n,in}) + \dot{m}_aC_a\,(T_{a,o} - T_{a,in})}{A_cG} \quad \text{(eq. 8)}$$

$$\eta_{PVT} = \eta_{th} + \eta_e/\eta_{pp} \quad \text{(eq. 9)}$$

where, β_r and A_c are the solar cells temperature coefficient and collector area, respectively. η_r is the efficiency of the solar cells at a reference temperature (T_r). η_e, η_{th} and η_{PVT} are the electrical, thermal and primary energy saving efficiencies, respectively. η_{pp} is the power generation efficiency of the conventional power plant.

4. Results and discussions

4.1. Model validation

Model validation of a proposed PV/T system is performed in two steps, at first the nominal operating cell

temperature (NOCT) of the PV module is predicted using model and then validated against NOCT value obtained from manufacturer's datasheet e.g. 47 °C (PV-MJU240GB). The percentage difference between predicted and datasheet value is less than 1.8%. Second step is a validation of thermal component of air heating against the experimental data (Table 2) for unglazed PV/T air heating system presented by Joshi et al. (2009). To ease the comparison, the nanofluid flow rate is set to be zero. During simulation, similar design and environmental conditions are considered, as presented in (Joshi et al., 2009), other information which is not given in this research were taken from the study by Abu Bakar et al. (2014).

Tab. 2: Simulated values by model against experimentally measured data by (Joshi et al., 2009)

Time (hour)		8	9	10	11	12	13	14	15	16	17
PV cells temperature (°C)	Exp	37.60	41.40	47.90	50.40	54.90	54.70	52.90	50.70	47.20	42.30
	Sim	38.01	41.65	48.52	50.85	55.70	55.50	53.58	51.32	47.79	42.66
Outlet air temperature (°C)	Exp	33.20	36.30	38.90	41.70	46.10	41.50	46.40	44.50	43.00	40.30
	Sim	33.59	36.71	39.33	42.21	46.69	42.11	46.91	44.12	43.49	40.77

Using validated model, the overall performance of a bi-fluid PV/T system is evaluated under different modes of fluid operation. During independent mode, one of the heat extraction fluids is kept stagnant, while other fluid is operated at a designated flow rate. For the simultaneous mode of fluids operation, both fluids are operated at the same time. During simulation, all heat transfer coefficients were calculated in real time.

4.2. Simulation results

To locate the best concentration, different weight fractions of Al_2O_3 nanoparticles in a base fluid have been considered. Generally, a variation of nanoparticles concentration affects directly the thermo-physical properties (thermal conductivity and specific heat in particular) of the colloidal solution, and hence the heat transfer rate. Variation of daily solar radiation and ambient temperature are shown in Fig. 2. Influence of Al_2O_3 nanoparticles concentration on the thermal conductivity ratio and specific heat ratio is shown in Fig. 3. Increasing the nanoparticles (np) concentration in the base fluid (bf) increases the thermal conductivity and decreases the specific heat of the Al_2O_3 nanofluid. It is observed that the thermal conductivity ratio (knp/kbf)) increased to 1.162 and the specific heat ratio (Cnp/Cbf) decreased to 0.954 when the Al_2O_3 weight fraction increased from 0 to 0.75 (wt%). This can be attributed to the higher thermal conductivity and lower specific heat of the Al_2O_3 nanoparticles compared to water as the base fluid.

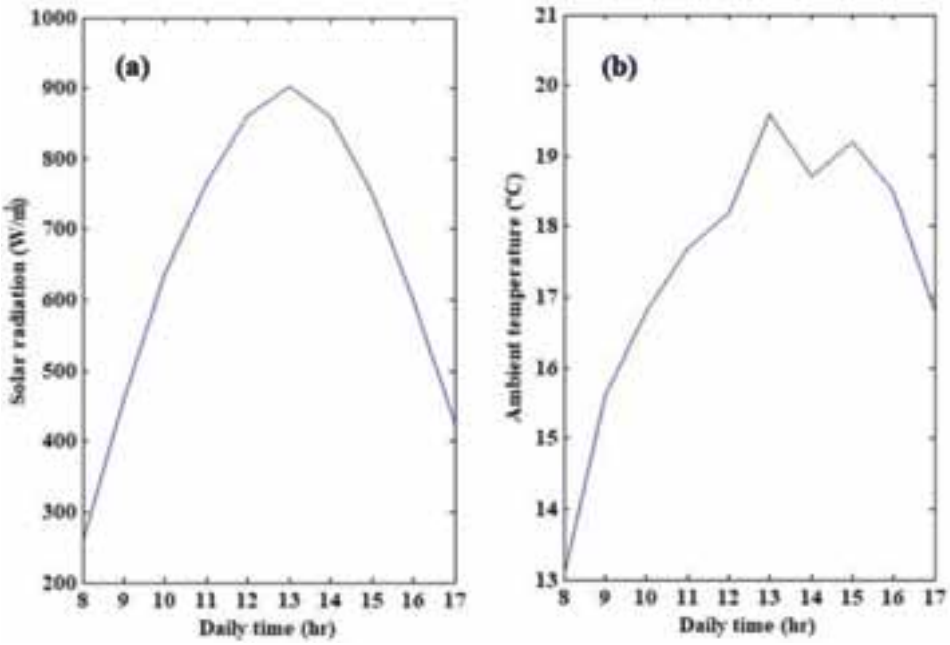

Fig. 2: Daily variation of (a) solar radiation (b) ambient temperature

The PV cells temperature has been predicted using different working fluids both simultaneously and independently. Fig. 4 depicts the PV cells temperature under different modes of fluid operation namely: Al_2O_3/air, water/air, nanofluid, air, and without the heat transfer fluid. Compared to the PV temperature obtained without working fluid (69.4 °C), the average PV temperature drop by 7.8, 9.2, 11.3, and 13.6 °C when either one or two fluids are operated such as air, Al_2O_3 nanofluid, water/air, and Al_2O_3/air, respectively. It is worth to note that introducing bi-fluid heat extraction component, in particular, Al_2O_3/air, underneath the PV module increases not only its electrical efficiency but also produces high-temperature heat at the same time.

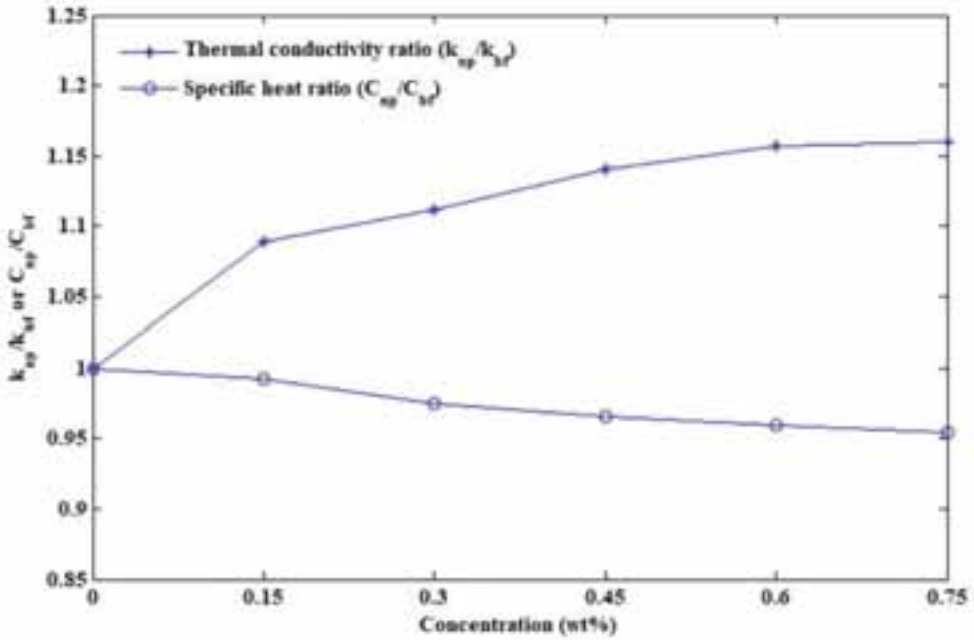

Fig. 3: Variation of thermal conductivity ratio and specific heat ratio of Al_2O_3 with concentration (wt%).

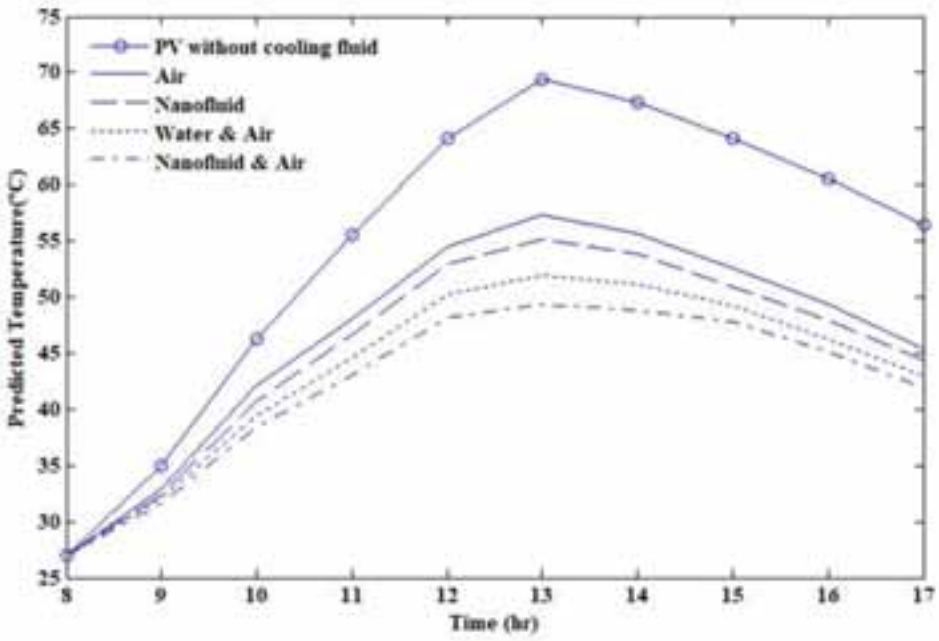

Fig. 4: Predicted PV temperature using different coolant fluids and modes of fluid operations.

The effect of different modes of fluid operation on the daily total efficiency of a PV/T system is observed by varying nanofluid or water flow rate at a fixed air flow rate of 0.05 kg/s (Fig. 5). The total efficiency of the bi-fluid PV/T system is considerably higher than the system with a single heating component. The simulation results show that the overall energy efficiency of a Al_2O_3/air based PVT was found significantly higher than that

of the cases with water/air and nanofluid heat exchanger systems, owing to additional thermal and electrical energy produced. The use of nanofluid as a heat extraction component for PV/T system provides excellent overall energy performance in comparison with either water or air.

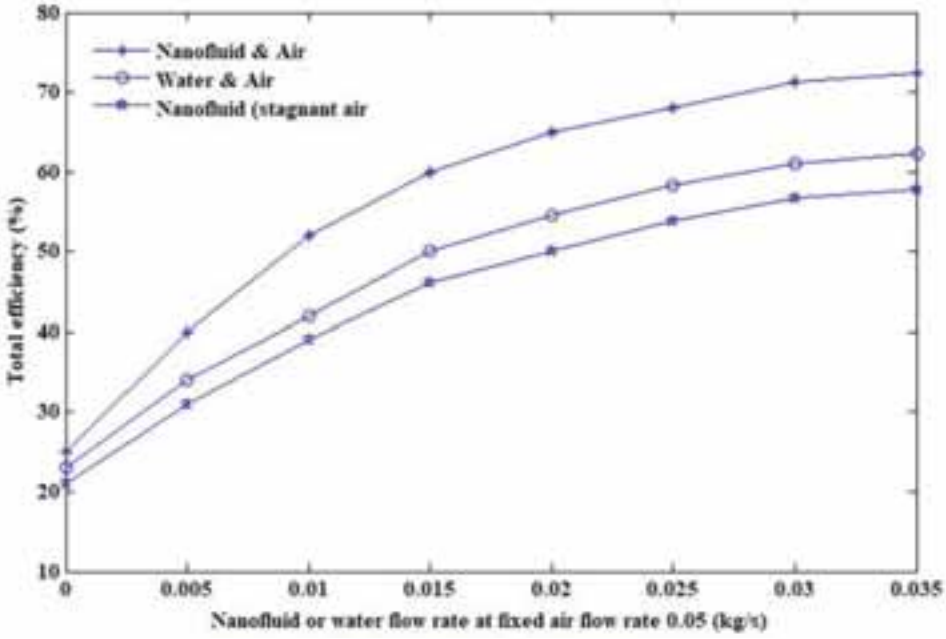

Fig. 5: Total PV/T efficiency with varying nanofluid or water flow rate at fixed air flow rate of 0.05 kg/s.

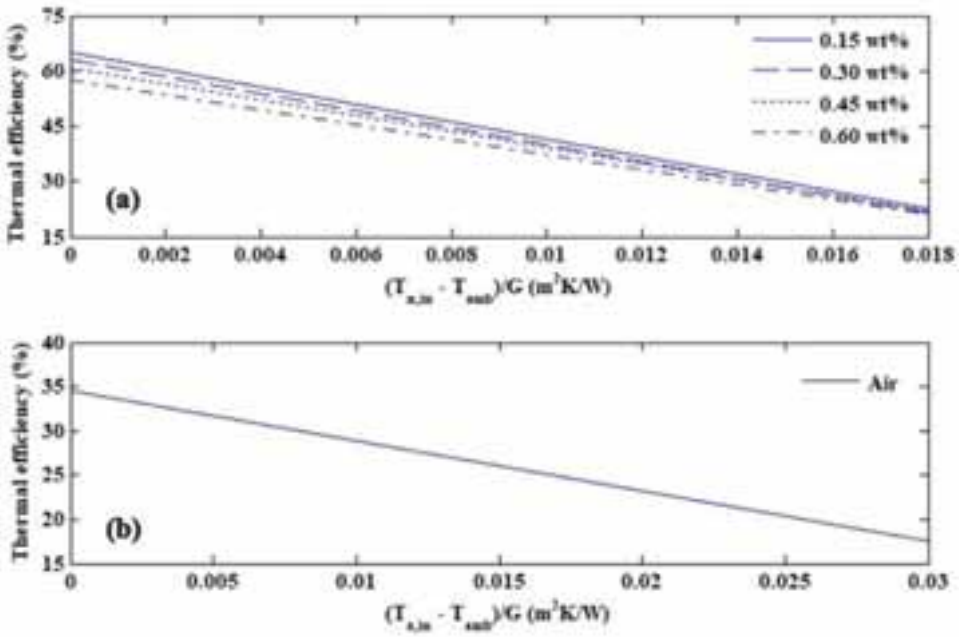

Fig. 6: PV/T thermal efficiency (a) with different concentration of Al_2O_3 at stagnant air (b) with varying air flow rate at stagnant nanofluid.

Even though the model is developed considering dual-fluid heat exchangers for the dual-fluid PV/T system. However, by setting one of the fluids in stagnant mode, the given model can also be used for a single fluid operation. Fig. 6 compares the thermal efficiency of the PV/T system with Al_2O_3 nanofluid and air at zero reduced temperature. In addition, the influence of nanoparticle concentrations on the collector performance is also investigated, as shown in Fig. 6a. In this paper, four nanofluid concentrations (0.15 wt%, 0.3 wt%, 0.45 wt%, 0.6 wt%) were selected to investigate. It is observed that the zero-loss thermal efficiencies of the PV/T system with Al_2O_3 nanofluid and air were found to be 65.3% and 34.5%, respectively. Furthermore, the thermal

efficiency of the PV/T system increases with increasing the weight fraction of Al_2O_3 nanoparticles in the base fluid. It should be noted that changing the nanoparticles concentration from 0.15 to 0.6 wt% results in a thermal efficiency enhancement from 58% to 65.3%, respectively. The higher thermal efficiency of PV/T system with nanofluid as a coolant can be explained by an improvement of thermal conductivity of the base fluid by dispersing nanoparticles (Sharma et al., 2017). Thus, enhancement of heat transfer coefficient between the absorber and circulating fluid is observed.

In order to evaluate the overall performance of a nano-engineered dual-fluid PV/T system, it is important to investigate the effects of the simultaneous fluid operation on primary energy saving efficiency. Influence of variable mass flow rate of Al_2O_3 nanofluid (at fixed air flow rate) and air (at a fixed nanofluid flow rate) on the primary energy saving efficiency is shown in Fig. 7. Increasing the nanofluid flow rate from 0.005 to 0.03 kg/s with fixed air flow rate at 0.015 kg/s, 0.035 kg/s, and 0.055 kg/s the maximum primary energy saving efficiency were 88.6%, 89.3% and 90.2%, respectively. Whereas, increasing air flow rate from 0.02 to 0.12 kg/s with fixed nanofluid flow rates at 0.008 kg/s, 0.013 kg/s, and 0.018 kg/s these values were found to be 78.9% to 79.3% and 79.8%, respectively. It is important to note that the percentage increase in the primary energy saving efficiency with the variable nanofluid flow rate is considerably higher than the variable air flow rate. This can be explained by the fact that nanofluid has higher average thermal conductivity than water and air. Therefore, the solar heat being sufficiently absorbed from the PV panel by the circulating nanofluid when the flow rate of air is kept constant.

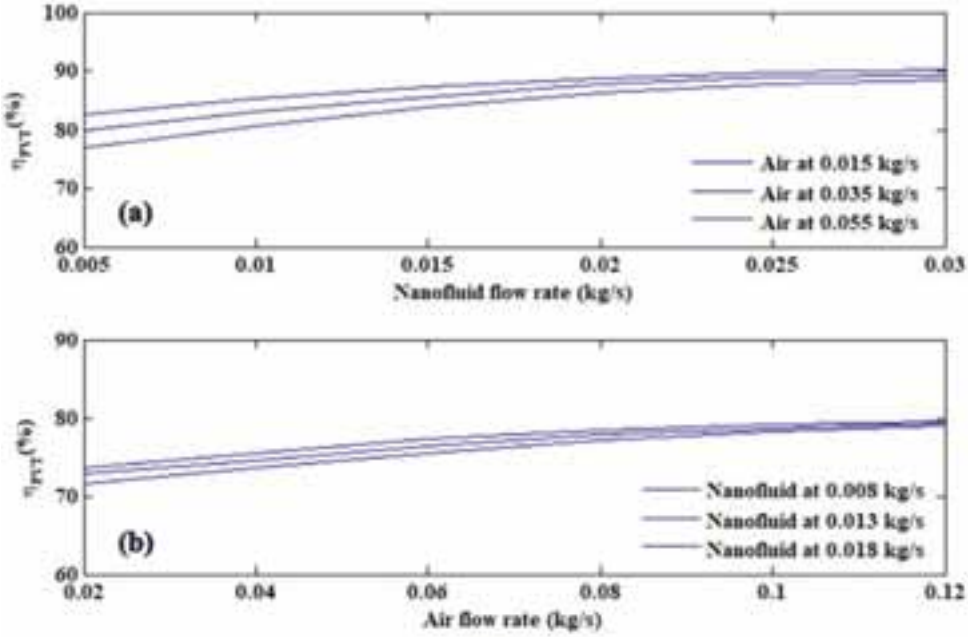

Fig. 7: Primary energy saving efficiency (a) variable nanofluid flow rate at fixed air flow rate (b) variable air flow rate at fixed nanofluid flow rate.

5. Conclusion

The transient numerical analysis of a bi-fluid PV/T system which incorporates the simultaneous application of Al_2O_3 nanofluid and air heat extraction components is performed. The developed transient model can be used to predict the PV/T system's performance for both independent and simultaneous modes of fluid operation. All heat transfer coefficients were calculated in real time during the simulation. The heat transfer rate to the flowing air is improved by introducing a set of baffles transverse to the air flow. The model of a nano-engineered dual-fluid PV/T system is developed and validated against the experimental data given in the literature. The use of Al_2O_3 nanofluid plus air as the dual heat exchanger system provides excellent overall energy performance for the PV/T system in comparison with water plus air and other conventional heat transfer fluids. The developed transient mathematical model can able to accurately predict and optimize the collector performance under a

wide range of varied operating and climatic conditions.

Abstract

A photovoltaic-thermal (PVT) collector is a solar collector that combines a photovoltaic module with a solar thermal collector, which produces electricity and heat at the same time. Depending on the medium used for collecting thermal energy, there are two types of PVT collectors: air-type and water-type. The integration of PV modules with a thermal collector can cause a temperature rise of the PV module, which in turn decreases the efficiency of the PVT collector. In order to obtain better performance of air-type PVT (PVT/a) collectors, it is necessary to extract the heat, in the form of hot/warm air, from the PV module, which then decreases its temperature. This article presents the performance of a new design of a PVT/a collector that uses air as the heat recovery fluid. In this study, an advanced PVT/a collector were newly developed, and its electrical and thermal performance was analyzed from experimental results in outdoor conditions. The results indicated that the thermal and electrical efficiencies of the PVT/a collector were, on average, approximately 30 % and 7 %, respectively.

1. Introduction

A photovoltaic-thermal (PVT) collector is a solar collector that combines a photovoltaic module with a solar thermal collector, which produces electricity and heat at the same time. Depending on the medium used for collecting thermal energy, there are two types of PVT collectors: air-type and water-type. The integration of PV modules with a thermal collector can cause a temperature rise of PV the module, which in turn decreases the efficiency of the PVT collector. Ooshaksaraei et al. (2017) investigated four types of air-based bifacial PVT collectors by experimental and analytical methods under steady-state conditions [1]. Tomar et al. (2017) studied analytical models for four PVT/a collectors with different layers. The electrical and thermal efficiency were compared under outdoor condition [2]. Jaaz et al. (2018) experimentally tested a compound parabolic concentrator (CPC) along with PVT/w where the cooling process of the CPC was conducted using water jet impingement technique [3]. Tomar et al. (2018) made five PVT/w collectors with different cell types, namely mono-crystalline (m-Si), polycrystalline (p-Si), amorphous silicon thin film (a-Si), cadmium telluride thin film (CdTe) and copper indium gallium selenide (CIGS) photovoltaic modules. In the paper, theoretically calculated results were experimentally validated in outdoor ambient environment [4]. In order to obtain better performance of air-type PVT (PVT/a) collectors, it is necessary to extract the heat, in the form of hot/warm air, from the PV module, which decreases its temperature. The thermal and electrical performance of a PVT/a collector depends on their design affected airflow and heat transfer. In this light, there is need for an advanced design of PVT/a collector to improve the uniformity of the air flow and the heat transfer. This article presents the performance of a new design of a PVT/a collector that uses air as the heat recovery fluid.

In this study an advanced PVT/a collector was newly designed and made, and their performance was analyzed

doi:10.18086/swc.2017.18.09 Available at http://proceedings.ises.org

through experimental results. The aim of this study is to characterize the thermal and electrical performance of a new collector design of a PVT/a collector under both steady-state conditions.

2. Advanced Air-Type PVT(PVT/a) Collector Design and Experiment

2.1. Advanced Air-Type PVT (PVT/a) prototype

For this study, a prototype of an advanced air-type PVT (PVT/a) collector was developed, as shown in Fig.1. The PVT/a collector consists of a special PV module and absorber plates as a baffle for uniform of air flow; it has a 0.7m^2 PV area and an air layer of 80mm for collecting hot air. The glass to glass type (G/G) PV module was designed with 123W$_p$ mono-crystalline silicon PV for the advanced PVT/a prototype. PVT/a prototype were developed as shown in Fig.1. It has an absorber consisting of both photovoltaic (PV) cells and thermal absorbers in alternate rows. There are four thermal absorbers equally spaced in the PVT/a collector. They are located in the air cavity behind the glass PV glass assembly such that air can circulate above and below the thermal absorbers. The thermal absorber is made out of a thin metal sheet with highly selective blue coating. The PVT/a prototype have a gross are of 1.63m^2, and the PV modules' efficiency used for the collectors was 7.6% under standard test conditions (STC).

In outdoor experiment, the PVT/a prototype were tested. The back surface temperature of the glass-PV-glass assembly was measured with 5 surface thermocouples located in the middle of each PV row along the collector length; that is thermocouples referred to as Td1, Td2, Td3, Td4 and Td5 were arranged from the bottom to the top of PVT/a collector equidistantly. In addition, a distribution box was added at the second module outlet to promote flow uniformity across the cavity.

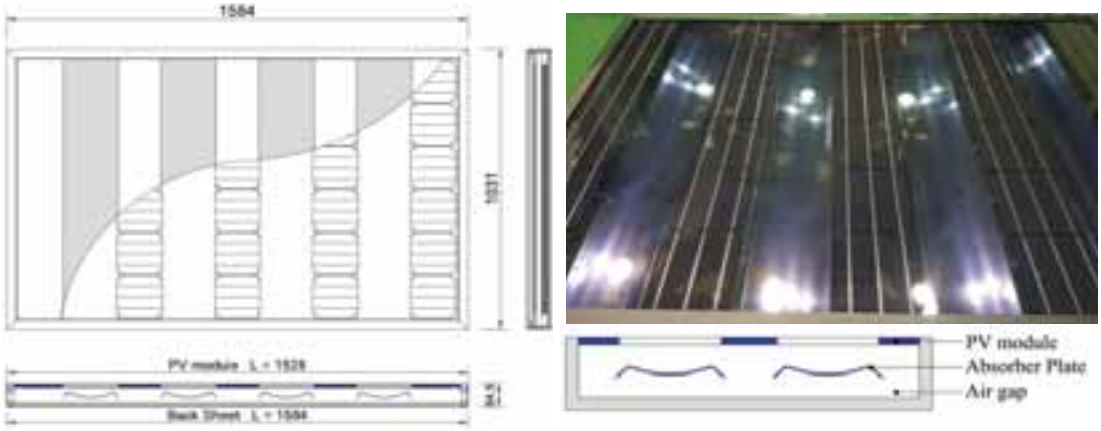

Fig. 1: Prototype design of the advanced PVT/a collector

The advanced PVT/a collector were also tested under outdoor conditions based on the ASHRAE 93-2013 [1] and ISO 9806 standards [2]. Several experimental devices were installed to measure the temperature of the PV laminate backside, the air layer, and the exhausted air, as well as the electrical power of the PVT/a collector. A T-type thermocouple was used to measure the temperature and an I-V curve tracer with Maximum Power Point Tracking (MPPT) was installed for measuring the electrical performance. For the measurement of the air flow rate, flow meters were installed inside the pipes of the inlet and outlet of the PVT/a collector. A data acquisition instrument was also connected to record all of the data related to the thermal and electrical performance of the PVT/a collector and the outdoor conditions.

The PVT/a Testing facility is an open-loop air circulation system. It includes the equipment required to circulate and control the amount of air entering and leaving the PVT/a collector as well as the sensors providing the information required for quantifying the amount of thermal energy that is being recovered. It is an open-loop system because the air heated by the collector is not recirculated in the loop, but rejected outdoors. However, ambient air is preheated in a chamber to temperature of 35 ^{o}C before being supplied to PVT/a collector. Some components for the thermal characterization are located in the air-loop chamber while some others are mounted directly on the multi-functional grid. The air-loop chamber sits separately with system and is connected to the

PVT/a collector on the multi-functional grid with two flexible ducts, one for the inlet and one for the outlet. To control the pressure inside the collector, the PVT/a testing facility uses two blowers to circulate air in the PVT/a collector. The blower located upstream of the collector, the inlet blower, operates in positive pressure and the blower located downstream of the collector operates in negative pressure (see Figure 2). For the experiment, air flowrate of 120kg/h was settled in a PVT testing facility. The experiment was carried out on September 2017. Fig. 2 shows the advanced PVT/a collector and the experiment setup.

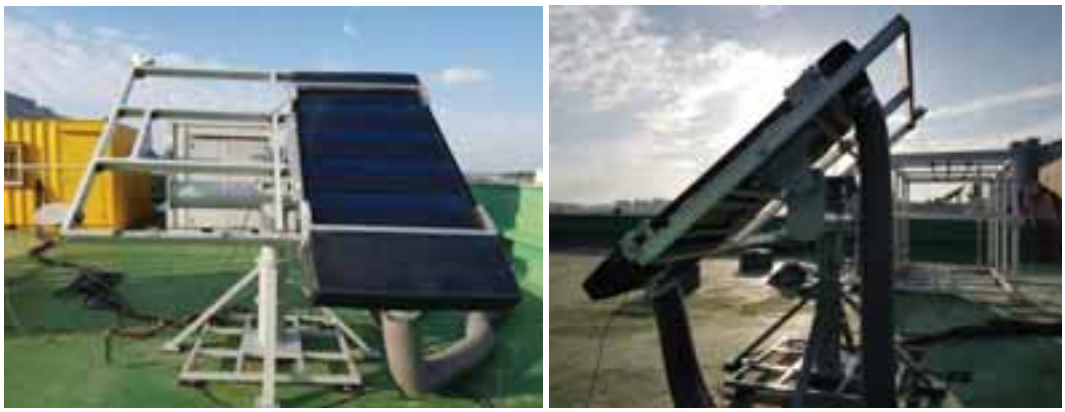

Fig. 2: Outdoor experiment setup

3. Results and Discussion

3.1. Temperature characterization

On the basis of the experimental results, the temperature characterization of the advanced PVT/a collector is presented in figure 3, 4. In Fig. 3, it was found that the advanced PVT/a collector has a temperature gradient, as the temperature of the PV laminate backside is 50~64℃ at ambient of 29℃ and average irradiance of 870 Wm^{-2}. The temperatures at bottom and top part of PV backside are 50~53℃, 62~64℃, respectively.

Fig. 4 presents the inlet and outlet air temperature of PVT/a at the steady-state conditions. This graph show that the air temperature rise of the inlet and outlet of the PVT/a where a difference of 17 °C can be observed at the outdoor condition at ambient of 29 ℃ and irradiance levels of 870 Wm^{-2} with a flowrate of 120 kg/h.

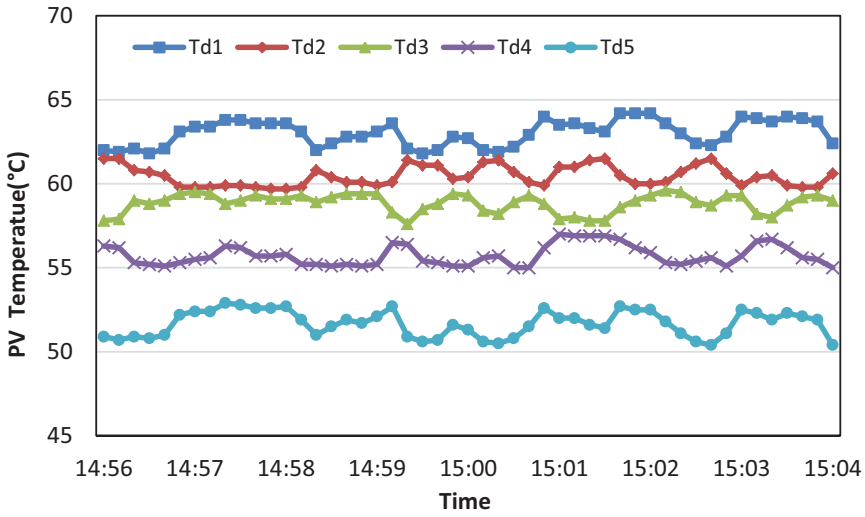

Fig. 3: PV backside (five points) temperatures of the PVT/a collector

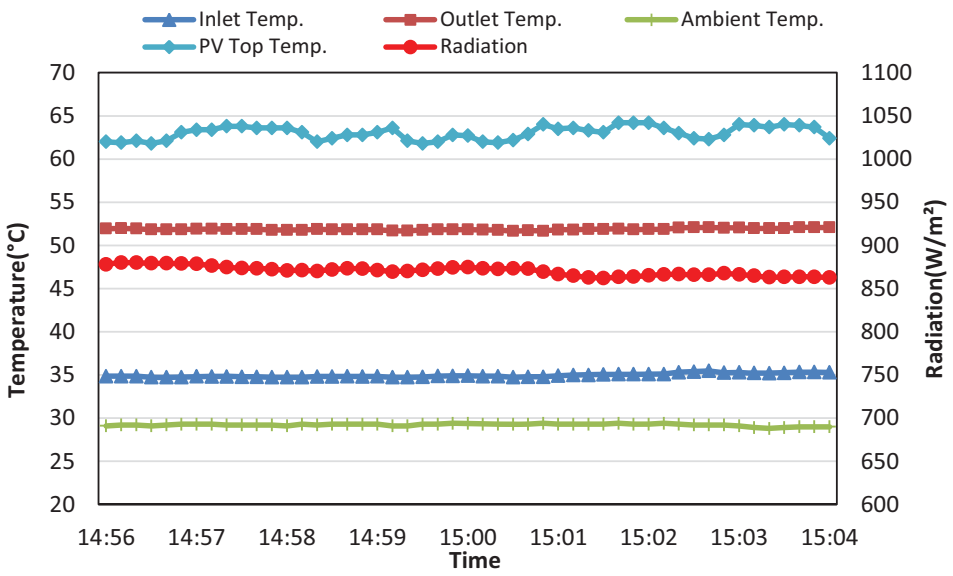

Fig. 4: The air temperature of inlet and outlet of PVT/a collector at the outdoor of steady-state condition

3.2. Thermal and Electrical performance

The thermal performance of PVT/a collector can be characterized by the air temperature difference of the PVT/a collector. On this basis, the thermal efficiency is determined as a function of the solar radiation (G), the mean fluid temperature (T_m) and the ambient temperature (T_a). The steady-state efficiency is calculated by the following equation [7]:

$$\eta_{th} = \frac{\dot{m}\, C_p\, (T_o - T_i)}{A_{pvt}\, G} \qquad \text{(eq. 1)}$$

η_{th} thermal efficiency [-]
A_{pvt} collector area [m^2]
T_o collector outlet air temperature [$^{\circ}$C]
T_i collector inlet air temperature [$^{\circ}$C]
$\dot{m}$ mass flow rate [$m^3\ h^{-1}$]
C_p specific heat [$J\ kg^{-1}\ K^{-1}$]
G irradiance on the collector surface [$W\ m^{-2}$]

The thermal efficiency of the PVT collectors was conventionally calculated as a function of the ratio $\Delta T/G$, where $\Delta T = T_m - T_a$. Here, T_m and T_a are the PVT collector's mean fluid temperature and the ambient temperature, respectively, and G is the solar radiation at the collector surface. Hence, ΔT denotes the measurement of the temperature difference between the inlet fluid and ambient air relative to the solar radiation. The thermal efficiency, η_{th}, is expressed as

$$\eta_{th} = \eta_0 - \alpha_1 \frac{\Delta T}{G}$$

where η_o is the thermal efficiency at zero reduced temperature, and α_1 is the heat loss coefficient.

The thermal efficiency as a function of the ratio $\Delta T/G$ is shown in Fig. 5. As it can be observed, the thermal efficiency decreases with ratio $\Delta T/G$. This thermal performance dependency to ratio ΔT/G indicates that the prototype behaves like conventional solar thermal collector.
From the measurement results for the advanced PVT/a collector, it can be seen that the thermal performance can be expressed as in Fig. 5. The thermal efficiency of the PVT/a collector can be therefore be described by the relational expression, $\eta_{th} = 0.3709 - 5.5371(\Delta T/G)$. Thus, the collector thermal efficiency (η_0) at zero reduced

temperature is 37%, which indicates relatively high performance. The heat loss coefficient (α_1), which can have an effect on reduction of thermal efficiency was 5.54 (℃ $m^2 W^{-1}$), which is can be observe low heat loss ratio. The average thermal efficiency of the PVT/a collector is about 30% under outdoor test conditions and with the given X axis coefficients ($\Delta T/G$).

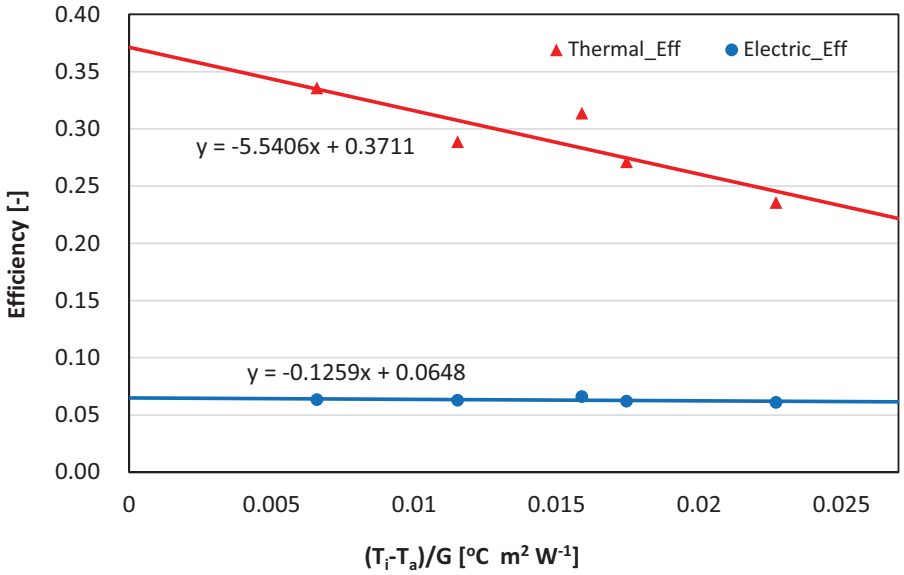

Fig. 5: Thermal and electrical efficiencies of the PVT/a collector

The electrical efficiency depends mainly on the incoming solar radiation and the PV module temperature. It is calculated with the following equation:

$$\eta_{el} = \frac{I_m V_m}{A_{pvt} G} \qquad \text{(eq. 2)}$$

where, I_m and V_m are the current and the voltage of the PV module operating under a maximum power.

The electrical efficiency of the PVT/a collector can be expressed with the following relational expression: η_{el} = 0.0648-0.1259(ΔT/G). The highest electrical efficiency of the PVT collector is 6.5% with the given X axis coefficients ($\Delta T/G$). As shown in Figure 5, the electrical efficiency is positive with regard to the X axis coefficients, as compared to the thermal efficiency. This occurs because, in spite of identical test conditions of the X axis coefficients, the electrical performance of the PVT/a collector was affected immediately by the PV temperature in addition to the X axis coefficients ($\Delta T/G$), i.e., ambient temperature, mean fluid temperature and solar radiation.

4. Conclusion

This paper presented the steady-state thermal and electrical performance of a new prototype of an advanced PVT/a collector. The design of this prototype is unique because its absorber consists of a combination of both photovoltaic cells and thermal absorbers in alternate rows. Experimental measurements were taken in outdoor conditions one PVT/a collector operated in open-loop.

Experimental results performed outdoors at the steady-state showed that at a flowrate of 120 kg/h and an irradiance level of 870 W/m², a temperature rise of 17°C.

The results show that at zero reduced temperature, the thermal and electrical efficiency levels of an advanced

PVT/a collector are 37% and 7%, respectively. Due to the unique design, the power generation is relatively low. Therefore, the advanced PVT/a collector had better thermal performance than the electrical performance.

Assessing suitable fields of application for PVT collectors with the characteristic temperature approach

Manuel Lämmle, Korbinian Kramer, Michael Hermann
Fraunhofer Institute for Solar Energy Systems ISE, 79110 Freiburg, Germany

Abstract

PVT collectors co-generate heat and electricity and a single component. There are various PVT collector technologies available, with varying efficiencies and thus varying fields of application. But which PVT collector technologies are suitable for which fields of application?

The characteristic temperature approach is a novel method, which correlates the electrical and thermal yield with the mean operating temperatures T_{char}. Thus, the complexity of the system is reduced to a single temperature. T_{char} is therefore an apt indicator to assess suitable fields of applications for PVT collectors and select the most suitable collector technology. Moreover, the characteristic temperature approach allows a preliminary dimensioning of a PVT system and estimate yields of different technologies.

Keywords: PVT system; system simulations, Hybrid PV/Thermal collector; yield assessment

1. Introduction

PVT collectors can be classified according to their design (unglazed, glazed, concentrating), their heat transfer medium (water, air), and their PV cell technology (Zondag 2008). In Europe, unglazed PVT collectors have the highest market share, but their application is limited to low temperature systems due to high collector heat losses. Glazed PVT collectors offer an enhanced thermal efficiency owing to reduced thermal losses by a transparent front cover. Spectrally selective low-emissivity (low-e) coatings in glazed PVT collectors reduce infrared radiative heat losses, yet at the cost of a drop of electrical efficiency (Lämmle et al. 2016). Concentrating PVT collectors can be realized out from low to high concentration ratios, with the possibility of both stationary and tracked operation. Concentrating PVT collectors potentially achieve very low heat losses and high temperature levels (Chow 2010).

These considerations demonstrate that each collector technology has its specific temperature levels and accordingly suitable applications. From an energetic point of view, the annual electrical and thermal yields of PVT collectors in typical system installations are of major interest.

2. Characteristic temperature approach

2.1. Definition of the characteristic temperature T_{char}

As is generally known, the fluid temperatures have a strong influence on the instantaneous performance of PVT collectors. The electrical efficiency of silicon PV cells drops by approximately 0.4 % per Kelvin of increased cell temperature owing to the negative power temperature coefficient γ. Also the thermal efficiency drops due to higher heat losses at higher absorber temperatures.

To investigate the influence of the annual operating temperatures, a new system indicator was introduced in Lämmle et al. (2017), which characterizes a PVT system based on its mean operating temperatures. The characteristic operating temperature T_{char} is defined as the annual, irradiance-weighted, mean fluid temperature in the collector:

$$T_{char} = \frac{\int G\, T_m dt}{\int G\, dt} \qquad \text{(eq. 1)}$$

with the instantaneous irradiance in the collector plane G, and the mean fluid temperature T_m.

doi:10.18086/swc.2017.18.10 Available at http://proceedings.ises.org

2.2. Comparison of PVT collector technologies

Different flat plate, water-type PVT collector technologies are included in the assessment:

- a commercially available unglazed PVT collector without rear insulation,

- a glazed PVT collector with an anti-reflectance coated front cover

- a glazed PVT with a low-emissivity coating on the PVT absorber (Lämmle et al. 2016)

- a conventional PV module and a flat plate collector for comparison purposes

Concentrating PVT collector technologies are not included in this analysis. An initial comparison of energy yields revealed no energetic benefit of applying currently available concentrating PVT collector technologies in the central European climate.

Fig. 1 compares the electrical efficiency at standard test conditions and the thermal efficiency curves of the investigated technologies. The detailed efficiency parameters can be found in Lämmle et al. (2017).

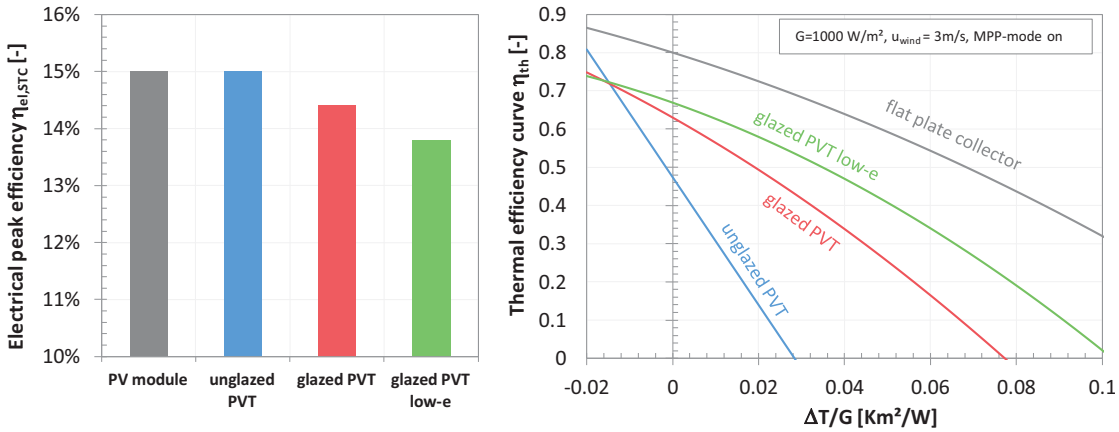

Fig. 1: Comparison of the standard efficiency of PVT collector technologies.

A conflict of interest between a high electrical vs. a high thermal efficiency can be observed, which results from the trade-off between a good optical performance vs. thermal insulation.

2.3. Analysis of correlation between yields and T_{char}

System simulations were carried out to analyze the correlation between collector yields and the characteristic temperature. For this purpose, several different types of PVT systems were analyzed, including systems for domestic hot water (DHW) heating in single and multi-family-homes, as well as combined DHW and space heating systems with and without heat pump. To achieve a wide variation of operating temperatures, the key system parameters of collector area and storage volume were varied. Simulations were carried out for the German location of Würzburg, and the detailed assumptions and results can be found in (Lämmle et al. 2017).

Analyzing the correlation between the characteristic temperature T_{char} and electrical and thermal yields, characteristic curves for each collector technology are found (Fig. 2). In the diagrams, each point represents results of a specific annual system simulation run and different types of PVT systems with varying system dimensions are included therein.

Due to the observed strong correlation between yields and T_{char}, the characteristic temperature describes the effect of the PVT system on yields independent from the system type. T_{char} is therefore a suitable indicator to characterize the thermal operating conditions of PVT systems. Depending on T_{char}, different PVT collector technologies can exploit their specific strengths. Therefore, the most suitable PVT collector technology has to be selected to match the given T_{char} of the PVT system.

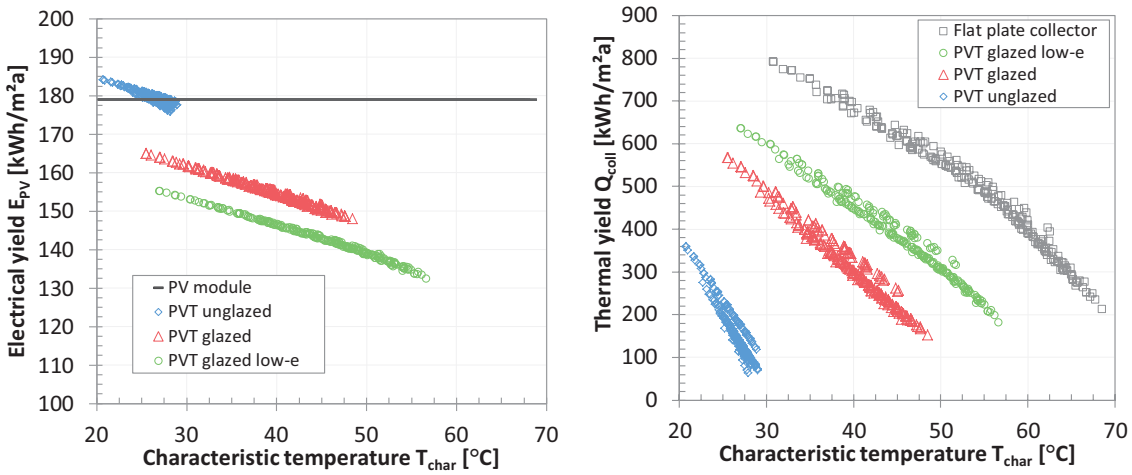

Fig. 2: Characteristic curves of the electrical and thermal collector yield of different PVT technologies as function of the characteristic temperature T_{char} (Lämmle et al. 2017).

2.4. Exemplary application of the characteristic temperature approach

To assess the applicability of PVT collectors in specific systems the following schematic procedure can be applied:

1. Identify T_{char} for the present application. This can be either done by a single annual simulation run or T_{char} can be estimated from operating temperatures of known systems
2. Read specific yields from Fig. 2
3. Size collector field to achieve the required electrical or thermal target output
4. Calculate the total electrical and thermal output of the PVT system

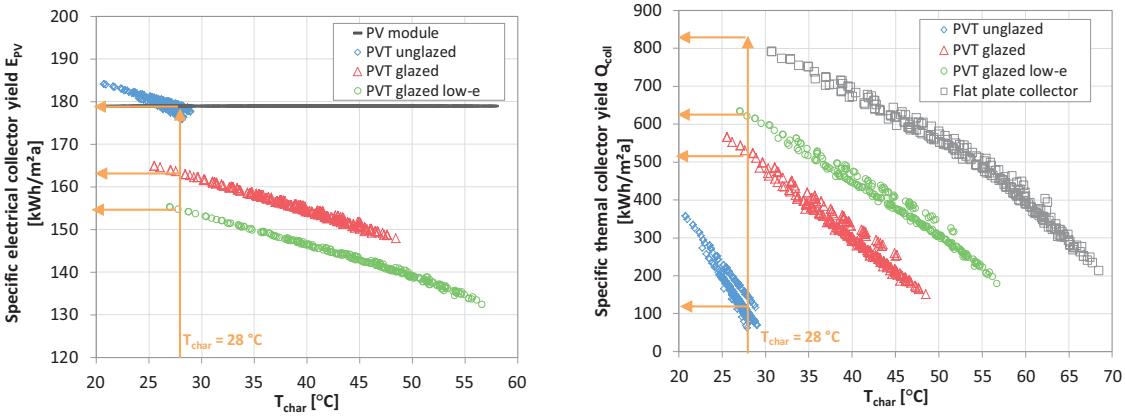

Fig. 3: Exemplary application of the characteristic temperature approach for the preliminary design of a PVT system with a characteristic temperature T_{char} = 28 °C at the location of Würzburg, Germany

Fig. shows the exemplary application of this procedure for a hot water system in an office building with a characteristic temperature of T_{char} = 28.0 °C. With the knowledge of T_{char}, the electric and thermal yields can be read from the graph. While the unglazed PVT collector reaches the highest electrical yields, the glazed PVT collector with low-e coating reaches the highest thermal yields.

Depending on the local energy demand, priority is either given to high electrical or high thermal yields. Typical energetic evaluation criteria include, amongst others, the specific yields per square meter of collector area, the roof area required to meet the required local solar energy demand, or the maximum energetic electricity and heat output a specific roof area can reach. If cost functions are supplied, also levelized costs of electricity and heat can be calculated. All these evaluation criteria can be preliminarily assessed by means of the characteristic temperature approach.

3. Assessing suitable fields of applications for PVT collectors

A central motivation for PVT collectors is the optimization of the overall combined electricity and heat output. As PVT collectors co-generate solar electricity and heat from the same area, potentially highest overall yields can be achieved. To quantify the combined electricity and heat output as a single value, primary energy yields are used. The primary energy yield per square meter of collector area is given by:

$$Q_{PE} = f_{PE,el}\, E_{PV} + f_{PE,heat}\, Q_{coll} \qquad \text{(eq. 2)}$$

with the primary energy factors for electricity $f_{PE,el}$ = 2.0 and for heat $f_{PE,heat}$ = 1.1 (DIN V 18599-1:2013-05), and the specific electrical and thermal yield E_{PV} and Q_{coll}.

Fig. 4 plots the primary energy yield Q_{PE} as function of the characteristic temperature T_{char} for the previously mentioned PVT systems. On account of the dependence of electrical and thermal yields from T_{char}, a strong correlation is also observed between T_{char} and primary energy yields, resulting in characteristic curves for each collector technology.

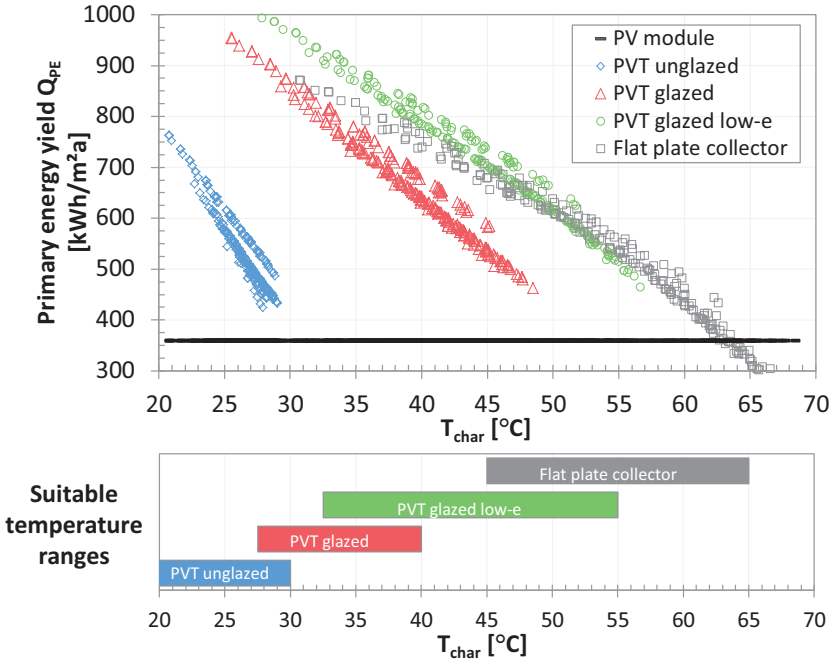

Fig. 4: Primary energy yields and derived suitable temperature ranges per PVT collector technology.

For an optimized utilization of available solar areas, the primary energy yield needs to be maximized.

Firstly, this can be achieved by reducing $T_{char.}$ As both the electrical and thermal efficiency benefit from low operating temperatures, a reduction of the fluid temperatures affects an increase of both electrical and thermal yields. For instance, low characteristic temperatures are achieved by smaller dimensions of the PVT array, larger storage volumes, and lower storage temperatures.

Secondly, the primary energy yields can be maximized by an adequate selection of a suitable collector technology, which matches the characteristic temperature. From Fig. 4, suitable temperature ranges can be derived for each collector technology. The following temperature ranges, and accordingly suitable fields of application, seem recommendable:

- **Unglazed PVT collectors** for very low operating temperatures near or below ambient of T_{char} < 30 °C.
- **Glazed PVT collectors** for low to medium operating temperatures of T_{char} < 40 °C.
- **Glazed PVT collectors with low-e** for medium operating temperatures of T_{char} < 55 °C.
- For higher temperatures, **concentrating PVT collectors** or a side-by-side installation of **flat plate collectors and PV modules** might achieve an optimized primary energy yield.

4. Conclusion

The operating temperatures in PVT systems are of pivotal importance, since both the electrical and thermal performance depend on it. The characteristic temperature approach puts these operating temperatures into the focus by introducing the new indicator T_{char}, which specifies the mean annual operating temperatures of the PVT system.

The characteristic temperature approach can be used to preliminarily design a PVT system and evaluate the technical and economic feasibility. Depending on the temperature level T_{char} of a specific PVT system, the most suitable collector technology can be selected. T_{char} is therefore a good indicator to assess the applicability of different PVT technologies in different PVT systems with varying temperature levels.

Reverse Engineering Prototype Solar PV/Thermal Collector Properties from Empirical Data for Use in TRNSYS Type 560

Nelson Sommerfeldt[1] and Patrik Ollas[2]

[1] KTH Royal Institute of Technology, Dept. of Energy Technology, Stockholm (Sweden)

[2] RISE Research Institutes of Sweden, Built Environment Division, Borås (Sweden)

Abstract

Using the known physical characteristics of a prototype photovoltaic-thermal (PVT) collector components and raw test data from a prematurely terminated ISO 9806 test, the objective of this study is to reverse engineer a thermal resistance value for the heat exchanger assembly for use in the theoretical TRNSYS model Type 560. Modeling is done using both TRNSYS as well as commercial heat transfer software TAITherm. Performance is measured by the mean absolute error and correlation of the outlet temperature and thermal power, as well as the differences in total thermal energy generated. The results show a thermal resistance of 0.005 to 0.010 m^2 K W^{-1} in TAITherm and 0.010 to 0.040 m^2 K W^{-1} in Type 560. TAITherm gives better statistical indicators which is likely due to the inclusion of thermal mass in the model. The results have informed prototype development and can be used in further systems modeling.

Keywords: PVT, Prototype, Testing, Simulation, TAITherm, TRNSYS, Validation

1. Introduction

Photovoltaic-thermal (PVT) hybrid modules absorb solar radiation and can convert it into electricity and heated fluids. There is a broad range of design concepts, however the most feasible solution for building applied or integrated products is a flat plate collector (Michael et al., 2015). In this arrangement, PV cells are mounted to a flat plate heat exchanger with cooling channels on the opposite side. With a glass front, this hybrid absorber can be used directly, known as an unglazed collector, or insulated from the environment with the glazing separated by an air gap over the PV. Insulation is most commonly added to the rear of the panel as well, but is not necessary.

PVT collectors are predominantly used for direct domestic hot water or space heating, and recently there has been growing interest in combining them with heat pumps (Hardorn, 2015). There are numerous potential system configurations, and one such configuration with relevance for Sweden is PVT in conjunction with ground source heat pumps (GSHP) (Sommerfeldt and Madani, 2016). If placed on the cold side of the heat pump, there are mutual benefits for each component; there is more energy captured from the solar collectors, the heat pump can receive a higher inlet temperature that improves the coefficient of performance (COP), and excess heat can be delivered to the borehole(s) for long-term storage.

A Swedish startup company is developing a system solution for integrating PVT collectors with GSHP. Unsatisfied with existing PVT products, they have decided to develop their own specifically designed for a GSHP application. Laminating PV cells directly to the absorber plate is difficult due

doi:10.18086/swc.2017.18.11 Available at http://proceedings.ises.org

to the need of a clean environment while also maintaining good electrical insulation between the absorber and PV cells (Zondag, 2008). PV manufacturing has matured to where the lamination process occurs with very high quality and low cost due to automation and economies of scale. This scale has yet to reach PVT collectors, which can be three to five times more expensive than a PV module due to the additional materials and complexity.

It is much simpler to take an off-the-shelf PV module and affix a heat exchanger to the rear side, either mechanically or with an adhesive. The greatest drawback of this approach is the reduced heat transfer between the PV cells and working fluid, thus reducing the electrical and thermal efficiencies (Zondag, 2008). However, if the cost of creating the heat exchanger can be substantially reduced, the loss of performance may be acceptable. This may be particularly so for PVT collectors in combination with heat pumps, where operating temperatures are much lower than most previous applications, thus removing the need for glazing and insulation due to lower losses (and potential gains) from the ambient air.

The Startup has gone through several prototype rounds tested in multiple installations, and has settled on a glass-glass PV module with an aluminum manifold mechanically pressed against the back. Using a glass backer allows greater contact with the heat exchanger and increases durability at the expense of increased thermal resistance. Opposite the PV module, the manifold has a trough to fit a 12 mm copper pipe, which is also mechanically fixed. Both interfaces are lined with thermal grease to encourage heat transfer. A cross section of the design is given in Figure 1 where it is compared with the models used in this study.

Two prototypes were tested according to ISO9806:2013 parameters during the autumn of 2016 at the RISE facility in Borås, Sweden with the goal of determining thermal performance coefficients of the empirical model described by Perers et al. (2012). However, issues with pressure drop and an unbalance flow were found late in the test cycle and were unable to be corrected before outdoor testing was forced to end for the winter. The result was a lack of data for making the necessary regressions, however there is enough raw data available to perform an empirical confirmation of theoretical models.

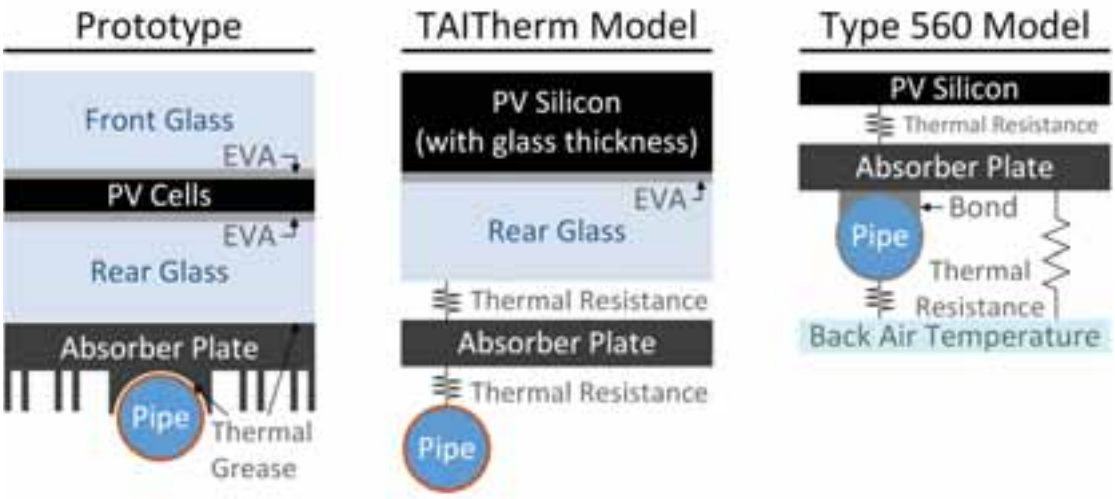

Figure 1 - Cross sectional representations of the PVT prototype, TAITherm, and Type 560 models (not to scale)

2. Objective and Methodology

With what is known about the PV module and heat exchanger construction, most of the collector's physical properties are fixed. The most critical missing characteristic is the conductive heat transfer behavior between the PV module and the pipes carrying the heat transfer fluid. Therefore, the primary objective is to determine a thermal resistance value between the PV module and the heat exchanger assembly to better understand the efficiency penalty of the design over dedicated PVT modules. This is done using the commercial heat transfer software TAITherm (ThermoAnalytics, 2016), which uses a numerical, finite volume approach. The motivation for using this modeling approach is twofold, 1) to capture the unconventional geometry of the heat exchanger, and 2) to independently control fluid streams for recreating the imbalanced flow observed during testing.

Collector development is just one part of a larger goal of PVT plus GSHP systems modeling, which is being done using the well-known tool TRNSYS (Klein et al., 2009). Therefore, the results from TAITherm need to be transferred into TRNSYS, which is most easily done using Type 560 whose theoretical model construction is most similar to TAITherm and the prototype. Given the differences between models, it is unlikely that the parameters will transfer directly, therefore the tuning process will be performed for TRNSYS as well. The results will also give a better understanding of the behavior of Type 560 which may be accounted for in systems models.

3. Method

Meeting the objectives involves a multistep process of constructing the model in TAITherm, manually tuning unknown parameters to achieve a best possible fit to empirical data, transfer of model settings into TRNSYS, and a manual re-tuning of parameters. The unknown parameters tuned with thermal resistance include; flow rates in each collector, absorptance and emittance of the PV module, and convection coefficients on the front and rear.

The mixed outlet temperature of the heat transfer fluid is used as the primary calibration measurement and thermal power used as a secondary indicator. In the TAITherm model, thermal power is calculated using the volumetric flow rate, fluid density, and inlet temperature measurements with modeled outlet temperature. In Type 560, thermal power is output directly from the model. Performance is measured using differences in total thermal energy generated as well as mean absolute error (MAE) and correlation of the outlet temperature and thermal power time series.

3.1 TAITherm Model Description

The TAITherm geometry is a 2.5 dimension mesh, meaning that the components are represented with surfaces and assigned multiple layers with individual properties. The PV module is represented by a 1.658 m by 0.992 m flat plate with 60 elements (10 x 6). The plate has three layers; the PV cells, plastic EVA encapsulate, and the rear glass as shown in Figure 1. A notable omission is the front glass layer. This is due to TAITherm's inability to model transparent and opaque layers together in a single part. The density of the glass and silicon are similar, so to adjust for the missing mass the thickness of the PV layer is made to encompass both the PV and glass. The layer thicknesses and material properties are given in Table 1. The primary sources for the physical characteristics of the module are the PV module spec sheet (Perlight PLM-260M) and from Armstrong and Hurley (2010).

Table 1 - Material properties of the TAITherm model

Layer	Material	Thickness	Density	Conductivity	Specific Heat
-	-	*mm*	*kg m^{-3}*	*W m^{-1} K^{-1}*	*J kg^{-1} K^{-1}*
PV	Silicon	0.225 + 2.5	2330	148	677
EVA	EVA	0.5	960	0.7	2090
Rear Glass	Glass	2.5	2530	1.8	500
Tube	Copper	1	8954	390	383
Fluid	Water	-	Vary w/ temp	0.6	4186

The heat exchanger is represented by flat plat and a collection of six tubes, each a single layer part. As can be seen from the screen shot in Figure 2, the parts are not physically connected, but manually using a conduction link with a user input thermal resistance parameter. Both links are given the same thermal resistance since they are both mechanically pressed and have thermal grease between the parts. Inside the tubes are 1-D fluid streams that have convective heat transfer with a coefficient calculated using the pipe geometry, fluid velocity, and duct flow models incorporated into TAITherm. There are six pipes with corresponding fluid streams for each module, and the flow rates of each can be set independently. The streams all stem from a single fluid node and recombine into a single fluid node, which represent the measured inlet and outlet temperatures.

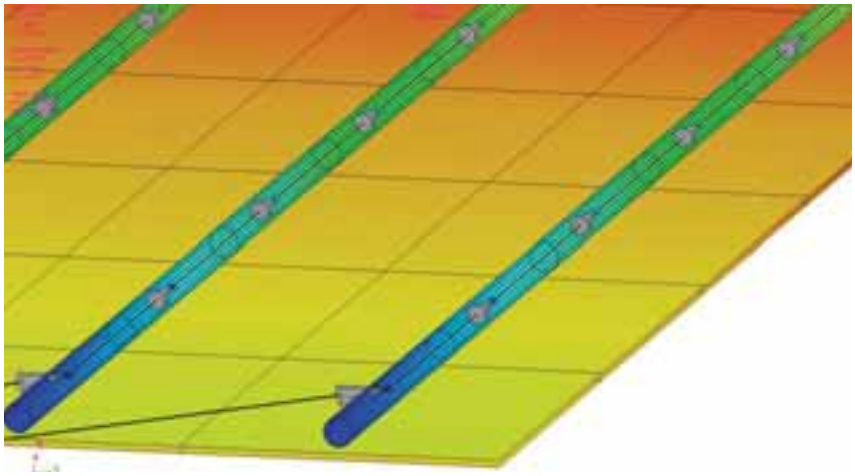

Figure 2 - Detailed view of the TAITherm model backside, showing the PV and heat exchanger parts

The internal heat transfer model within TAITherm is a dynamic, numerical solver based on first principle physics and has highly flexible inputs for boundary conditions. The measured irradiance is imposed directly on the front PV surface. PV generation is not modeled but instead the measured power is removed as heat from the back PV surface. Long wave infrared radiation was measured during testing and converted into sky temperature (T_s) using Equation 1 (Gliah et al., 2011), which is then used for radiant exchange. The collectors are mounted parallel with an asphalt roof within 15 cm, therefore the roof is the only rear view factor and is assumed to be the air temperature.

$$T_s = \left(\frac{Q_{lw}}{\sigma}\right)^{1/4} \qquad \text{Eq. 1}$$

$Q_{lw} = Long\ wave\ infrared\ irradiance\ (W\ m^{-2})$
$\sigma = 5.670\ x10^{-8}\ W\ m^{-2}\ K^{-4}$ (Stefan-Boltzmann constant)

3.2 Type 560 Model Description

Type 560 is one of two PVT models available from TESS, the makers of TRNSYS, and is based on the Hottel and Whillier model, later modified by Florschuetz, and described by Duffie and Beckman (2013). A full derivation and description is also available in the TESS library documentation and therefore will only be briefly reviewed here. The thermal model is the same as a standard solar thermal collector with fin-and-tube construction as shown in Figure 1. The primary modification is that the glazing has been removed and a PV model has been added on top of the absorber plate. One improvement of Type 560 over previous models is the inclusion of a thermal barrier between the PV cells and the absorber plate, a notable point of inefficiency in a PVT collector (Zondag, 2008). The calculation comprises of a set of 10 analytical equations are that solved iteratively since the power output of the PV cells is dependent on their temperature, which is also a function of the thermal collector.

The geometry and model construction of Type 560 and the TAITherm model are similar in several ways; the front glass of the PV module has been omitted, the thermal resistance between the PV cells and absorber plate can be set directly, and dynamic convection coefficients can be applied to front and back surfaces and to the working fluid. Major differences in 560 include modeled PV generation, rear insulation by default (represented by a thermal resistance input), the conduction between the absorber plate and tubes is defined with conductivity rather than thermal resistance, and there is no consideration for the collector's thermal mass.

3.3 Testing Conditions

Testing was performed on two prototype collectors, plumbed in parallel, and mounted on a south-facing roof at a 45° slope. Data was collected between September 19th and October 6th, 2016 using a five-minute time step. Three distinct periods are used in this study and are chosen due to the variation in inlet temperatures and their relatively long, continuous duration. The nominal volumetric flow rate in all of the testing is 240 l/h, equivalent to 0.02 l/s-m^2.

Test One occurs on September 19th, which was a warm and partly cloudy day, using a 10°C target inlet temperature. There are 9.5 hours of data total between 10:11 and 19:46, and Figure 3 shows the ambient air temperature, calculated sky temperature, total irradiance (measured in the collector plane), and wind speed.

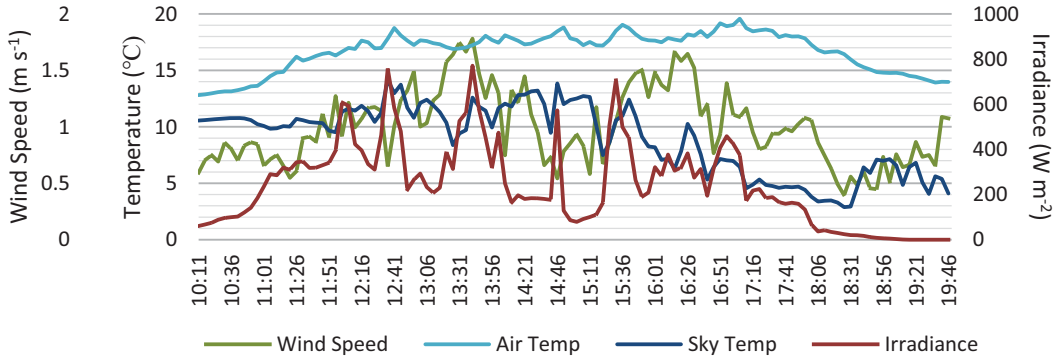

Figure 3 - Measured climate data for Test One

Test Two begins in the morning of October 5th and ends in the early afternoon on October 6th. During the mornings, there are some clouds but otherwise the skies are mostly clear with little wind as shown by the climate data in Figure 4. The inlet temperature target was 20°C, however the actual values are closer to 19°C.

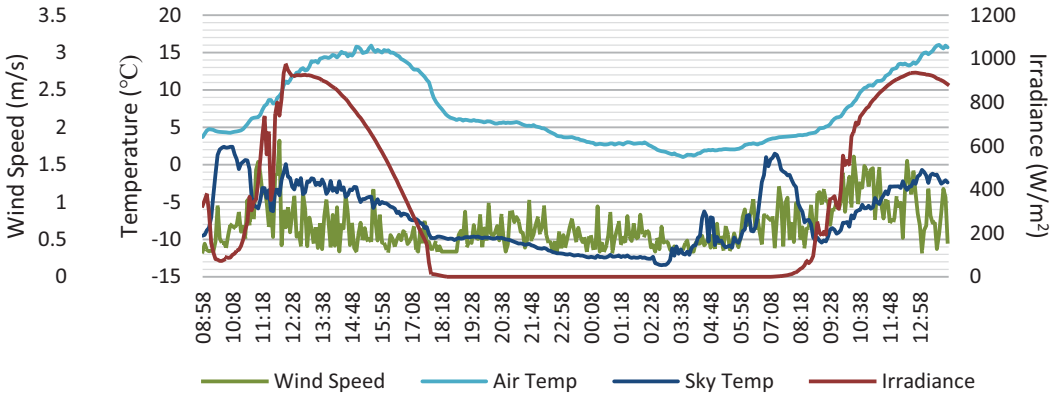

Figure 4 - Measured climate data for Test Two

Test Three is the longest at just over 46 hours, beginning the morning of September 24th and concluding in the morning of September 26th. During the majority of the test there were partly cloudy skies with little wind at night and a gentle breeze during the day, shown in Figure 5. The target inlet temperature here is 30°C, however most of the test has temperatures between 28°C and 29°C.

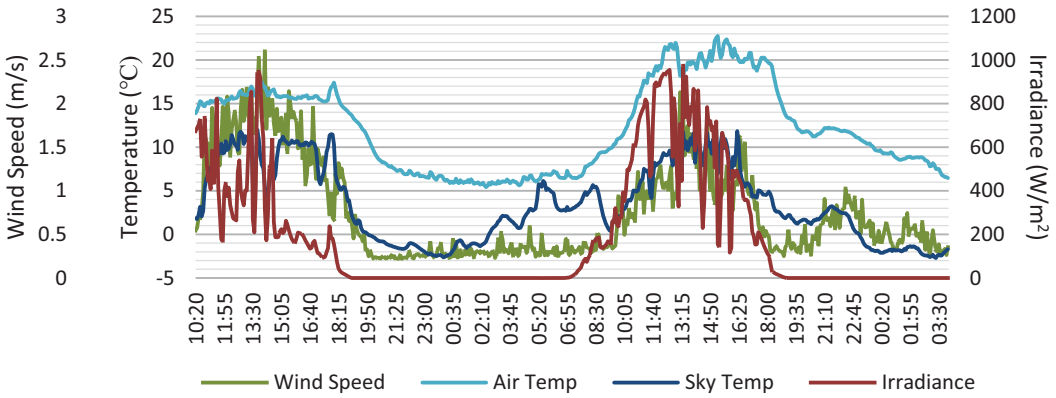

Figure 5 - Measured climate data for Test Three

4. Results

The first step in the tuning process is to determine the flow rates in each collector. An IR image taken during testing discovered the flow imbalance and is used here to compare with TAITherm results, shown in Figure 6. The post-processor in TAITherm allows the visualization of thermal gradients, however only the thermal patterns are considered and not the absolute temperature values. The image suggests that the majority of flow is through the right collector and several flow distributions (2%/98%, 1%/99%, 0%/100%) tested have determined that effectively all of the working fluid is passing through the right collector. Passing any significant amount of fluid through the left collector leads to a much less pronounced thermal gradient, however a negligible flow of 0.6 l/h is passed through the left collector for solver stability.

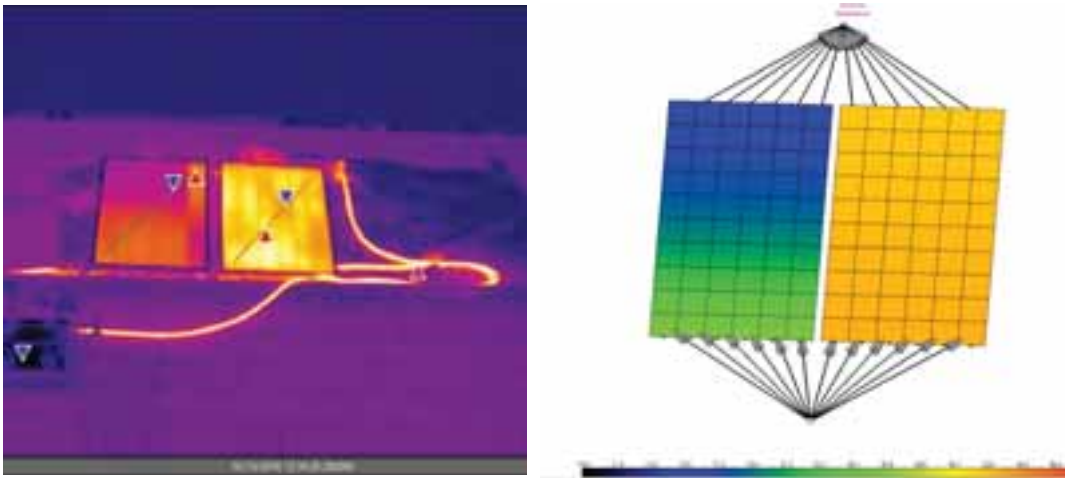

Figure 6 - IR image (left) during testing and TAITherm model (right) with 100% flow in the right collector

Convection on the front side is assumed to be wind dominated and several coefficient models have been tested, including; McAdams (1954), Test et al. (1981), and custom coefficients during the tuning process. Convection coefficients include a high degree of uncertainty (Mirsadeghi et al., 2013), and wind direction was not measured during testing which limits the ability to adjust the model for specific conditions. The commonly used McAdams model is found to be acceptable and is used on the front surface in all cases. The rear side of the collector was tested with both variable and constant convection coefficient models. All external convective heat transfer is modeled with the ambient air temperature.

Time series results are presented for each test in the following sections, while Table 2 with the statistical indicator results for all tests is given at the end of the section. Other common parameters include absorptance and emittance, which is found to be acceptable in all models at 0.85 and 0.90, respectively. It should also be noted that the range of plausible bond conductivities had an insignificant effect on the results for Type 560, meaning the primary tuning parameters are limited to the resistance between PV cells and absorber plate, rear convection coefficient, and the working fluid coefficient.

4.1 Test One

The thermal resistance discovered in TAITherm for Test One is 0.005 m^2 K W^{-1}, which applies to both the PV-absorber and absorber-tube interfaces. In Type 560, a resistance of 0.015 m^2 K W^{-1} is found to be a better fit. This only applies to the PV-absorber interface but includes the EVA and glass not included in the TAITherm value. The McAdams convection model is also an improvement for Type 560 where a fixed convection coefficient of 5 W m^{-2} K^{-1} is more suitable in TAITherm.

The time series results for temperature and power (both thermal and electric) are shown in Figure 7 and Figure 8, respectively. In these figures, it can be seen that the TAITherm model tracks the measured data more consistently than Type 560, with less pronounced peaks and valleys during strong irradiation events. This is confirmed with the performance indicators given in Table 2, where the TAITherm model is shown to have a lower MAE and higher correlation.

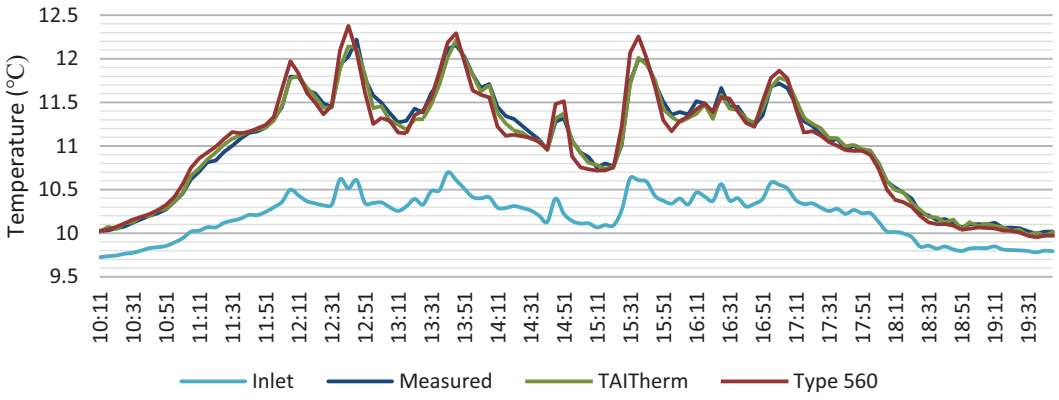

Figure 7 - Measured and model fluid outlet temperatures for Test One

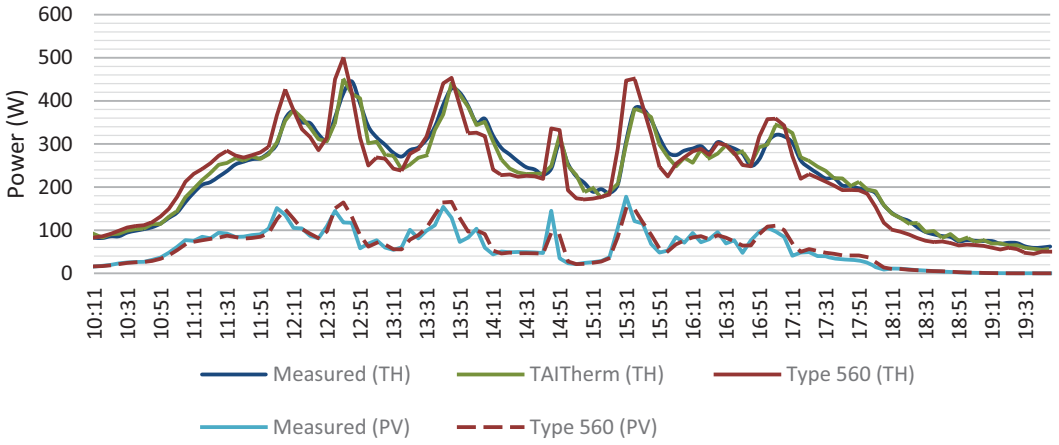

Figure 8 - Thermal and electrical power results for Test One

4.2 Test Two

The thermal resistance in Test Two for TAITherm is again 0.005 m^2 K W^{-1} while in Type 560 0.010 m^2 K W^{-1} is found to be a better fit. Once again the McAdams convection model is an improvement for Type 560 while a fixed coefficient of 5 W m^{-2} K^{-1} works better in TAITherm. The time series results shown in Figure 9 and Figure 10 show that Type 560 is tracking the measured data more closely when the irradiance is steadier with the clear skies. The performance indicators in Table 2 show a worse performance for TAITherm but approximately the same for Type 560 as in Test One.

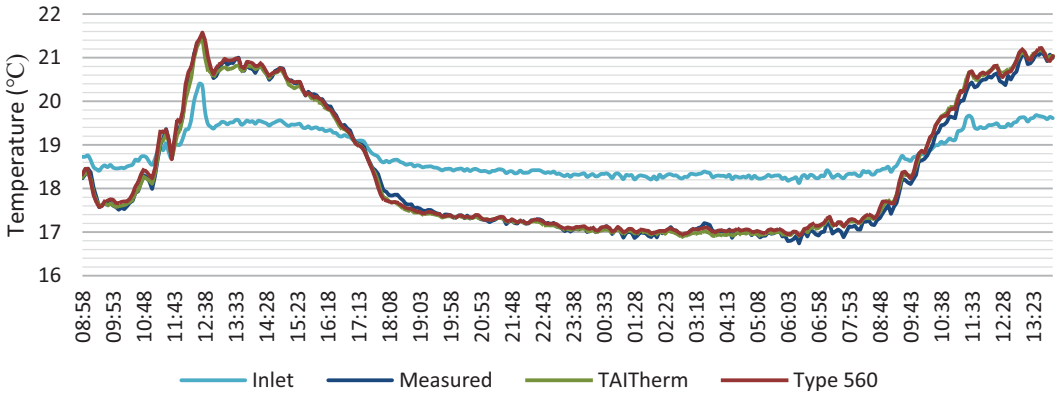

Figure 9 - Measured and model fluid outlet temperatures for Test Two

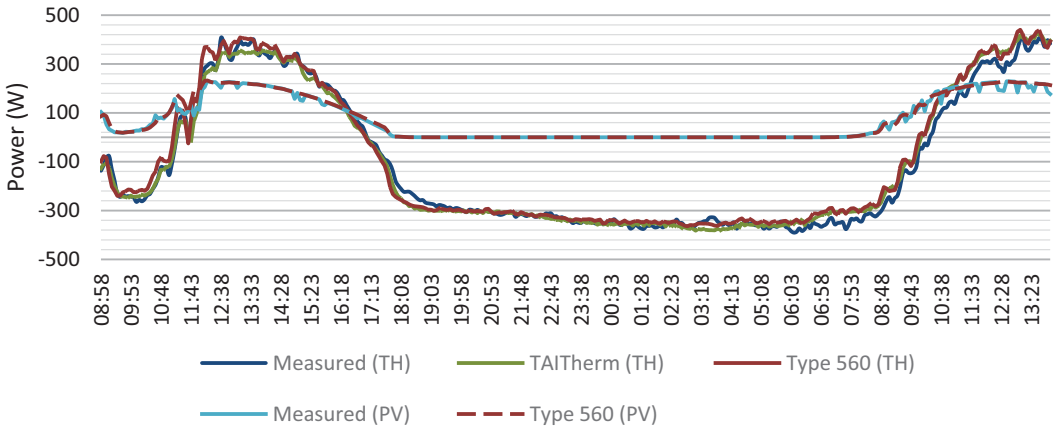

Figure 10 - Thermal and electrical power results for Test Two

4.2 Test Three

The thermal resistance in Test Three for TAITherm is increased to 0.010 m^2 K W^{-1} and 0.040 m^2 K W^{-1} for Type 560. In this test a static rear convection coefficient is best for both models and is the same in each at 6 W m^{-2} K^{-1}. The time series results shown in Figure 11 and Figure 12 are more difficult to interpret due to the longer timespan, however fluctuating irradiance again leads to a lower correlation for Type 560 during the daytime. The statistical indicators are notably worse for both models for this test as compared to the others.

5. Discussion and Conclusion

The tuning process is slow and tedious, however here it has produced two well performing models. The absolute uncertainty of the temperature probes is 0.1 K, therefore it is encouraging that MAE values are consistently below this. Besides uncertainty, the errors that remain are likely due to variations in the convection coefficients. Without knowledge of wind direction, it is difficult to know air speeds underneath the collectors. This is an addtional challenge with this type of PVT collector since the lack of insulation on the rear results in more sensitive convection gains or losses. In an actual installation, it is common to have skirting around the array such that air is not likely to pass underneath, which suggests a fixed coefficient will be more useful in systems modeling. Nevertheless, within this study the errors remain acceptably small particularly when considering larger systems models and annual simulations.

TAITherm produces results that are consistently better than Type 560, which is likely due to the modeling of thermal mass. With its glass-glass construction and thick aluminum extrusions, the PVT collector is approximately 35 kg, which is enough to potentially slow the response time of the heat transfer to the working fluid. This is seen in the time series data where there are rapid fluctuations in irradiance. It also appears in the Test Two statistical results, which had the most steady outdoor conditions and Type 560 performed the best. Adding thermal mass with other TRNSYS models in the system (e.g. pipes) could be a method to slow the thermal response. It is worth noting that this issue largely applies to studies where short time steps are critical. The energy generation values are within acceptable tolerances such that daily, monthly, or annual production is likely to be

reliable. This study does not quality as a full validation, however, and making these claims with certainty will require additional testing of the models against other data sets.

The modeling performed in this study has been valuable for several reasons. First, the thermal resistance values, summarized in Table 3, help place the performance of the prototype within other designs and/or products. Chow describes the thermal resistance between the PV cells and absorbers as being perfect when equal to 0.0001 m^2 K W^{-1}, and defective at 0.040 m^2 K W^{-1} (Chow, 2003). In this context, the 0.010 to 0.015 m^2 K W^{-1} values found with Type 560 in the first two test is relatively good, however the significantly higher value in Test Three is a cause for concern. A sensitivity analysis of this input is worthwhile when doing annual systems modeling, and the results here now provide a plausible range of values.

Table 3 - Thermal resistance parameters for each test and model (in m^2 K W^{-1})

	Test One	Test Two	Test Three
TAITherm	0.005	0.005	0.010
Type 560	0.015	0.010	0.040

Secondly, most solar thermal collector studies use the quadratic efficiency model. Having a theoretical PVT model is beneficial in that new designs without known efficiency coefficients can be modeled within systems, but it is important to have appropriate characteristics. The comparison between TAITherm and TRNSYS is useful because it validates the tuning process by having a second, fundamentally different model with similar results and it highlights the impact of the model structure on input parameters and the particular behavior of Type 560.

PVT Wrap-Up:
Energy Systems with Photovoltaic-Thermal Solar Collectors
-
Technology, Market, Experiences

Daniel Zenhäusern, Evelyn Bamberger, Aleksis Baggenstos and Andreas Häberle

SPF Institute for Solar Technology, HSR University of Applied Sciences, Rapperswil (Switzerland)

Abstract

While the interest in Photovoltaic Thermal (PVT) solar collectors is growing, the related practical knowhow and experience are still rather sparse. In this context, a review study on PVT was carried out, focusing on three main aspects: 1) Technology : different types of collectors, different ways of integrating PVT into energy systems, energetic yields of different system configurations, 2) Market overview : PVT industry, available products, principle fields of application, 3) Experiences : experiences from 7 pilot plants with collector areas between 50 m^2 and 3500 m^2, additional PVT plants in operation, points of view of different actors involved in the planning, construction and operation of PVT systems. In this article, we present the key outcomes of the study.

Keywords: Photovoltaic-Thermal Collectors, PVT Collectors, PVT Review

1. Introduction

PVT collectors integrate photovoltaic and thermal solar energy conversion in a single device and thereby reach high yields per area. In situations where roof area is limited, and particularly in the light of new regulations requiring a part of the energy demand of buildings to be produced on site, PVT collectors provide an attractive option. In order to answer the growing interest in PVT, in particular from house builders and installation companies, the presented wrap-up study, mandated by the Swiss Federal Office of Energy, aims to give a concise overview of the PVT technology, the PVT market, and the experiences made with PVT in real system operation. Besides a thorough literature research, a survey as well as a number of interviews were carried out among the different actors related to PVT, such as manufacturers, distributors, planners and installers. The study further included several case studies, based on data acquired by different research groups. The full report of the study was published in german in Ref. (Zenhäusern, et al., 2017). The present article summarizes its key results.

2. Technology and Market

Different concepts of PVT collectors have been considered in applied research for about 40 years. Extensive reviews of the diverse developments, as well as entry points to the relevant literature are provided by Refs. (Zondag, 2008; Michael, et al., 2015). Numerous manufacturers have brought PVT products to the market. However, while new products regularly enter the market, other manufacturers withdraw from the PVT sector. Earlier market-related review studies were presented in Refs. (Adam, et al., 2014; Cremers, et al., 2015; UK Department for Business, Energy & Industrial Strategy, 2016). The PVT sector has gained interest in recent years. Among the reasons for this upsurge are the increased spread and the price drop of photovoltaic modules, as many PVT products are extensions of standard PV modules. In the case of Switzerland, the rise of interest in PVT collectors was particularly triggered by the increasing need of low-temperature heat for the regeneration of ground heat sources in heat pump systems.

doi:10.18086/swc.2017.18.12 Available at http://proceedings.ises.org

For the market survey in the present study, PVT collectors were grouped in three categories: collectors working with a liquid heat carrier medium divided into products with and without cover (transparent cover to reduce convective heat losses) and air-based collectors (typically without cover).[1] The survey with main focus on Switzerland and neighbouring countries revealed 53 PVT collector manufactures in 17 countries (Figure 1). The large majority of products (38) corresponds to liquid-cooled uncovered PVT collectors with or without heat insulation on their backside. 6 products are covered liquid-cooled collectors, and 9 products are uncovered air-cooled PVT collectors.

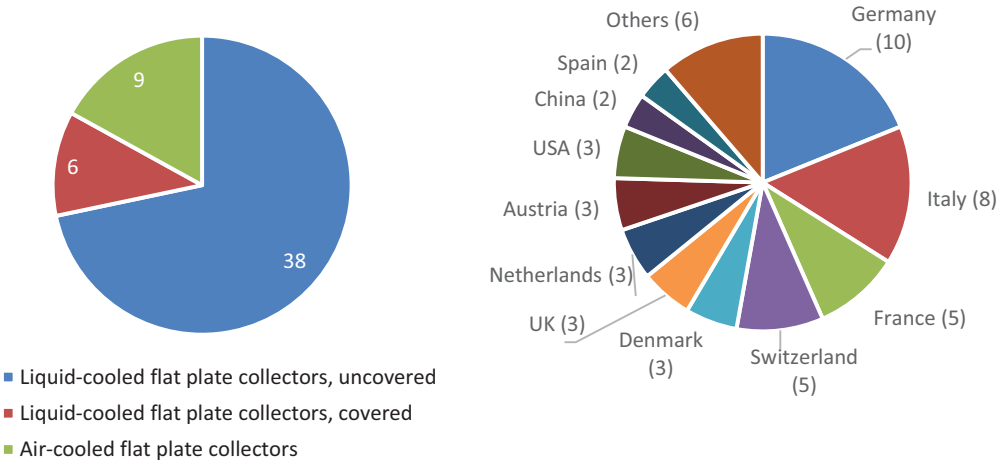

Figure 1: PVT products grouped in collector type categories (left) and number of manufacturers in the different countries (right).

3. System integration of PVT collectors

Like in the case of conventional solar thermal collectors, the thermal efficiency of the different types of PVT collectors strongly depends on their operating temperature. Thermal power curves for typical market-available products of the different categories are shown in Figure 2.

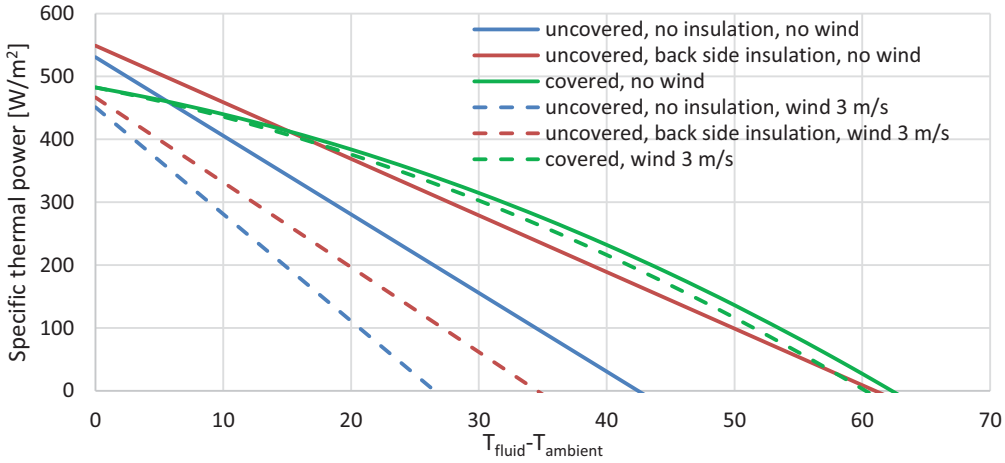

Figure 2: Thermal power of typical liquid-cooled PVT collectors at maximum electrical power point (MPP), related to the gross collector area and for a global solar irradiance of G=1000 W/m².

Expectable annual gross heat and electricity gains as well as differences in electricity gain compared to pure PV modules were calculated with the software Polysun, for different liquid-cooled PVT collectors and different operating temperatures. The gross heat and electricity gains correspond to the heat and electricity yields one would obtain, if the thermal circuit was turned on and operated at the specified temperature, whenever the thermal efficiency of the collector at this temperature is positive. Figure 3 shows the results for the climate of Zürich (CH) with a yearly solar irradiation on the horizontal plane of 1109 kWh/m² and a mean ambient temperature of 9.9 °C.

[1] Concentrating PVT collectors were not considered in this survey.

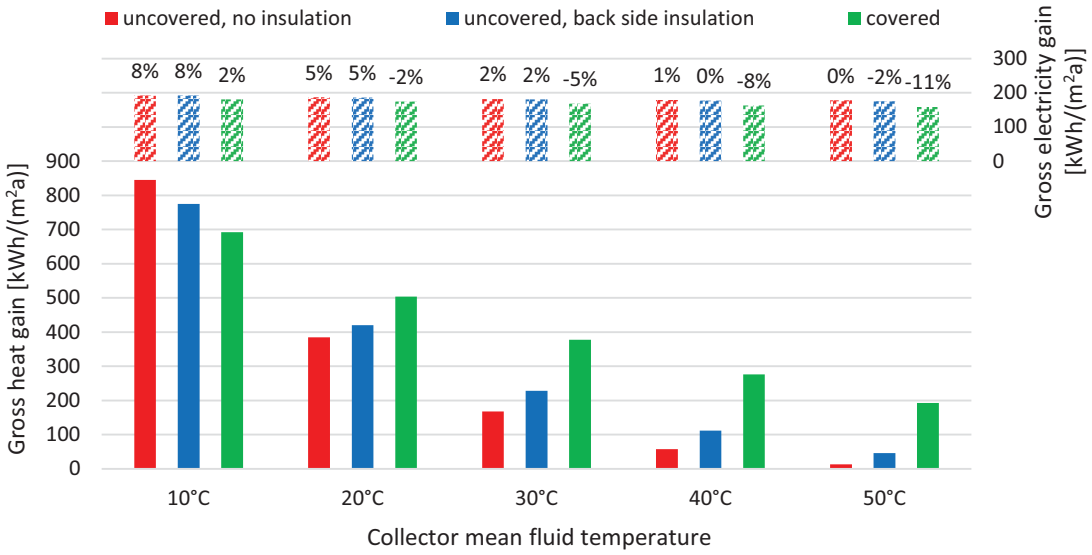

Figure 3: Gross heat and electricity gains for different liquid-cooled PVT collector types, climate of Zürich (CH), collector orientation south, inclination 45°. Percentages correspond to the difference in electrical yield compared to pure PV modules.

For low operating temperatures, the heat gains include converted solar irradiation as well as ambient heat collected in periods where the collector is operated below ambient temperature. Therefore, for low operating temperatures, uncovered collectors and collectors without back side heat insulation have an advantage. For higher operating temperatures, i.e. which over the year predominantly lie above ambient temperature, heat insulation and transparent covers are advantageous. In systems where the heat is always needed at temperatures above 50 °C, only covered collectors can contribute a notable amount of heat.

The lower the operating temperatures, the higher are the electrical yields. The percentage values in Figure 3 indicate the additional electrical yield compared to a standard PV module with average ventilation on the rear side. *Uncovered PVT modules without rear insulation* achieve the highest additional electricity yields. Their maximum (stagnation) temperatures correspond to the temperatures of pure PV modules. When no heat is extracted, they have the same electrical yield. *Uncovered PVT collectors with rear insulation* achieve similar additional electrical yields at low temperatures. As they can reach higher temperatures, their electrical yield at high temperatures is somewhat below the yield of PV modules. *Covered PVT collectors* generally reach lower electricity yields compared to uncovered ones. This is due to higher reflection losses at the transparent cover and due to longer periods of operation at higher temperatures. Compared to pure PV modules, a slight increase of electricity production can be achieved at low operating temperatures, in spite of the additional reflexion losses. At higher operating temperatures, however, their electrical yield can lie considerably below the one of PV modules. Therefore, in systems with covered PVT collectors, it is important to avoid long periods without heat consumption (stagnation).

Systems with uncovered liquid-cooled PVT collectors

From the above discussion, it is clear that uncovered PVT collectors are most suited for low-temperature applications. An important field of use is their integration in heat pump systems, where the low-temperature heat most commonly serves the following purposes: a) regeneration of a ground heat source, b) regeneration of a latent heat (ice) storage, c) regeneration of a cold sensible heat storage, d) pre-heating of a groundwater storage, and e) direct heat source of the heat pump (Figure 4). Variants a)-d) can all be combined with variant e). Further, all variants can be supplemented with the option to directly deliver solar heat to the secondary side of the heat pump, i.e. for example to a hot water or a space heating storage tank. This option is profitable to the energetic efficiency of the system. The quantitative benefit depends on storage temperatures and volumes. Further, one has to consider the additional complexity of the system.

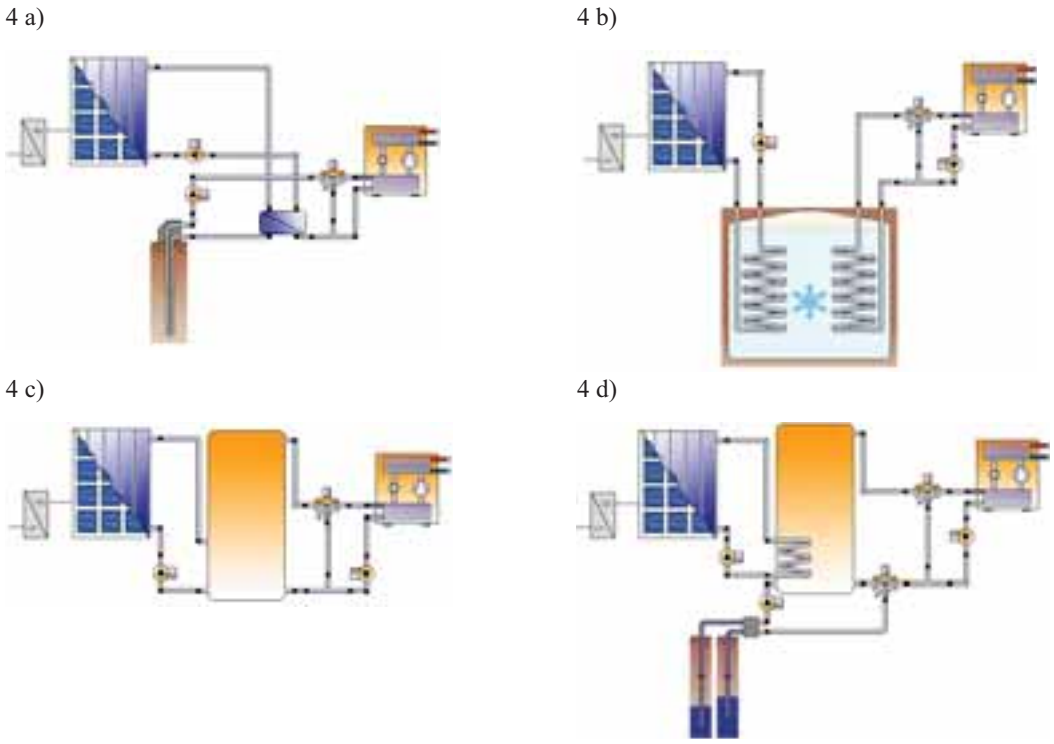

Figure 4: Schematics of different variants for integrating uncovered PVT collectors on the primary (source) side of a brine/water- or water/water-heat pump system. The heat sinks, which would be on the right side of the heat pump, are not depicted. (Schematics were made with the Software Polysun.)

Besides being integrated on the primary (source) side of heat pump systems, uncovered liquid-cooled collectors are also used in systems where they directly provide useful heat at the required temperature level. The applications basically correspond to the classical variants of solar thermal systems, such as: a) domestic hot water (pre-)heating, b) pool heating, and c) domestic hot water heating plus space heating (Figure 5).[1]

Systems with covered liquid-cooled PVT collectors

Regarding only the thermal part, covered PVT collectors can essentially be used like covered (glazed) solar thermal flat plate collectors. Most common is their application in systems for domestic hot water preparation with or without solar assisted space heating (Figure 5). A major difference to systems with pure thermal collectors lies in the handling of stagnation situations. In fact, several market-available covered PVT collectors must not be exposed to extended periods of stagnation at high temperatures, due to the low temperature resistance of the involved materials. Hence, the use of such products requires a fail save stagnation prevention on the system level, such as an additional heat dump (e.g. heat exchanger to ambient air) together with an appropriate system control.

Systems with air-cooled PVT collectors

Air-cooled PVT collectors are predominantly used in open systems. Ambient air is aspirated by a ventilator and guided behind the PV cells. The warmed-up air is often used for direct space heating or ventilation (Figure 6 a). The same configuration can serve be used for space cooling. An additional application is the use of the pre-heated air on the source side of an air/water-heat pump, for hot water preparation or space heating, permitting a rise of the performance factor of the heat pump (Figure 6 b). Further interesting applications of air-based PVT collectors include drying plants (e.g. for agricultural products or wood) and the ventilation of indoor swimming pools or enamelling plants.

[1] For the case of domestic hot water (DHW) preparation, a “pre-heating” system is dimensioned such that it reaches a solar fraction around 20 %, while a standard solar DHW system reaches a solar fraction around 50 %.

Systems installed

In Switzerland, there are at present about 300 PVT systems in operation, with an estimated total area of 15'000 m^2. The vast majority of the plants uses liquid-cooled uncovered PVT collectors. According to the interviewed companies, in almost 50 % of the systems the PVT heat serves the (pre-)heating of domestic hot water (DHW), sometimes in a combination with space heating. In more than 40 % of the systems, the collectors are combined with heat pumps, where the solar heat is most commonly used for the regeneration of ground heat sources. A smaller share of the systems (< 10 %) uses PVT for pool heating. Given the generally large size of installations for ground source regeneration, this application makes for the largest part of the total installed collector area.

4. Survey results

A survey was conducted among two groups, manufacturers of PVT modules on one hand and planners/distributors/installers of PV, PVT and solar thermal systems on the other hand. Besides a number of other questions, participants of the survey were asked about the motivation of house builders for choosing PVT. The corresponding answers are shown in Figure 7.

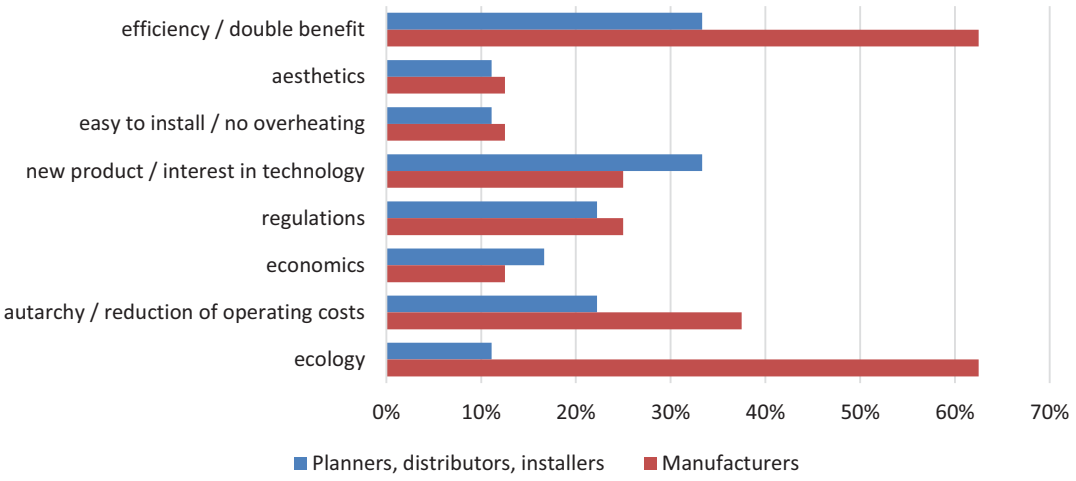

Figure 7: Motivations of house builders for choosing PVT collectors, as seen by manufactures and planners/distributors/installers respectively. The bars show the percentage of answering companies, which mentioned the corresponding argument.

Answers to the question about what should change in order to foster the deployment of PVT are shown in Figure 8. “high costs” and “sparse know-how” are raised as important aspects by both groups, manufacturers of PVT as well as distributors/planners/installers. It is interesting to notice that only the latter group mentions that product design and efficiency of PVT collectors should be improved.

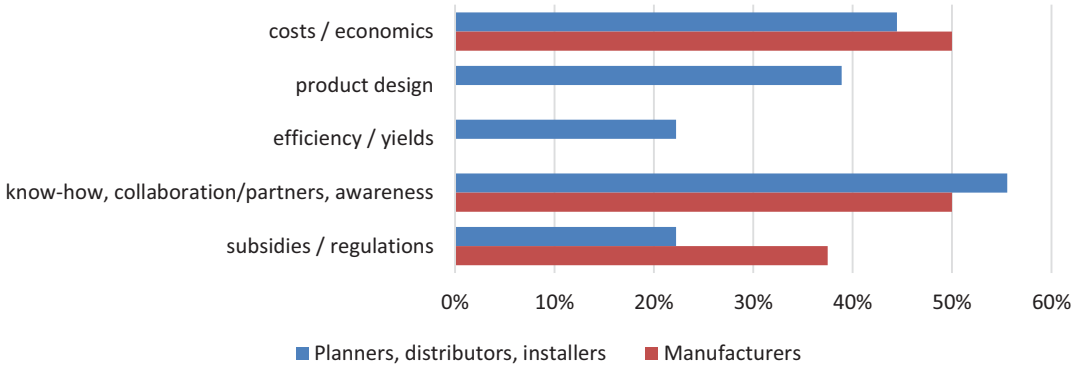

Figure 8: Survey results to the question about what should change, in order to foster the deployment of PVT.

5. Case studies

In Switzerland, 7 large PVT plants with collector field areas between 50 m^2 and 3500 m^2 were built in connection with so-called Pilot and Demonstration (P&D) projects, which received public financial support. In these installations, PVT is used for ground source regeneration, pre-heating of ground water providing heat to a heat pump, and in connection with a low-temperature heat distribution network, respectively. All installations are equipped with detailed monitoring and data acquisition systems and their performance is analysed by different research groups. In the full report of the presented review study, all these projects are briefly presented together with the main results obtained by the respective groups and references to further information (Zenhäusern, et al., 2017). Two examples of pilot plants are shown in Figure 9 and Figure 10. Based on measurement data of various projects (P&D and other), one can state that standard uncovered liquid-cooled PVT collectors in a typical Swiss climate reach an electrical yield of ~ 170 kWh m^{-2} a^{-1} plus a thermal yield of ~ 150 kWh m^{-2} a^{-1} (DHW), ~ 250 kWh m^{-2} a^{-1} (DHW pre-heating), 300 – 400 kWh m^{-2} a^{-1} (regeneration of ground source), and > 400 kWh m^{-2} a^{-1} (pre-heating of ground water at the source of a heat pump), respectively.

Zondag, H. A., 2008. Flat-plate PV-Thermal collectors and systems: A review. *Renewable and Sustainable Energy Reviews,* Vol. 12.

Paper formatting

The manuscript must be written in English. The paper title should be written in Arial, 14 point, bold. The section headings should be numbered, in **Arial 12 pt bold**, the sub-sections in *Arial 11 pt italic*. The standard font for the manuscript is Times New Roman for the text and Symbol for special characters. Body text should be justified as block, 10 pt, in single column format. Line spacing is at multiple of 1.15

The paper size is A4 (210 mm x 297 mm). Margins are 19.0 mm top; 25.4 mm right and bottom and 30.0 mm left. Do not change the paper formatting and do not insert page numbers, headers or footers! Papers using incorrect formatting may be rejected for publication in the proceedings if the author does not make corrections. Insert the lead author name in header starting on the second page. References must be formatted exactly as shown in the examples given below. The sections and sub-sections must be numbered by the author(s); do not use automatic paragraph numbering.

Please use the styles that are defines in the Word Document (under the Style Menu) to format the text instead of directly setting the fonts. The styles are

- *SWC_heading1* for first level section headers
- *SWC_heading1.1* for second leven section headers
- *SWC_text* for the body
- Styles for table and figure captions.

This will ensure that the margins for the sections are also correct and will result in less work for you and a consistent layout for our conference proceedings

Tables, figures, equations, and lists

3.1. Tables

All figures and tables must be cited in the text, numbered in order of appearance and followed by a centered title. Each table column should contain a brief explanatory heading.

Tab. 1: Table captions (8 pt) should be justified as block and placed above the table

Table Header	Header	Header
Tables	Text	Text

3.2. Figures

Figures should be submitted with a resolution of minimum 300 dots per inch and followed by a figure caption, justified as block. Please make sure that the axes and any text within the figure are legible with a minimum font size of 8.

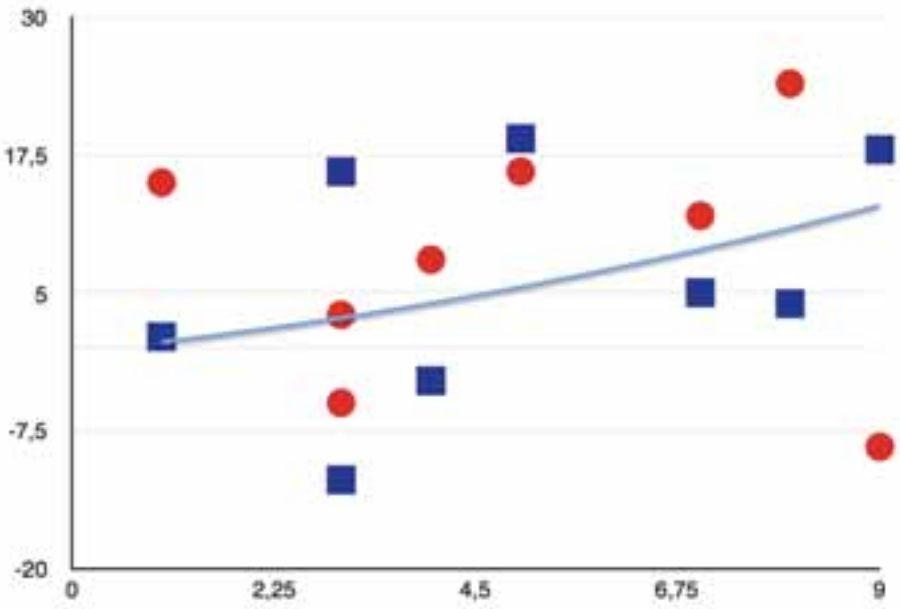

Fig. 1: Figure captions (8 pt) should be justified as block and placed below the figure

3.3 Equations

Equations should be arranged to the left, with characters similar to that of the body text and should be numbered.

$$\frac{1}{2\pi}\int_0^{2\pi}\frac{d\theta}{a+b\sin\theta}=\frac{1}{\sqrt{a^2-b^2}} \qquad \text{(eq. 1)}$$

$$\sin\alpha\pm\sin\beta=2\sin\tfrac{1}{2}(\alpha\pm\beta)\cos\tfrac{1}{2}(\alpha\mp\beta) \qquad \text{(eq. 2)}$$

3.4 Lists

- Bulleted lists can be used to arrange information more clearly in the text.

References

All references should be made according to the guidelines, as shown below.

Please ensure that each reference cited in the text is also present in the reference list (and vice versa). Any references cited in the abstract must be indicated completely. Unpublished results and personal communications are not recommended in the reference list, but may be mentioned in the text.

For web references, at least the full URL should be given and the date when the reference was last accessed. Any further information, if known (DOI, author names, dates, reference to a source publication, etc.), must also be given. Web references can be listed separately (e.g., after the reference list) under a different heading if desired, or can be included in the reference list. DOI must be included if available.

4.1 Text

All citations in the text should refer to:

1. *Single author*: the author's name (without initials, unless there is ambiguity) and the year of publication;

2. *Two authors*: both authors' names and the year of publication;

3. *Three or more authors*: first author's name followed by "et al." and the year of publication. Citations may be made directly (or parenthetically). Groups of references should be listed first alphabetically, then chronologically.

Example: "as demonstrated (Allan, 1996a, 1996b, 1999; Allan and Jones, 1995). Kramer et al. (2000) have recently shown ...."

List:

References should be arranged first alphabetically and then further sorted chronologically if necessary. More than one reference from the same author(s) in the same year must be identified by the letters "a", "b", "c", etc., placed after the year of publication.

Examples for references:

Reference to a journal publication:

Van der Geer, J., Hanraads, J.A.J., Lupton, R.A., 2000. The art of writing a scientific article. J. Sci. Commun. 163, 51-59.

Reference to a book: Strunk Jr., W., White, E.B., 1979. The Elements of Style, third ed. Macmillan, New York.

Reference to a chapter in an edited book: Mettam, G.R., Adams, L.B., 1999. How to prepare an electronic version of your article, in: Jones, B.S., Smith, R.Z. (Eds.), Introduction to the Electronic Age. E-Publishing Inc., New York, pp. 281-304.

Use of units and symbols:

For the use of units and symbols, please see the appendix below.

Appendix: Unites and Symbols

1. Units

The use of S.I. (Système International d'unités) in papers is mandatory. The following is a discussion of the various S.I. units relevant to solar energy applications.

Energy
The S.I. unit is the joule (J ≡ kg m^2 s^{-2}). The calorie and derivatives, such as the langley (cal cm^{-2}), are not acceptable. No distinction is made between different forms of energy in the S.I. system so that mechanical, electrical and heat energy are all measured in joules. Because the watt-hour is used in many countries for commercial metering of electrical energy, its use is tolerated here as well.

Power
The S.I. unit is the watt (W ≡ kg m^2 s^{-3} ≡ J s^{-1}). The watt will be used to measure power or energy rate for all forms of energy and should be used wherever instantaneous values of energy flow rate are involved. Thus, energy flux density will be expressed as W m^{-2} and heat transfer coefficient as W m^{-2} K^{-1}. Energy rate should not be expressed as J h^{-1}.
When power is integrated for a time period, the result is energy that should be expressed in joules, e.g. an energy rate of 1.2 kW would produce 1.2 kW x 3600 s = 4.3 MJ if maintained for 1 h. It is preferable to say that

Hourly energy = 4.3 MJ

rather than

Energy=4.3 MJ h^{-1}.

Force
The S.I. unit is the Newton (N ≡ kg m s^{-2}). The kilogram weight is not acceptable.

Pressure
The S.I. unit is the Pascal (Pa ≡ N m^{-2} ≡ k^2 m^{-1} s^{-2}). The unit kg cm^{-2} should not be used. It is sometimes practical to use 10^5 Pa = 1 bar = 0.1 MPa. The atmosphere (1 atm = 101.325 kPa) and the bar, if used, should be in parenthesis, after the unit has been first expressed in Pascals. e.g. 1.23 x 10^6 Pa (12.3 atm). Manometric pressures in meters or millimeters are acceptable if one is reporting raw experimental results. Otherwise they should be convened to Pa.

Velocity
Velocity is measured in m s^{-1}. Popular units such as km h^{-1} may be in parentheses afterward.

Volume
Volumes are measured in m^3 or litres (1 litre = 10^{-3} m^3). Abbreviations should not be used for the litre.

2. Flow

In S.I. units, flow should be expressed in kg s^{-1}, m^3 s^{-1}, litre s^{-1}. If non-standard units such as litre min^{-1} or kg h^{-1} must be used, they should be in parentheses afterward.

Temperature
The S.I. unit is the degree Kelvin (K). However, it is also permissible to express temperatures in the degree Celsius (°C). Temperature differences are best expressed in Kelvin (K).
When compound units involving temperature are used, they should be expressed in terms of Kelvin, e.g. specific heat J kg^{-1} K^{-1}.

3. Nomenclature and Symbols

Tables 1-5 list recommended symbols for physical quantities. Obviously, historical usage is of considerable importance in the choice of names and symbols and attempts have been made to reflect this fact in the tables. But conflicts do arise between lists that are derived from different disciplines. Generally, a firm recommendation has been made for each quantity, except for radiation where two options are given in Table 5.
In the recommendations for *material properties* (see Table 1), the emission, absorption, reflection, and transmission of radiation by materials have been described in terms of quantities with suffixes 'ance' rather than 'ivity', which is also sometimes used, depending on the discipline. It is recommended that the suffix 'ance' be used for the following four quantities:

$$\text{emittance } \varepsilon = \frac{E}{E_b}\left(or \frac{M_s}{M_{sb}} \right)$$

$$\text{absorptance } \alpha = \frac{\Phi}{\Phi_i}$$

$$\text{reflectance } \rho = \frac{\Phi}{\Phi_i}$$

$$\text{transmittance } \tau = \frac{\Phi}{\Phi_i}$$

where E and ϕ is the radiant flux density that is involved in the particular process. The double use of α for both absorptance and thermal diffusivity is usual, as is the double use of ρ for both reflectance and density. Neither double use should give much concern in practice.

Table 1: Recommended symbols for materials properties

Quantity	Symbol	Unit
Specific heat	c	J kg^{-1} K^{-1}
Thermal conductivity	k	W m^{-1} K^{-1}
Extinction coefficient^{+}	K	m^{-1}
Index of refraction	n	
Absorptance	α	
Thermal diffusivity	α	m^2 s^{-1}
Specific heat ratio	γ	
Emittance	ε	
Reflectance	ρ	
Density	ρ	kg m^{-3}
Transmittance	τ	

$^{+}$ In meteorology, the *extinction coefficient* is the product of K and the path length and is thus dimensionless.

Table 2: Recommended symbols and sign convention for sun and related angles

Quantity	Symbol	Range and sign convention
Altitude	α	0 to ± 90°
Surface tilt	β	0 to ± 90°; toward the equator is +ive
Azimuth (of surface)	γ	0 to 360°; clockwise from North is +ive
Declination	δ	0 to ± 23.45°
Incidence (on surface)	Θ, i	0 to + 90°
Zenith angle	Θ_z	0 to + 90°
Latitude	Φ	0 to ± 90°; North is +ive
Hour angle	ω	-180° to +180°; solar noon is 0°, afternoon is +ive
Reflection (from surface)	r	0 to + 90°

Table 3: Recommended symbols for miscellaneous quantities

Quantity	Symbol	Unit

Performance Measurement, Durability and Reliability

Advanced Testing and Quality Assurance Methods for Solar Thermal Systems and Components

Dominik Bestenlehner, Harald Drück and Stephan Fischer

Solar and Heat Technology Stuttgart (SWT)

Pfaffenwaldring 6, 70569 Stuttgart, Germany

bestenlehner@swt-stuttgart.de, www.swt-technologie.de

Abstract

Reducing costs and increasing efficiency is important for solar thermal test laboratories. However, this aspect is in contrast to the requirements for high quality and reproducible tests. To overcome this problem the present publication shows methods and procedures in combination with an "all-in-one test facility" to provide both, high quality and reproducible test results within shortest time requiring as less human resources as possible. Furthermore, the reliability of the test methods in combination with the described test facilities is shown by means of .validation measurements.

Keywords: solar thermal, test facility, performance testing, durability and reliability testing, quality assurance, test procedures, standards, certification

1. Introduction

Testing of solar thermal systems and components is mandatory for quality assurance. Furthermore, detailed tests and reproducible test methods ensure the conformity of related products with requirements of certification schemes.

Most certification schemes such as Solar Keymark in Europe, SRCC in the US, Golden Sun in China and SHAMCI in the Arab region require several tests, both for durability and reliability as well as tests for the thermal performance of the related products. To perform all required tests in an accurate and reproducible way, appropriated test facilities are needed by the testing laboratories. These test facilities usually absorb both, a high financial investment and huge amounts of man power to operate the test facilities. To overcome this problem an all-in-one test facility for solar thermal collectors, stores and systems was developed a few years ago. As the regulations and standards have now changed, the "all-in-one test facility" was redesigned, further developed and improved to fulfill the latest state of the art technology for testing solar thermal products.

2. Durability and reliability testing

For testing the performance, reliability, durability and safety solar thermal collectors according to the standard ISO 9806:2017 several tests and therefore various test facilities are necessary.

Besides the test for the determination of the thermal performance the most complex test procedures related to durability and reliability are the following six tests:

- the high-temperature resistance test,
- the determination of the standard stagnation temperature,
- the exposure and pre-exposure test,
- the external and internal thermal shock test,
- the rain penetration test.

Beside these tests the following, minor challenging tests are required:

doi:10.18086/swc.2017.19.01 Available at http://proceedings.ises.org

- Internal pressure tests of fluid channels,
- Freeze resistance test
- Mechanical load test with positive and negative pressure
- Impact resistance test

Usually, for each of those test procedures a single test facility is required comprising a test stand and measuring equipment. Furthermore, for the operation of the test facility qualified test engineers are necessary.
For example, the **exposure test** requires a test stand for the solar thermal collector, a data logger, temperature sensors and a pyranometer. The **external thermal shock test** requires also temperature sensors, a data logger and a flow rate measuring device. A smart combination of the different test facilities and a clever arrangement of the order the tests are performed reduces not only the measuring equipment and the number of test facilities itself, but also the personal's workload. Furthermore, the time required for testing can be reduced remarkable

E.g. on a sunny day during that the exposure test is carried out, also the external thermal shock test can be performed. Using such kinds of synergy effects requires that the facility for the exposure test additionally fulfills the requirements of the external thermal shock test. In this case, several tests of the test sample can be performed without remarkable additional effort.
If the rain penetration is also performed directly after the exposure test and on the same test facility, the measuring equipment such as the flow rate measuring equipment can be used twice as well.

To reduce the required financial effort and the human resources six test procedures of the above mentioned standard have been combined into one single test facility. So the smart combination of the individual tests related to the test sequence but also related to the test facility itself allows for an effective use of resources.

The above mentioned tests have to be performed consecutive but the test sample can be mounted during the entire test sequence on the same test facility. Even for the external and internal thermal shock test as well as for the rain penetration tests it is not necessary to install the collector to be tested on a different test facility. Fig 1 shows a schematic of the test facility during the exposure test (left) and the rain penetration test (right).

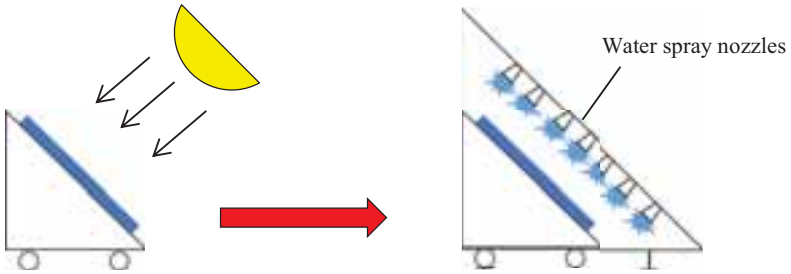

Fig. 1: Test facility for combining the exposure test facility (left) and the rain penetration test facility (right); for performing the rain penetration test the exposure test facility is removed under the water spray nozzles for the rain penetration test facility – or vice versa

For situations and countries where water shall not be drained after spraying it on the collector, a new rain penetration test facility with water recycling was designed. After spraying onto the collector, the water is collected and flows via a channel into a bucket. From there a pump transports the collected water into a store. A second pump transports the water from the store again through the spray nozzles onto the collector. Self-evident, the inclination angle of this test facility is variable and can be adjusted infinitely. Fig. 2 shows a rendering of the new designed rain penetration test facility. A mounted splash guard avoids the waste of water.

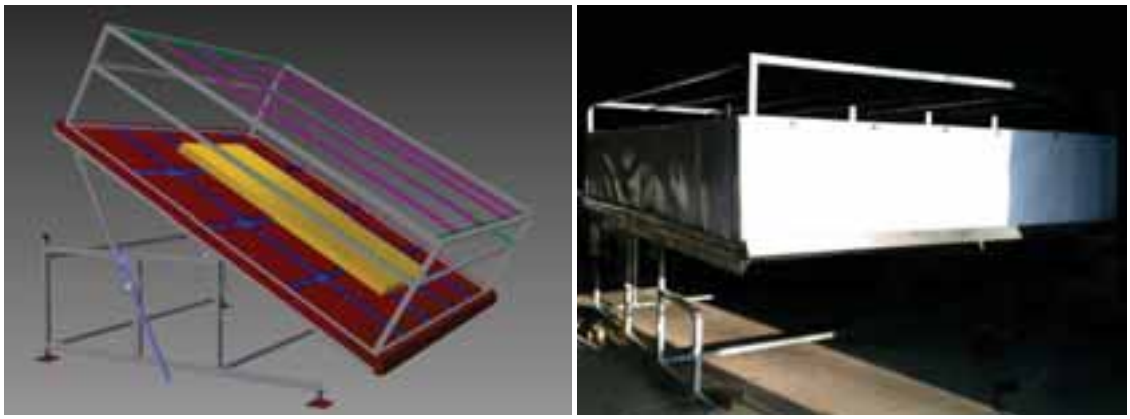

Fig. 2: Rendering (left) and picture (right) of the newly developed rain penetration test facility, which allows water recycling

3. Thermal performance testing of solar thermal systems and solar collectors

The combination of test procedures for testing the thermal performance of solar domestic hot water systems according to ISO 9459-2 and -5 together with the one of solar collectors according to EN 12975 have been already published (Bestenlehner). Due to the replacement of the EN 12975-2 by ISO 9806 some minor changes related to the hydraulics and the measuring equipment have been realized.

However, the test rig for thermal performance testing has been revised significantly to allow a more flexible and multifunctional use. The inclination angel is now adjustable to every desired angle between 0° (horizontal) and 90° (vertical). On the one hand, adjusted to the horizontal, it allows for an easy installation of the test sample. On the other hand, façade collectors intended to be mounted vertically can be tested as well. Additionally the horizontal position of the test rig allows even for testing of solar thermal systems equipped with a self-supporting frame such as e.g. non-pressurized thermosiphon systems mainly produced in Asia. Fig 3 shows renderings and Fig. 4 a picture of the newly designed test rig for performing thermal performance test of solar thermal systems and collectors.

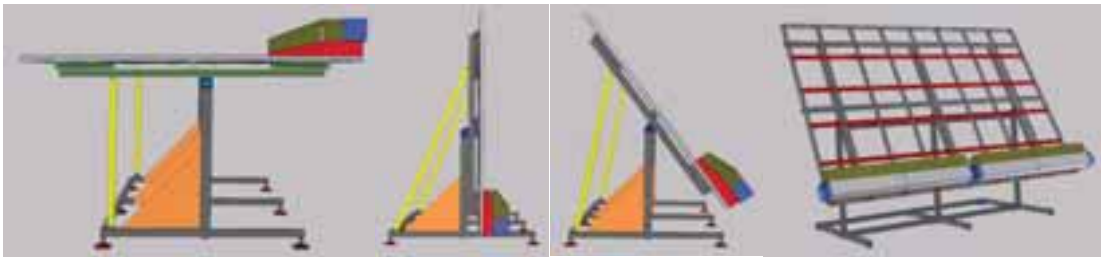

Fig. 3: Renderings of the newly designed test rig for thermal performance tests of solar thermal systems and collectors

Fig. 4: Picture of the newly designed test rig for thermal performance tests of solar thermal systems and collectors

4. Thermal performance testing of thermal energy stores

A third issue for the update of the test facility was the aim to combine the capability of performing tests according to four different test procedures in one test facility in order to determine also the thermal performance of hot water stores using the same test facility. With regard to hot water stores, the test methods of the following standards have been implemented: EN 12977-3, -4, EN 12897, EN 15332. Whereas the test methods defined in the EN 12977 part 3 and 4 are detailed procedures to determine the characteristics of hot water stores and combistores, the test methods described in EN 12897 and EN 15332 are procedures to determine predominantly the heat losses of the store.

Since it is not everywhere possible to install such an all-in-one test facility for testing up to 4 solar thermal collectors, systems and hot water stores in parallel, a small and handy test facility was developed. This test facility is designed for performing tests for the determination of the heat losses of hot water stores according to the above-mentioned standards. Fig. 5 shows a picture of such a test facility.

Fig. 5: Picture of the handy and mobile test facility for the determination of the heat loss rate of hot water stores

5. Validation measurements

To ensure the reliable and reproducible operation of the updated “all-in-one” test facility, validation measurements concerning thermal performance testing have been performed successfully. Exemplarily, the results of the validation measurement of a solar thermal system are presented and discussed in the following. The system under investigation was a thermosiphon system with 1.98 m² solar collector area and a hot water store with 180 L and a jacket heat exchanger. Fig 6 shows the solar thermal fraction of the related solar thermal system at different locations calculated on the basis of the determined test results. The hot water load plotted as tapped hot water volume is varied between 80 L/d and 600 L/d. The results show a decreasing solar thermal fraction with increasing daily load volume, which is quite obvious. The deviation was calculated between the reference measurements and the measurements performed with the updated test facility. All measurements have been performed using the same test samples or solar thermal system respectively. The deviation in the solar fraction is for all measurements below ±2 % (relative).

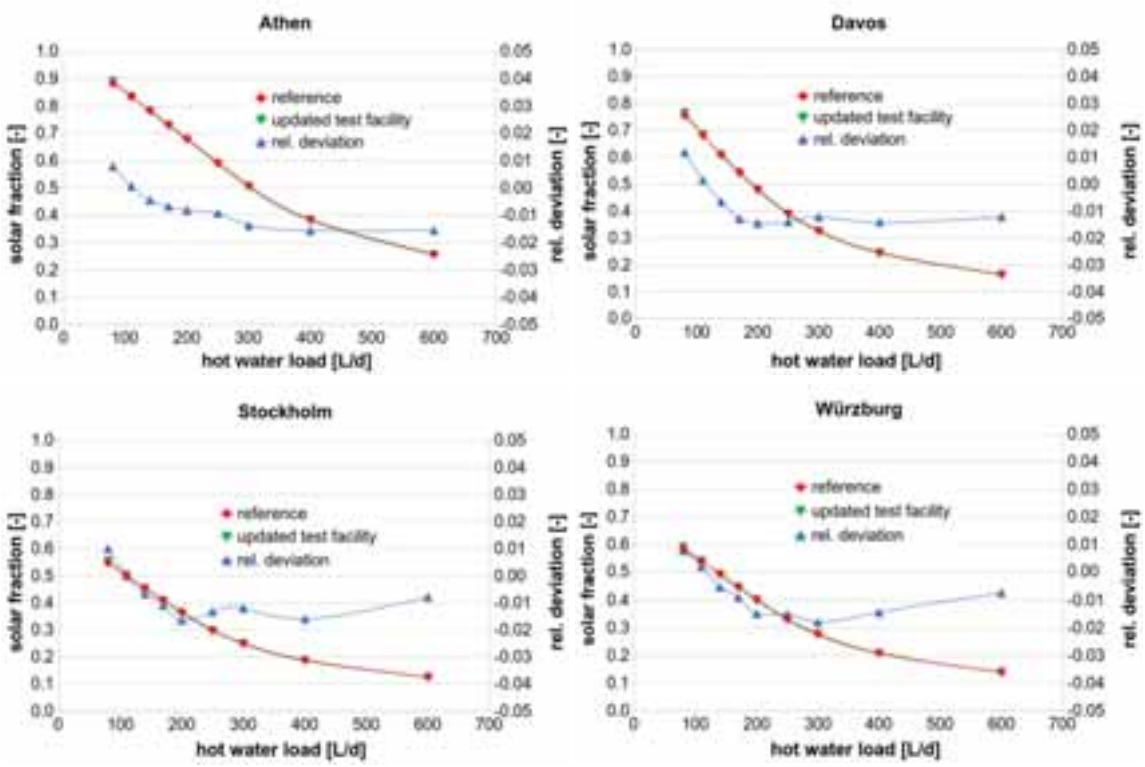

Fig. 6: Presentation of the validation measurements; solar fraction (left ordinate) and deviation (right ordinate) between tests performed with the original and the updated test facility versus tapped hot water volume

6. Summry

The results of the evaluated solar thermal system show that the updated all-in-one test facility enables reliable and cost effective testing. The relative deviation of 2 % of the test results referring to the solar fraction is far below the required limits. The mandatory tests according to the new international standard ISO 9806:2017 the high-temperature resistance test, the determination of the standard stagnation temperature, the exposure and pre-exposure test, the external and internal thermal shock test, and the rain penetration test can be reliable and cost-effective performed with the updated all-in-one test facility.

SOLAR THERMAL COLLECTOR'S DEGRADATION – INFLUENCE OF CORROSIVITY INSIDE AND OUTSIDE THE COLLECTORS

M.J. Carvalho[1], S. Páscoa[1], N. Mexa[1], R. Gonçalves[1], J. Correia[1], A. Gano[1], T. Diamantino[1]

[1] LNEG - Laboratório Nacional de Energia e Geologia I.P., Lisboa (Portugal)

Abstract

Influence of atmospheric corrosivity on solar thermal collector's degradation was studied by exposure of flat plate collectors to two different corrosivity environments, one urban Outdoor Exposure Testing (OET) site with medium corrosivity (C2-C3) and a very high/extreme corrosivity (industrial and marine) (C5-CX) atmosphere highly polluted and simultaneously with highly airborne salinity. Results of thermal performance measurements after two years of exposure in the two OET sites are presented, as well as the evaluation of the corrosion rate inside the collectors, with zinc as reference material, atmospheric contaminants, temperature and relative humidity. For the measurement of temperature and relative humidity inside the collectors, in house produced data acquisition system and sensors were used and are shortly described. Collectors were dismantled and optical properties of the absorbers were measured.

Keywords: *Solar thermal collectors, atmospheric corrosivity, thermal performance degradation*

1. Introduction

Solar thermal collectors (STC) have to withstand stress conditions like high temperatures, high humidity, ultraviolet irradiance or wind and snow loads depending on the geographic location. Literature points out to dependence on other influences like prevailing wind conditions, contaminants like chlorides, SO_2 and NO_x, global solar irradiation, wetness time and precipitation (Köhl et al., 2004; Slamova et al., 2016).

Although for certification of solar thermal collector (e.g. Solar Keymark, SRCC), the testing standards applied, namely ISO 9806:2013, consider a set of tests which address testing of collector resistance to most common adverse conditions when collectors are in use, these tests do not address long term collector durability.

In order to better know how different environmental conditions influence STC, as well as collector components, two OET (Outdoor Exposure Testing) sites were used to expose collectors and collector components. The two OET sites represent an urban climate (Lumiar-Lisboa) and a maritime climate with industrial influence (Sines) (Diamantino et al., 2017). The results of collector exposure will be presented in this work for the two OET sites after two years of exposure. Corrosion rate for zinc, atmospheric contaminants, temperature and relative humidity inside de collectors are also presented. Collectors were dismantled and absorber optical properties measured.

2. Materials and methods

2.1. Exposure of STC at OET sites

STC studied were Flat Plate Collectors with tempered glass cover, commercially available. Their main characteristics are described in Table 1.

For each collector model, two samples were exposed in each OET sites (see Figure 1). Thermal performance was measured before exposure for each collector model. For three of the models, zinc standard specimens were installed inside one of the collector samples. After two years exposure, thermal performance was measured. Preliminary results for one of the OET sites were presented in (Carvalho et al., 2016). Summary of all thermal performance results are presented in this work, in section 3.2.

Fig. 1: Installation of collectors in OET sites - Urban (left); Maritime/Industrial (right)

2.2. STC thermal performance evaluation method

Thermal performance tests of solar thermal collectors were performed according to ISO 9806:2013, using quasi-dynamic test method. The comparison is made based on the power curve as defined in ISO 9806:2013 for normal incident irradiance of 1000 W m^{-2} (Direct irradiance = 850 W m^{-2}; Diffuse irradiance = 150 W m^{-2}).

Initial thermal performance was measured only in one collector of each reference. Final results of thermal performance were measured for all collector models exposed. The collectors with installed reference materials were dismantled for inspection and for evaluation of the corrosion rate in zinc samples as well as atmospheric contaminants (chlorides, nitrates and sulphates).

2.3. Optical properties of absorbers

Optical properties of absorbers were also measured. Information on optical properties of absorbers used in each collector exists and will also be presented (initial values) and compared with the performed measurements of the absorber samples extracted from collectors, after two years exposure.

The measured optical properties were solar absorptance (α_s) and thermal emittance (ε_t). The solar absorption (α_s) was measured using a Perkin Elmer's Spectrophotometer Lambda 950 UV/VIS/NIR with a 150 mm integrating sphere.

The thermal emittance (ε_t) was initially determined with a portable emissometer, Devices & Service Company model AE-AD3, which measures a surface emittance at 80 °C of temperature and corrected for a temperature of 100 ºC based on later measurements using a Spectrophotometer Frontier IR/NIR of Perkin Elmer, with integrating sphere.

2.4. Zinc corrosion rate inside STC and atmospheric contaminants evaluation

In each of the collectors referenced in Table 1 with *, five (5) replicates of zinc metal samples were put in the air gap between absorber and glazing (Carvalho, et al, 2016), to evaluate the corrosivity of the microclimate after approximately two years exposure. Zinc samples inside the collectors are equal to the zinc samples placed outdoors to comparatively evaluate the atmospheric corrosivity. The corrosion categories of outdoor exposure test sites were obtained by determination of the corrosivity based on corrosion rate measurement of standard specimens (carbon steel, zinc, copper and aluminum) according to ISO 9223: 2012 and ISO 9226:2012 during

main period of STC exposure.

The atmospheric contaminants present in the solar absorber surfaces, inside the collectors, were also collected by Bresle method (ISO 8502-6, 2006) and analyzed by Ion chromatography. Atmospheric contaminants were analyzed in three different parts of the collectors (1, 2 and 3). In Figure 2 is possible to see the zinc reference materials (5 samples) and where environmental contaminants were collected (1, 2 and 3),

Fig. 2: STC with zinc reference materials and the indication where environmental contaminants were collected after dismantling of collectors

2.5. Measurement of STC inside temperature and relative humidity

Aiming STC's internal temperature and relative humidity measurement and analysis over a predefined period under real working conditions, a custom real-time monitoring and data-logging programmable smart data acquisition system was developed and prototypes were implemented for 'in-situ' data collection in the two OET sites.

Due to the internal ambient working STC conditions, with peak temperatures exceeding 120 ºC, most commercial relative humidity (RH) measuring and logging equipment do not comply with these specifications, mainly due to temperature restrictions of most of the relative humidity electronic sensors available in the market.

The developed system has the following specifications:

- two custom sensor probes for insertion in two STC's, each with one resistive thermal platinum sensor (Pt_{100}) and one high temperature capacitive relative humidity sensor (see Figure 3a):
  - temperature measuring range: -10 to 150 ºC with ±0.1 ºC resolution;
  - relative humidity range: 0 to 100% (non condensing) with ±5 % resolution, with [-10 ºC, +150 ºC] working temperature range;
- programmable sampling periods sets, ranging from 1 sample/min (1440 Samples/Day), as maximum sample rate, to 1 sample/ 4 Hours (6 Samples/Day) as minimum sampling rate;
- system power autonomy of at least one year, for a full set of variables data logging with a sampling period greater than 15 min;
- local data logging of the acquired data using internal non-volatile flash memory;
- data communication with an external computer for system configuration and data gathering using a standard USB2.0 interface;

This custom smart data acquisition and processing unit (see Figure 3b) enables the simultaneous monitoring and data logging of two separate, but adjacent, solar thermal collectors, being its hardware based on a low power, high performance 16-bit microcontroller. This custom unit includes extra functionalities for increased flexibility in signal acquisition, local data processing and external data communication, without compromising system's energy autonomy. Special attention was paid to the system's power consumption in order to keep the intended system's autonomy, being used ultra-low power electronic circuits whenever possible.

The system was developed having in mind an high configurability and flexibility in data acquisition and logging, in order to perform internally all data processing for an 'all digital' information output, along with optimized algorithms to minimize the system's power consumption when active.

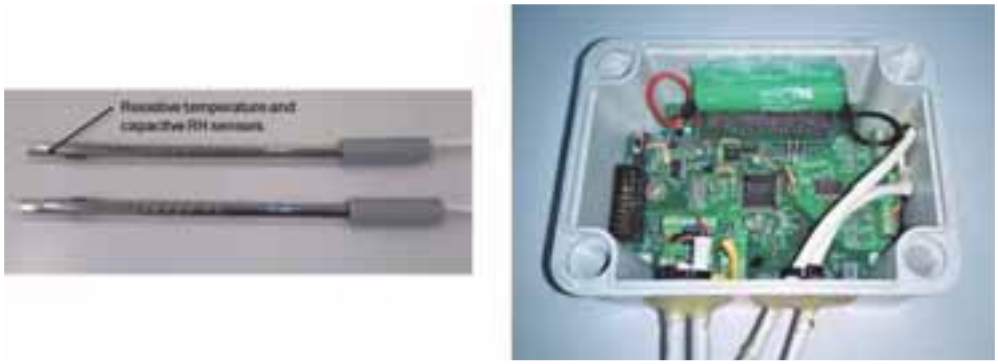

Fig. 3: Collector's internal sensor probes with resistive platinum Pt100 temperature sensor and a high temperature capacitive sensor for relative humidity (Left); b) Custom smart data acquisition and processing unit (right).

A custom user interface software (see Figure 4) was also developed for system's configuration and logged data gathering. The software application runs under Windows environment, allowing an easy system's operation. The logged data can directly be imported into Excel datasheets using a standard text file with CSV format, being each recorded sample stamped with Date/Time information from the system's internal real-time clock, synchronized with the computer's clock when the system is initially configured to start acquisition.

This smart monitoring system is presently being enhanced to include, in the near future, new sensors for other collector's physical environmental variables, like ambient temperature and relative humidity, internal absorber working temperature, UV irradiation, etc,

Fig 4. System's user interface for configuration and data gathering

2.6. Scanning Electron Microscopy (SEM) with Energy Dispersive X-ray Spectroscopy (EDS)

The morphology of solar absorber surfaces (after two year of exposure in Sines OET sites) were examined using a Philips Scanning Electron Microscope, Model XL30 FEG with Energy Dispersive X-ray Spectroscopy (EDS) associated. Before observation, the samples were cut in a cut-off machine to a 1.0 cm X 2.0 cm size. After that, for better conduction, samples were gold coated in the Emitech K575X turbo sputter coater, for 5 seconds.

3. Results and Discussion

3.1. OET sites characterisation

The characterization of Sines and Lumiar-Lisboa OET sites is presented in Table 2 with indication of yearly values in terms of main climatic parameters. A more detailed presentation of ambient temperature and global irradiance can be seen in Fig. 5. Table 3 and 4 present the corrosion rates and atmospheric corrosion categories for Sines and Lumiar-Lisboa OET site, respectively.

These results show the different environmental parameters and corrosivities of Sines and Lumiar-Lisboa OET sites. Both have similar temperature and relative humidity mean values, although Sines with slightly higher mean values. The differences lie in atmospheric contaminants (chlorides and sulphur dioxide deposition values) with much higher values in Sines. In terms of corrosivity, Sines has a high corrosivity for aluminum (category C4), very high for steel and zinc (category C5) and extreme for copper category CX. Lumiar-Lisboa with low corrosivity for aluminum and steel (category C2), medium for zinc (category C3) and medium-high for copper (category C3-C4).

In Figure 5 it is represented the frequency distribution of irradiance and ambient temperature of both OET sites (September 2016 to August 2017). Although ambient temperature average values are slightly higher in Sines, Lumiar-Lisboa has higher ambient temperature amplitudes. The irradiance behavior is similar in both OET sites although with higher irradiance values for Sines.

3.2. STC thermal performance and optical properties after approximately two years exposure

In a previous paper (Carvalho, et al, 2016) the thermal performance evaluation for collectors exposed in Sines after one and two years exposure was presented. In this work, only results with two years exposure, both for Sines and Lumiar-Lisboa, are presented. In Table 5 the periods of exposure of these collectors are listed.

Tab: 5 – Exposure dates of STC in Sines and Lumiar-Lisboa OET sites

	Model (Ref.)	Installation date	Uninstallation data	Exposure time (month)
Sines	S_A2 *(**)	11-04-2014	01-06-2016	26
	S_C2 * (**)	09-05-2014	01-06-2016	25

*one (1) replicate with zinc metal samples; ** Temperature and humidity measurements inside the collector

After approximately two years of exposure (see Exposure time in Table 5), the collectors with zinc samples were tested for thermal performance and dismantled after. Measurement of optical properties was performed in different points of the absorber. These results also presented in this section.

Fig. 6 to 8 show the collector's power curve according to the definition of ISO 9806:2013, comparing the thermal performances after exposure with the initial thermal performance, measured in collectors of the same type before exposure.

In Table 6 the average relative difference between the power curves is presented.

Fig. 6 and 7 show the thermal performance after two years of exposure in Sines and Lumiar-Lisboa OET sites for collectors with aluminum absorbers and PVD coatings (Mirotherm ® and Eta plus ®, respectively) (models A and C). After two years exposure in Sines and Lumiar-Lisboa, collector A does not show significant degradation – average power difference of -0.9% and -1.8%, respectively. Collector model C exposed in Sines shows degradation – average power difference of -6.2%. After two years in Lumiar-Lisboa no significative difference is observed in this collector (model C) – average power difference of -1.1%.

Fig. 8 shows the impact of two years of exposure of collectors with copper absorber and paint coating SUNCOLOR TS S Black (Model D). The collector exposed in Sines shows sixthly lower power curve while in Lumiar-Lisboa the collector exposed after two years shows higher thermal performance – average power difference of +3.0%.

Tab. 6: Average difference of power curve relative to initial peak power (%) in the temperature range 0-90 K

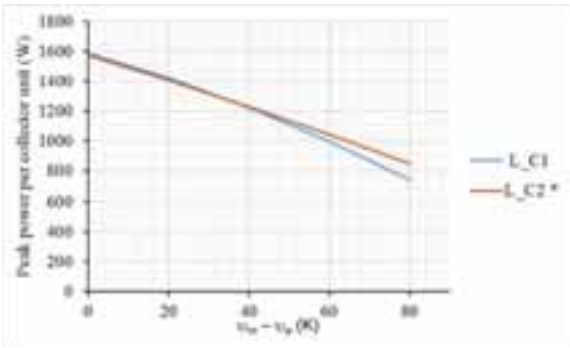

Fig. 7a): Power curves of collector model C (L_C1 – initial measurement: L_C2 * – measurement after two years).

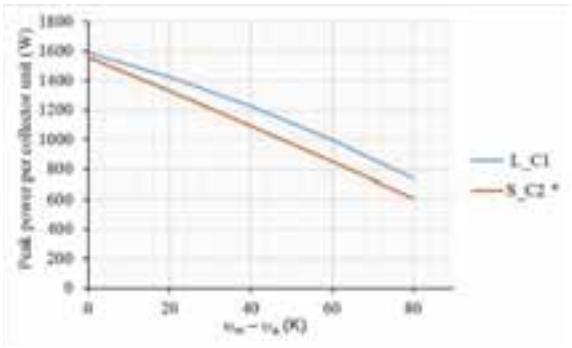

Fig. 7b): Power curves of collector model C (L_C1 – initial measurement: S_C2 * – measurement after two years).

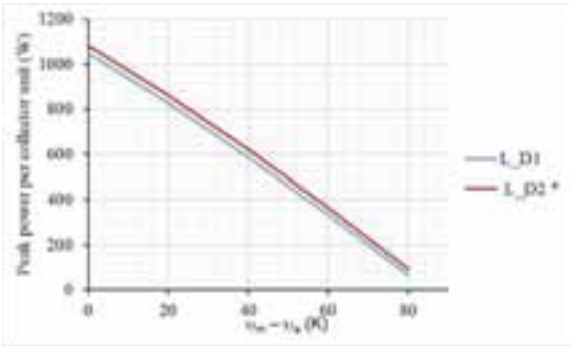

Fig. 8a): Power curves of collector model D (L_D1 – initial measurement: L_D2 * – measurement after two years).

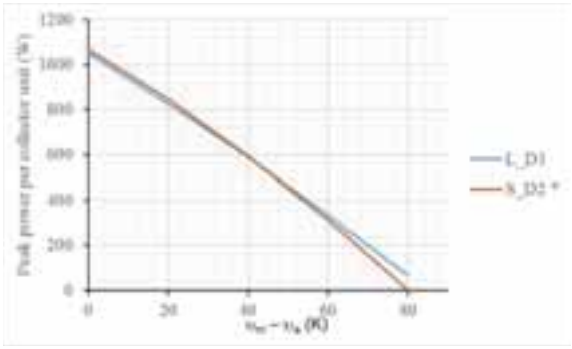

Fig. 8b): Power curves of collector model D (L_D1 – initial measurement: S_D2 * – measurement after two years).

In Table 7 the optical properties of the absorbers of the three collector models are listed. Initial values were obtained from measurement of thirty samples of the absorber used in each collector. The values after two years of exposure were measured in different sections of the collector's absorber after dismantling.

The initial values of the optical properties correspond to average values of thirty samples with corresponding standard deviation. The values after approximately two years correspond to values of measurements made on two or three different samples of the absorber (top, center and bottom) and, when more than one measurement was made, the standard deviation is given.

For collectors A with aluminum substrate and PVD coating, the variation in the solar absorptance is in agreement with the change in peak power (see Fig. 6) for both Sines and Lumiar-Lisboa. The thermal emittance shows a

higher change in Lumiar-Lisboa than in Sines. There are no significant differences between values in the center and bottom of the collector.

For collectors C the solar absorptance does not show significant difference although some change in peak power measured (see Figure 7) is observed. A change in glass transparency may be the reason for this. For Lumiar-Lisboa a higher change in thermal emittance is also observed and this change is not uniform. In Sines, the bottom part of the absorber shows higher thermal emittance values while in Lumiar-Lisboa the center part of the absorber shows higher thermal emittance values.

Tab. 7: Optical properties of collector absorber coatings

Note: Figures in parentheses indicate that the standard deviation observed is lower than the measurement uncertainty.

	2	1.0	<1	<1		
	3	8.0	2.0	<1		

Tab. 9: Zinc corrosion rate and results of chemical analysis inside the STC in Lumiar-Lisboa OET site.

STC	Position inside collector	Chlorides (mg L^{-1})	Nitrates (mg L^{-1})	Sulfates (mg L^{-1})	Zinc corrosion rate inside collectors r_{corr} (g m^{-2} y^{-1}) (SD)	Corrosion category according to ISO 9223:2012
A	1	<0.5 (QL)	<0.5 (QL)	<0.5 (QL)	47.76 (3.12)	C5
	2	0.74	<0.5 (QL)	<0.5 (QL)		
	3	<0.5 (QL)	<0.5 (QL)	<0.5 (QL)		
C	1	0.5	<0.5 (QL)	<0.5 (QL)	- (*)	-
	2	0.7	<0.5 (QL)	<0.5 (QL)		
	3	1.4	<0.5 (QL)	<0.5 (QL)		
D	1	0.53	<0.5 (QL)	<0.5 (QL)	6.84 (0.24)	C3
	2	1.0	1.0	<0.5 (QL)		
	3	1.1	<0.5	<0.5 (QL)		

(QL) - Quantification limit; (*) It was not possible to evaluate the zinc corrosion rate because the reference materials fell due to the degradation of the polymeric screws that held them.

From the presented results, it is possible to see that the concentration of contaminants is higher at the base of the collectors relative to the top and to the middle. The concentration of contaminants in the absorber surfaces is highest for collector D and lowest for collector A in Sines OET site. The collectors in Sines show higher contaminants concentration than in Lumiar-Lisboa.

It is also possible to see that in Sines, collector D has, for zinc a lower corrosivity than collectors A and C. Between collectors A and C, the corrosivity inside collector C is higher than in collector A. This can be related to the fact that collector C showed a higher concentration of contaminants and reaches higher internal temperatures (Figure 9).

Although temperature and humidity inside collector D was not monitored, its thermal performance clearly indicates that the collector has lower stagnation temperature than collectors A and C. The tightness also seems to be smaller with respect to the collectors A and C.

In Sines the zinc corrosion rate inside the collectors can be associated with the contaminants but the temperature seems to be a determining factor.

The corrosivity inside the collector A is lower in Lumiar-Lisboa than in Sines. However, for the collector D the zinc corrosion rate in Lumiar-Lisboa collector is a little higher than in Sines. Although the concentration of contaminants is lower in Lumiar-Lisboa than in Sines, this may be justified by the fact that a great condensation has been observed in the case of this collector in Lumiar-Lisboa, much higher than in the collector exposed in Sines. Taking into account that zinc reaches in air-saturated water the higher corrosion rate between 60-80ºC (X. G. Zhang, 2011), it can justify the little higher corrosion rate observed in Lumiar-Lisboa. The greater condensation in Lumiar's collector may have contributed more to zinc corrosion than the higher concentration of contaminants in Sines.

3.4. Environmental characterisation of collectors inlet

Figure 9 shows the maximum measured values of temperature in collector models A and C, in Sines and Lumiar-Lisboa, respectively. Figure 10 shows the average measured values of humidity in collector models A and C, in Sines and Lumiar-Lisboa respectively.

The measurement period is different in Sines and Lumiar-Lisboa but it covers in both cases almost one year. In Sines measurements where made between June 2015 to April 2016 and in Lumiar-Lisbooa between December 2014 to October 2015.

The sensors were placed in the upper left or right corner of the collectors.

The measurements show higher temperatures in collector C then in collector A. This is coherent with the relative humidity values that are higher in collector A then in collector C, although results for Lumiar-Lisboa in February and March are not in agreement with this tendency.

On a daily bases the evolution of temperature and relative humidity can be seen in Figure 11.

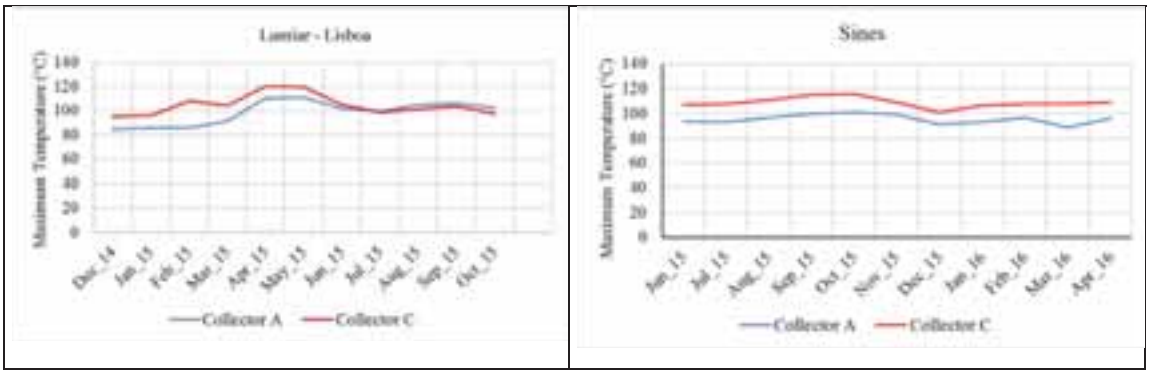

Fig. 9: Maximum measured values of temperature in collector models A and C

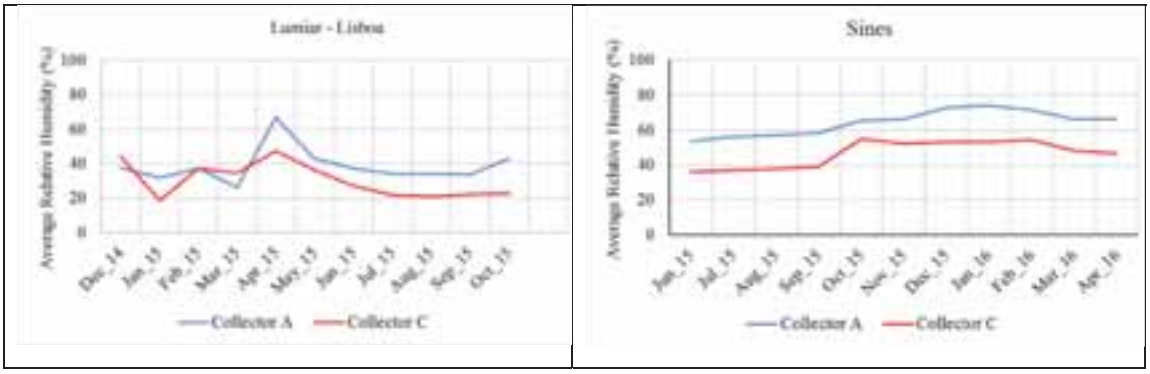

Fig. 10: Average measured values of humidity in collector models A and C

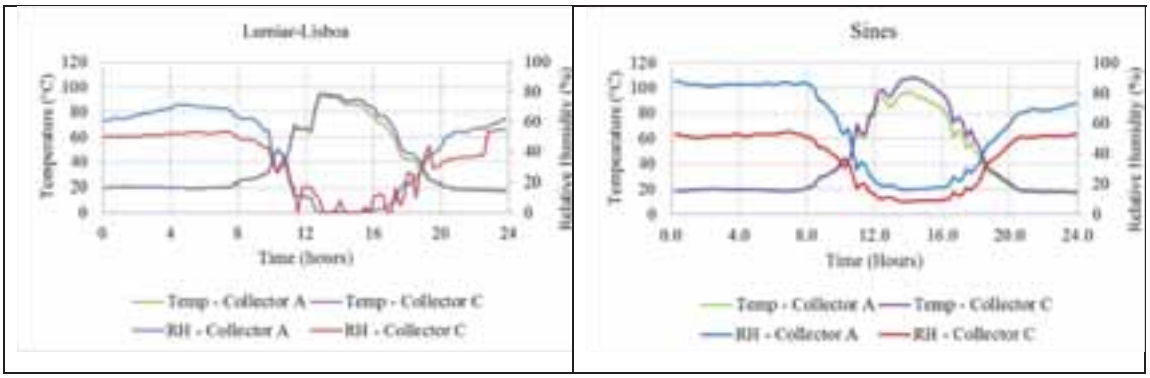

Fig. 11: Representation of one day data (Temperature and relative humidity for collector models A and C) in Lumiar-Lisboa (left) and Sines (right).

3.5. Scanning Electron Microscopy (SEM) with Energy Dispersive X-ray Spectroscopy (EDS)

Table 10 presents SEM micrographs and EDS spectra obtained on solar absorber surfaces inside STC after two years of exposure in Sines OET site.

By SEM was possible to observe the selective surfaces from the three STC and to verified that the surface where there are major changes due to corrosion is on the surface of the collector C, where the chlorine and sulfur elements are present in the corrosion products.

In collector A sodium chloride deposits are observed on the surface but no corrosion products are detected by SEM on the surface.

On the surface of collector D are also visible atmospheric contaminants and some coating cracking / degradation, as well as sodium chloride deposits. Considering that this coating initially had some application defects, it is not possible to distinguish if these observed changes are due to initial corrosion process or to the initial defects of the application.

Tab. 10: SEM micrographs and EDS results of the chemical elements identified on solar absorber surfaces inside STC in Sines OET site after two years

STC	SEM micrographs	EDS spectrum of chemical elements detected
A		C		D		
4. Conclusions

After two years exposure, the measurement of thermal performance of the STC shows higher decrease in Sines than in Lumiar-Lisboa for collectors A and C. The decrease in thermal performance is higher for collector C than collector A, especially in Sines. These results are in agreement with higher level of contaminants, especially chlorides, and also in line with the corrosion rates for zinc measured in Sines and Lumiar-Lisboa for collectors A and C.

In the case of collector D, the variation of the thermal performance does not show a clear relation to the location. This may be because the manufacturing process of the collector is not completely controlled. Differences in initial thermal performance of each collector were not detected since the initial measurement was done in only one collector of model D. The low corrosion rates for zinc in this case may be a result of much lower temperature levels in this collector. Although the temperature and humidity was not monitored in this case, the thermal performance of the collector indicates a lower stagnation temperature than in collectors A and C.

The contaminants present on the different solar absorber surfaces were also different depending on the type of collector. Different ventilation rates and higher temperatures in collectors A and C may explain these differences in terms of contaminants and zinc corrosion rate.

The contaminants detected on the absorbers are mainly chlorides in all collectors and nitrates (Sines OET). The concentration of sulfates and nitrates are low and in some cases below the limits of quantification. From the observations by SEM made for the absorbers of collectors exposed in Sines, we may correlate changes due to

corrosion in collector C to the presence of contaminants. In the case of collector A, although chlorine was present on the surface, no corrosion was observed. The high corrosion resistance of PVD present in collector A relatively to collector C is in agreement with the results presented for these selective surfaces exposed in OET sites (Diamantino et al. 2017) and in accelerated aging tests (Diamantino et al, 2016).

Two years exposure is still a short period to correlate thermal performance decrease with corrosion due to atmospheric contaminants but it is possible to identify the importance of chloride for locations like Sines and the need to introduce this contaminant in the accelerated aging tests for qualification of absorber surfaces. ISO 22975-3:2014 only considers sulfur as contaminant.

Test Procedure for Accelerating Aging of Solar Thermal Collectors

Stephan Fischer[1]

[1]Research and testing center for solar thermal systems (TZS), Institute of Thermodynamics and Heat Transfer, University of Stuttgart (ITW), Pfaffenwaldring 6, 70550 Stuttgart, Germany

Abstract

Based on the experience and data gained during a 3 year exposure of different solar thermal collectors under different climate conditions (tropical, arid, arid maritime, moderate and cold alpine) and system simulations using TRNSYS a test procedure for accelerating aging of solar thermal collectors has been developed and exemplary conducted on flat plate collectors. The overall test procedure which comprises a UV resistance test, a salt mist test, a humidity test, a temperature cycle test and an extended high temperature test is introduced and described in detail.

Key-words: collector test, accelerated aging test, lifetime prediction

1. Introduction

During their lifetime solar thermal collectors are exposed to a variety of partially overlapping aging effects. These are introduced on the one hand from the system type and the mode of operation resulting in different inlet temperatures of the heat transfer fluid. On the other hand site-specific climatic conditions have an important impact on the aging process as shown by B. Traub et al. (2012) and P. Kofler et al. (2013).

To assess and judge the durability and reliability of solar thermal collectors for different system types and different locations a test procedure which takes into account these different ageing processes is needed which goes far beyond the existing durability and reliability test sequences which are documented in the ISO 9806 (2013) testing standard. Thus a test sequence was developed within the German project *Speed*Coll taking into account all relevant kinds of different ageing processes a solar thermal collector is exposed during its lifetime. The test sequence comprises the following tests:

- Initial test
- UV resistance test
- Salt mist test
- Humidity test
- Temperature cycle test
- Extended high temperature test
- Final assessment

The test conditions of each single test can be chosen according to the desired climate and system type the collector will be used for. The different test conditions were derived from a three year long outdoor exposure and monitoring at 6 different test sites (Stuttgart (Germany), Freiburg (Germany), Zugspitze (Germany), Gran Canaria (Spain), Sede Boker (Israel) and Cochi (India)) and from the results of simulations using TRNSYS. Table 1 shows the different climates of the exposure sites.

The data monitored included besides the weather data also the measurement of different temperatures within the collectors as the absorber temperature and the temperature with in the glue joint between the glass cover and the frame and the humidity in the collector between the absorber and the glass cover. The resistance of the tested collectors against the single tests is rated by different criteria. These criteria include lasting and the function of the collector or single components influencing changes and include incidences like brakeage of the glass cover or frame, fogging and a reduction of thermal performance.

doi:10.18086/swc.2017.19.03 Available at http://proceedings.ises.org

Tab. 1: Climates and exposure sites

Climate	Exposure site	Remarks
Tropical climate	Cochi (India)	Hot, humid and wet (Monsun) conditions
Arid climate	Sede Boqer (Israel)	Hot, dry and sandy
Arid maritime climate	Gran Canaria (Spain)	Saline atmosphere
Moderate climate	Stuttgart (Germany)	-
Moderate climate	Freiburg (Germany)	-
Cold alpine climate	Zugspitze (Germany)	High mechanical load through wind and snow loads

2. Initial test

Before the collector will go through the actual aging tests the following initial tests will be carried out

1. Thermal performance test according to ISO 9806, section 20 "Performance testing of fluid heating collectors" to assess the thermal performance prior to aging testing.
2. Mechanical load tests according to ISO 9806, section 16 "Mechanical load test with positive or negative pressure" with a load (positive and negative) of 2400 Pa to ensure a minimum resistance against wind and snow loads. The load (positive and negative) of 2400 Pa is applied 10 times.

3. UV resistance test

To pre-age the collector and to assess the ability of the collector construction including collector parts as polymeric sealing, transparent covers, adhesives and other potential parts sensitive to ultraviolet (UV) radiation the collector is tested using an artificial UV source.

The test setup consists of a climate chamber, light sources and instrumentation with the following specifications:

- Maximum UV radiation (280 nm – 400 nm) shall not exceed 230 W/m² at any location in the collector plane
- The homogeneity of the UV-radiation shall be in the range of ± 15 %. Homogeneity shall be measured at least at 6 locations, evenly distributed over the collector plane.
- Relative humidity in the climate chamber shall be in the range of 15 % ± 5 %
- The temperature in the climate chamber shall be controlled to a value which results in a surface temperature of the collector frame of 80 °C ± 2 °C, measured at location of frame at the top of the collector in an area which is not directly irradiated.
- All temperatures are measured with a standard uncertainty of ± 1 K.

The collector is placed in the climate chamber at a tilt angle of at least 60° and parallel to the light source. The light source is turned on and the climate chamber is set to 15 % relative humidity. Afterwards the temperature within the climate chamber is adjusted such that the surface temperature of at the location of the collector frame at the top of the collector in an area which is not directly irradiated reaches 80 °C ± 2 °C. When this temperature is reached the test begins. During the test ambient temperature, frame temperature and UV irradiance (280 nm – 400 nm) is measured and recorded. The test is completed after an UV irradiation of 280 kWh/m² is reached.

After the test the collector is visually examined and obvious changes or damages like decolouring, changes in structure or surface are documented.

4. Salt mist test

Collectors are often installed close to the sea side and are exposed to significant loads of salt in the air. The test is intended to assess if and to what extend salt will enter the collector and deposit on the absorber and other parts of the collector.

The test setup consists of a salt mist chamber according to EN 60068-2-52:1996 (EN 1996), section 4. A natrium chloride (NaCl) solution of 3 % ± 0.5 % is used. The pH-value of the solution is in the range of 6.5 to 7.2. The salt mist chamber is qualified for the measurement using working standards according to EN ISO 9227:2012 (EN 2012). The working standard is placed in the salt mist chamber at a tilt angle of 70° and is exposed for 48 h a salt mist spray at an ambient temperature of 35 °C ± 2 °C and a relative humidity of more than 90 %. The removal of the working standard shall be 85 g/m² ± 20 g/m²after the test. A pumped heat transfer loop using a suitable heat transfer liquid, with the collector forming part of the loop.

The collector is placed in the salt mist chamber at a tilt angle between 30° and 60° and connected to the heat transfer loop. Afterwards the test cycle as shown in Table 2 is performed on the collector.

During the test the relative humidity and the temperature with in the salt mist chamber shall be measured and recorded. The test is completed when altogether 22 cycles (see Table 2 and Figure 1 are completed.

Tab. 2: Test cycle salt mist test

Phase (duration)	Description
Humid phase (5 h)	Heat transfer loop on, mean heat transfer fluid temperature ϑ_m = 60 °C ± 2 °C. Ambient temperature with in the salt mist chamber ϑ_a = 40 °C ± 2 °C. Relative humidity φ > 90 %
Salt mist phase (2 h)	Heat transfer loop on, mean heat transfer fluid temperature ϑ_m = 60 °C ± 2 °C. Ambient temperature with in the salt mist chamber ϑ_a = 35 °C ± 2 °C. Relative humidity φ > 90 %
Humid phase (10 h)	Heat transfer loop off, ambient temperature with in the salt mist chamber ϑ_a = 40 °C ± 2 °C. Relative humidity φ > 90 %
Salt mist phase (2 h)	Heat transfer loop off, ambient temperature with in the salt mist chamber ϑ_a = 35 °C ± 2 °C. Relative humidity φ > 90 %
Humid phase (5 h)	Heat transfer loop off, ambient temperature with in the salt mist chamber ϑ_a = 40 °C ± 2 °C. Relative humidity φ > 90 %
Drying phase (24 h)	Heat transfer loop on, mean heat transfer fluid temperature ϑ_m = 60 °C ± 2 °C. Ambient temperature with in the salt mist chamber ϑ_a = 23 °C ± 2 °C. Relative humidity in the range of 30 < φ < 70 %

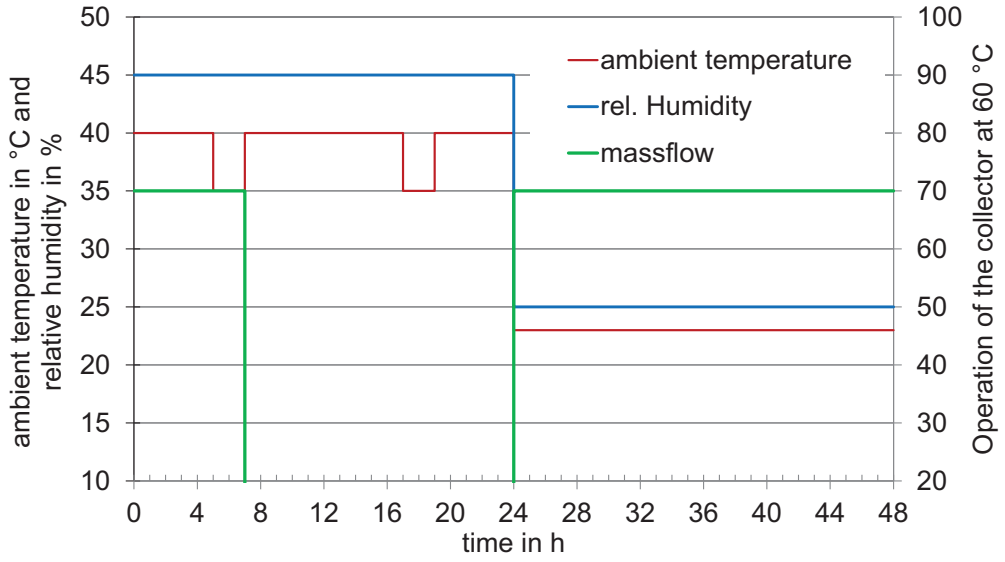

Fig. 1: Schematic test cycle salt mist test

5. Humidity test

The humidity test is designed to test the durability of the collectors against high humidity and is realized by the accelerated simulation of the day night cycle within a climate chamber. Figure 2 shows the graphs of temperature and relative humidity within the climate chamber as well as the switching points for turning on and off of the irradiance and the mass flow. Figure 3 shows the resulting graphs of the temperature and the relative and absolute humidity within the air gap between the absorber and glass cover of a tested collector. The graphs during the humidity test are very close to the data recorded during the real exposure as shown by Fischer et al. (2016).

This test cycle accelerates the outdoor exposure by the factor of 4. The boundary conditions like ambient temperature relative humidity as well as the hemispherical irradiance can be adjusted when required.

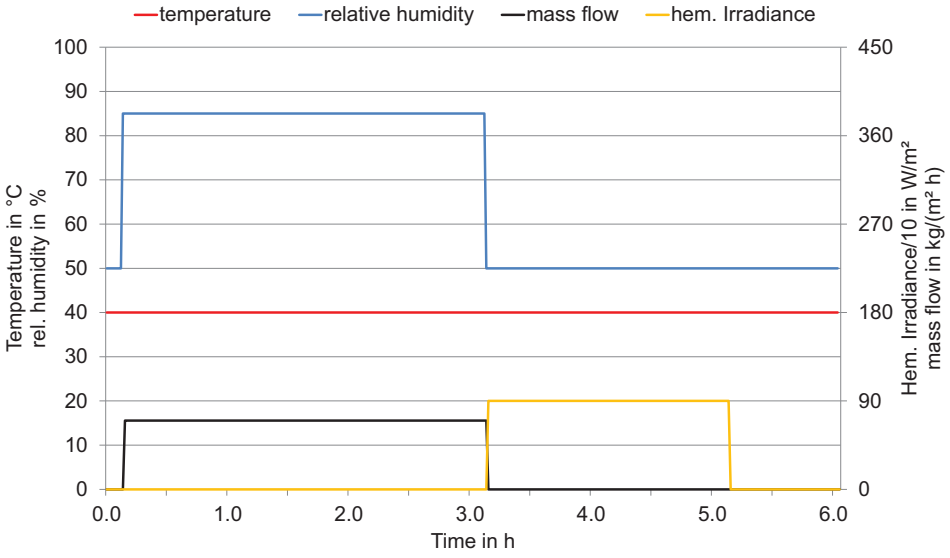

Fig. 2: Temperature, relative humidity, hemispherical irradiance and mass flow during the humidity test cycle

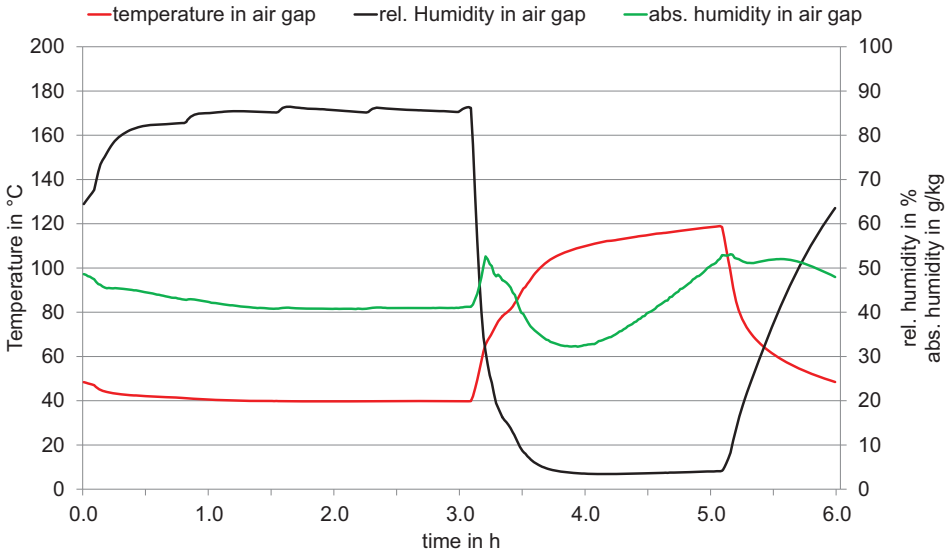

Fig. 3: Temperature, relative and absolute humidity within the air gap between absorber and glass cover of a tested collector during the humidity test

6. Temperature cycle test

During operation a collector and its components will undergo numerous temperature cycles during its lifetime. This test is intended to assess the ability of the collector design to withstand these temperature cycles without damage.

The test setup consists of a climate chamber and instrumentation with the following specifications:

- A climate chamber suitable for the operation in the range of -45 °C to + 95 °C
- The temperature in the climate chamber at quasi-stationary conditions is controlled to a value which results in a surface temperature of -40 °C ± 2 °C and +90 °C ± 2 °C respectively at the top of frame of the collector.
- Instrumentation for the measurement of the relative humidity.
- All temperatures are measured with a standard uncertainty of ± 1 K.

The collector is placed in the climate chamber at ambient conditions (room temperature and corresponding relative humidity). The air in the climate chamber is cooled down to a temperature leading to a temperature at the surface of the frame at the top of the collector of -40 °C ± 2 °C and held at this temperature for 1 h. Afterwards the climate chamber is set to a temperature leading to a temperature at the surface of the frame at the top of the collector reaches +90 °C ± 2 °C and held for 1 h, see Figure 4. During the whole test the temperature and relative humidity within the climate chamber as well as the frame temperature at the top of the collector are measured and recorded. The test is completed when altogether 200 temperature cycles are completed.

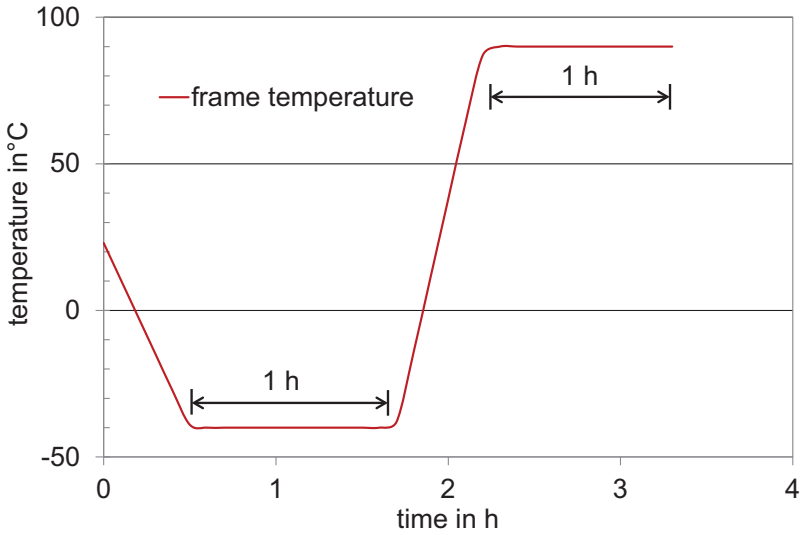

Fig. 4: Schematic test cycle of temperature cycle test

7. Extended high temperature test

This test assesses the ability of the collector to withstand high temperatures during operation and lifetime like they may occur during times with high solar irradiance and high ambient temperature while no heat is removed by circulating the heat transfer fluid (stagnation). Times when the collector needs to withstand these high temperatures are:

- When empty during installation.
- When empty during any period of maintenance.
- When filled with heat transfer fluid or steam at stagnation conditions.

The absorber temperature ϑ_{abs} used for the test is the absorber temperature which will be reached at hemispherical radiation G of 1100 W/m² and an ambient temperature ϑ_a of 50 °C and shall be calculated

according to the following equation (1)

$$\vartheta_{abs} = 50°C + \frac{-a_1 + \left(a_1^2 + 4\eta_0 a_2 1100W/m^2\right)^{0.5}}{2a_2} + 20°C \quad \text{(eq. 1)}$$

The collector parameters η_0, a_1 and a_2 are taken from thermal performance measurement during the initial test.

7.1 Method 1: Test setup, conditions and procedure

The test setup of Method 1 consists of a climate chamber, solar simulator and instrumentation with the following specifications:

- A combination of climate chamber and solar simulator which allows to heat the absorber to the required test temperature ϑ_{abs} and to keep this temperature constant to ± 2 K. The irradiance level in the collector plane shall be between 900 W/m² and 1200 W/m².
- A temperature sensor to measure the absorber temperature ϑ_{abs} is positioned at two-thirds of the absorber height and half the absorber width. It is fixed firmly in a position to ensure good thermal contact with the absorber. The sensor shall be shielded from solar radiation.
- A temperature sensor is positioned on the frame at the top of the collector. The sensor shall be shielded from solar radiation.
- Instrumentation for the measurement of the relative humidity.
- All temperatures shall be measured with a standard uncertainty of ± 1 K.

The collector is placed in the climate chamber at a tilt angle of at least 60° and parallel to the solar simulator. All but one of the fluid pipes are sealed to prevent cooling by natural circulation of air. The climate chamber is set to 50 % relative humidity. Solar simulator and climate chamber are set to an irradiance and temperature that the absorber temperature according to equation 1 ± 2 °C is reached. At this stage the test begins and runs for 8 h. Afterwards the solar simulator is shut down and the ambient temperature is set to 25 °C. After 4 h the solar simulator and climate chamber are turned on again until the absorber temperature has stayed another 8 hour time period at the test temperature ± 2 °C. The collector should be visually inspected daily during the cooling phase and any it´s appearance shall be reported. During the whole test the relative humidity and the temperatures of the absorber, the collector frame and of the ambient are measured and recorded. The test is completed when altogether 15 temperature cycles (see Figure 3) are completed.

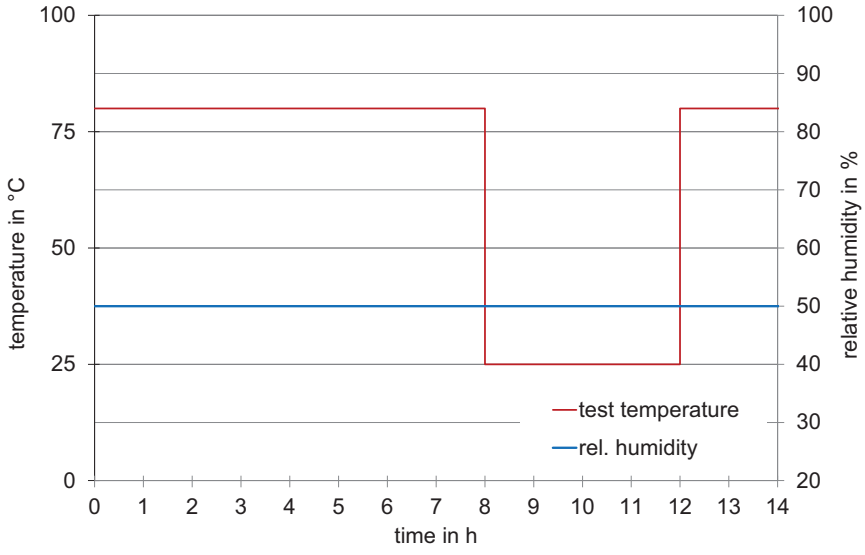

Fig. 5: Schematic test cycle of extended high temperature test

7.2 Method 2: Test setup, conditions and procedure

- A pumped heat transfer loop using a suitable heat transfer liquid, with the collector being part of the loop. A suitable heat transfer fluid is one that will remain in its liquid state at the test temperature and the maximum operating pressure of the collector.
- A temperature sensor to measure the absorber temperature ϑ_{abs} is positioned at two-thirds of the absorber height and half the absorber width. It is fixed firmly to ensure good thermal contact with the absorber. The sensor is shielded from solar radiation.
- A temperature sensor is positioned on the frame at the top of the collector. The sensor shall be shielded from solar radiation.
- Instrumentation for the measurement of the relative humidity.
- All temperatures shall be measured with a standard uncertainty of ± 1 K.

The collector is mounted at a tilt angle of at least 60° and connected to the heat transfer loop. The climate chamber is set to 50 % relative humidity. Heat transfer loop and climate chamber are set to temperatures that the absorber temperature according to equation 1 ± 2 °C is reached. The mass flow rate shall be adjusted in a way that the heat transfer fluid will not lose more than 2 K while passing through the collector. At this stage the test begins and runs for 8 h. Afterwards the heat transfer loop is shut down and the ambient temperature is set to 25 °C. After 4 h the heat transfer loop and climate chamber are turned on again until the absorber temperature has stayed another 8 hour time period at the test temperature ± 2 °C. The test is completed when altogether 15 temperature cycles (see Figure 5) are completed.

7.3 Inspection

After the test the collector is visually inspected for any changes or damages like permanent deformation, glass or adhesive brakeage any structural failure, any burning, scorching, or heat shrinkage, outgassing and any effect likely to impair the serviceability of the collector.

8. Final assessment

After the collector went through all accelerating aging tests the following final tests will be carried out to assess the impact of the previous test on the performance of the collector:

1. Thermal performance test according to ISO 9806, section 20 "Performance testing of fluid heating collectors" to assess the thermal performance prior to aging testing.
2. Mechanical load tests according to ISO 9806, section 16 "Mechanical load test with positive or negative pressure" with a load (positive and negative) of 2400 Pa to ensure a minimum resistance against wind and snow loads. The load (positive and negative) of 2400 Pa is applied 10 times.

When the tests have been completed the collector used for the tests is dismantled and inspected. All abnormalities shall be documented and accompanied by photographs. The collector and all of its components shall be described and should be photographed (glazing, absorber, absorber coating, insulation, housing, inlet and outlet ports, glazing supports and retainers, seals, gaskets, back sheet, etc.).

9. Summary and outlook

In the framework of the German research project *Speed*Coll " Development of Accelerated Ageing Tests for Solar Thermal Collectors and their Components" a test procedure for the accelerated aging of collectors has been developed and was carried out. The proposed test conditions of the single tests can be adopted according to specific climatic and operational requirements. Thus the proposed test procedures allow an assessment of the impact of the operation and climatic conditions during the lifetime of the collector.

Currently the test sequences are further developed with in the follow-up research project *Speed*Coll2 "Estimation of the service life of solar collectors and its components". The aim of the project are accelerated aging tests which allow the estimation of the service life of solar collectors and its components depending on the climate and the operation conditions the collectors will be used at.

PVT Performance Prediction

Ulrich Fritzsche, Markus Schweiger, Florian Reil
TÜV Rheinland Energy GmbH, Cologne (Germany)

Abstract

Photovoltaic Thermal (PVT) hybrid modules producing electricity and heat in parallel are becoming more relevant in the Solar Thermal market. Especially PVT modules in combination with heat sinks operating in low temperature ranges like heat pumps are showing perfect conditions for that kind of combination. One important topic for a broader market implementation and distribution will be a clear and overall performance characterization with respect to electrical and thermal power measurements and their interaction.

The presented project has validated a method for a junction (module) temperature forecast based on the thermal behavior of PVT's under consideration of mean fluid temperature, ambient temperature and wind speed. This approach will give the required link between thermal collector testing and electrical PV module characterization and provide a clear distinction of responsibilities for the thermal and PV experts and laboratories.

Keywords: PVT, Performance prediction, junction temperature, module temperature

1. Motivation

As for most PVT applications it is not possible to use temperature probes for direct measurement of the cell temperature, a new approach without additional sensors inside the PVT construction was developed.

Based on the method of the equivalent cell temperature ECT [IEC 60904-5:2011] it is possible to receive all required information for a detailed description of the overall thermal behavior including the cell/ junction temperature.

$$ECT = 25°C + \frac{1}{\beta}\left[\frac{U_{OC2}}{U_{OC,STC}} - 1 - \alpha\ ln\left(\frac{G_2}{1000}\right)\right] \qquad \text{(eq. 1)}$$

A general equation to estimate the module temperature by field measurements is described in IEC 61853-2:2016:

$$T_m - T_{amb} = G/ (u_0 - u_1 * v) \qquad \text{(eq. 2)}$$

As this approach is not covering the main influence of PVT's, the fluid temperature dependency, it is not applicable for modules combined with a thermal heat absorber. Therefore, a new model or equation was developed to cover also this influence.

This new approach which will be presented in the next clause was already introduced before in the project report "Harmonization and Standardization of multi-functional PVT Solar Collectors (PVT-Norm)" Fritzsche et al. (2016). The current work should validate the indoor steady state results with dynamic outdoor field results. A detailed field test of two similar PVT modules with (PVT 1) and without thermal back-side insulation (PVT 2) was performed over several months to provide a large set of data with a wide range of environmental conditions.

doi:10.18086/swc.2017.19.04 Available at http://proceedings.ises.org

2. Procedure

Based on the long experience of performance testing of PVT's and the results of absorber temperature estimation right from the beginning of our testing it was obvious, that the behavior of the module resp. cell temperature could be described similar to that of the thermal performance, but with an opposite sign as the temperature is rising and not decreasing with higher fluid temperatures. Figure 1 is showing an excellent example, how the measurement points from the steady state indoor test are distributed and how the resulting curves will look like.

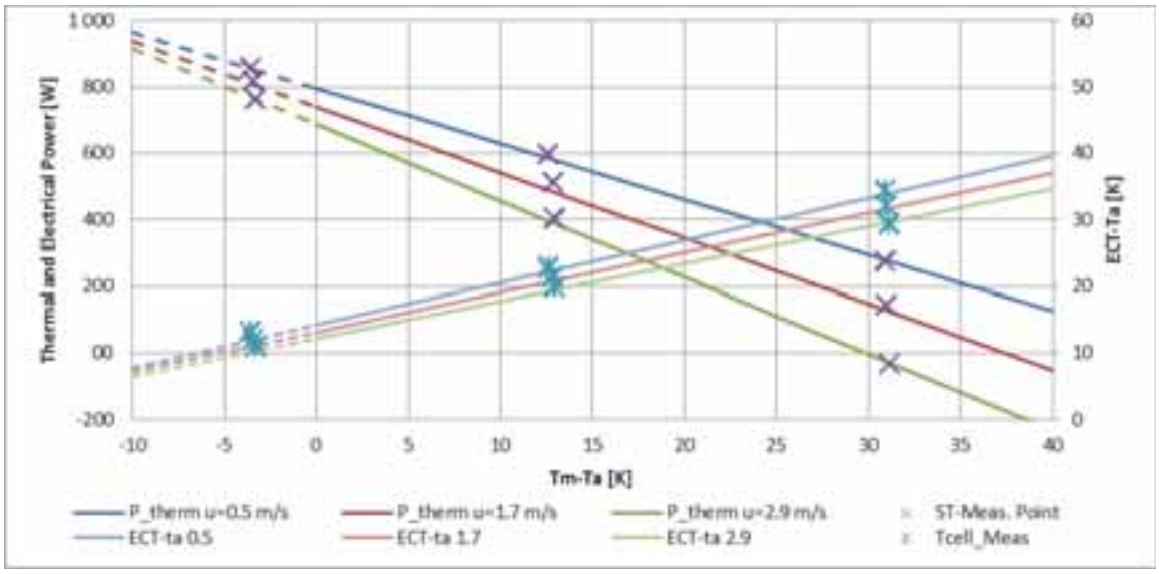

Fig. 1: Example of thermal performance and cell over temperature measurement points and resulting curves

EN ISO 9806:2013 is giving the following equation 3 for the steady state testing of "uncovered" collectors.

$$\dot{Q} = \dot{A}_G \cdot G'' \left(\eta_{0,hem}(1 - b_u u) - (b_1 + b_2 u) \frac{\vartheta_m - \vartheta_a}{G''} \right) \qquad \text{(eq. 3)}$$

The new equation describing the cell over temperature is based on the regular equation for thermal performance of unglazed collectors. By changing the sign, the gradient of the cell (absorber) over temperature could be described as seen in equation 4. It was evaluated, if the global irradiance has to be taken into account, but the influence of wind and fluid temperature was dominating, that the global irradiance was finally neglected.

$$\vartheta_{cell} - \vartheta_a = \vartheta_{cell,0}(1 - d_u u) + (d_1 + d_2 u)\,(\vartheta_m - \vartheta_a) \qquad \text{(eq. 4)}$$

With:

ϑ_{cell} = cell (absorber) temperature

$\vartheta_{cell,0}$ = cell (absorber) temperature conversion point

d_u = wind dependence of the conversion point

d_1 = heat „gain" coefficient

d_2 = wind dependence of heat gain coefficient

The units are currently following the EN ISO systematic. The nomenclature itself is open for discussion, but describes the different coefficient in the best way.

3. Test sequences

As mentioned before, two similar PVT modules with and without a thermal insulation were used for the validation of the procedure. After an initial indoor test of electrical and thermal properties, the modules had performed an outdoor field test over several months.

3.1. Initial steady state testing

Beside a characterization of the electrical performance according to standard test conditions STC, a detailed indoor performance test was. The collectors were tested according to EN ISO 9806:2013 with the steady state test method for uncovered collectors. This method requires a constant high irradiance level and three different inlet temperatures with three different wind speed ranges.

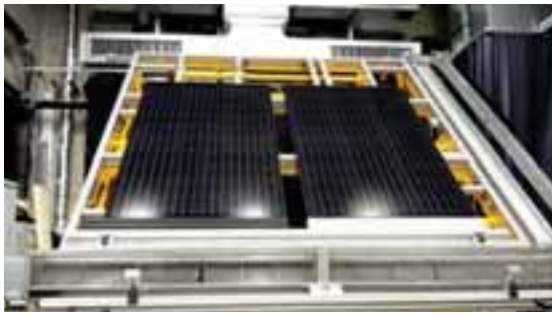

Fig. 2: Indoor steady state test set up

It is obvious, that those requirements are really hard to fulfill, if this procedure should be applied outdoors. As the boundary conditions within a sun simulator are stable and highly reproducible, it was always the preferred method at TÜV to test this wind dependent collector types.

During thermal performance testing, the electrical part of the PVT was operating in the so called MPP Maximum Power Point controlled by an electronic load. In addition to that, the load was measuring the PV module IV curve every five minutes. Even, if not the full IV curve is necessary for the ECT method; at least the open circuit voltage signal has to be detected regularly.

The parameter sets describing the thermal performance according to equation (3) as well as the cell temperature above ambient (4) were determined for the two used test samples are described in table 1 and 2.

Tab. 1: Data set for prediction of the thermal performance of the two test samples

	PVT 1 with back side insulation		PVT 2 without back side insulation	
	Value	**Standard deviation [%]**	**Value**	**Standard deviation [%]**
$\eta_{0,hem}$ [ ]	0.490	0.9	0.538	1.6
b_u [s/m]	0.055	8.3	0.048	14.6
b_1 [W/(m²K)]	9.336	2.5	13.805	3.4
b_2 [J/(m³K)]	1.574	7.5	1.905	10.4

Tab. 2: Data set for prediction of the module (cell) temperature above ambient

	PVT 1		PVT 2	
	Value	**Standard deviation [%]**	**Value**	**Standard deviation [%]**
$\vartheta_{cell,0}$ [°C]	19.82	1.12	14.65	1.11
d_u [s/m]	-0.047	10.3	-0.058	9.79
d_1 [ ]	0.651	1.80	0.653	1.29
d_2 [s/m]	-0.030	16.6	-0.032	13.3

3.2. Field Test

As described before, the two samples had been sent to our outdoor test field in Italy after initial indoor testing. There we've extended the already existing infra structure to monitor not only the electrical the PV long term performance, but also the thermal behavior of PVT modules.

Beside additional sensors as Pyrgeometer for long wave irradiation detection or wind speed sensors to measure the wind speed in the aperture area, a thermal testing loop for two samples had been realized.

Fig. 3: Field test set up

Delayed tests for certification of the products are the reason, that only about four month from October to January had been available for the final validation of this procedure. The initial plan was at least half a year including the summer and autumn.

3.3. Final steady state testing

After that outdoor field test, the samples had been sent back to Cologne to undergo a final test under the sun simulator. As this test was showing performance degradation, these values had not been used for the final validation. As the field measurement didn't show any degradation over time, the vertical transport of the samples might be the reason for that minor degradation.

Nevertheless, the final tests had been used to perform the tests not only according to the "old" method described in EN ISO 9806:2013, but also according to the new method described in the 2017 release of the standard. The comparison of both methods didn't show significant deviations, that the applicability of this new equation for so called WISC collectors under the sun simulator was confirmed.

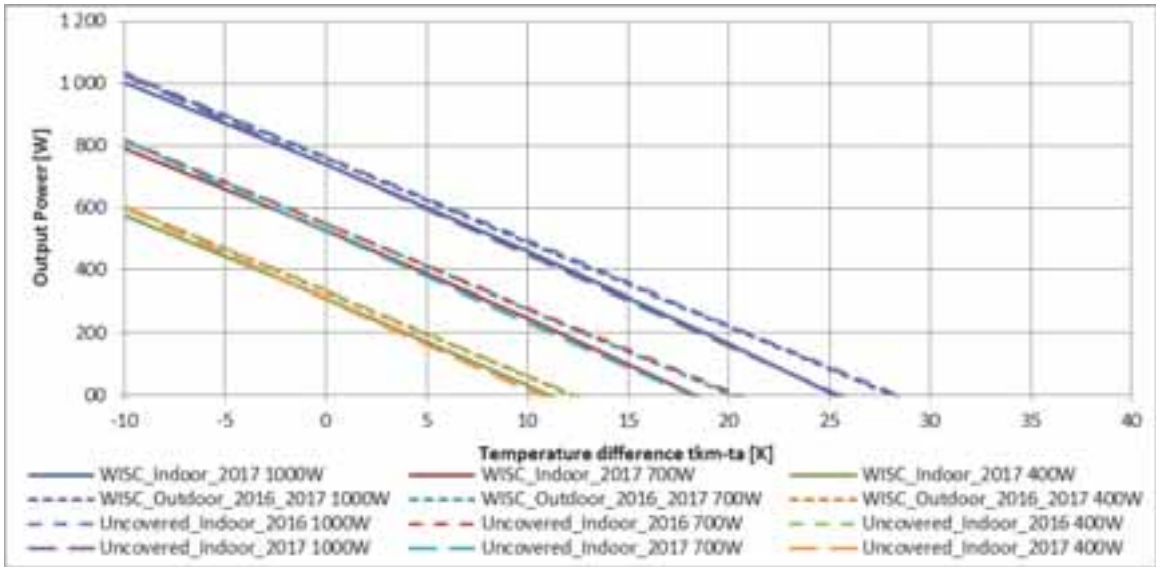

Fig. 4: Comparison of initial and final test performance tests for the PVT 2 collector without thermal insulation

4. Validation

The validation of the new model was made on the basis of the resulting electrical performance. Even, if the model itself gives only the module temperature above ambient, the final aim is a precise prediction of the electrical output. This approach was also necessary, as the electrical output was measured with a much higher resolution than the open circuit voltage signal during the IV-Curve measurement.

The limit for the minimum irradiance level was set to 200 W/m² not only because of spectral response of the cells, but also because of higher uncertainties during this low irradiance performance.

4.1 PVT 2 without thermal insulation

In figure 5, you will find the comparison results between measured and calculated electrical output for the PVT without thermal insulation.

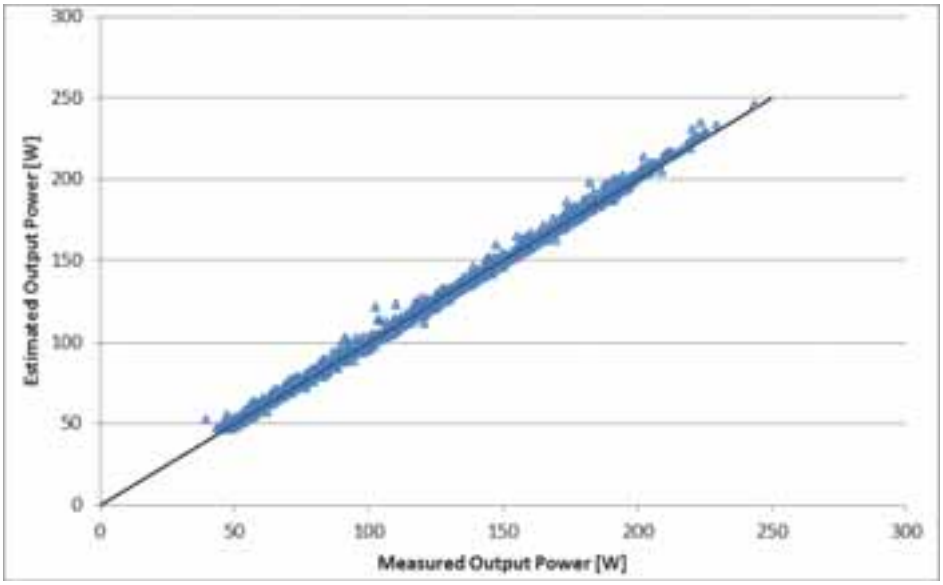

Fig. 5: Precision of measured and calculated electrical performance

In general, the comparison of simulated and measured output power fits quite well as shown in figure 5. The energy difference during irradiance levels above 200 W/m² over the complete test period is about 0.14%. The used quality figure described as the integral of the absolute deviation (energy of deviation) divided by the measured energy is only 1.3 %.

The following figures 6 & 7 are showing representative days and the resulting deviation of measured and estimated electrical output. For a long term prediction, these short time depending deviations up to a few percentages are not relevant and could be neglected.

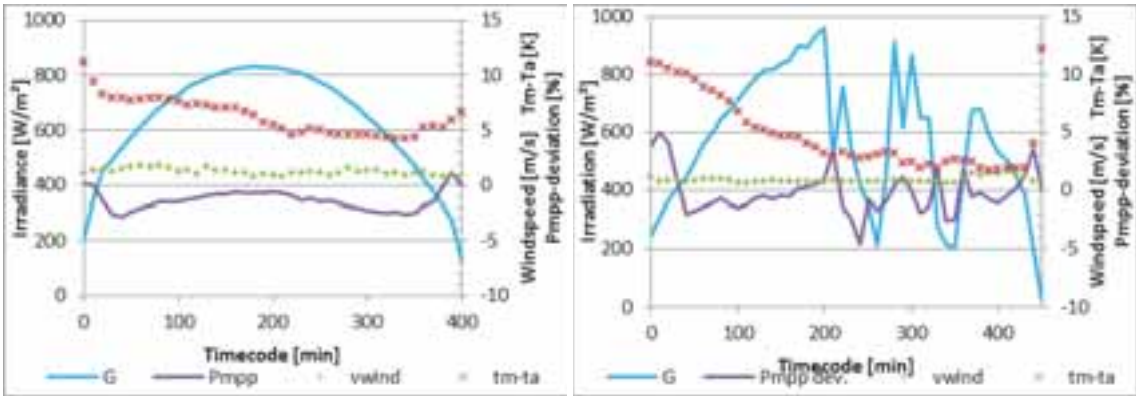

Fig. 6 & 7: Representative days for clear sky and partly cloudy days

4.2 PVT 1 with thermal Insulation

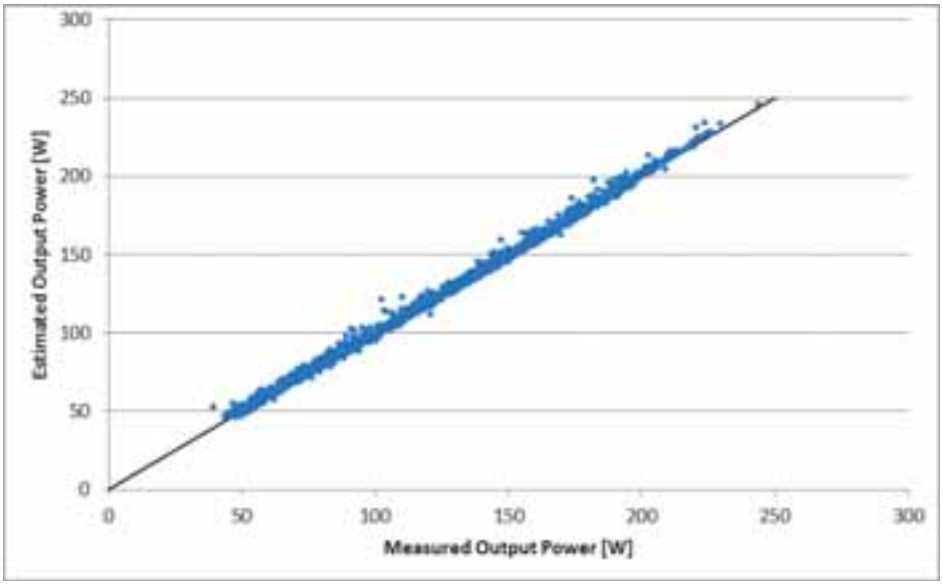

Fig. 8: Precision of measured and calculated electrical performance

In general, the comparison of simulated and measured output power fits quite well as shown in Fig. 8. The energy difference during irradiance levels above 200 W/m² over the complete test period is about 0.24 %. The used quality figure described as the integral of the absolute deviation (energy of deviation) divided by the measured energy is only 1.8 %.

The following figures 9 & 10 are again showing representative days and the resulting deviation of measured and estimated electrical output for the sample with thermal insulation.

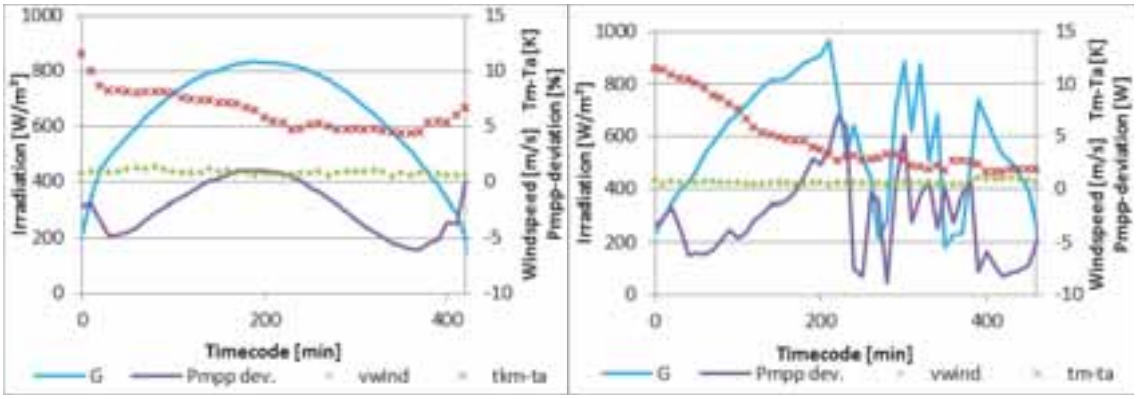

Fig. 9 & 10: Representative days for clear sky and partly cloudy days

The resulting deviation between measured and calculated output power and energy is slightly higher than for PVT 2. But even this higher deviation is still more than appropriate for a long term energy yield.

5. Conclusion

5.1 Model for estimation of cell temperature of PVT's

This model is showing promising results with an appropriate accuracy. As you can see below in Fig. 6, 7, 9, 10, there is still a daytime depending deviation as well as deviations based on quick irradiance changes, but this is not relevant for long time or annual performance prediction. From current perspective, this might be solved by using a 2-node model, where the cell is the first and the fluid the second note. As this model is not referred in the collector standard or necessary for the described purposes, this might be a solution for R&D, but not for certification and general performance indication.

Beside the accuracy, a clear distinction of the different responsibilities is given. Beside a regular determination of the open voltage signal and the already required performance under MPP, no additional electrical measurements are necessary.

An accurate measurement of the wind speed over aperture will be the main challenge for outdoor measurements.

5.2 Performance Indicator for PVT collectors based on NMOT conditions

A harmonized and realistic presentation of the electrical as well as thermal performance of PVT's is a main requirement for a broader distribution and acceptance of this technology. Currently, there's no harmonized way to present these results and a direct comparison of the performance of different PVT's is nearly impossible. Furthermore, the partly used unrealistic presentation based on reference conditions, which will never occur at the same time will result in unrealistic expectation and disappointed owner or user.

The performance indication based on standard test conditions, which will usually be used for PV modules are not applicable for PVT. These conditions are fixed to a cell temperature of 25°C and could never consider the thermal behavior in an appropriate way. One opportunity for PVT's is a performance indication based on Nominal Module Operation Temperature conditions, as these are considering a realistic module temperature in the field as basis. Not only for PVT, but also for standard PV modules, the performance at NMOT as described in IEC 61215-2:2016 is a much more realistic performance indicator than the performance at a fixed cell temperature of 25°C and 1000 W/m² irradiance.

Beside the conditions at NMOT, additional reference conditions for the collector inlet temperature or the mean collector fluid temperature has to be defined. To distinguish between different applications of PVT's as combined with heat pipes, pools or as pre-heater, there should be a set of different inlet temperatures available.

To cover the main fields of application the inlet temperature levels 10 K below ambient, ambient and 10 K above ambient might be a reasonable range. Considering the ambient temperature of 20°C for NMOT, this would result in mean fluid temperatures of 10, 20 and 30°C. A possible nomenclature would be $NMOT_{PVT10}$.

Table 3 is showing exemplary results for the PVT 1 with thermal insulation.

Table 3: Performance indication based on NMOT conditions with a global irradiance of 800W/m², 20°C ambient temperature and a wind speed of 1 m/s

	Mean Fluid Temperature [°C]	Equivalent Cell Temperature @ NMOT [°C]	Electrical Power @ NMOT [W]	Electrical power gain [%]	Thermal Power @ NMOT [W]
$NMOT_{PVT10}$	10	29.5	197.7	8.2	747
$NMOT_{PVT20}$	20	35.8	192.3	5.2	567
$NMOT_{PVT30}$	30	42.0	187.0	2.3	476
NMOT	PV module	46.9	182.8	-	-

If the mean fluid or the inlet temperature should be used need to be discussed. The use of the mean fluid temperature would be much easier, but if we think about an overall indication as used in the Solar Keymark data sheets and calculated also of the electrical energy yield in the future, it might be worse to start directly with fixed defined inlet temperatures. This would be applicable, if the resulting means fluid temperature for these fixed inlet temperatures will be calculated in advance.

6. Outlook

In the framework of this small project PVT Field evaluation, a new approach to estimate the cell temperature of PVT collectors under consideration of the thermal working point was developed. This model is independent from the chosen collector model and could be used for indoor and outdoor measurements.

To reach more confident, further validations with additional PVT collectors should be performed. Therefore, existing monitoring results might be used or new field measurements need to be performed.

As a final step, a technical specification out of an IEC or ISO work item may be published. In the meantime, certification schemes like Solar Kemyark or SRCC might consider this model for an appropriate performance indication in the frame of their individual data sheets.

A flexible software framework for self-adapting algorithm-based fault detection and diagnosis in solar heating systems

Matthias Georgii, Christoph Schmelzer, Hagen Braas, Janybek Orozaliev and Klaus Vajen

Institute of Thermal Engineering, University of Kassel (Germany)

Abstract

A software framework for algorithm-based fault detection in solar heating systems is described. It automatically links modular algorithms in order to perform the best applicable fault detection methods considering the data available for each monitored system. It follows an object-oriented design, where algorithm objects communicate their needed data and parameter inputs, offered outputs as well as constraints via corresponding objects to a path finder. Special effort is made to enable the creation of flexible measurement data requests that do not need to know sensor names in advance. In this paper the basic concepts and implementation approaches to achieve this flexibility in the software framework are described. Finally, exemplary results are shown for a set of algorithms that were implemented in the software framework to determine gradual leakage in a monitored system and bring the capabilities of the framework to life.

Keywords: Solar heating, fault detection, function control, monitoring

1. Introduction

Solar heating systems for moderate climates are equipped with an auxiliary heater which is able to cover the whole heat demand on its own. Hence, faulty behavior of the solar part of the heating system often remains undetected by the end user, at least for a longer period. Higher fossil energy consumption and increased degradation of installed components may be the consequence. But the complexity of these systems can make it time-consuming (and thus expensive) even for an expert to assess the functioning or to detect faults of the solar heating system. Moreover, several faults may only occur temporarily under certain circumstances and remain hidden during an inspection. Therefore, automatic function control of solar heating systems is preferable.

However, the possibilities to automatically detect (and localize) faults depend on the system type, the underlying hydraulics, available measurement instrumentation and known system parameters. So, different approaches, additional assumptions or conditions may be necessary to detect a certain fault for different systems, implying different levels of accuracy that can be reached. Hence, it was the aim to design a FDD software package which can automatically adapt itself to such boundary conditions of each system (i.e. the available data basis) and subsequently perform the best applicable FDD algorithms.

To enhance automated fault detection for solar heating systems, ongoing research is important and necessary. This includes identifying relevant and observable symptoms of different faults for different systems and operation conditions, deriving algorithmic descriptions to check for these symptoms and faults, and -even more challenging- finding acceptable threshold values that differentiate between faulty and normal operation. Besides that, constant questioning and advancement of the best ways to implement and structure fault detection systems is important. One approach for a self-adapting fault detection system is presented here.

2. Basic concept

Since network-connectable data loggers and controllers get more common, a server-based approach for fault detection and diagnosis (FDD) of solar thermal systems (STS) is considered here. This means that measured data will be transferred from local data loggers to central servers which are tasked to monitor many solar thermal systems simultaneously. The local controller will only perform function control routines which either can be implemented easily without extra cost, or which check for conditions that require immediate response from the controller, e.g. to avoid damages in the STS. On the central server, the FDD analysis is performed and the results

doi:10.18086/swc.2017.19.05 Available at http://proceedings.ises.org

are passed to some "action module" which decides how to proceed (e.g. store to some database, write alarm messages, communicate with the controller, …). Such a centralized server-based solution allows for easy maintenance and continuous improvements of the FDD analysis routines that immediately benefit the whole user base. Furthermore, it does not require more powerful (and thus expensive) controllers in order to perform increasingly complex algorithms which are not part of the intrinsic control task. The software framework described here focuses on the part of the FDD analysis, i.e. how to extract faults and malfunctions in the STS from the available measurement data which is accessible in databases.

To achieve a FDD software package that can flexibly adapt itself to the available data basis, the whole procedure of fault detection and diagnosis is split into small subtasks which then will be managed automatically. This modular approach starts with the underlying FDD method which is described in Isermann (2006) and was also used by Küthe et. al (2011). It features several levels that are passed consecutively, as shown in fig. 1. Starting from measured values (e.g. the collector temperature), features are generated via appropriate feature algorithms. Features are (combined) properties of measured signals or some information derived thereof (e.g. nonzero flow rate in solar loop). Symptom algorithms then check related features for exceptional values to generate symptoms. Symptoms specify unusual or undesired states in the STS (e.g. unwanted cooling through collector during night). In the last step, fault algorithms usually combine several symptoms to identify the fault(s) which might cause the observed symptoms (e.g. malfunctioning check valve). Note that the outputs of symptom and fault algorithms are "statements about" symptoms and faults, since the result may also be their nonexistence. Hence, it is possible to differentiate whether a symptom or fault was checked for at all, and to make use of a "confirmed nonexistence".

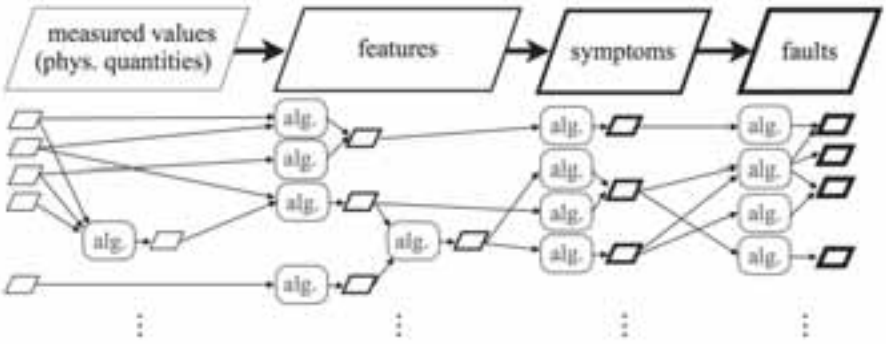

Fig. 1: Levels of the FDD method and exemplary algorithms of each level with their links. Each rhomboid denotes a specific quantity (i.e. a certain sensor/measuring point, feature, symptom, fault)

The FDD algorithms described in the previous section can be considered as "special knowledge" solving a small subtask under certain prerequisites and hence are part of a "knowledge base". Also, all information available about hydraulic schemes, each system's installed sensors as well as properties (called parameters here) of those sensors and of other installed hydraulic components contribute to the knowledge base. The software framework described here can access the knowledge base and then automatically link the knowledge found in order to apply it to a specific STS. The knowledge base can be extended easily over time, and every new piece of information will automatically be used wherever applicable. This distinction between knowledge base and automated knowledge linking is also indicated in fig. 2 where important software elements are depicted along with the interconnecting information flow.

3. Main software elements

In this section, first the structure of the knowledge base is described, on top of which the software framework will work. After that, the mechanism needed to communicate inputs, outputs and constraints between algorithms and the framework is presented. In the third subsection, the process of knowledge linking utilizing the communication mechanism is explained. The next subsection then sketches how the single parts are put together and which steps are performed during a particular investigation of a STS. The last subsection summarizes how data can be accessed and manipulated within an algorithm.

3.1 Knowledge base

As mentioned above, the knowledge base holds all FDD algorithms and known properties of STS, their

components and measurement equipment. Two things are essential for every FDD analysis: what is the type/ hydraulic design of the STS, and what sensors are intended to measure which quantity. Also, the names for sensors and components have to be defined. For this purpose, each STS that is to be investigated by the FDD software must be assigned to both a hydraulic scheme and a sensor scheme. The hydraulic scheme is – in the easiest case – a name that uniquely identifies the hydraulic layout of a STS. The possibility to compose a hydraulic scheme from several hydraulic modules as described in (Dröscher et al., 2009) will also be implemented in future. Moreover, for a given hydraulic scheme, names can be defined for components (except sensors) in the STS layout (e.g. "primary solar pump"), along with their types (e.g. "pump"). Also default parameters for the components of the hydraulic

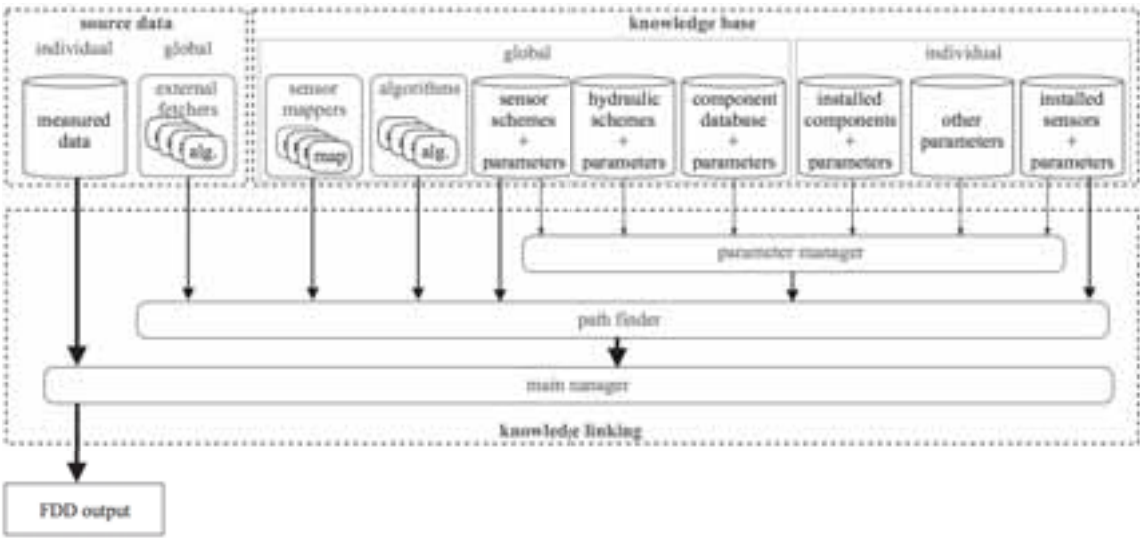

Fig. 2: Main software elements and the information flow

scheme may be provided if reasonable. All these component names and their default parameters are stored in a central hydraulic schemes database.

For each hydraulic scheme, one or several sensor schemes can be defined. The sensor scheme uniquely identifies the set of possible sensor names, where each sensor name is unambiguously linked to the measured quantity and a measuring location. Again, for each sensor also default parameters may be stored here (e.g. typical maximal flow rates or temperatures). By specifying the hydraulic scheme and the sensor scheme for each STS, the software framework knows the namespaces that are used to identify sensors and components in its data tables. A STS may also provide an *individual* installed sensors and installed components table, where individual parameters can be stored and override the default values in the scheme tables.

Moreover, a central component and sensor database is available. Here, for each component/sensor type, specific products can be registered along with known parameter values. Reversely, component or sensor parameters (e.g. collector efficiency, or measurement uncertainties) can be retrieved when type, manufacturer id, product id and parameter name are known.

Algorithms can be added by simply copying the corresponding python module file(s) into a specified directory. To be recognized by the framework, the module files must contain algorithm objects which are created by invoking a central factory function offered by the framework.

3.2 Communication mechanism

Each algorithm is confined to a small subtask and is valid under certain premises. For automatic linking, the surrounding management framework has to know the output of each algorithm as well as the required input quantities. In the design used by the framework, algorithms are objects which communicate their output quantity and input quantities via so-called "label" objects. Normally, each algorithm defines exactly one output label, only fault algorithms may have several fault labels as output. Besides these requested input labels, an algorithm can also request parameters and set up constraints that must be fulfilled in case of execution. Parameter requests and constraints are also objects. Parameters in this context are defined as fixed values that are looked up in the corresponding databases in the knowledge base (they might have been stored there by parameter identification algorithms, but the latter will not be integrated in regular FDD investigations). The most common constraints limit

an algorithm to a set of valid hydraulic schemes. But also parameter constraints can be created, demanding that the parameter could be looked up and has the required value. Algorithm objects, label objects, parameter objects and constraint objects are generated in a module file by calling the corresponding central factory functions offered by the framework. The factory functions make sure that objects of the correct types are used.

The label objects describe a certain input or output quantity, but hold in their attributes much more information than a simple name: For instance, whether it is an offer or a request, what kind of data it is associated with (just a single value, or multiple values linked to points in time, etc.), the dimension and unit for the offered or requested data, and so on. Label objects provide methods to check whether they match each other to allow for comparisons. For the simplest class of labels, the matching rule looks for equality of the relevant attributes. Some attributes like "unit" are always irrelevant and never influence matching, since two data sets containing the same quantity in different units are equivalent in view of the information content. Such standard labels can have only one match or none. But also label classes with more sophisticated matching rules exist (see below). However, such labels can encounter multiple matches. In that case, the best or preferred match has to be selected.

While features, symptoms and faults can simply be labeled with meaningful unique names to link offers and requests, the situation is somewhat more difficult for measurement data, as will be explained in the following. In order to request measured data, an algorithm needs to specify it (or the corresponding sensor) in a well-defined way. An obvious approach would be to set up a universal naming scheme, according to which each sensor of each STS gets an unambiguous name, in the sense that equivalent sensors in different STS get the same name. Such a naming scheme should include all aspects that might be needed for differentiation (e.g. quantity and some hierarchical description of position, like "T_solarloop_primary_return"). But this results in sensor names that are cumbersome in simple setups, while the naming scheme still may fail in cases where an unforeseen degree of distinction is needed. It also doesn't account for the fact that differently named sensors of different systems may serve the same purpose in some context, thus necessitating several algorithms, with their only difference being the sensor name requested. For instance, an algorithm needing the flow temperature coming to a heat storage from the solar loop might have to request "T_solarloop_secondary_supply" (supposing an according naming scheme) in case of the solar loop being connected via an external heat exchanger, but "T_solarloop_primary_supply" in case of an internal heat exchanger. Therefore, we take a more flexible approach by including an additional layer: the "PHYSICALQTY" label objects that describe a measurement data request in general terms, i.e. without knowing hydraulic details and from the perspective of measurement purpose. While PHYSICALQTY labels describe sensor requests, offered sensors are still identified via sensor names which are contained in the sensor label objects. But in contrast to a universal naming scheme, these sensor names can be chosen freely within the sensor schemes that were introduced in the previous subsection. Hence, the sensor names can be adapted to the needs of the hydraulic layout. To link PHYSICALQTY requests and offered sensor labels, sensor mappers (compare fig. 2) must be provided for each sensor scheme.

In the context of PHYSICALQTY labels, also the advanced label matching methods come into play. In principle, PHYSICALQTY labels have several attributes that hierarchically narrow down the requested measuring purpose. Here matching rules can be implemented that only check the equality up to the level of detail that is demanded by the request label. For instance, it is possible to generate labels that request the flow temperature in the solar loop, but do not care whether it is measured close to the collector or close to the heat sink. Due to the advanced matching rule, there is no need to create a mapping link just for this request variant. It is sufficient if the PHYSICALQTY label with highest level of detail was linked, easing the mapping effort.

Hence, to request measured data for an algorithm, one still can use the corresponding sensor name via a sensor label object. This leads to the implicit constraint, that the algorithm can only be applicable if the investigated STS also refers to the hydraulic scheme and sensor scheme where the sensor name is defined. This is welcome for algorithms which are valid for only one hydraulic scheme. For algorithms applicable to several hydraulic schemes resp. sensor schemes, the requested measured quantity is specified in general terms via corresponding PHYSICALQTY labels.

To summarize, we want to emphasize four advantages of PHYSICALQTY labels when compared to the utilization of a universal sensor naming scheme: Firstly, these are objects and not strings that are composed in a fixed pattern, making it easier to access the contained information and to alter the constituent parts in future. Secondly, the description of a measuring point does not need to include every aspect that might play a role in some special contexts. Instead, only measuring points which are quite common on many hydraulics need to be addressable with sufficient precision by PHYSICALQTY labels, since only those might be used in universal algorithms which do not depend on the peculiarities of the hydraulic scheme. Thirdly, a universal naming scheme starts from possible

measurement points in hydraulic layouts and makes sure to assign each one a unique name, meaning each "offer" is identified unambiguously. The PHYSICALQTY labels reversely describe sensors from the perspective of requests (which are unaware of hydraulic details), so not each offered, but each requested quantity is uniquely identified. This means that different PHYSICALQTY labels may point to to two different sensors in one hydraulic scheme, but to just a single sensor in another hydraulic scheme. To illustrate this, let one request be the sensor that measures the temperature of the heat carrier coming from the solar loop to the heat storage, and the other request the sensor measuring the flow temperature in the main (primary) solar loop before the heat sink. These are two different measuring points when an external heat exchanger is present (primary and secondary supply temperature), but a single one for an internal heat exchanger. Fourthly, with PHYSICALQTY labels, also requests of sensor collections can be defined, like "all available storage temperature sensors" or "all available output temperature sensors for parallel collector fields". To translate PHYSICALQTY labels to the delivering sensor labels, corresponding sensor maps are provided in the knowledge base for each sensor scheme (compare fig. 2).

3.3 Linking process (path finder)

To make use of the gradually growing knowledge base for a particular investigation, you need to check the applicability of all known algorithms, find linking possibilities and select the best ones. This is the task of the surrounding management framework, specifically the "path finder" (see fig. 2).

The path finder will search for known algorithms starting in a configurable root directory, but can be told to import just certain types of algorithms. For instance, for each algorithm a maximum automated execution frequency/minimum time interval can be specified, since some algorithms may need to look at larger timescales to work properly, meaning it also makes no sense to call them too often. The path finder is also given a threshold time interval, making it ignore all algorithms that have higher minimum time intervals. Hence, a path finder for daily evaluations will omit algorithms that do not add value if called more often than once a month, but monthly path finder will import them as well as daily algorithms.

To start the path search, the path finder fetches the set of installed sensors at the STS. It uses the sensor mappers from the knowledge base to determine the set of deliverable PHYSICALQTY labels. For every algorithm imported, it is checked if required input data can be supplied, if requested parameters could be looked up successfully by the parameter manager (compare fig. 2) and if all constraints are fulfilled. The parameter manager knows how to access all parameter tables and will look for a parameter at all relevant places. For instance, an equipment-dependent sensor parameter will first be searched in the individual installed sensors table. If not successful, it will try to retrieve manufacturer id and model id (first individual, then default) and use them to search for the parameter in the central component database. A specially treated kind of algorithms are external fetchers which may deliver data from external weather databases. These external fetchers normally are only activated by the path finder, if the data cannot be provided by sensors installed at the heating system.

As illustrated in fig. 1, several applicable algorithms providing the same output quantity may exist. For instance, the simple feature "it is night" could be calculated more accurately, if the zip code of the STS is known, but can also be given, if only the country is known. Thus, the algorithms are branded with a ranking score which rates the reliability and accuracy of an algorithm under the prerequisite of accurate input data. If several algorithms delivering the same output are applicable, the situation is resolved depending on the configuration of the path finder. It can be configured to choose the best algorithm a priori, based on the ranking score of the algorithm. Alternatively, each of those algorithms is added to the execution list to calculate the output quantity. Then the result data set with the highest reliability score will be chosen for further use. The reliability score of the output data will be calculated via the reliability scores of the inputs and the ranking of the algorithm.

Algorithms can not only have inputs of the lower level, but also of the same level (compare fig. 1). This allows for "virtual" sensors (e.g. calculating heat sums) as well as sophisticated features derived from other features. To make sure to detect all linking possibilities, the path finder iteratively checks the applicability of algorithms with inputs of the same level. It will adjust the execution order automatically, but avoid creating circular references.

At the end of the path search, when no algorithms can be added any more, the path finder removes all algorithms from the execution list that are placed on dead end execution paths. Dead ends are defined by giving a threshold target level to the path finder, usually being the symptom level. In that case, only algorithms that contribute to at least one symptom generation would be executed. However, also symptoms that are not used by any operable fault algorithm would be generated, as they might be of interest when post-processing the FDD results.

Because many comparisons of label objects have to be made during a path search, the path finder uses data structures for its internal input/output registries that on the one hand utilize fast membership testing via hashing methods, on the other hand also minimize the number of unavoidable matching comparisons. This means the comparison effort for the path search shows rather linear than quadratic growth with increasing number of algorithms.

3.4 Main manager

The main manager is responsible for performing all steps that are necessary to perform an FDD analysis for a given STS and time range. Based on provided configuration parameters, the main manager creates instances of the pathfinder and the parameter manager. Also, all necessary fetchers are initialized. Each fetcher knows how to look up certain kind of information in a certain database table. Now the path finder imports the algorithms and sensor mappers and determines the set and order of algorithms to execute. After that, the set of sensors needed as inputs is determined. Their measurement data are fetched from the database and packed into a data collection object, where they can be preprocessed. The data series can be checked for boundary values and/or plausibility, where the preprocessing parameters are gathered from individual installed sensor or sensor scheme table. Invalid values are registered and considered as data gap. Small data gaps may be interpolated (depending on the sensor's preprocessing parameter), larger data gaps are retained and registered. Also, a reliability score may be computed. Optionally, a sensor may be totally removed from the list of available sensors, necessitating a new path search. Of course, it is also possible to skip the preprocessing procedure here and perform it already before inserting new measurement data into a database holding sanitized data. In any case, it is ensured that in the end all measured data arrays are synchronized with one equidistant gapless timeline determining the fundamental time resolution of all subsequent calculations. If necessary, data points are mapped or interpolated accordingly.

When the data collection of all needed preprocessed measurement data is created, it is passed from one algorithm to the next. Each algorithm retrieves the requested input data from the collection via its input label objects. Thereby, the label request is first mapped to the right offer in the data collection (e.g. a PHYSICALQTY to the real sensor data), if necessary. Furthermore, the data is automatically converted to the requested unit as needed. Finally, the result data is added to the data collection, where it gets labeled automatically. After the execution of the last algorithm, the data collection can be passed to some "action" module responsible for final processing, which is not in the focus here. Commonly the results would be stored in some database where they can be accessed later, but also immediate triggering of alarm messages could be implemented here. For the algorithm development and testing tasks, the data collection is passed to our result visualization and evaluation tool.

3.5 Data sets

The core of each algorithm object is its method where real processing takes place. When an algorithm retrieves input data from the data collection via the request label, the data is returned as data set object. Different kinds of data set types exist, with continuous data sets being the most common one. They contain the data as array and a corresponding timeline object. The timeline object provides many convenient methods e.g. to locate days, weeks, months and so on, or to determine the day of the week for each point. Also, sub-timelines can be created easily. Likewise, especially the continuous data sets offer convenient methods of often needed operations. For instance, time averages over a specified time interval, daily/weekly/monthly sums, shifting data by a specified time range, determining start or end points in mask arrays, and other signal processing methods or filters like smoothing will be added. This makes it easier to write the processing steps in a few lines of codes for many algorithms.

4. Validation

The software framework is developed and employed in our academic environment where a few STS are monitored. In particular, two STS for domestic hot water preparation in multi-family houses (MFH) are available that serve as regular heat sources under real use conditions, but may be used for experiments as well. Since they are equipped with an extensive measurement instrumentation, these systems allow to generate real life data of the STS when a deliberately induced fault is present. More information regarding the MFH STS can be found in (Schmelzer et al., 2015).

Dozens of algorithms for features, symptoms and faults are already implemented in the knowledge base of the

software framework. They were checked against measurement data from the MFH STS as far as possible, or adopted from previous projects. Of course, the correct operation of the software framework including path finder and all implemented mapping and matching functionalities were checked with dedicated test algorithms and test cases, but also confirmed when used for the algorithm development and validation.

To bring the capabilities of the framework to life, exemplary results of a set of advanced algorithms are shown. They were implemented in the software framework, aiming to detect gradual leakage in the solar loop when a pressure sensor is available. Based on a validated physical model of the temperature-dependent pressure in the solar loop and related sensitivity analysis studies, the expected pressure signal and uncertainty margins are calculated as features with help of several temperature signals from the STS. The model only considers states when the pump is off and no stagnation occurs. Hence, according features provided by other algorithms are used as input, too. From a first version of algorithms which used several sensors that are only available at the MFH STS, a more

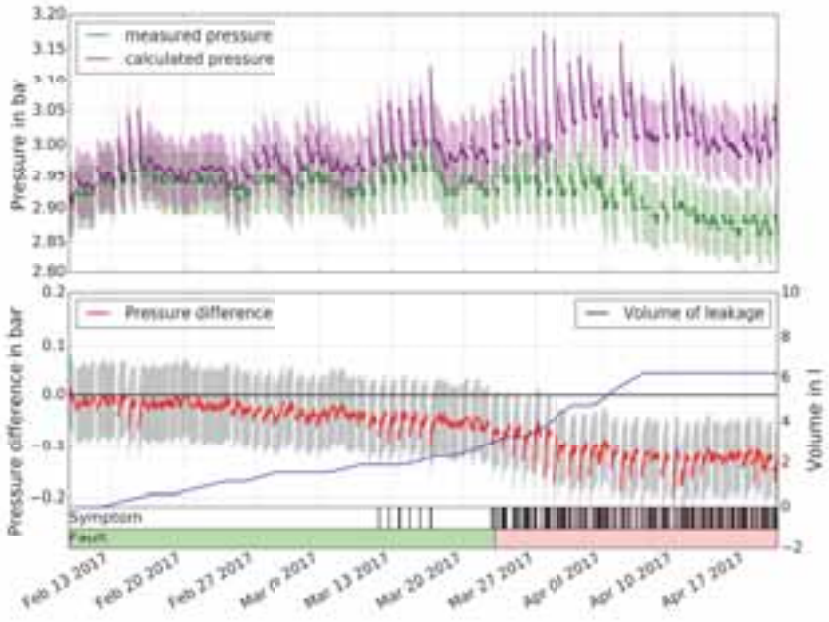

Fig. 3: Measured (green) and calculated (violet) pressure signals incl. their uncertainties, their difference (red) incl. uncertainty (gray), the cumulated leakage volume (blue) and the times where the corresponding symptom and fault are recognized.

simplified version using more common sensors was developed. They both performed similar well and were able to detect the gradual leakage quite soon. The results of the simplified set of algorithms are shown in fig. 3. On the MFH STS, a gradual leakage was initiated on purpose and the total leakage volume measured (blue line fig. 3). Fig. 3 shows the calculated and measured pressure signals and their difference including the corresponding calculated uncertainties. At the bottom it is indicated where symptoms are recognized and for which days faults are reported. Although only 3 liter (<5% of fluid in collectors and supply/return pipes, <2% of expansion vessel volume) were lost in total, and although the measured pressure stayed on the same level, the leakage was detected correctly by the algorithms. While a detection approach looking only at absolute pressure drops would have failed, the implemented algorithms could derive that the pressure should have increased in normal operation. Reversely, no leakage was detected in the leakage-free operation times. However, in order to be applicable, a pressure sensor as well as several parameters like size of the expansion vessel and the (rough) fluid volume must be available. Hence, it is useful for medium to large STS. Algorithms that require fewer parameters, yielding in higher uncertainties, will be derived, too. Thanks to the path finder of the software framework, the best applicable algorithms of these variants will be chosen automatically.

5. Summary

A flexible software framework for fault detection and diagnosis was presented. It automatically links modular algorithms and other information from the knowledge base to flexibly adapt itself to the boundary conditions of each solar thermal system. Hence, it can perform the best faults detection methods in dependence of the information available. In this paper, the underlying concepts and implementation approaches to achieve this flexibility were introduced. The usefulness and interaction of offer and request label objects, data set and algorithm

objects and the functioning of the path finder and the overall procedure were described. Exemplary results for algorithms detecting a gradual leakage were also shown. The FDD software framework and the corresponding algorithms currently are developed and tested in an academic environment where a few well known systems are monitored.

ABSORBER SURFACE DURABILITY STANDARD TESTING ISO 22975-3 VS. MEASURED THERMAL STRESS AT EXTREME TEST SITE

Thomas Kaltenbach[1], Markus Heck[1] and Karl-Anders Weiß[1]

[1] Fraunhofer-Institute for Solar-Energy-Systems ISE
Heidenhofstr. 2, 79110 Freiburg, Germany

Abstract

Solar absorbers, as a key component in solar thermal collectors, are in the focus of this paper. A well introduced durability testing method for the solar absorber is the testing procedure described in ISO 22975-3 [1]. This standard testing procedure is applicable to the determination of the long term behavior and service life of selective solar absorbers for use in vented flat plate solar collectors.

Different samples of solar absorbers on aluminum and copper substrates are characterized before, during and after the accelerated ageing tests and outdoor exposure with various methods, including FT-IR spectroscopy and microscopic technologies like AFM microscopy to measure the degradation on different scales.

It turned out, that the corresponding testing time of the procedure for high temperature test was less than in the standard ISO 22975-3. Therefore, the standard testing procedure is testing at higher thermal loads then the extreme test sites with high absorber temperature in constant stagnation mode.

1. Introduction

Depending on their location and prevalent climatic conditions, the components of solar thermal collectors have to bear high climatic and mechanical stresses. Besides high temperatures, UV-light, wind, snow, humidity or saline and corrosive atmospheres can be causes for a rapid degradation of materials and components.

Despite these well-known obstacles for solar thermal installations in extreme climates, the aging processes with regard to different climatic and operational conditions are only partially analyzed. To qualify and enhance the durability of solar thermal systems and improve the opportunities on a world-wide scale, the development of suitable accelerated aging tests is necessary. The project “SpeedColl”[2] is dedicated to the research on these issues.

The aging effects occurring in solar collectors with glass covers are determined primarily by the temperature level in the collector. This temperature level has significantly increased during the last years due to the enhancement of the collector efficiency and the trend towards systems with higher solar fractions with the resulting increase in stagnation times and temperatures. Furthermore, durability analyses of new products on the market such as spectrally selective absorber layers are needed, since only little is known about their long-term behavior.

Next to the influence of increased temperatures, other causes for aging have to be analyzed too, especially UV-radiation, moisture and the influence of saline atmospheres. Furthermore the frequent use of solar thermal collectors in Mediterranean regions for the preparation of domestic hot water generation and solar cooling, a quality check regarding the impact of the saline atmosphere predominating close to the sea-shore in these countries is necessary. This will be emphasized in detail in the “SpeedColl” project. This paper will focus on the influence of the stress factor temperature on the absorber. The samples are provided by the industrial project partners.

Of all components in solar thermal systems, solar collectors experience the highest climatic and mechanical stress. They are subjected to high temperatures and, depending on the location, variable and extreme weather conditions. Just as coastal and sun-rich regions offer large potential for solar energy use; the systems installed in these areas

doi:10.18086/swc.2017.19.06 Available at http://proceedings.ises.org

are exposed to especially high levels of UV radiation, humidity and salt air. As a result, the collectors often age and degrade faster.

In "SpeedColl" actual environmental stress data such as humidity, UV radiation, temperature and salt concentration are determined. The data collection varies from tests carried out in alpine, moderate and maritime locations through to measurements in arid and tropical regions. Test stands are installed on the Zugspitze, the highest mountain in Germany, as well as in Freiburg, Stuttgart, Gran Canaria, the Negev Desert and in India. Additionally the solar collectors and components undergo accelerated aging tests in the laboratory. Using the collected data, the researchers validate the procedures of the aging tests, which provide information about the collector's thermal performance over its entire lifetime. The results also serve as a basis for standardization.

2. Absorber surface durability testing

The absorber surface durability testing specifies a failure criterion of a solar absorber based on changes in optical performance of the absorber. The optical properties of interest are the solar absorptance α and the thermal emittance ε. The testing according to ISO 22975-3 specifies durability testing procedures focused on resistance to high temperatures and condensation of water on the absorber surface as well as high humidity.

Within the test procedure, the reference of the thermal load for the assessment of the thermal stability of the absorber coating was measured in a flat plate collector. The collector was exposed in Freiburg, Germany. The absorber temperature was measured in stagnation over one day of clear conditions with a maximum global irradiation of 930 W/m². The total annual load assumed 30 days of stagnation. The maximum stagnation temperature was 184°C. [3].

In the "SpeedColl" project, the absorber samples are exposed to outdoor weathering at five test sites with different climatic conditions with continuous monitoring of the micro and macro climatic conditions. Since a direct exposure of absorbers is not adequate to the real situation of the solar absorbers in solar thermal collectors, the test samples were mounted above the solar absorber with purpose-built galvanically insulated spacers in a commercial solar thermal collector. The absorber temperature is continuously monitored. To receive also information of the corrosivity of the micro climate inside the collector, test coupons of four different metals are placed inside the collector, too. The ambient climatic conditions in terms of corrosivity are also measured as a reference next to the test collector [4].

The temperature of the solar absorber inside the test collector is measured continuously during exposure in order to set up a data base for the development of suitable accelerated lifetime tests.

Accelerated ageing tests with a variation of the relevant parameters, temperature and condensed water on the absorber surface are performed in climatic cabinets. Especially tests with condensed water at high temperature levels are used for the qualification of the materials since this is seen as the most demanding factor and relevant for the application of solar thermal systems in sunny regions.

For collectors placed in marine environments chloride ions from sodium chloride are considered to be major corrosion agent in these regions [5].

3. Characterization methods

The spectral measurements were carried out with a Fourier transform spectrometer Bruker Vertrex70 equipped with two integrating spheres (a PTFE coated sphere for the shorter wavelength-range ($\lambda < 2{,}0$ µm) and a diffuse-gold coated sphere for the IR ($\lambda > 1{,}7$ µm) in order to measure both the directly reflected and the scattered radiation. The diffuse part of the reflectance was calibrated with a PTFE standard from National Institute of Standards and Technology (NIST) for the solar range and from National Physical Laboratory (NPL) for the thermal range. The specular part in the solar and the infrared ranges was calibrated with an aluminum mirror from NPL. The accuracy of the reflectance data was better than 1 % in the solar range and better than 2 % in the IR. The solar absorptance/reflectance was calculated by weighted integration of the spectral reflectance with the solar spectrum AM 1.5 according to ISO 9845-1. The thermal emittance was calculated by weighted integration of the spectral reflectance with the Planck Black Body radiation distribution at a temperature of 373 K.

4. Weathering tests

The samples are exposed to outdoor weathering at five test sites with different climatic conditions under continuous monitoring of the climatic conditions (temperature, humidity, wind, precipitation, UV) and the collector micro climate (temperature and humidity inside the collector). In order to gain worst-case-data some of the test sites are positioned in extreme climates with very harsh conditions (Table 1).

Tab. 1: Exposition of collectors at locations with extreme climates

Climates	**Location**
Tropical	Kochi, India
Alpine	Schneefernerhaus, Zugspitze, Germany
Aride	Sede Boker, Negev Dessert, Israel
Maritime	Pozo Izquierdo, Gran Canaria, Spain
Moderate	Stuttgart and Freiburg, Germany

Figure 1 shows the temperature distribution of the same commercial vented flat plate solar collector type at the 5 different explosion sits within the “SpeedColl” project. The collectors were not actively cooled; therefore they were in constant stagnation mode.

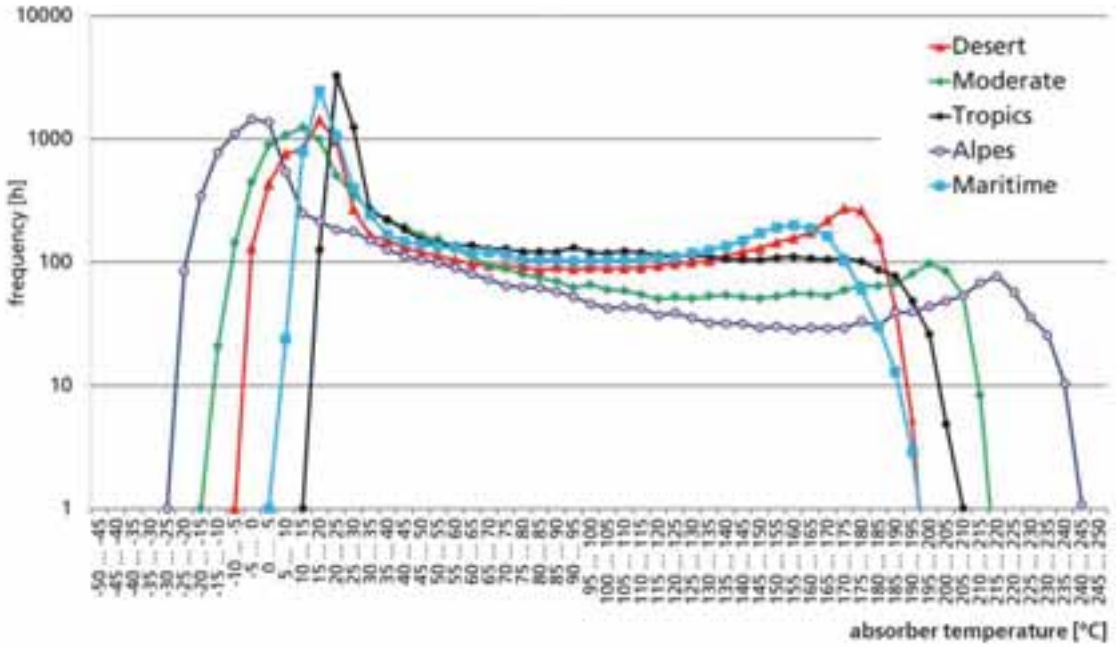

Fig. 1: Histogram of the absorber temperatures [°C] at different exposition sites, measured period from 12/2013 to 11/2014, Negev desert (arid) in Israel; Freiburg (moderate) in Germany; Kochi (tropical) in India; Zugspitze (alpine) in the German Alps and Gran Canaria (maritime) in Spain

The alpine exposition site reached the biggest temperature spread of the absorber temperature with minimum temperature of -30°C and maximum temperature of 245°C.

5. Service life testing

To measure the load during an operating time of one year of the absorber coating the effective mean temperature T_{eff} turns out to be a suitable parameter. It is defined in equation 1.

$$\exp\left(-\frac{E_T}{R}\cdot T_{eff}^{-1}\right)=\int_{T_{min}}^{T_{max}}\exp\left(-\frac{E_T}{R}\cdot T^{-1}\right)\cdot f(T)\cdot dT \qquad \text{(eq. 1) [6]}$$

with

f(T)	the temperature frequency function for the observed load over one year
T_{max}, T_{min}	maximum or minimum absorber temperature of the load
E_T	activation energy

For thermal degradation f(T) is the time in one year, during which the absorber temperature lies between T and T+dT. For degradation by condensation and high humidity, f(T) is the time in one year, during which the absorber temperature lies between T and T+dT, and the relative humidity in the collector exceeds 99% or condensation takes place on the absorber.

The effective mean temperatures of the same commercial vented flat plate solar collector type with a chosen activation energy of 50 kJ/mol as a lower estimate at the 5 different explosion sits within the “SpeedColl” project are shown in figure 2.

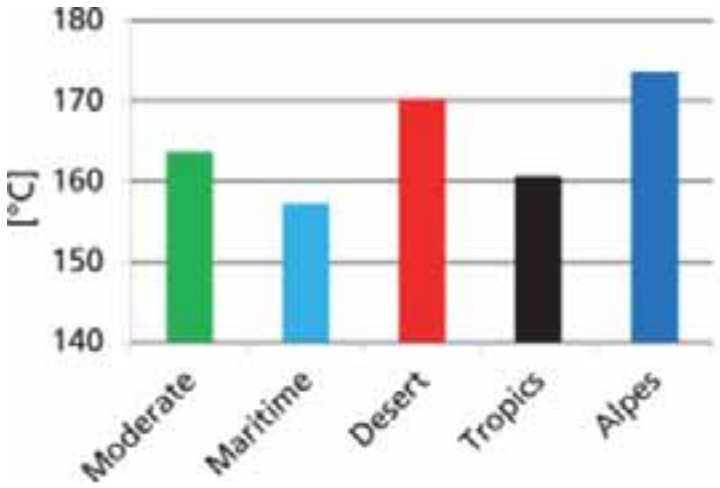

Fig. 2: Effective mean absorber temperature [°C] at different exposition sites, measured period from 12/2013 to 11/2014 with an activation energy of 50 kJ/mol, Freiburg (moderate) in Germany; Gran Canaria (maritime) in Spain; Negev desert (arid) in Israel; Kochi (tropical) in India and Zugspitze (alpine) in the German Alps

The alpine exposition site led to the highest effective mean temperature of 174°C. With this measured thermal load we used the same time transformation function for the assessment of the thermal stability of the absorber coating like it was done in the standard testing procedure ISO 22975-3.

The corresponding testing time for the procedure for the execution of the high temperature testing to 25 years lifetime based on the Arrhenius relationship is shown in figure 3 for three different testing temperatures as a function of the activation energy.

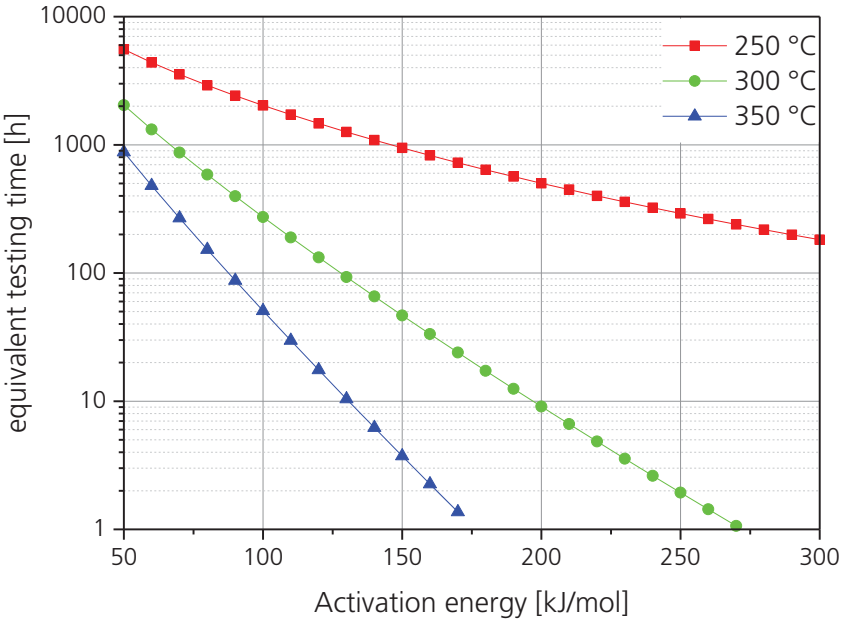

Fig. 3: Testing time equivalent to 25 years lifetime with measured thermal load of Zugspitze (alpine) in the German Alps for 250°C, 300°C and 350°C testing temperature as function of the activation energy

In figure 4 the corresponding testing time for the procedure for the execution of the high temperature to 25 years lifetime according to ISO 22975-3 is shown for three different testing temperatures as a function of the activation energy.

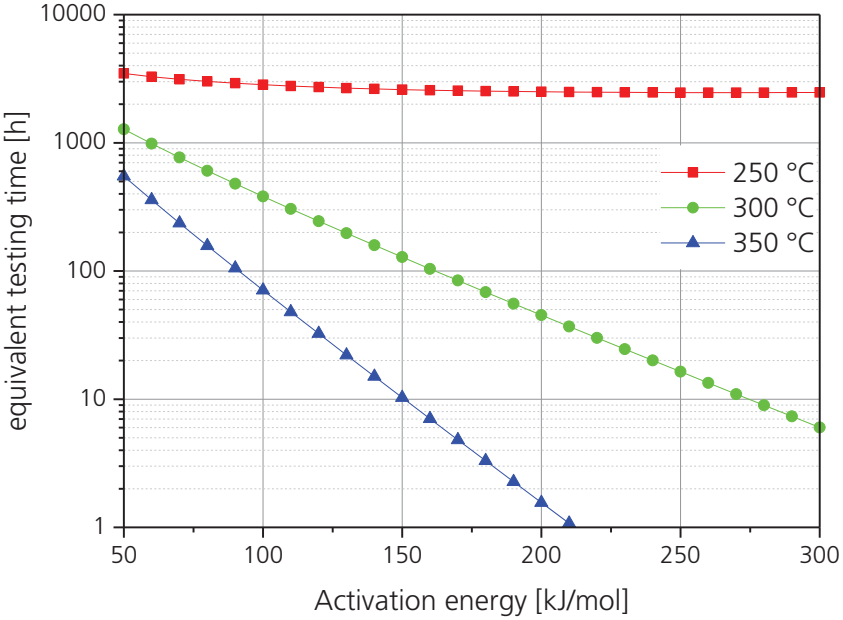

Fig. 4: Testing time equivalent to 25 years lifetime according to ISO 22975-3 with thermal load of Zugspitze (alpine) in the German Alps for 250°C, 300°C and 350°C testing temperature as function of the activation energy

It turns out, that the corresponding testing time for the procedure for the execution of the high temperature test determined in the project was less than the testing time in the standard. For example with an assumed activation Energy E_T of 100 kJ/mol the testing time equivalent at a testing temperature of 300°C is 273 h and for ISO 22975-3 the testing time equivalent is 381 h.

Therefore, the standard testing procedure is testing at approx. 40% higher thermal loads then the extreme alpine test site with high absorber temperature in constant stagnation mode.

6. Conclusion and outlook

The relevant physical properties of the material samples were measured before and after the exposure to accelerated ageing tests and outdoor weathering. The results of the initial optical characterization of the test-samples proved a very good homogeneity. The standard deviation out of 21 test panels for the solar absorptance value α is 0,001 and for the thermal emittance value ε the standard deviation is 0.003. This assumes an excellent production quality

It turned out, that the corresponding testing time of the procedure for high temperature test for the alpine test site was less than in the standard. Therefore, the standard testing procedure is testing at higher thermal loads then the extreme alpine test site with high absorber temperature in constant stagnation mode.

Thus the standard testing procedure ISO 22975-3 fully covers the aging behavior of absorbers in terms of high temperature loads even at the condition measured at the extreme alpine test site, where the highest absorber temperatures within the “SpeedColl” project were measured.

The effects of high humidity and condensed water in terms of the stability of the absorber coating will be addressed in the current “SpeedColl2” project.

Abstract

Solar thermal appliances (STAs) can be made as an integrated part of the building/housing using building material housings (BMH), which ultimately make these appliances more user friendly, durable and weather resistance. This paper presents fabrication and testing of three different solar thermal appliances. Appliances are developed for water heating and cooking purposes, these are: Building material housing solar water heater (BMSWH), Fixed structure solar concentrator (FSSC), Community size solar cooker (CSSC). According to the test results, the thermal performances of CSSC and BMSWH are found satisfactory even after 2 and 10 years, respectively. Two meals cooking for 8 to 10 persons can be done in CSSC on a sunny day and in BMSWH (62 liter) water can be stored near 60 ºC. Due to building material housing, systems have good durability and high weather resistance. For FSSC thermal profile and cooking test show it's cooking ability (100-200 gm rice within 45 minutes to 1.5h) in peak sunny hours in lesser time than box type solar cooking. Fix structure makes the system user friendly and building material structure decreases payback period of the system.

Keywords: solar water heater, solar cooker, solar concentrator, building material

1. Introduction

Human civilization has been witnessing a gradual shift towards cleaner fuels- from wood to coal, from coal to oil, from oil to natural gas; renewable is the present demand. It is quite obvious that solar energy is the most promising current and future option among all non-renewable and renewable energy resources used currently across the globe. Energy form the sun can be utilized in two ways: (i) in the form of heat or thermal energy called solar thermal applications and (ii) in the form of electrical energy called solar photovoltaic applications. In all nations, a major share of total energy consumption is utilized by the household sector for water heating and cooking purpose. Solar thermal applications have immense potential especially in domestic and industrial sector to meet thermal energy demand of the world (Dzioubinski and Chipman, 1999; Sen, 2004; Thirugnanasambandam et al., 2010; Mahavar et al., 2012a, 2012b; Mahavar, 2015).Therefore, in the present research work our interest have been to provide cost effective, user friendly and durable solar thermal appliances for the domestic or small industries.

Solar thermal appliances (STAs) e.g. water heater, solar concentrator, box–type solar cookers, solar stills and dryers work on direct application of solar power. These all appliances have some common components: (i) absorber/receiver, (ii) glaze, (iii) insulation, (iv) casing and (v) reflector. In the present piece of work we have focused our attention on building materials (bricks, cement and their composite) to use as casing material of different solar thermal appliances (Sukhatme, 2007).

With building material housing (BMH) STAs can be made as an integrated part of the building, which ultimately make this appliances more user friendly and durable. BMH casing is highly weather resistant hence increase the life time of the appliance and decreases payback period of the appliance. This casing also favorable to increase thermal performance of appliances as it has low thermal conductivity. In order to test building material as casing in STAs we have fabricated different solar thermal appliances viz. community size solar cooker, fixed structure solar concentrator and solar water heater. The experimental studies of fabricated appliances have been done as per Indian and international standard (Nayak, 2000; BIS, 2000; Belusko, 2004; Sukhatme, 2007; Hossainb, 2011). The thermal performances of appliances are found quite satisfactory even for long time duration of 2 to 10 years. It reveals that building material casing can makes STAs more convenient to use (due to fix structure), increase durability and weather resistance.

2. Literature review

In a small capacity domestic solar water heater (SWH) a closed shallow rectangular box made of metal sheet (absorber) is contained in a housing which supports a glass cover on the top and, insulation material that surrounds the bottom and sides of the absorber tray. In a close-coupled SWH system the storage tank is horizontally mounted above the solar collectors on the roof and the hot water naturally rises into the tank through thermosyphon flow (Sukhatme, 2007; Mahavar , 2015). Different type of solar water heaters have been developed and tested by several researchers (Hossainb, 2011; 5, Mahavar, 2015). This literature also reveals that a few researches have been done to make solar water heaters as integrated part of housing by use of building material casing (Sengar, 2007; Marwal, 2012). As far as solar concentrators concern, these are the most effective for collecting solar radiations. This is due to high concentration ratio and high thermal energy collection ability (Mahavar et al., 2016). Five main solar concentrator technologies can be identified: (i) compound parabolic concentrator (CPC) (ii) parabolic trough concentrator (PTC) (iii) linear fresnel reflector (LFR) (iv) parabolic dish with fixed focus (e.g. Scheffler) (v) parabolic dish with moving focus. A number of solar concentrator has been developed from very large to small scale for a wide range of applications viz. power generation, thermochemical reactions that involve production of synthetic gas and hydrogen, production of hybrid solar-fossil fuel and solar thermal detoxification and recycling of waste materials (Kaushika and Reddy, 2000; Sonune and Philip, 2003; Lovegrove, 2011; Reddy, 2013). Besides these applications these systems are also used for solar cooking. Considering above aspects a parabolidal dish solar concentrator has been fabricated for cooking in peak sunny hours. A parabolidal dish solar concentrator is a point focal collector that requires dual axes sun tracking to concentrate solar energy onto a receiver located at the focal point. Instead for tracking keeping the structure fix cooking can also be performed in short duration at local noon. This cooking time is lesser than the box type solar cookers and as system does not require tracking so it is also easy to handle by users. Use of building material housing for structure of concentrator makes the system more durable and weather resistance. Concentrating on this, fixed structure solar concentrator (FSSC) is consisted of building material.

The other solar thermal appliance i.e. box type solar cooker consists of a rectangular enclosure insulated on the bottom and sides, and having one or two transparent covers on the top called glazes. Solar radiation enters through the upper glaze and heats up the absorber and container containing food stuff. Different types of solar cookers (box type , focusing type and advanced or indirect type) have been developed by many researchers (Panwara, 2012; Mahavar et al., 2012a, 2012b, 2013, 2015, 2017; Cuce and Cuce, 2013; Punia, 2013) using different kind of materials for different components. A considerable work has also been done for development of community size solar cooker (Nahar, 1993; Piroschka, 2014) i.e. a cooker which serve cooking for 8 to 20 persons. Senger.et al. (2011) have developed a building material housing solar cooker for cooking need of 2 to 4 persons. Fabrication of community size solar cooker using building material has not been done yet (Punia, 2013).

Hence, building material casing has been used for fabrication of various solar thermal appliances and its long term effect has also been tested for these appliances.

3. Fabrication of appliances

All the systems are installed (facing south) at open rooftop of Department of Physics, University of Rajasthan, Jaipur (26.92ºN, 75.87ºE). Building material housing solar water heater (BMSWH): This system is shown in Fig. 1. Mainly system consists of a solar collector and a storage tank. The details of these components are given in Table 1. Fixed structure solar concentrator (FSSC): This system is shown in Fig. 2. The dimensions of system are: 0.7 m diameter, 0.2 m height and 0.15 m focal length. An aluminum sheet of diameter 0.09 m, 0.3 mm thick and 0.013 kg mass is used as receiver for measurement of thermal profile. A steel pot (coated with thin black coat) of diameter 0.1 m is used for cooking placing at focal length distance. Community size solar cooker (CSSC): The cooker has been designed in such a way that length to width ratio is about four, so maximum radiation reflected from the reflector falls on the glass cover. Since aperture of the system is very large, the glaze has been designed in two pieces, each of dimension 100×60 cm^2. The lid is hinged at the top of the cooker and is used to reflect the solar radiation onto the cooker aperture. The cooker size is sufficient to cook two meals per day for 8 to 10 persons. System is shown in figure 3 and 4, and the component details are given in Table 2.

4. Experimental study of appliances

4.1. Experimental set-up

On a number of days the experimental studies of all the systems have been conducted at the University of Rajasthan, Jaipur (26.92˚N, 75.87˚E). In these experiments, the solar radiation intensity (I_s) on a horizontal surface was measured using a pyranometer (Nation Instruments Ltd. Calcutta, instrument no. 0068). CIE-305 thermometer with point contact thermocouples (accuracy 0.1 ºC) was used to measure the temperatures at different locations of the CSSC and FSSC; viz. the water load (T_w), and the absorber plate (T_P). For BMSWH eight channel MS 1208 Multispan thermometer (accuracy 1 ºC) is used with J-type thermocouple to measure temperature of inlet (T_{in}), outlet (T_{out}) and storage tank (T_s) temperature. Ambient temperature (T_a) was measured using a mercury thermometer (accuracy 0.1ºC) placed in an ambient chamber. The measurements of temperatures of different regions were carried out on clear sunny days at every 10 minutes interval for the duration of 10:00 to 16:00 Indian Standard Time (IST) for CSSC and BMSWH. For FSSC this time interval is 5 minute and experimental time period is around local noon. The experimental arrangement of temperature measurements is shown in Fig. 4 for CSSC. Other instruments namely pyranometer and mercury thermometer were situated within 5 meter distance of this arrangement during testing.

4.2. Thermal Profiles

For solar water heater temperature of inlet (T_{in}), outlet (T_{out}) and storage tank temperature (T_s) are measured and reported in Fig. 5. Sengar, (2007) and Marwal, (2012) have also studied the system with different other components. For the reference thermal profiles of system measured in 2006 is also shown in Fig. 6 and 7 (Sengar, 2007). Fig. 8 shows the temperature profile of FSSC. The thermal performance of CSSC has been measured without load and with load. These are depicted in Fig. 9 and 10.

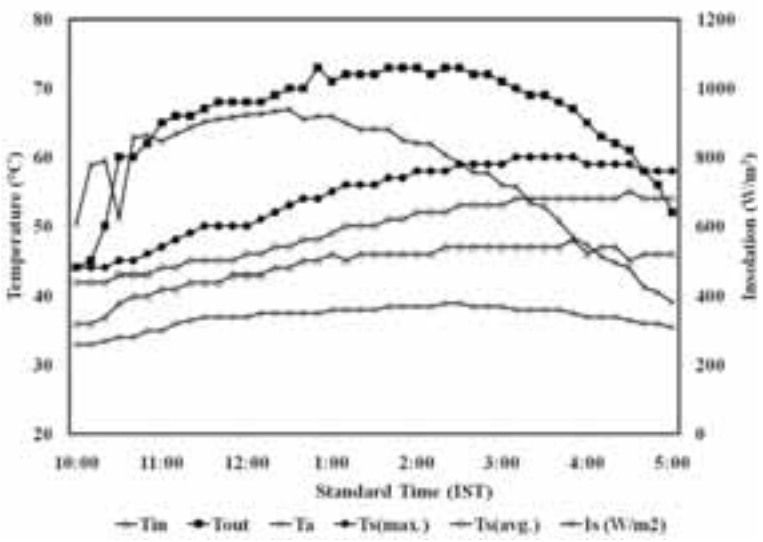

Fig. 5: Thermal profile of BMSWH (close loop) on 21 June 2017 with PMMA double glaze (T_a, T_{in}, T_{out} and T_s are ambient, inlet water, output water and storage tank water temperatures, I_S is solar insolation).

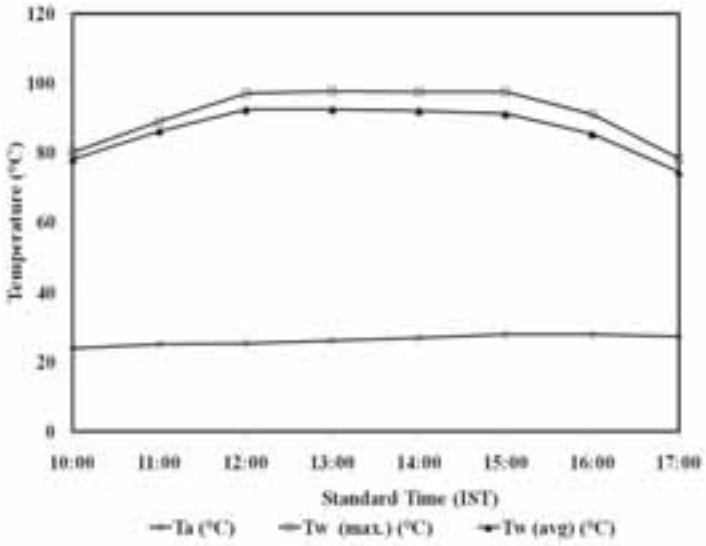

Fig. 6: Thermal profile of BMSWH (open loop) on 25th Nov. 2006 with single glass glaze (T_a and T_w are ambient and output water temperatures) (Sengar, 2007).

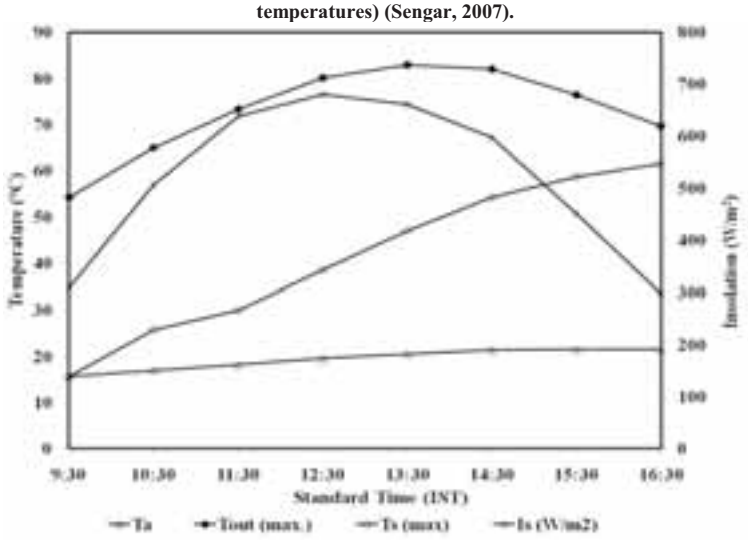

Fig. 7: Thermal profile of BMSWH (close loop) on 21 Dec. 2006 with single glass glaze (T_a, T_{out} and T_s are ambient, output water and storage tank water temperatures, I_S is solar insolation) (Sengar, 2007).

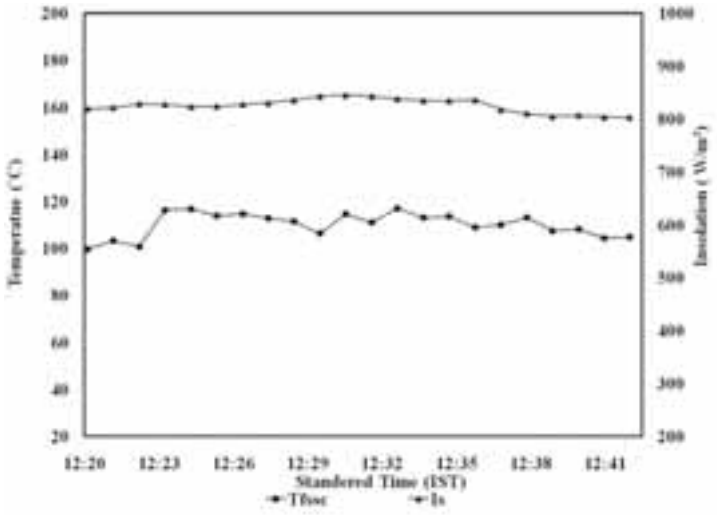

Fig. 8: Temperature profile of FSSC on 20 Jun 2015 (T_{fssc} is receiver temperature and I_S is solar insolation).

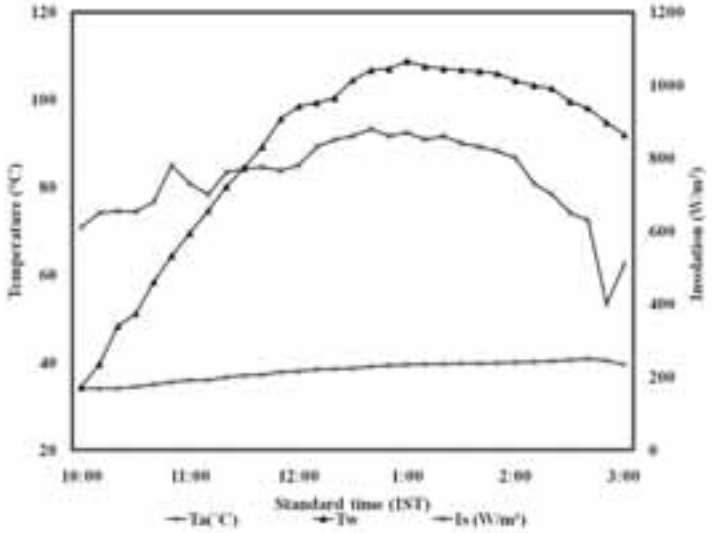

Fig.9: Measured temperature profiles and radiation intensity during sensible heating test of CSSC (8 kg water load) on 08 April 2012 (T_a and T_w are ambient and load water temperatures, I_S is solar insolation).

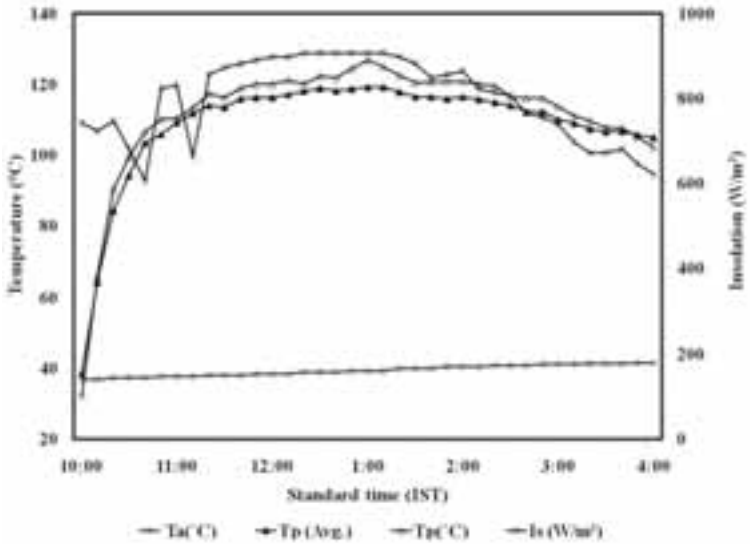

Fig. 10: Temperature profile of the different components (T_p- base plate, T_a-ambient, T_p (avg.)- average plate) of CSSC and variation of solar insoltion (I_s) with the standard time on 12 July 2014.

5. Results and discussion

Building material housing solar water heater: Initial experimental studies (in year 2017) are performed with PMMA glaze for BMSWH. The representative experimental observations for close loop cycle are plotted in Fig. 5. The maximum outlet water temperature is about 74 ºC and storage tank temperature reaches around 60 ºC. System thermal performance has also studied by Sengar; (2007) and Marwal; (2012). This is shown in Fig. 6 and 7. For slow mass flow rate in open loop cycle the maximum outlet temperature was recorded about 90 ºC in 2006 (Fig. 6). These tests were conducted with single glass glaze and hybrid insulation. A comparison of Fig. 5 with reference thermal profile Fig. 7 reveals that system thermal performance is quite good (storage temperature 60 ºC) even after more than 10 years. Although components of system (glaze, insulation, storage tank etc.) have been changed yet the casing is same. It indicates building material casing makes the system good weather resistance and increases the durability. System is still under the testing for determination of different characteristic parameters of a solar water heater.

Fixed structure solar concentrator: Fig. 8 shows that FSSC receiver attained a maximum temperature of 117 ºC at local noon and remains above 100ºC for about 20 minutes for insolation around 800 W/m^2. In FSSC cooking of rice is also done in a pot of diameter 10 cm and height 6 cm. The observed cooking time is 45 min. for 100 gm rice cooking which required 200 gm of water to cook. Hence, FSSC is suitable for cooking of boiling type food in peak sunny hours.

Community size solar cooker: The diurnal variation of water load temperature, solar insulation and ambient temperature for 8kg water load are depicted in Fig. 9.The results of these figures are used to calculate the second figure of merit. Figure shows that in 1 h 30 min water load attained temperature about 80 ºC and it is sustained for more than 3 h. This reveals that two meals cooking for 8 to 10 persons can be done in this cooker as per ref. (Mahavar et al., 2015). The value of second figure of merit (F_2) (using T_{w1}=63.8ºC,T_{w2}=95.1ºC, τ=5400 sec. , average values for the ambient temperature 39.2ºC insulation is 806 W/m^2) calculated as per ref. (Mahavar et al., 2012a) is found to be 0.416 . Fig. 10 represents the diurnal variation of solar insolation, absorber plate and ambient temperature of CSSC under no lad condition. The temperature of the absorber plate increases with time until it achieves the maximum values around 1:00 p.m. The maximum temperature of the absorber plate T_p is recorded to be 126.9ºC. The absorber plate temperature remains above 100ºC for most of the time. This stagnation test as per ref. (BIS, 2000) assures the satisfactory thermal performance of community size solar cooker. This test is conducted after more than two years in 2014 with same components and still the thermal performance of the system is found satisfactory, it indicates the good weather resistance and durability of the system due to the building material casing.

Hence, building material housing can serve as good casing material for solar thermal appliances and using this casing these appliances can be made an integrated part of the building/housing.

6. Conclusion

Solar thermal applications (STAs) have immense potential especially in domestic and industrial sector to meet thermal energy demand of the world. Beside all the development of STAs, there is still need of user friendly, more durable and weather resistant appliances with good thermal performance. Paper concludes that the appliances (water heater, solar concentrator and solar cooker) developed using building material housing have good thermal performance for long duration of 2 to 10 years or even more years. Hence, with building material casing STAs can be developed as integrated part of the housing or small industries and can be more popularized for hot water and cooking need of individual houses in effective way.

Photovoltaics

Study on Crawler-Type Solar EV

Toru Fujisawa[1], Yuki Nemoto[1], and Takashi Kawaguchi[1]

[1] Kanagawa Institute of Technology, Atsugi (Japan)

Abstract

In this study, a photovoltaic module was installed on the rooftop of a crawler vehicle. If the power grid is unable to supply electricity, the crawler-type solar electric vehicle (solar EV) is able to travel on rough ground and has a self-charging function owing to solar energy absorption. The crawler can move in various ground conditions, such as asphalt, soil, grass, and gravel. Driving experiments were performed under different conditions, and we measured the photovoltaic current, voltage, acceleration, and power consumption. As a result, the solar fraction is compared with the vibration, it was found that solar fraction of the crawler-type solar EV was achieved 40-44 % on a winter clear day, power consumption of the motor was not proportional to z-axis acceleration. For specified solar fraction, ratio between PV and motor ratings was around 30 %, it is larger than scooter-type solar EV.

Keywords: Crawler, Solar EV, PV System, Solar Fraction, Farm Car

1. Introduction

After the Great East Japan Earthquake of 2011, as damaged infrastructure needed a longer time to return to a normal state, many Japanese people considered harvesting solar energy for daily life, and also for automobile use. Solar EV is a unique name proposed by the regulation of the World Solar Challenge (WSC 2012). In Japan, a company (Fukuzawa-Oder, 2015) produced a crawler-type solar-power-driven planter for Chinese yams (*Dioscorea batatas*). In recent years, we found the motivation for this study from our university students, aiming at developing sustainable solar-powered EV. It is a low-cost and reusable vehicle with potential applications in areas such as agriculture, delivery use (Toru Fujisawa and Takashi Kawaguchi, 2016), on uneven surfaces, or in rural areas with a stand-alone photovoltaic system.

2. EV conversion

The solar EV is converted from an old grain thresher, OSHIMA Harvester MK-100 (fabricated by Oshimanoki, 1983–1986), as shown in Fig. 1. Its driving seat and photovoltaic module are reused components. The aluminum frame, synchronous motor, lead-acid battery, inverter, and boost-type maximum power point tracker (MPPT) are new components needed for conversion to a solar EV. Tab. 1 gives the specifications of the grain threshing machine. Tab. 2 lists the major components of the converted crawler-type solar EV. Fig. 2 shows a side view of the crawler-type solar EV. In the figure, each major component is indicated. The electrical system of the crawler-type solar EV is shown in Fig. 3.

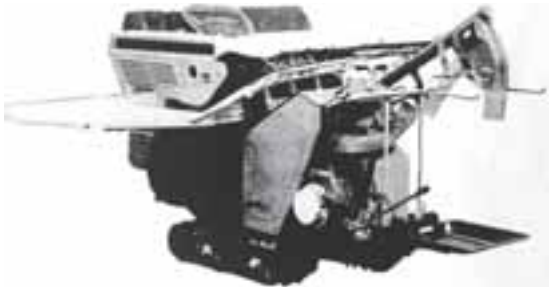

Fig. 1: Oshima MK-100 thresher

doi:10.18086/swc.2017.20.01 Available at http://proceedings.ises.org

Tab. 1: Specifications of the grain thresher

Length	Width	Height	Tread	Mass
1,743 mm	878 mm	1,586 mm	635 mm	181 kg
Max speed of powertrain	**Max Engine Power**	**Engine**	**Compression Ratio**	**Fuel**
1,800 rpm	3.5 PS	G510L NA 192 cc	6.2	Unleaded petrol

The traveling speed of the thresher can be selected, at 0.38 m/s, 0.43 m/s, and 0.91 m/s, using its transmission gear. We considered traveling safety and decided to avoid using a highest-speed gear. When the engine pulley rotates 10 rounds in the lowest gear, the crawler travels 1.2 m on the road. This means that the vehicle speed can be calculated from the rpm of the driving unit.

Tab. 2: Specifications of major components for converted crawler-type Solar EV

Battery	Motor	Inverter	PV module	Tracker	Pyranometer
VRLA 12 V × 4, 20 Ah	FBLM86 PMSM 660 W	BLD4820 ≤ 1200 W	MD-HH210T 210 W	Boost PT-209U	Silicon sensor ML-020VM

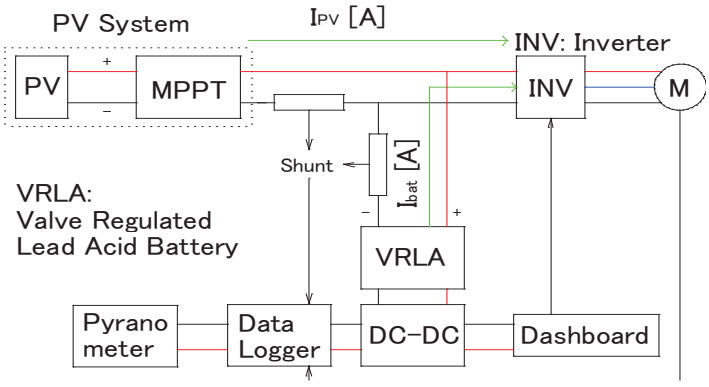

Fig. 3: Block diagram of electrical system

Fig. 4 shows outdoor solar charging in summer and an indoor garage view with undergraduate students in winter. Fig. 5 represents the PV system output current, valve regulated lead acid (VRLA) battery current, and motor current while climbing backward a step from asphalt to greenbelt ground, as in Fig. 4.

Fig. 4: Converted crawler-type solar EV (Left: outdoor charging in summer, Right: in a garage in winter)

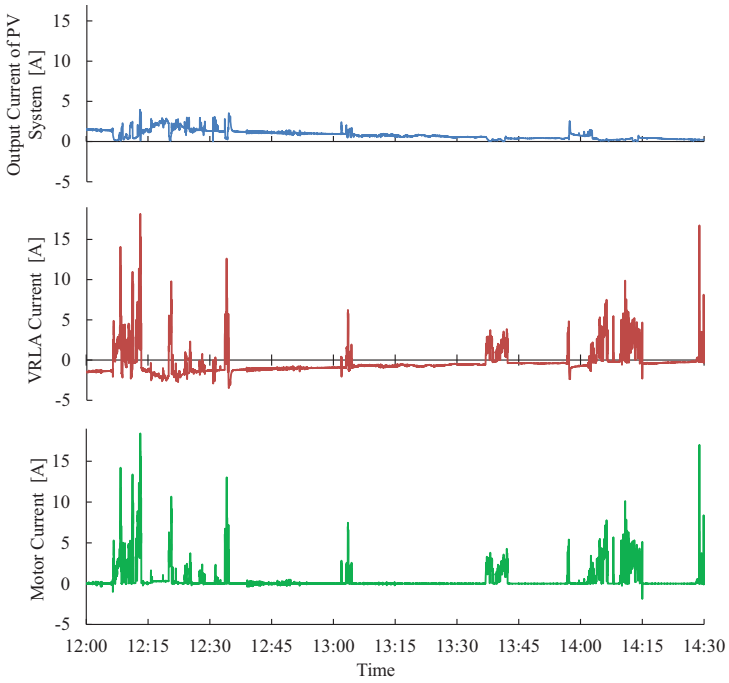

Fig. 5: Motor current and PV system output current in summer (climbing backward a step from asphalt to greenbelt ground)

3. Evaluations

3.1. Solar Fraction

The solar fraction (F_s) was calculated using the output PV power (P_{pv}) and consumed power using load (P_{load}).

$$F_s = \frac{\int P_{pv} dt}{\int P_{load} dt} \qquad \text{(eq. 1)}$$

$$P_{pv} = I_{pv} V_{bat} \qquad \text{(eq. 2)}$$

$$P_{load} = I_{bat}V_{bat}, \qquad \text{(eq. 3)}$$

Here, I_{pv} is the output current of the peak power tracker, V_{bat} is the voltage of the lead-acid battery (same as the load voltage), and I_{bat} is the current of the battery. These data, along with the irradiance, accelerometer output, and revolution speed (12 pulses per revolution) of the motor are recorded by a 10-channel data-logger (GRAPHTECH GL220A) every 100 ms.

A three-axis accelerometer, Kionix KXSC7-2050, was installed under the driving seat near the center of mass, as shown in Fig. 6. The output from this sensor is also recorded simultaneously in the same interval by the logger. To evaluate the vibration of the vehicle, the root mean square (RMS) value of the z-axis acceleration a_z is calculated as

$$RMSA = \sqrt{\frac{\sum_{i=1}^{n} {a_z}_i^{\,2}}{n}}. \qquad \text{(eq. 4)}$$

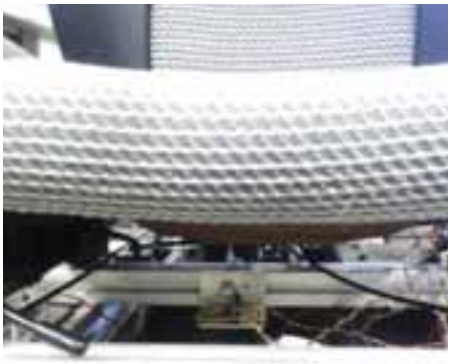

Fig. 6: Installation position of three-axis accelerometer

3.2. Experiments

Three different experimental surfaces are shown in Fig. 7. The grain diameter of gravel was ~15–40 mm, and the glass depth was ~20–40 mm. The experimental results of speed vs. power consumption on the three different surfaces, gravel, grass, and asphalt, are shown in Fig. 8. Fig. 9 shows the z-axis acceleration for the RMS value vs. vehicle speed. From this figure and the previous one, it can be observed that the z-axis acceleration does not always directly affect the power consumption of the driving load.

(a) gravel **(b) glass** **(c) asphalt**

Fig. 7: Ground surface conditions

As a result, the power consumption was greater on gravel and glass than on asphalt. On the other hand, the RMS value of the z-axis acceleration is smaller on grass and on asphalt than that on gravel. The solar fraction for each

condition is calculated using eq. 1 and listed in Tab. 3.

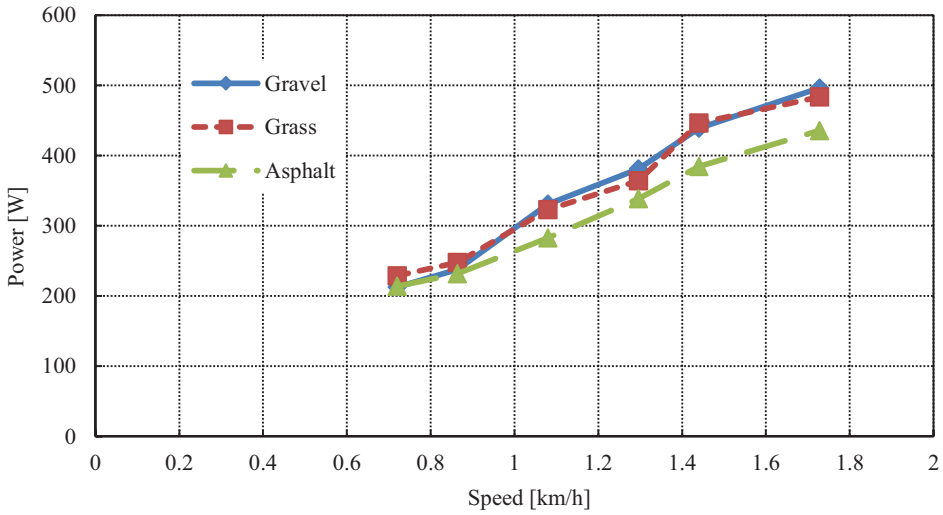

Fig. 8: Speed vs. average power consumption for three different roads

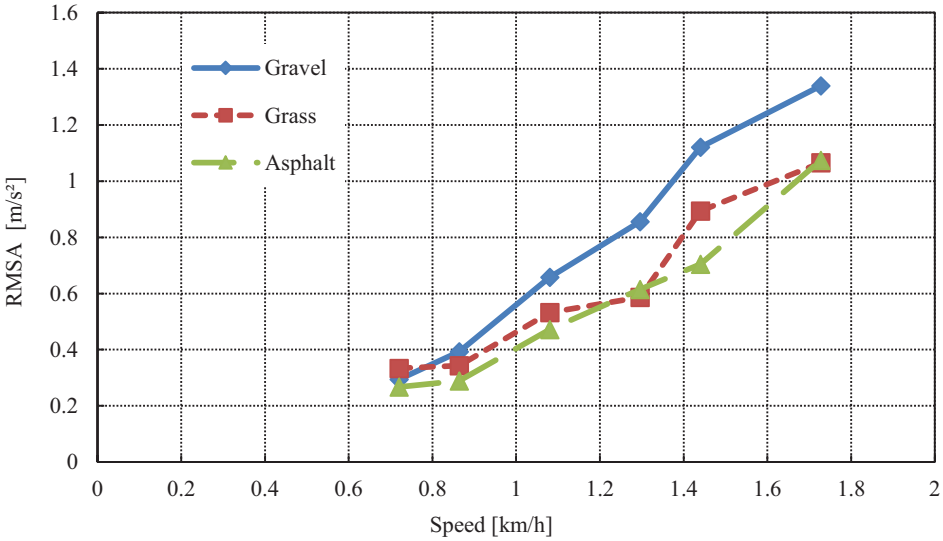

Fig. 9: RMS acceleration of vertical direction (z-axis) vs. vehicle speed

Tab. 3: Solar fraction of crawler-type solar EV on different flat surfaces on a clear winter day

Motor Speed	Gear	Speed [km h^{-1}]	Gravel 15th Dec 17	Grass 26th Jan 17	Asphalt 21st Jan 17
1000 [rpm]	First	0.720	60.9 %	56.6 %	60.6 %
	Second	0.864	54.5 %	52.3 %	55.9 %
1500 [rpm]	First	1.08	39.2 %	40.1 %	45.8 %
	Second	1.30	34.0 %	35.6 %	38.3 %
2000 [rpm]	First	1.44	29.5 %	29.0 %	33.7 %
	Second	1.73	26.1 %	26.8 %	29.7 %
Average			40.7 %	40.1 %	44.0 %

Solar Altitude [deg.]			30.9	25.9	34.8

4. Discussions

Tab. 4 presents the comparison between various solar EVs. The power unit, mass, PV rating, battery capability, travel distance per charge, and solar mileage are discussed. Fig. 10 shows the ratio between the PV and power unit ratings in terms of the specified solar fraction for comparison. Spirit is the name of the racing solar car that participated in the WSC 2013 Adventure class, the Gyro Canopy is a converted solar EV scooter, and the Prius PHV is TOYOTA's first commercial solar EV that can incorporate electric power into its power battery storage while driving.

Tab. 4: Three different types of Solar EV and plug-in HEV with photovoltaic roof (including 60-kg driver)

	Motor	Mass	PV	Motor / Mass	Battery	PV / Motor	Distance	Solar mileage	Duration
	[kW]	[kg]	[kW]	[W/kg]	[kWh]	[-]	[km/charge]	[km/day]	[h]
Racing solar car KAIT Spirit	2.0	220	1.3	9.52	5.0	0.65	350	300	4.3
Crawler solar EV	0.66	245	0.21	2.69	0.6	0.32	1.5	0.6	0.6
Gyro canopy converted solar EV	1.5	210	0.13	7.14	1.3	0.87	19.5	2.4	0.2
Prius PHV	80	1810	0.2	44.2	10	0.0025	60	6	0.1

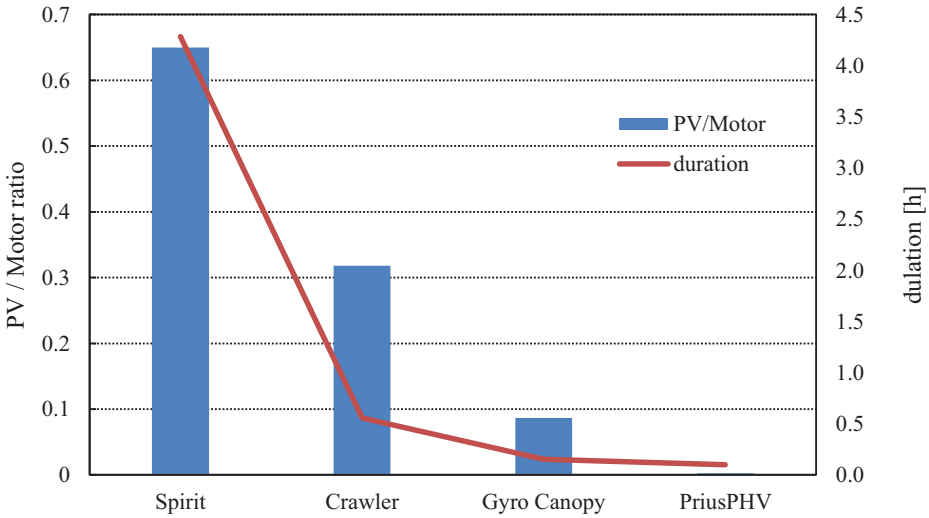

Fig. 10: The ratio between PV and power ratings

5. Conclusions

From the outdoor driving experiments with the converted crawler-type solar EV, the following conclusions were drawn:

- The solar fraction was 44% on the asphalt road on a sunny winter day.
- The consumed power was proportional to the vehicle speed, and the lowest curve was obtained on an asphalt road.
- The crawler-type solar EV is affordable with a 660-W synchronous motor and a VRLA battery with a nominal power of 48 V.
- The highest power consumption rate was obtained on asphalt, achieving 10 km/kWh in the lowest gear.
- The rating power ratio of PV/Motor for the crawler-type solar EV was 0.32.

Farm-use cars or robotic vehicles are necessary for Japanese rural agriculture, as the rapidly aging society with

fewer children has become the largest problem for Japan's future.

Beam Splitting with a Luminescent Solar Concentrator in a Hybrid Photovoltaic/Thermal Collector

Maja Gajic[1], David Rodriguez-Sanchez[1] and Gary Rosengarten[1]

[1] RMIT University, School of Engineering, Melbourne (Australia)

Abstract

This work investigates the combination of two non-imaging types of concentrating solar technologies: the luminescent solar concentrator, that generates electricity via photovoltaic cells and the compound parabolic concentrator, used normally with a thermal receiver. The luminescent solar concentrator in this new application is used as a cover for the solar thermal collector (the CPC) whilst at the same time concentrating a specific wavelength band of light to its edges where solar PV cells convert photons to electricity. Absorption of a part of the solar spectrum occurs in the LSC, whilst the rest of the solar spectrum can be captured as thermal energy in the CPC, essentially forming a new type of spectral splitting hybrid solar collector that can produce electricity and medium temperature heat. A small prototype hybrid CPC and LSC collector was tested in the lab using a solar simulator. This proof of concept device compared a high transmission and low transmission LSC and demonstrated the experimental basis of the new type of PV-T collector. An outdoors flow experiment was undertaken, measuring instantaneous thermal efficiency and electrical output.

Keywords: solar photovoltaic, solar thermal, hybrid

1. Introduction

The sun is the world's most abundant energy source and means of harvesting it include photovoltaic cells to create electricity and solar thermal collectors to generate heat. Low temperature heat can be used for domestic applications where in urban environments available space is often limited. By combining solar thermal and photovoltaics in one system, roof space can be saved and potentially efficiency can be increased. Photovoltaic technologies can only convert photons with energies above their bandgap to electricity, with the remainder of the solar spectrum wastefully generating heat. In a hybrid configuration that heat is not wasted but collected instead.

This work combines for the first time two types of non-imaging solar concentrators, the luminescent solar concentrator (LSC) and the compound parabolic solar thermal collector in a hybrid configuration as shown in Fig. 1. The LSC cover acts as a beam splitter of solar radiation. The absorption and emission spectra of the fluorescent molecules within the LSC device select a part of the spectrum, where ideally it is totally internally reflected to the solar PV cells attached to the edges of the LSC. The rest of the solar spectrum is transmitted through the LSC cover to the solar thermal collector.

There are many potential applications for such a technology depending on what the desired outcome is. The CPC solar thermal collector can be designed for domestic applications requiring low temperature heat or for commercial applications where medium temperature heat is required (up to approximately 200 °C). Currently the LSC can generate modest amounts of electricity that could potentially power peripheral devices or sensors. This is due to the low power conversion efficiencies of the device, with the world record device achieving 7.1 % with expensive gallium arsenide PV cells (Slooff et al., 2008).

There is of course a trade-off between electricity generated and thermal energy collected and one or the other could be prioritised depending on loads and needs. The potential applications for hybrid photovoltaic and thermal (PV-T) collectors are more numerous in urban environments where roof space is often limited (Ramos et al., 2017). By making better use of the solar source, PV-T collectors can save on space and improve energy collection efficiency.

2. Hybrid CPC and LSC Collector

2.1 Luminescent solar concentrator

Luminescent solar concentrators consist of a fluorescent material embedded in a waveguide such as poly methyl methacrylate (PMMA). Photons that fall within the absorption spectrum of the fluorescent material can be absorbed and then isotropically emitted at a longer wavelength. Ideally these re-emitted photons are propagated to the edge of the waveguide via total internal reflection (Debije and Verbunt, 2012). Solar PV cells (or other absorbers) can then be attached to the edges of the device to convert photons to electricity. An important benefit of LSCs is that they can concentrate both diffuse and beam radiation (Smestad et al., 1990) and they have a wide acceptance angle, which allows them to function without tracking. The acceptance angle is defined as the maximum angular deviation of a ray with respect to the normal to the aperture plane, which allows the ray to be intercepted by the receiver. Additionally, the fluorescent dye can be chosen to emit photons that the solar PV cells can convert with higher efficiency. Conventionally their use has been envisaged to be in the urban environment to reduce the environmental impact of buildings (Gajic et al., 2017; Kanellis et al., 2017).

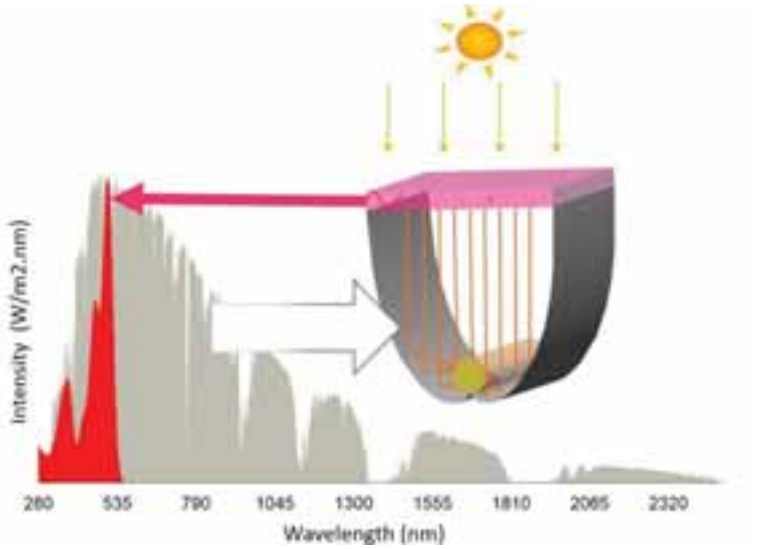

Fig. 1: Schematic of LSC and CPC hybrid collector overlaid with solar AM 1.5 spectrum (grey) and Lumogen Red 3505 fluorescent dye absorption spectrum (red)

2.2 LSC design and fabrication

For the small-scale prototype hybrid CPC and LSC, two LSCs were fabricated from commercially available fluorescent sheets as shown in Fig. 2. A pink sheet, commercially manufactured by Evonik ("Evonik Industries," 2017) and a red sheet named Mars Red 4t56 available from online retailers. The properties of the LSCs are summarised in Table 1. Since these fluorescent sheets were commercially procured, it was not possible to determine the exact concentration of fluorescent dye or even confirm the fluorescent material. The pink sheet is assumed to contain the dye Lumogen Red 305, estimated from spectroscopic properties. The solar AM 1.5 averaged absorption was measured for the pink sheet to be 8.6 % and red sheet to be 32.8 %. The high transparency of the pink sheet is useful for collecting most of the energy as heat in the solar thermal collector while the higher absorbing red sheet transmits more energy to the PV cells. The absorption spectra of the two LSCs and the AM 1.5 spectrum is shown in Fig. 3. The figure shows how that the red sheet absorbs much more of the visible spectrum than the pink sheet, which will enhance transmission to the PV cells. The fluorescent sheets were cut to size and the edges were optically polished with very fine sand paper and polishing oil. Sunpower high efficiency back contact PV cells were diced and cut to fit the edge of the LSC. These cells are very well suited to LSC applications as they have all the wiring on the back. The thickness of the cells is 3 mm and for the prototype LSCs, cells of length 9.5 cm and 5 cm were fabricated. The pink and red LSCs have the 9.5 cm cells placed along the 10 cm edge of the LSC and along the 15 cm length both 9.5 cm and 5 cm cells were attached. Each had attached wiring that was connected in parallel externally.

2.3 Compound parabolic concentrator

The compound parabolic concentrator was developed by Roland Winston when he was investigating means of efficiently detecting Cherenkov radiation (Hinterberger, 1966). The discovery of the CPC led to the development of the field of non-imaging optics, whose designs approach and even realise the maximum concentration allowable for a given acceptance angle, due to removing the need for point to point mapping required by conventional optics (Rabl and Winston, 1976; Winston, 1970; Winston et al., 2009; Winston and Welford, 1978).

Ideally, the CPC concentrates all rays that fall within its acceptance half angle, Θ_A. The acceptance angle will determine the hours of light that can be collected as CPC designs are almost always non-tracking. The concentration ratio C of a two-dimensional CPC is determined by the ratio of the aperture area to the area of the receiver and quantifies the increase of solar flux on the receiver. C is inversely related to the acceptance angle and this means we can achieve higher concentration ratios, but at the expense of hours of sunlight that can be concentrated. A two-dimensional CPC can be considered as trough like and this shape is ideal for thermal applications where a cylindrical receiver such as an evacuated tube can be placed along the focal length of the collector (Herrick, 1982; Karwa et al., 2015). A cross sectional view is shown in Fig. 4. An involute shape CPC with an entrance aperture, d_1, and receiver radius, r, has a concentration ratio as shown in eq. 1. Θ_A is the acceptance half angle and ideally all incident rays at and below this angle will be transmitted to the receiver.

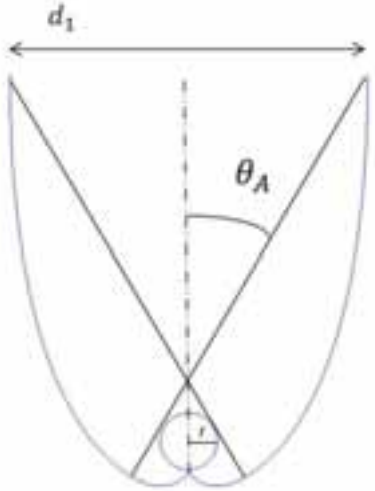

Fig. 4: Involute shaped compound parabolic concentrator

$$\text{Concentration ratio} = \frac{1}{\sin(\theta_A)} = \frac{d_1}{2\pi r} \qquad \text{(eq. 1)}$$

There is a large potential for solar technologies to meet industrial process heat needs, where medium temperatures are required (90 - 250 ˚C). CPCs offer a simple robust solution that has the potential to meet these needs. It has also been shown that CPCs can perform better than other solar collectors over a wide range of temperatures and without tracking (Brunold et al., 1994; Carvalho et al., 1995; Gallagher et al., 1993; Gu et al., 2014). As CPCs can reach the maximum allowed concentration for a given acceptance angle they are the best choice for a proof of concept collector that utilises a cover made up of a luminescent solar concentrator.

2.4 Compound parabolic concentrator for proof of concept hybrid collector

A small proof of concept prototype CPC and LSC hybrid was developed in this work. The CPC is designed with an aperture area of 15 cm and an absorber of radius 0.87 cm, giving a concentration ratio on the absorber of 2.74. An extruded profile of length 10 cm was generated and using CAD software, a profile was created as shown in Fig. 5 (right). The height was truncated by 70 % to save on material costs and to allow for a thinner collector

profile. The profile was then 3D printed with ABS polymer, and coated with highly reflective sputtered aluminium. The properties of the CPC are summarised in Table. 2. The involute compound parabolic shape was designed to be combined with a cylindrical receiver made up of an absorber within an evacuated tube and a 3 mm clearance gap between absorber and glass envelope. The evacuated receiver was supplied by commercial suppliers. However, the datasheet of the selective surface was not provided. The hybrid prototype under test conditions is shown in Fig. 5 (left).

Tab.2: CPC specifications and values

CPC specifications	Value
Radius absorber	0.87 cm
Gap between absorber and glass	3 mm
Aperture	15 cm
Concentration ratio	2.74
Acceptance angle	21.4 °
Mirror reflectance	AM 1.5 averaged 91 %
Truncation of height	70 %
Cost to 3D manufacture	$ 200 (material cost only)

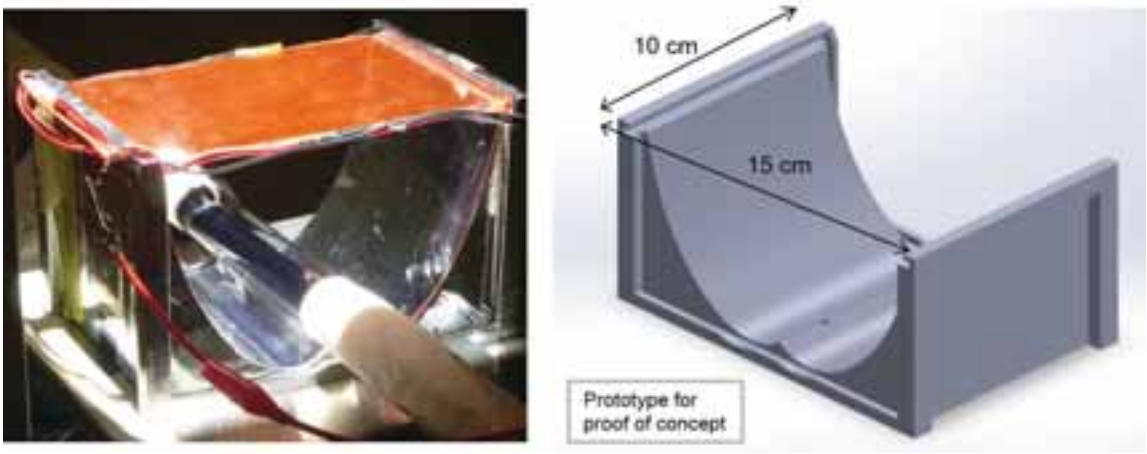

Fig. 5: Prototype hybrid under indoor test conditions (left), image of 3D printed prototype CPC (right)

4.2 Experimental setup

Indoor performance testing of the hybrid collector was analysed under a triple-A rated solar simulator. A 1000 W/m^2 radiation flux at the aperture plane of the CPC was set up using a calibrated pyranometer. To measure electrical performance of the LSC cover, I-V curves were taken with a Keithley 2400 source measuring unit. The indoor experimental set up is shown below in Fig. 6. The experiment compared both the pink and red LSC covers. I-V curves were measured under three different conditions shown below.

- LSC only (without the CPC) placed onto an absorbing material (TiNOX). This is necessary to stop reflected photons passing back into the LSC.
- LSC coupled with the CPC collector at the start of illumination (cold).
- LSC coupled with the CPC collector and after three hours of illumination (after 3 hours).

Thermal performance was characterised by measuring the stagnation temperature of various configurations of the device. Performance testing of solar collectors describes stagnation temperature as maximum achievable collector temperature. This occurs at zero flow conditions where the heat input is equal to the heat loss. The collector is illuminated at a constant radiation until this maximum temperature is reached, providing a useful comparison of the different configurations.

The thermal receiver used in the experiment is shown in Fig. 7. The 10 cm length required was left bare while the remainder of the tube was wrapped in foil and the ends were insulated. The tube is comprised of a selective surface absorber in an evacuated tube. To measure the stagnation temperature three k-type thermocouples were placed in the tube - one at the far end, one in the middle in the active area and one at the near end of the entrance.

A data logger is used to measure the temperature and the hybrid configuration was left to stagnate under the solar simulator for up to 3 or more hours, with at least 5 measurements made of each configuration.

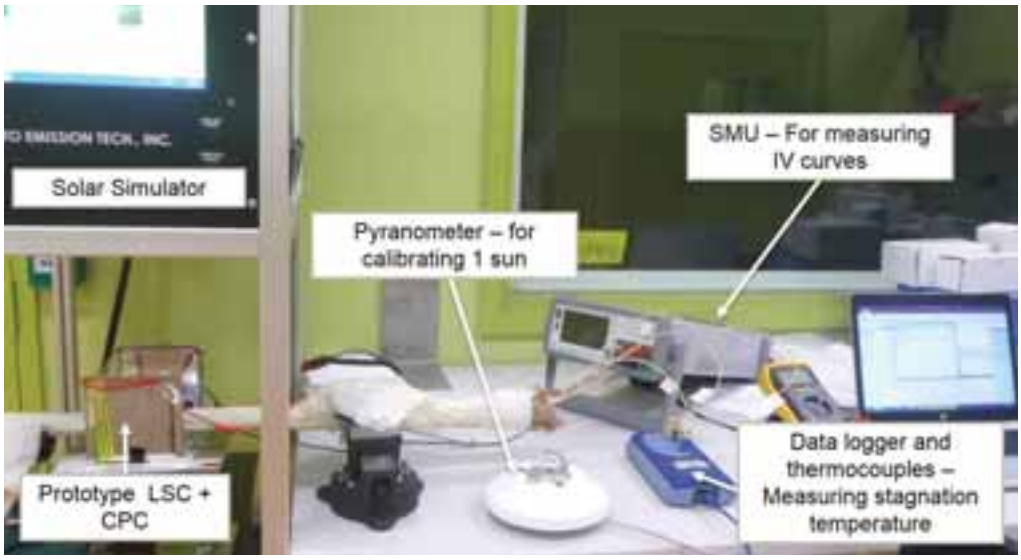

Fig. 6: Indoor experimental test setup

Fig. 7: Evacuated thermal receiver used in the stagnation tests

4.3 Results

The stagnation temperature test results on various configurations of the hybrid CPC and LSC are shown in Fig. 8. The stagnation temperatures reached for the different configurations (ambient subtracted) were: 208 ˚C for the CPC without an LSC cover, 192 ˚C for the CPC with the pink LSC cover, 150 ˚C for the CPC with the red LSC cover and 77 ˚C for the tube on its own under one sun illumination. This value is representative of the poor quality of these tubes we received from the manufacturer, an evacuated tube with a proper vacuum and a good selective surface should be able to stagnate at over 200 ˚C without concentration.

Pink and red LSC I-V curves were measured twice during the stagnation experiment; at the beginning of the experiment, and after three hours of continuous illumination under the solar simulator. The performance of both LSCs decreased after three hours, the pink LSC short circuit current reduced by 40 % and the red LSC short circuit current reduced by 16 % (results are summarised in Table 3). This is an interesting result considering LSCs are claimed to decouple the heat generating area, since it's the LSC that receives light and heats up and is thought not to transmit much heat to the solar PV cells around the edge. It remains unclear however if it is the PV cell around the edge of the device that is heating up, if the performance of the polymer itself is degrading or even if the behaviour of the fluorescent material changes with temperature. When the temperature of a polymer such as PMMA is increased its refractive index changes due to a change in its thermo-optic coefficient (Zhang et al., 2006). This behaviour has received little attention in LSC literature. An analysis of thermal performance of LSCs was completed by (Rajkumar et al., 2015), who studied the temperature of LSCs under illumination. The authors found the surface of the LSC reached a temperature of 50 ˚C after one hour and the edge mounted PV cells remained 10 ˚C cooler (the ambient temperature recorded in their lab was 21.5 ˚C and under the solar simulator was 34.5 ˚C). All these effects come into play as well as ambient temperature and presence of heat transfer due to convection (higher convective heat transfer coefficients outside than inside the lab).

Measurements were also taken by placing the LSC only, on a highly absorbent “black” material TiNOX that does not reflect any photons back into the LSC. The I-V curves under the various conditions are summarised in Fig. 9. It can be seen that simply placing the LSC on the CPC improves performance due to reflected photons from within the collector getting a chance to be captured by the LSC, that is the performance of the LSCs improves compared with simply measuring on a black absorber TiNOX. The reason for this is that some isotropically emitted photons from within the LSC are emitted into the CPC at angles that do not result in them being transmitted to the receiver and hence reflect back into the LSC. This is an interesting result showing LSCs perform better in this new application than on their own.

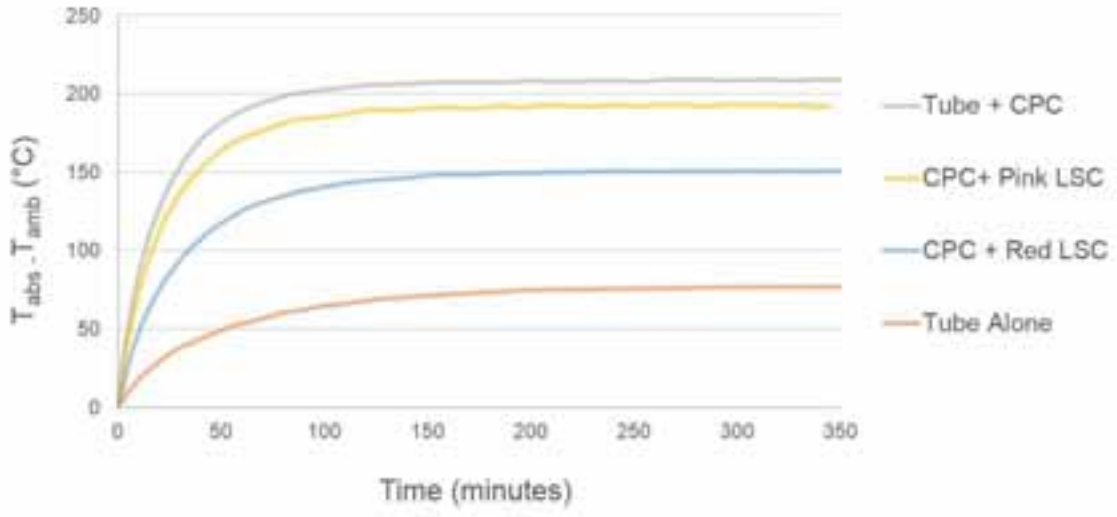

Fig. 8: Results of stagnation temperature test of hybrid CPC and LSC collector

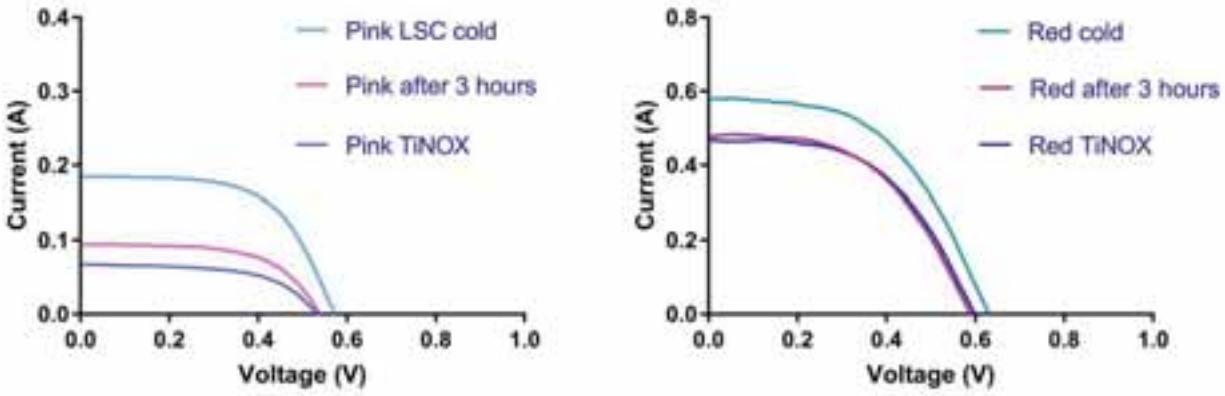

Fig. 1: I-V curves under different configurations of the hybrid prototype with the pink LSC (left) cover and red LSC cover (right)

Tab. 3: Summary of results

Hybrid prototype configuration	Short circuit current of LSC	Power conversion efficiency of LSC	Stagnation temperature (T_{abs}-T_{amb}) ˚C
Red LSC on CPC After 3 hours	485 mA	0.98 %	150 ˚C
Red LSC on CPC	578 mA	1.3 %	
Red LSC on TiNOX	473 mA	0.99 %	
Pink LSC on CPC After 3 hours	111 mA	0.2 %	191 ˚C
Pink LSC on CPC	185 mA	0.43 %	
Pink LSC on TiNOX	68 mA	0.14 %	
Evacuated tube on its own			77 ˚C

3. Full Scale Roof Experiment

3.1 Introduction

In the previous section a small prototype hybrid CPC and LSC was shown to reach high stagnation temperatures even with the LSC cover that absorbs a small proportion of the solar spectrum. In this section we extend this work to investigate a full length, 1-meter long CPC. This full-length collector was connected to a solar test rig on a rooftop facility at RMIT University in Melbourne as shown in Fig. 10. The collector was mounted in the east-west direction on the test rig and connected to a high temperature fluid delivery system. The CPC was covered with LSCs and flow experiments were performed whilst I-V measurements were made of the LSCs that had been wired together. This work demonstrates the benefits of using this system as a decoupled photovoltaic and thermal collector capable of delivering medium temperature heat and electricity.

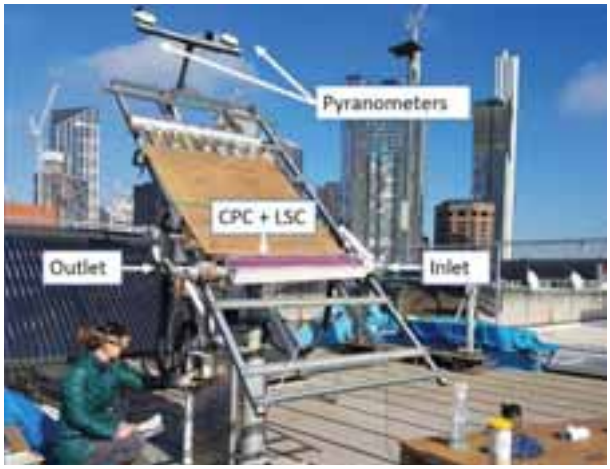

Fig. 10: Experimental setup for full length CPC and LSC collector mounted on two axis tracker

3.2 LSC design

A large sheet of Evonik PLEXIGLASS Red 3C50 GT was cut into four modules to cover the 1 m length CPC collector. Four modules of 25 cm length x 12 cm width were fabricated to cover the CPC collector. The thickness of the sheet was 3 mm and the edges were all polished until they became optically smooth using sandpaper and polishing oil. Sunpower back contact PV cells were coupled with silicone gel along the top edge and bottom edge but not sandwiched in between modules as they would heat up too much and it would be difficult to seal the collector.

3.3 CPC design

A one-meter length CPC was fabricated out of timber in the workshop using a CNC router. The specifications of the CPC are slightly different to section 2 of this paper, the properties of the receiver remain the same but the aperture is reduced to 11 cm. The CPC was sanded smooth and then coated with high gloss polyurethane ready for the reflective foil to be laid down. The reflective film, purchased from an online retailer was found to have a solar weighted reflectivity of 90 %. The receiver consisted of an evacuated tube with a selective surface absorber purchased from commercial suppliers, a second batch with the same specifications as the tube used in the indoor experiments.

3.4 Experimental setup

The CPC and LSC hybrid collector was mounted east-west orientation onto a test rig that also performs two-dimensional solar tracking. Tracking was used to keep the collector normal to the sun for performance measurements, to minimise as much as possible non-normal incidence angle effects. This is a standard method for testing solar collectors as found in the AS/NZS 2535.1:1999 standards. The hybrid collector is connected to the closed loop fluid delivery system that is composed of a heater and cooling fan that can control the input temperature of the collector via a PID controller and thermocouple at the heater outlet (not shown in Figures). To determine the collector efficiency several measurements need to be made: the fluid temperature at the collector inlet, T_{in}, the fluid temperature at the collector outlet $T_{out,}$ mass flow rate, irradiance incident on the collector and collector area. In this way the useful energy absorbed in the fluid (Therminol 66) can be calculated as shown in eq. 2.

$$Q = \dot{m}\, C_p\, (\mathrm{T_{out}} - T_{in}) \qquad \text{(eq. 2)}$$

Then the instantaneous thermal efficiency of the collector can be calculated as shown in eq. 3.

$$\eta = \frac{\dot{m}\, C_p\, (\mathrm{T_{out}} - T_{in})}{A\, G} \qquad \text{(eq. 3)}$$

Where A is the collector area and G is the global irradiance on the collector (measured with the pyranometer). The measurements were made after waiting for the inlet temperature and mass flow rate to stabilise, then the values were recorded for at least 10 minutes at a rate of one measurement per second. Then the inlet temperature

was increased again and the process repeated. The efficiency was calculated for each sample and then averaged. To maximise ΔT, the temperature increase in the collector it was necessary to aim for as low mass flow rate as practical whilst maintaining flow in the turbulent regime.

3.5 Results – electrical output

The LSC cover was made up of four LSC modules with Sunpower solar PV cells along the two long edges. All the cells along the top of the LSC and all the cells along the bottom of the LSC are connected in parallel as shown in Fig. 11, these form two outputs at both the top and the bottom of the collector. The I-V curve measurements were taken with a laptop and Ketithley source measuring unit that were brought to the roof and connected to the LSC for measurement. Several measurements were taken, initially and after several hours of tracking. At least four measurements were taken at a time and averaged.

Fig. 12 left shows the I-V characteristics when the top row and bottom row were connected together in series. Fig. 12 right shows the P-V curves comparing top/bottom outputs connected in series (purple) and parallel (pink). The series connected output in pink has a maximum power of .220 W and performs better than the parallel connected output achieving only 0.167 W. With a power input on to the LSC area of 120 W gives an overall LSC cover efficiency of 0.183 %. This is an efficiency based on the AM 1.5 solar spectrum. The low power conversion efficiency can be explained by the low initial absorption of highly transparent pink Evonik sheet that initially only absorbs 8.6 % of the solar AM 1.5 spectrum, making this type of LSC suitable for generating modest amounts of power and transferring most of the solar energy to the thermal receiver.

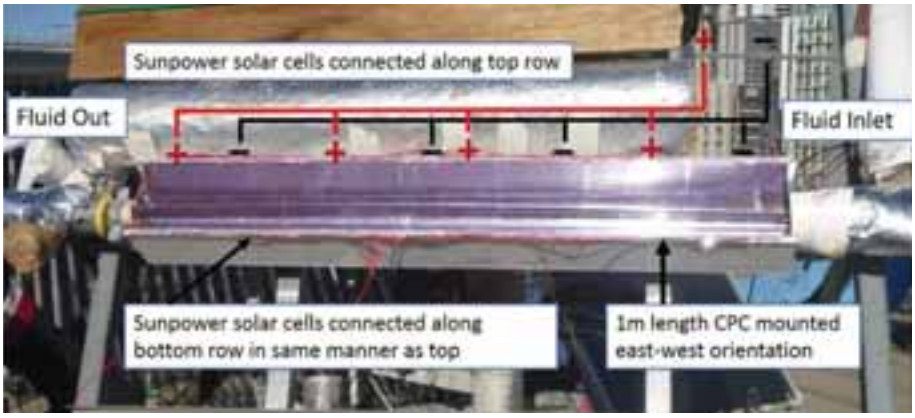

Fig. 2: LSC wiring for full length module

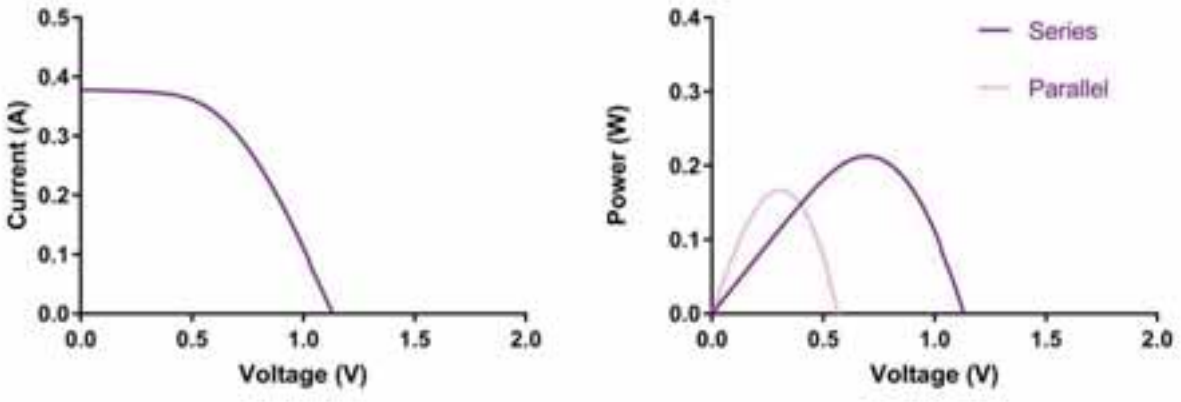

Fig. 12: I-V curve showing top and bottom output connected in series (left), P-V curve comparing top and bottom connected in series and in parallel (right)

3.5 Results – instantaneous thermal efficiency

The thermal performance of the collector was determined by obtaining values of instantaneous efficiency for combination of measured incident radiation, inlet/outlet temperatures and flow rate in a steady or quasi steady state. The useful power extracted is determined by eq. 3 and the thermal efficiency as a function of fluid inlet temperature is shown in Fig. 13. An uncertainty analysis was completed and the reason for the large error bars is due to the small ΔT across a single tube. While each RTD that measures inlet and outlet temperature has an uncertainty of +/- 0.082 ˚C when uncertainties are propagated due to taking a difference between the two measurements the uncertainty of ΔT becomes +/- 0.117 ˚C. Due to the high viscosity of the thermal fluid employed during the tests, a high flow rate had to be set in the experimental rig to assure turbulent flow and enhance heat transfer. This high flow rate decreases proportionally ΔT as shown in eq 2. In future work, a different heat transfer fluid which allows operating at lower flow rates or a longer receiver may be considered to increase the temperature at the outlet and minimise uncertainties in the measurements.

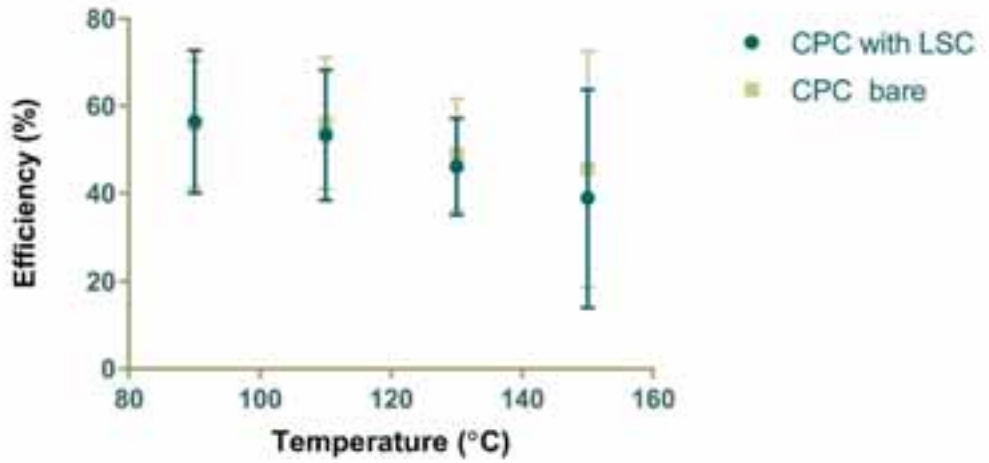

Fig. 3: Instantaneous thermal efficiency measured at different inlet temperatures

4. Conclusion

We successfully demonstrated the experimental basis for a new type of hybrid photovoltaic and thermal concentrator based on two non-imaging technologies, the CPC and the LSC. As a solar thermal collector requires a cover we have demonstrated a new type that generates electricity with LSCs. Utilising commercially available large area fluorescent sheets we demonstrated experimentally with a small prototype that a photovoltaic-thermal collector can work well when an LSC is used as a cover for a CPC. A small 10 cm x 15 cm prototype was stagnated in indoor test conditions and found to reach temperatures of up to 208 ˚C without an LSC and 191˚C with an LSC with a high transmission. In this configuration a small amount of thermal energy is sacrificed for a modest gain in electricity generation. Outdoor testing was completed on a full-length CPC and LSC hybrid collector with four LSC modules. It was found that less losses occurred (noticed by a much better fill factor) when the two sides of cells were connected in series, producing over 220 mW compared to parallel. I-V measurements were taken again after several hours of operation and it was found the performance of the LSCs did not decrease. This was most likely due to the experiment being run during cold days when ambient temperature was around 10-12 ˚C. The thermal efficiency was measured for a variety of temperatures and varied between 55 % and 40 % but with a high uncertainty. We demonstrated an LSC works well as a cover for a solar thermal receiver, although only generating modest amounts of power. The near future holds exciting possibilities of precisely engineering optical properties of LSCs. Perhaps one day we will be able to fabricate LSCs bottom up, molecule by molecule similar to 3D printing and once materials breakthroughs occur and LSCs can be engineering with tightly controlled optical properties, allowing for better performance of this type of PV-T collector.

Abstract

In recent times, more and more countries are choosing the alternative of generating clean energy. The photovoltaic (PV) energy installed is rapidly increasing around the World. PV cells are made with semiconductor materials such as Si, GaAs, among others. Despite the quality controls in the manufacture and manipulation of the panels, damages occur during their manufacturing, installation, use or of wear due to environmental factors, doing it necessary a periodic review. Manual inspections become expensive and largely inefficient due to the big extensions of PV plants. For this reason, it is necessary to automate the inspection task. This paper presents a methodology for the selection of equipment used to make inspections of faults in solar panels using aerial thermography, based on the review of the state of the art and the latest equipment technology available.

Keywords: Aerial thermography, photovoltaic inspection, photovoltaic thermography, faults diagnosis

1. Introduction

Renewable energies are an adequate answer to the actual problems of energy deficit. The negative effects caused by fossil fuels are disheartening due to their harmful impact on climate change, marine and terrestrial ecosystems. The impact generated is so big that there have been appreciable increases in the expected extinction rates.

Nowadays, more countries are choosing the alternative of generating clean energy. An example of this is Portugal, which used solar, wind and hydroelectric energy during four days, supplying the entire country network using natural sources of energy generating zero carbon emissions.

It is therefore necessary to be aware of the current environmental situation by promoting the use of clean energy. Solar radiation is a renewable source harnessed from photovoltaic cells, which are made with semiconductor materials such as Si, GaAs, among others. Despite the quality controls in the manufacture and manipulation of the panels, damages occur during their installation, their use or of wear due to environmental factors. The environmental exposure is one of the factors that most contributes to the underproduction of the modules. Optical degradation is a common effect produced as a consequence of a prolonged sun exposure, generating a discolored appearance and favoring the increment of temperature and humidity in the module. This affects electrical characteristics of the module and produces electrical mismatches which can lead to fractured cells that generate remarkable power losses (Tsanakas et al., 2016), doing it necessary a periodic review.

Also, due to the big extensions that modules cover, manual inspections become expensive and largely inefficient as a result of the capture conditions such as solar angle, irradiance levels, among other factors, which must be taken into account. For this reason, it is necessary to automate the inspection task. An alternative technique often used today, is to perform a photogrammetric flight with Unmanned Aerial Vehicles (UAVs), considering parameters such as the area covered by each photograph, separation between flight lines, among others.

doi:10.18086/swc.2017.20.03 Available at http://proceedings.ises.org

The inspection of solar panels using aerial thermography with UAVs is a topical issue. During the years 2015, 2016 and 2017 it has had 6, 9 and 13 publications respectively in high impact magazines, which confirms that aerial thermography is a very active area of research at the present time.

Different methodologies have been explored for the detection of faults in solar panels, some of them are: the analysis of electrical measurements to classify abnormal behavior in the characteristic curve IV, infrared thermography (IRT) and electroluminescence (El). The first alternative can be impractical and costly since it requires that each module must be monitored. Alternatively, IRT and EL allow non-invasive quantification of the damage presented by the photovoltaic module.

The main objective of this paper is to study the equipment that has been used in the researched presented up to now, with the objective of proposing a methodology for the selection of equipment for fault detection with thermography applied to photovoltaic plants and considering the requirements for the protocol of image capture. To achieve that goal, a comprehensive review of the equipment used for fault inspection in solar panels using thermography is accomplished and a methodology for the selection of equipment is proposed, highlighting relevant aspects in thermographic cameras and UAVs.

2. Method

The applied methodology used to fulfil the objectives of this paper has been the research on the necessities and aspects involved in thermographic inspections of PV plants, the key characteristic of sensors and platforms and the current technologies available in the market. The results have been obtained by means of reviewing the current literature in relation with this topic; investigating the available technology in the market contacting manufacturers and distributors of this instrumentation and by the internet and collecting information about the most important aspects with the aid of professional operators. More than thirty different parties have been contacted, from which relevant information and key points have been obtained.

3. Results and discussion

Nowadays, 80% of the energy produced worldwide is produced from fossil fuels, generating therefore a negative impact on the environment and increasing the CO_2 emissions and increasing the global warming. Consequently, it is necessary to change to renewable alternatives that replace non-renewable energy sources. A clean alternative is the solar energy, which is produced from photovoltaic modules manufactured with GaAs and monocrystalline and polycrystalline Si, being more efficient in the monocrystalline configuration. Each kW produced by photovoltaic systems reduces 0.6 kg the CO_2 emissions (Elibol et al., 2017).

Photovoltaic modules present faults throughout different stages, being the environmental exposure the one that most contributes to the underproduction of the modules. Optical degradation is a common effect produced as a consequence of a prolonged sun exposure, generating a discolored appearance and favoring the increment of the modules temperature and humidity. This affects electrical characteristics of modules and produces electrical mismatches which can lead to fractured cells, generating remarkable power losses (Tsanakas et al., 2016).

Different methodologies have been explored for the detection of faults in solar panels, some of them are: the analysis of electrical measurements to classify abnormal behavior in the characteristic curve IV, IRT and El. The first alternative can be impractical and costly since it requires that each module must be monitored. Alternatively, IRT and EL allow non-invasive quantification of the damage presented by the photovoltaic module, measuring the temperature difference that the faulty modules present. Due to the large area that current photovoltaic sites take up, an adequate way to carry out the inspection is using UAV, where the photogrammetric routes are plotted, considering times to cover the total area and the amount of frames per second or overlap of images

The research on this topic has had an important impact since the year 2015, when the use of UAVs and portable thermographic cameras in aerial vehicles was integrated to the inspection and diagnosis of photovoltaic modules. This impact can be shown in Fig. 1 which has been obtained by examining the bibliography Scopus database for the last years, using the following search equation: PV AND UAV AND THERMOGRAPHY AND PUBYEAR > 2014 AND PUBYEAR < 2018 AND (LIMIT-TO (PUBYEAR,2017) OR LIMIT-TO (PUBYEAR,2016) OR LIMIT-TO (PUBYEAR,2015)). This figure represents the high impact of this topic, in

which the number of published articles has increased from 6 articles in 2015, to 9 in 2016 and 12 articles so far this year. The research centers and universities that lead this research at to now are: Universia degli Studi di Napoli Federico II, Politecnico di Milano, Korea Institute of Civil Engineering and Building Technology.

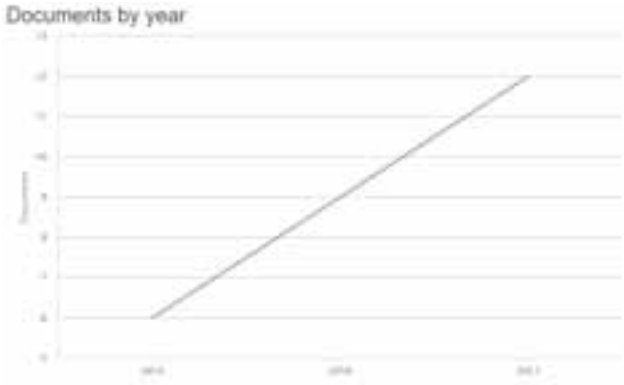

Fig. 1 EB1 impact of the theme between 2015-2017

The results obtained regarding the characteristics of the instrumentation used in the research reported so far are presented throughout the following paragraphs. Different offline processing techniques are introduced and analyzed.

There are different manufacturers which offer alternatives for the inspection and diagnosis of defects in PV plants. One example of this is the manufacturer Workswell, which proposes the use of its thermographic cameras in different applications, as the building diagnosis, roofs and high voltage lines inspections. This manufacturer has developed high spectral range thermographic cameras that combine the thermographic and visual images, as they incorporate a RGB camera. Additionally, there are some tier one brands which are starting to offer ready-to-flight products for the inspection of PV plants, as for example DJI and Workswell. These brands offer the possibility of using a DJI S900 with a Workswell thermographic camera and the software Workswell CorePlayer for the image post-processing. This software has different functionalities, as modifying the emissivity or the reflection temperature values, obtaining thermal curves, geometrical delimitation of relevant areas using dots or rectangles or generating reports. The equipment reported in (Wiris, n.d.) is summarized in Tab. 1.

Tab. 1: UAV and Thermographic camera characteristics reported in (Wiris, n.d.)

UAV	**Characteristics**		**Thermographic camera**	**Characteristics**	
DJI S900	**Flight controller**	A2	Worskswell Wiris (integrated RGB camera)	**Resolution (pixels)**	640x512 - 336x256
	Total Weight (kg)	3,3		**Temperature sensitivity (mK)**	50 to 30
	Power Battery	LiPo (6s 10000 mAh)		**Spectral range (um)**	7,5 to 13
	Max Power consumption (W)	3000		**Weight (g)**	<400
	Hover time (min)	18		**Memory**	32 GB
	Hover environment temperature (°C)	-10 to 40		**Temperature ranges (°C)**	25 to 150
	Takeoff Weight (kg)	4,7-8,2		**Accuracy**	+-2% or +- 2 °C
	Dimensions (mm)	460x450x360		**IR Color Palettes**	19 interchangeable in real time
	Type	Hexacopter		**Emissivity**	Adjustable

The main equipment used in (Addabbo et al., 2017) is an UAV Matrice 100 of DJI and a thermographic camera Flir Tau 2. Their main characteristics are summarized in Tab. 2. Additionally, it is used a RGB DJI Zenmuse X3 camera to obtain visual images. In this research, the UAV performs a defined flight plan over the modules to capture the thermographic and visual images separately.

Tab. 2: UAV and Thermographic camera characteristics reported in (Addabbo et al., 2017)

UAV	Characteristics		Thermographic camera	Characteristics	
DJI Matrice 100	**Flight controller**	N1	Flir Tau 2	**Resolution (pixels)**	640x512 - 336x256
	Total Weight (kg)	2,3		**Temperature sensitivity (mK)**	50 to 30
	Power Battery	LiPo (6s 10000 mAh)		**Spectral range (um)**	7,5 to 13
	Max Power consumption (W)	3000		**Weight (g)**	112
	Hover time (min)	18		**Memory**	32 GB
	Hover environment temperature (°C)	-10 to 40		**Temperature ranges (°C)**	-25 to -135, -25 to -100
	Takeoff Weight (kg)	3,6		**Accuracy**	+-5% or +- 5 °C
	Dimensions (mm)	650		**IR Color Palettes**	15 interchangeable in real time
	Type	Quadcopter		**Emissivity**	Adjustable

The data taken by the optical RGB sensor is communicated through one of the drone buses with the embedded system equipped on board the UAV, called the Intel Joule 570X quad-core, where some processes are carried out, such as management of sensor acquisition, the storage of the acquired images and the detection algorithm, in which a task of labeling and identification of the panels is executed. The input data for the tracking and geo referencing algorithms require altitude data and GPS, which are extracted from the DJI on board SDK. The SDK can be modified using programming languages such as C or C ++.

For the definition of the thermographic images capturing protocol, a video/C&C port (GPIO) of the drone is used. This port is connected with the embedded system Joule 570X, which allows the control of the Gimbal by a serial port. Subsequently, the processing of the thermographic images is done offline.

In (Kauppinen et al., 2015) it is used a quadcopter Walkera QR X800 a thermographic camera Flir Tau 2 and a RGB camera GoPro Hero 3. As embedded system it is used a Raspberry Pi on board, which is connected with the terrestrial station through WLAN connection.

In order to perform the image acquisition protocol, they consider the meteorological conditions, such as measurements of air temperature, relative humidity using a Vaisala HM34C sensor and irradiance levels on the photovoltaic system with the Ophir PD-300-3W sensor.

The captures of the thermal images are obtained by operating the UAV manually, monitoring the live image from the terrestrial web browser and taking the images, only when they have the right scene. In this way it is eliminated the possibility that the UAV shadow projection interferes with the measurement. The images are stored in the memory of the Flir Tau 2 camera. On the other hand, the acquisition of RGB images is done automatically using the APM flight controller planner2. The resultant images are stored in the Raspberry Pi. In addition, in this research it is performed manual inspection of the site with a FLIR E300 thermal camera.

Tab. 3: UAV and Thermographic camera characteristics reported in (Kauppinen et al., 2015)

UAV	Characteristics		Thermographic camera	Characteristics	
Walkera QR X800	**Flight controller**	Walkera FCS800	Flir Tau 2	**Resolution (pixels)**	640x512 - 336x256
	Total Weight (kg)	3,9		**Temperature sensitivity (mK)**	50 to 30
	Power Battery	LiPo (6s 10000 mAh)		**Spectral range (um)**	7,5 to 13
	Max Power consumption (W)	-		**Weight (g)**	112g

	Hover environment temperature (°C)	-15 to 65		**Temperature ranges (°C)**	-25 to 135°C, -25 to-100
	Takeoff Weight (kg)	3		**Accuracy**	+-5% or +-5 °C
	Dimensions (mm)	620x620x460		**IR Color Palettes**	15interchangeable in real time
	Type	Quadcopter		**Emissivity**	Adjustable

In (Aghaei et al., 2015) it is used a UAV PLP-610 Nimbus Platform and a Flir A35 thermographic camera, which main features are summarized in Tab. 4. Some of the most relevant issues to be considered while performing a flight plan and capturing the images are described in the paper, as reflections or shadows produced by the surrounded vegetation, clouds, other module structures or by the own drone. The geo referencing data is not considered in this study.

The thermographic image processing is done offline using Matlab. The flow diagram of the algorithm goes from the conversion of the IR image to RGB, later to grayscale to perform a Gaussian type filtering. To the resultant image is applied Laplace algorithm and a diagnosis is issued. If the panel is healthy, the post processing is finished, otherwise, in case of detecting a defect in the module, it is established the degradation percentage of the photovoltaic module.

Tab. 4: UAV and Thermographic camera characteristics reported in (Aghaei et al., 2015)

UAV	Characteristics		Thermographic camera	Characteristics	
PLP 610 Nimbus Plataform	**Cruise Speed (kts)**	0-20	Flir A35	**Resolution (pixels)**	320x256
	Operational range (km)	0.25		**Temperature sensitivity (mK)**	50 to 30

In (Tsanakas et al., 2017) it is used a hexacopter Condor AY-704 with an Optris PI450 on board and a conventional Single Les Reflex (SLR) connected to the UAV. The embedded system is not described in the paper. The image capturing conditions complied with IEC 62446-3 TS first edition standard in relation with the minimum irradiance, soft clouds and maximum wind speed. The resultant images are represented in an

interactive map without connection, similar to Google Earth. The fault processing algorithm is implemented on the ortomosaic in Matlab. Additionally, when an anomaly is found in the image, a manual inspection and I-V electrical characterization curve are performed on site, as validation of results.

Tab. 5: UAV and Thermographic camera characteristics reported in (Tsanakas et al., 2017)

UAV	Characteristics		Thermographic camera	Characteristics	
Condor AY 704	**Flight controller**	-	Optris PI450+lightweight mini PC	**Resolution (pixels)**	382x288

In (Zhang et al., 2017) it is used an octocopter DJI Spreading Wings S100 with a Flir Tau 2 on board. Additionally, it includes an image storage module that allows saving image and positioning data at the same time. The image acquisition is performed with flight speed of 2 m/s and flight height of 20 and 40 meters with respect to the module. The image capture schedule corresponds to the time period between 10:00 am and 12:00 pm, corresponding with the maximum irradiance. Image processing is offline; the flowchart of the algorithm developed includes a preprocessing stage, recognition of each individual module and detection of the anomaly.

Tab. 6: UAV and Thermographic camera characteristics reported in (Zhang et al., 2017)

UAV	Characteristics		Thermographic camera	Characteristics	
DJI S1000	**Flight controller**	A2	Flir Tau 2	**Resolution (pixels)**	640x512 - 336x256
	Total Weight (kg)	4,2		**Temperature sensitivity (mK)**	50 to 30
	Power Battery	LiPo (6s 10000 mAh, to 20000 mAh)		**Spectral range (um)**	7,5 to 13
	Max Power consumption (W)	4000		**Weight (g)**	112g
	Hover time (min)	15		**Memory**	32 GB
	Hover environment temperature (°C)	-10 to 40		**Temperature ranges (°C)**	-25 to 135°C, -25 to-100
	Takeoff Weight (kg)	6,0 to 11		**Accuracy**	+-5% or +-5 °C
	Dimensions (mm)	460x511x305		**IR Color Palettes**	15interchangeable in real time
	Type	Octocopter		**Emissivity**	Adjustable

In (Dotenco et al., 2016) it is used a Da Vinci Scara Bot X8 with a thermographic camera Optris PI450 and a RGB GoPro Hero3+. The inspection was always performed with a minimum irradiance of 600W/m^2 and a maximum of 1000W/m^2.

The processing of the thermographic images is done by means of a segmentation that allows identifying the region of interest, in this case the photovoltaic modules, from the information that does not contribute to the analysis, as the background.

The implemented algorithm is described in four stages: normalization, thresholding, orientation of photovoltaic modules estimation and correction and refinement. The first stage proposed, corresponds to thermal contrast. This procedure allows dismissing temperature values below a defined threshold. In the following stages it is done the automatic selection of thresholds in order to separate the solar panels from the background, using combinations of Gaussian models (GMMs).

Subsequent to the segmentation stage, it is proposed the extraction of information obtained from the average temperature values of each solar module and its cells. Additionally, the asymmetry measures of the histograms are used to provide information about the distribution of the temperature in the picture

Tab. 7: UAV and Thermographic camera characteristics reported in (Dotenco et al., 2016)

UAV	Characteristics		Thermographic camera	Characteristics	
Da Vinci Copters ScaraBot X8	**Flight controller**	Pixhawk	Optris PI450	**Resolution (pixels)**	382x288
	Total Weight (kg)	2,15		**Temperature sensitivity (mK)**	50 to 30
	Power Battery	6S Li-ion 15Ah		**Spectral range (um)**	7,5 to 13
	Max Power consumption (W)	4000		**Weight (g)**	380
	Hover time (min) payload 2400g	24		**Memory**	32 GB
	Hover environment temperature (°C)	-10 to 40		**Temperature ranges (°C)**	-25 to 135, -25 to 100
	Takeoff Weight (kg)	5.0		**Accuracy**	+-2% or +- 2 °C
	Dimensions (mm)	545x545x402		**IR Color Palettes**	15interchangeable in real time
	Type	Octocopter		**Emissivity**	Adjustable

In (Leva et al., 2015) it is used an UAV Nimbus PLP-610, as in (Aghaei et al., 2015), with a visible spectrum camera Nikon 1-v1.

In the article, it is developed a protocol for the acquisition of the images, which describes the characteristics and conditions of flight as altitude, and angles of capture, to detect faults and defects on the photovoltaic modules using only an RGB camera. The obtained results, allow establishing the relations on the flight height at which the acquisition of the images is done and the type of faults detected. The paper does not have a diagnosis that identifies the severity of the faults as they do not use thermographic images.

In order to properly evaluating the features of the instrumentation required in aerial thermography of PV plants it is necessary to consider some relevant aspects about the image capturing conditions that are analyzed throughout this paragraphs. These capturing conditions restrict the platform and sensors characteristics that can be used to obtain usable results. According to the review of the state of the art some of the most relevant characteristics for the selection of cameras correspond to the following items: resolution, ranges of temperature, sensitivity, precision, spectral range, calibration, memory, file transfer, interface, video resolution, weight, FOV, spatial resolution.

Tab. 8: UAV and Thermographic camera characteristics reported in (Leva et al., 2015)

UAV	Characteristics		Thermographic camera	Characteristics	
PLP 610 Nimbus Plataform	**Cruise Speed (kts)**	0-20	Flir A35	**Resolution (pixels)**	3906x2606
	Operational range (km)	0.25		**Dimensions (m)**	113x76x43.5
	Max Altitude (m)	150		**Lens focal length (mm)**	35
	Hover time (min)	25		**Weight (g)**	294g
	Weight (kg)	2,8		**Battery**	Nikon EN-El 15 Lithium-Ion
	Dimensions (mm)	300x980			
	Type	Hexacopter			

In order to obtain accurate and usable images, the camera should be on-board of a stable gimbal and the platform should be able to hover for obtaining detailed information. In this regard, the most appropriate platform to perform aerial thermography for PV plants inspections are the multirotor, also known as multirotor. There are different multirotor kinds generally classified in terms of the number of rotors that the UAVs have.

Additionally, the platform should have the capacity of carrying at least two different sensors, the thermographic and the visual camera. A visual image along with a thermographic image facilitates the identification of the defect mode, the detection of false hot spots, as bird drops or shadows and makes it easy to determine the exact location of the defect module in the PV plant.

Nowadays multirotor allow the autonomous operation mode by waypoints, which is a desirable option to avoid human errors that can be produced during the manual flight. In this case, it is necessary to have cartographic information of the site and if not, performing a flight previously to the inspection to feed the platform software.

The UAV batteries should be as long as possible to maximize the producing time and to optimize the inspection performance. There are different batteries options and several researches are being done in this respect during the last years. UAVs with Lithium Polymer (Li-Po) batteries can fly approximately from 10 to 40 minutes. A battery recharge cycle takes one hour and a half approximately. In order to perform an efficient inspection, it is convenient to have various batteries not to be recharging them during the inspection. There are several researches on innovative batteries that offer a greater energy density and reduce charge time, weight and volume, as graphene batteries.

The flight height of the UAV delimits the resolution that the sensors must have so as to acquire acceptable results. If the pixel size is higher than the cell size, the accuracy of the resultant images is not acceptable as smaller defect will not be properly identified. Therefore, the flight height restrings the sensor resolution required, considering also the lens used and the consequent field of view.

4. Conclusions

Although some authors mention the equipment used in their researches there is not a convenient study which compiles other available alternatives that meet the requisites established and their most relevant characteristics.

A procedure to indicate a review of the available equipment used in aerial inspection of photovoltaic plants was presented, in order to determinate and to analyze the key aspects that have to be considered to properly select the equipment to be used. The results are obtained by means of the examination all the information in relation to the characteristics of the instrumentation involved and the compilation of the UAVs and thermographic sensors alternatives with their available characteristics.

The necessary equipment consists mainly of a thermographic camera and an Unmanned Aerial Vehicle. In the case of UAVs, full compatibility with the camera must be guaranteed and factors such as maximum operating

temperature, flight controller, and flight autonomy are necessary characteristics for the selection of the equipment. According to the review of the state of the art, some of the most relevant characteristics for the selection of cameras correspond to the following items: resolution, ranges of temperature, sensitivity, precision, spectral range, calibration, memory, file transfer, interface, video resolution, weight, FOV, spatial resolution. These respects have been analyzed with the aim of informing about the essential aspects to consider while selecting the equipment for this application and of facilitating this selection to researchers. It is important to understand that the utility of the equipment is in many cases directly linked to the available budget, as the improvement of the features is usually associated with a notable increase in the price.

Abstract

It is essential for photovoltaic plants investors, operators and equipment manufacturers to identify the failure modes and rates of the system in order to reduce investment risk, to focus their maintenance efforts on preventing those failures and to improve longevity and performance of the PV Plant. In this paper, it is assessed the importance of the Failure Modes within a real existing portfolio in Spain and Italy of continuous operation since 2008 and it is identified the module level failure modes, which are imperceptible in the standard monitoring systems, through the application of thermographic inspection. The experimental Mean Time Between Failures (MTBF) and the failure rates are calculated and these ratios are used to define the ranking criterion to perform the Failure Mode, Effect and Criticality Analysis (FMECA) and to focus on the module level analysis. The conclusions highlight the most critical sub-system and failure modes within a photovoltaic PV plant.

Keywords: Failure Rate, FMECA, Photovoltaic reliability, PV Module Thermography

1. Introduction

It is essential for photovoltaic (PV) plants investors, operators and equipment manufacturers to identify the failure modes and rates that the main equipment experiences in order to reduce investment risk, to focus their maintenance efforts on preventing those failures and to improve longevity and performance of the PV Plant. The reliability is defined as the capacity of a component to maintain its functionality over the years.

The Failure Mode, Effects and Criticality Analysis (FMECA) is an inductive analytical method in which the results present the failure modes and the severity of the consequences with relatively high probability. The main objective is to identify the failure modes that have a relevant combined occurrence, severity and non-detection probability in order to set the preventive actions accordingly. Equipment manufacturers try to identify all the failure modes of its products in order to increase reliability and reduce warranty cost, by researching and emulating different situations using mathematical models and experimental Highly Accelerated Life Test (HALT) (Moorthy and Tamizhmani, 2016). Resulting from the analysis, a battery of measures is implemented to reduce the key factors occurrence, severity or non-detection probability. The FMECA is a broadly used technique to assess the quality being applied on the elaboration and/or definition of, for example, safety analysis, quality control points, high standard requirements, quality procedures, working instructions, or resources distribution (Colli, 2015). The failure mode analysis also justifies the importance of maintenance activities and the associated cost on PV Plants to prevent premature failure and relevant catastrophic problems.

The greater challenge that researchers address and indicate while investigating about PV systems failures is the lack of reliable real quantitative data since most of the operators are private and do not disclose the data

doi:10.18086/swc.2017.20.04 Available at http://proceedings.ises.org

or either they do not have enough capabilities to record the data (Colli, 2012).The existing publications base their studies on the few available open-access data and subjective evaluations from experts' opinions with limited experimental and scientific base. Through the implementation of advanced PV plant monitoring systems (Cristaldi et al., 2015), the implementation of Computerized Maintenance Management Systems (CMMS) and the feedback of the field technicians, it is possible to have an experimental database to assess the failure rate and the FMECA of the PV plants (Colli, 2012).This fact is one of the greater strengths of this paper, in which the information from the historical data of fifty-eight PV plants portfolio in Italy and Spain of a well-known photovoltaic operator since 2008 has been accessible.

Monitoring of the different system components that constitute the PV plant facilitates the detection of failures and, from the reliability point of view, allows the operator to improve the plant performance (Cristaldi et al., 2015). Nevertheless, in utility scale PV plants, typically the monitoring system trails the string series current of multiple modules connected and does not track the performance of the individual PV modules, which is the key element on a photovoltaic system. Therefore, it is specially complicated the detection of failures at this level and, even more difficult, the recognition of the failure cause and mode. Because of this reason, during the last years additional tests have been required by solar PV investors at the PV module level with the aim of controlling the individual module performance, for example, IV curves tracing, electroluminescence test and thermographic test. To complete the FMECA analysis of this paper, it has been considered that other source of information is needed for the module level assessment. Aerial thermographic inspections, in which an Unmanned Aerial Vehicle (UAV) carries a thermographic sensor, are recently becoming popular because it reduces the inspection cost and it is less time consuming than manual thermographic inspections and/or IV curve tracing. Thermographic tests have been applied at a module level to a sample of the base data to complete the FMECA of the whole PV Plant.

The main objective of the paper is to assess the importance of the Failure Modes in PV plants considering the information taken within a real existing portfolio in Spain and Italy of continuous operation since 2008, and the application of thermographic inspection to identify the module level failure modes. This goal is achieved by means of calculating the experimental failure rates and the Mean Time Between Failures (MTBF) of the systems of a sample of PV plants during a relevant time using the historical database facilitated by Solarig, a worldwide PV operator. Based on the results, it will be applied the FMECA technique to the system elements. Once the different Failure Mode in the field are identified, the analysis is focused in the Module level related failures by cataloging the root cause analysis and the identification process through drone or manual thermographic inspection.

2. Method

In this section, it is summarized the different steps that have being followed to accomplish the analysis and to get the desired results.

The first step lies in identifying all the system components that can be affected and can produce a failure mode within the PV plant (Tab. 1).

In the current research, the PV system has been simplified in eight possible affected elements and for each of these elements, it has been identified the possible sub-element originating the failure. These elements are: PV generator, inverter, MV transformer station, meter, security systems, communication systems, monitoring systems and civil works.

After that, it has been analyzed all the available historical data and defined the sample that has been used for each of the calculations. These calculations are performed for different PV plants with the historical data available. With this selected data, the failure rates and the MTBF are calculated for the whole system and each sub-system. The failure rate is calculated as the number of failure per PV plant per unit year and the MTBF as the inverse of the failure rate.

These ratios are used to define the ranking criterion, to perform the FMECA analysis and to focus on the module level analysis. Finally, thermographic tests have been applied at a module level to complete the FMECA of the whole PV Plant. The results obtained throughout this analysis are presented in the results section.

Tab. 1: Affected elements and possible causes analyzed

Affected Element	Sub-element / Cause	Affected Element	Sub-element / Cause
Photovoltaic generator	Modules	Security System	Control Unit
	Cable		Cameras
	Fuse		Sensors
	Structure		Cabling
	Others		UPS
Inverter	Control Board		Others
	Communication Boards	Communications System	Router
	Protections		Satellite/LAN connect.
	Display		Others
	Power Block	Monitoring system	Control Unit
	Contactors		UPS
	Others		Fiber Optics/ Cabling
MV Transformer Station	Transformer		Others
	MV Switchgear	Civil works	Manhole
	Auxiliary System		Roads
	Others		Fence
Meter	Meter		Others
	Current /Voltage transformers		
	Others		

3. Results and discussion

The scoring system to define the ranking criterion has been defined considering the available data and the subjective evaluations of solar experts with more than a decade experience. Three different ranking criteria have been developed, for the severity, detection and occurrence respectively. Each ranking follows a scale from 1 to 5, in which 1 denotes the best situation while 5 denotes the worst. As a result, the Risk Priority Number (RPN) goes from 1 to 125, where a highest value of RPN indicates a most risky situation.

For the definition of the Severity ranking criteria, it has been considered the cost of fixing the failure (spare parts and workforce) and the Loss of Profit (LOP) that the failure generates due to the reduction of energy production (in case it is necessary to shut down the plant or part of it). The fixing price has been considered in an interval from 0 €, in case the failure does not involve a fixing cost or it is negligible, as a wire that is not well fastened, an equipment badly labelled or a communication failure due to the operator, to 60,000 € in case of an extremely high fixing cost, as the fixing cost resulting from a fire. On the other hand, the loss of profit that has been considered is the following: 0 € when the failure does not produce disconnection of the PV site, 190 € when the failure produces a disconnection of approximately 1 hour, 950 € in case of half a day disconnection, 13,300 € in case of one week disconnection and 57,000 € in case of one month disconnection. With the combination of these two factors, it is obtained the Severity ranking criteria, showed in Tab. 2 and Tab. 3.

Finally, the Occurrence ranking criteria has been calculated based on the failure rates obtained for each failure mode in the portfolio analyzed and following the subjective evaluation of this data by photovoltaic experts with more than ten years of experience in this sector. The Occurrence based on the failure rates calculated is classified following this criterion: 1 for unlikely failures, 2 for remote probability, 3 for occasional probability, 4 for moderate probability and 5 for high probability.

Tab. 2: Severity ranking intervals calculated from the fixing price and the loss of profit that a failure produces

		Loss of Profit (LOP)				
		57.000 €	**13.300 €**	**950 €**	**190 €**	**- €**
Fixing Price (Spares and Workforce)	**60.000 €**	117,000 €	73,300 €	60,950 €	60,190 €	60,000 €
	15.000 €	72,000 €	28,300 €	15,950 €	15,190 €	15,000 €
	1.000 €	58,000 €	14,300 €	1,950 €	1,190 €	1,000 €
	500 €	57,500 €	13,800 €	1,450 €	690 €	500 €
	- €	57,000 €	13,300 €	950 €	190 €	0 €

Tab. 3: Severity ranking criteria

Rank	**X (Fixing Cost + LOP)**	**Description**
1	X <690 €	Minor failure with almost no influence in the performance of the plant and insignificant parts deterioration
2	1,950 €>X>690 €	Failure with low influence in the performance of the plant and parts deterioration
3	28,300 €>X>1,950 €	Failure with quite important influence in the performance of the plant and parts deterioration
4	60,950 €>X> 28,300 €	Failure with important influence in the performance of the plant and parts deterioration
5	X >117,000 €	Major failure with extreme influence in the performance of the plant and parts deterioration

The Detection criteria has been obtained following (Colli, 2015), and it is expressed in Tab. 4.

Tab. 4: Detection ranking criteria

Rank	**Description**
1	Almost certain that the problem will be detected (chance 81–100%)
2	High probability that the problem will be detected (chance 61–80%)
3	Moderate probability that the problem will be detected (chance 41–60%)
4	Low probability that the problem will be detected (chance 21–40%)
5	None/minimal probability that the problem will be detected (chance 0–20%)

Throughout analyzing the corrective maintenance reports that the plant technicians of the analyzed portfolio have uploaded to the CMMS during the last years, it has been identified 168 failures modes that appears in the operation of PV plants. Considering the previous detailed ranking criteria, it has been attributed a Severity, non-Detection and Occurrence number to each of the failure modes detected. Multiplying these three numbers it is obtained a Risk Priority Number for each of the failures. An extract of some of the main failure modes detected in the analysis is detailed in Tab. 5.

Tab. 5: Failure mode analysis table with the Severity, Detection, Occurrence and Risk Priority Number for some of the main failure modes identified in the analyzed portfolio of PV plants

Group	Element	Description Failure	S	D	O	RPN
Security syst.	CCTV	Camera/videorecorder/barrier/Sensor failure	1	3	5	15
Security syst.	CCTV	Communications failure	1	1	5	5
Meters	Meters	Erroneous meter configuration	1	3	3	9
Meters	Meters	Meter burnt	2	2	3	12
Meters	Meters	Communications failure	1	1	4	4

MV	Transformer	Oil leak	4	4	2	32
MV	Transformer	Fire	5	3	2	30
MV	Transformer	Deficient transformer tank ground connection	3	4	3	36

The reported failure modes are further analyzed throughout these paragraphs, in order to identify the ones that present a higher RPN and their possible causes and effects to be considered by operators. In Fig. 1 it is shown the sum of the RPN for each of the groups of elements under study and the accumulated RPN sum.

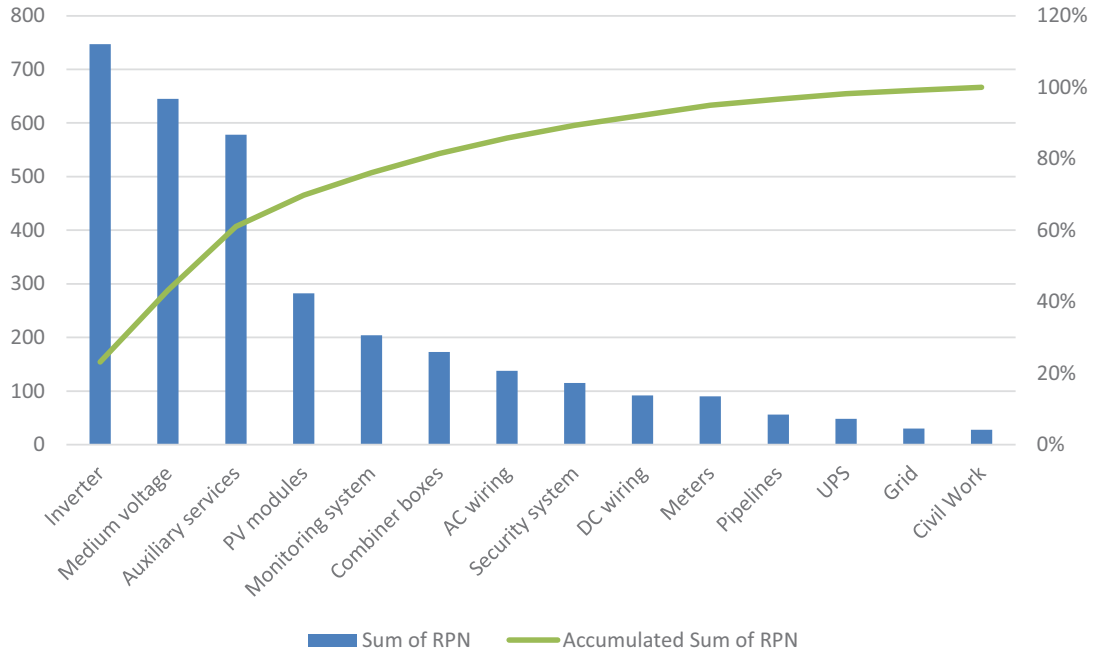

Fig. 1: Sum of RPN per group - FULL O&M

It can be seen that the inverter presents the higher RPN sum for the identified failure modes, followed by the medium voltage and the auxiliary services. Due to the fact that not all the groups present the same number of failure modes identified, it is necessary to know the average RPN in each of the groups. This analysis can be seen in Fig. 2. It can be seen that in this case, the groups that present a higher RPN in average are the medium voltage and the inverters, followed by AC wiring, combiner boxes, pipelines and PV modules.

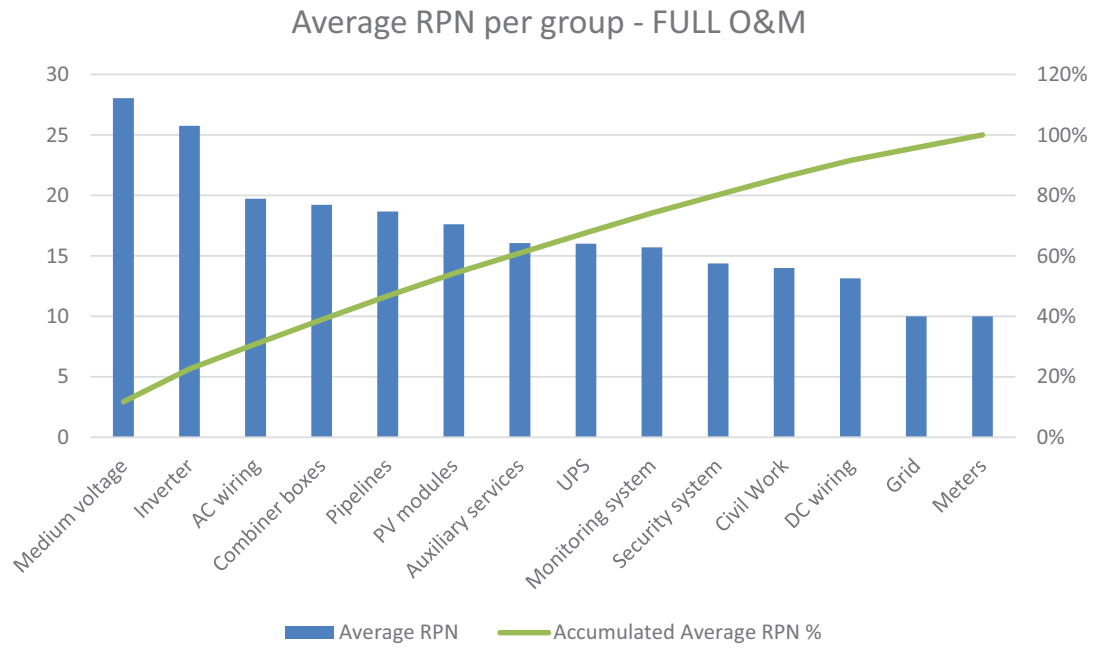

Fig. 2: Average of RPN per group - FULL O&M

As it has been previously mentioned, monitoring the different system components that constitute the PV plant facilitates the detection of failures and from the reliability point of view allows the operator to improve the plant performance (Cristaldi et al., 2015). Nevertheless, in utility scale PV plants, typically the monitoring system trails the string series current of multiple modules connected, or even the inverter current, which is the sum of the parallel string current, and does not track the performance of the individual PV modules, which is the key element on a PV system as it converts the incident irradiance into electric power and module's cost is commonly upon 50% of the total PV installations cost (Agroui, 2012). Therefore, it is specially complicated the detection of failures at this level and even more difficult the recognition of the failure cause and mode. To complete the FMECA analysis of this paper it has been considered that other source of information is needed for the module level assessment and that is why the final point of this research is in the way of studying the current possibilities for operators to detect module failures and therefore, increasing the energy output of the PV plant

During the last years, additional tests are required by solar PV investors at the PV module level with the aim of controlling the individual module performance, for example, electrical test, electroluminescence test and thermographic test.

Electrical test, as IV curves tracing, allow the detection of abnormal underperforming situations but do not allow identifying the cause neither location of the defective cell. Additionally, to perform these tests it is necessary to shut down the plant during the electrical inspection, which involves an important energy output reduction. Electroluminescence (EL) imaging is a non-invasive technique developed to detect the radiative recombination of charge carriers excited under forward bias in which the resultant light intensity is proportional to the voltage. Therefore any electrically inactive parts of the module or cell are represented as dark areas, as micro-cracks that are not visible, as well as broken contact fingers, which can be identified. Although improvements in EL imaging equipment, involving InGaAs uncooled detectors and InSb cooled ones, have encompassed the first steps for reliable outdoor measurements and fault diagnosis in PV sites, electroluminescence is typically performed in indoor laboratories following strict indoor conditions.

On the other hand, thermographic inspection is fast and simple to implement and giving results in real time, not being necessary to shut down the plant during the inspection. It is non-destructive, contact-less and allows the identification of defects and their exact location with great accuracy, representing a temperature distribution of the surface of the modules which discloses the defects. Nonetheless, despite being a reliable method, manual thermography presents some relevant drawbacks. It is a costly and time-consuming technique and there are some situations in which it is hard to detect the defective cells using manual thermography, as in locations in which the inclination of modules is too low or during the middle hours of the day in PV plants with trackers. That is why aerial thermographic inspections, in which an UAV carries a thermographic sensor, is recently becoming most popular because it reduces the inspection cost and it is less time consuming than manual thermographic inspections and/or IV curve tracing.

Thermographic tests have been applied at a module level to a sample of the base data to complete the FMECA of the whole PV Plant. Some of the module failures that generate a difference in the temperature are experimentally identified by thermographic techniques and their criticality is analyze, as the overheating in multiple or one cell, connection point, module box, whole module and one row or bypass circuit. The thermographic images obtained performing on-site manual thermographic inspection are presented in Fig. 3.

4. Conclusions

This paper presents a failure mode analysis of PV plants based on the analyses performed to the available data of a real existing portfolio in Spain and Italy of continuous operation since 2008. Throughout the paper, it has been analyzed which are the most critical sub-system and failure modes within a photovoltaic PV plant, resulting that inverters presents the higher RPN sum for the identified failure modes, followed by the medium voltage and the auxiliary services. On the other hand, it has been proved that the groups that present a higher average RPN are the medium voltage and the inverters, followed by AC wiring, combiner boxes, pipelines and PV modules.

This information is essential for PV operators and manufacturers to focus their efforts on preventing those failures and to contribute to the improvement of the reliability in PV installations.

Additionally, it has been performed a manual thermographic inspection to a PV plant to identify the module level failure modes, as typically in utility scale PV plants the monitoring system does not track the performance of the individual PV modules, which is the key element on a PV system as it converts the incident irradiance into electric power and module's cost is commonly upon 50% of the total PV installations cost. Some of the module failures that generate a difference in the temperature have been experimentally identified, as the overheating in multiple or one cell, connection point, module box, whole module and one row or bypass circuit.

Decoupling Crystallinity and Size of TiO2 Nanoparticles of TiO2: Application in Large Area Dye-Sensitized Solar Cells

Aiat Hegazy[1], Essam El-Shenawy[1] and Mohamed Abdelatef[1]

[1] National Research Centre, Cairo (Egypt)

Abstract

Dye-sensitized solar cells (DSSCs) have attracted great attention in recent years as a potential alternative to conventional silicon solar cells. However, a lot of current research is still focusing on enhancing their efficiency through the individual improvement of the DSSCs components, as well as their integration. Among these components, mesoporous TiO_2 plays an important role in the cell photoanode. Achieving well-crystallized small nanoparticles usually requires a room temperature synthesis, giving very small crystallites (4-10 nm) of TiO_2 anatase. As as-synthesized materials contain hydration water, a major drawback in DSSCs, we report how dehydration and crystallinity can be improved by annealing at a moderate temperature, without any sintering or significant particle coarsening. We report in this study a comprehensive study of the cell assembling, and its efficiency, characterized under AM 1.5 illumination with 100 mw/cm^2 light intensity.

Keywords: DSSC,TiO_2, nanoparticle, photovoltaic, anatase, solar cell, solar energy.

1. Introduction

Since their initial discovery (O'regan and Gratzel, 1991; Gratzel 2001) liquid-based dye-sensitized solar cells (DSSCs) are known as alternatives to conventional silicon-based photovoltaic devices. The first generation of liquid electrolyte-containing DSSCs display significant Power Conversion Efficiencies (PCE) > 14% (Mathew et al. 2014; Kakiage et al. 2015) at lab scale and 10% in module (Kazim et al. 2014), but the use of a liquid electrolyte becomes a burden for large-scale developments. Therefore, research on solid-state DSSCs (ss-DSSCs) has significantly increased over the last years reaching up 8.2% (Freitag et al. 2015) with the recent breakthrough of perovskites, especially organic-inorganic perovskites, which act as light harvester in place of organic dyes, and Hole Transporting Material (HTM)(Kazim et al. 2014). Nevertheless, TiO_2 anatase remains an important component in both types of DSSCs, as an electron collector. The reduction of interface transport resistance between all components is also a major requirement, which requires a high interfacial intimacy between components.

The electronic conduction in the protonated TiO_2 film, usually made of 20 nm TiO_2 particles, is the result of a complex mechanism in liquid DSSCs. First, the presence of both dye cations and iodine species, with the resulting formation of a positive layer on the surface of titania, create a Helmholtz double layer screening shell around the particles, which contributes to the reduction of the electron-hole recombination in TiO_2 (Cahen et al. 2000). It is also stated that the electrons are diffusing along the surface of the particles, as a result of a short screening Debye length (1.5 nm) (Cahen et al. 2000). If this limits the electron diffusion to a surface process for particles larger than 10 nm, we could wonder the effect of using smaller (sub-10 nm) nanoparticles, and if the whole volume will be used for conduction.

A major contributing factor to the efficiency of the titania-based photoanode is its structure, especially, the size of TiO_2 crystals. Although the reduction in crystal size influences positively the amount of dye adsorbed onto the surface and the dye-to-TiO_2 charge transfer, it affects negatively the total internal resistance of the cell as more grain boundaries are created per unit volume, reducing the light internal reflection. For example, it was demonstrated that mesoporous TiO_2 single crystals can deliver an enhanced mobility, good optoelectronic performances, and high material intimacy (Crossland et al. 2013).

doi:10.18086/swc.2017.20.05 Available at http://proceedings.ises.org

We prepared previously anatase nanocrystals at room temperature, as a result of synthesis parameters being finely optimized via a mixture design method (Hegazy and Prouzet, 2012). This nanopowder, already successfully tested for their photocatalytic properties, (Hegazy and Prouzet, 2013) could become the raw material for future roll-to-roll manufacturing of large-scale DSSCs, if the nanostructure can be dehydrated with thermal annealing without particle sintering or coarsening. As we demonstrated previously that the initial particle size can be preserved up to ≈ 400°C, (Hegazy and Prouzet, 2012) we decided to verify the efficiency of a dehydration treatment in this temperature range, and assess the photovoltaic properties of a DSSC assembled with this material. Different parameters in cell assembly were tested in order to improve the final structure and connectivity of the final TiO_2 photoanode. The influence of these parameters is reported in the present study, along with the assessment of our materials, in comparison with commercially available compounds assembled with the same method.

2. Experimental

2.1. Synthesis of TiO_2 nanoparticles

We reported the detailed study of this synthesis previously (Hegazy and Prouzet, 2012). This study allowed us to extrapolate the best composition, which would give both small nanocrystallites, and a pure anatase phase. This specific composition was chosen inside the composition mixture diagram giving the pure TiO_2 anatase phase. It corresponds to a composition between the (A) and (J) data points in the mixture phase diagram of our previous study (Hegazy and Prouzet, 2012).

2.2. Synthesis of the TiO_2 paste

The paste was prepared by mixing the TiO_2 nanopowder, with different organic additives used as plasticizers. Depending on their nature, we proceeded differently for their addition. In method 1, 0.35 g Pluronic™ P123, was dissolved into 5 mL EtOH, and then mixed with a suspension of 1.0 g of TiO_2 dispersed into 10 mL of EtOH. The resulting mixture was left at 100°C for 24 h, in a sealed vial. The vial was further cooled down before using the paste. In method 2, a mixture of Span™80/Tween™80 was prepared with the aim to obtain a final Hydrophilic Lipophilic Balance (HLB) of 13.6, (Hessien et al. 2012) and 0.035g of this mixture (equiv. one to two drops) was directly added into a suspension of 1g TiO2 in 10 mL acetic acid (N). The resulting paste was ground in a mortar to ensure good dispersion of the organics among the solid phase before being pasted.

2.3. Preparation of the TiO_2 film

The film was coated onto a FTO glass substrate, with doctor-blade method. The film thickness was controlled by the thickness of a 17 µm 3M adhesive tape, and the paste was spread with a glass rod over the space between the tape strips. The electrode was left to dry at 80°C for 3 hours. We cured organics used as plasticizers by either a thermal, or UV treatment. With the thermal treatment, the electrode was heated at 450°C for 30min, cooled down, and immersed into a 0.1M HCl aqueous solution for 2 hours. With UV treatment, the electrodes were exposed to an intense curing (300 W.inch^2) UV radiation for 20 min, before being immersed in the HCl solution. After analysis, we decided to combine both methods, and all electrodes used for the cell assembly, were made out of the TiO_2nanopowder, first annealed at 350°C for 4 hours, then cured at 450°C for 30 min, and exposed to UV. All electrodes were further grafted with the Z907 dye molecule. Adsorption of the dye was undertaken by immersing the TiO_2 electrode overnight in a 0.4 mM dye in 50:50 vol. t-butanol:acetronitrile solution. The grafted electrodes were finally washed with acetone to remove the excess of dye.

2.4. Counter electrode preparation

The presence of Pt nanoparticles at the surface of the counter-electrode is mandatory to achieve the reduction of the iodide/triiodide couple (Bonnemann et al. 2007). A commercial platinum paste (Platisol-T, Solaronix) was used as received and fired at 450°C for 30 min in order to remove organic binders. The electrode was immersed in DI water, before being sonicated for 20 minutes in ethanol, without any noticeable wrenching of the Pt layer from the substrate.

2.5. Cell assembly

The Pt electrode and the dye-adsorbed TiO_2 electrode were assembled as a sandwich-type, leading to a 5 cm^2 photoactive surface. The redox electrolyte was introduced to the cell by capillary action.

3. Results and discussions

3.1 Influence of treatment on structure of TiO_2

3.1.1 Thermal annealing

We have demonstrated in a previous study, that the crystallinity of as-synthesized TiO_2 anatase could be improved by a moderate thermal treatment without any dramatic change in the crystal size if the maximum temperature remained below 450°C (Hegazy and Prouzet, 2012). A fully dehydrated material is a compulsory requirement for use in DSSCs.

We analyzed by TEM the influence of annealing on the crystalline and particle structure for nanopowders annealed for 4 hours at 350 °C (Figure 1.a), 450°C (Figure 1.b), and 500°C (Figure 1.c). TEM diffraction reveals an improved crystallinity from 350 to 450°C (see figures inset), without drastic change in crystal size. HR-TEM investigation of the sample annealed at 450°C (Figure 1.d) confirms the formation of 10 nm average single crystal particles with high crystallinity. The inter-reticular distances of 3.62 Å and 2.1 Å correspond to the (101), and (200) planes, respectively. They are in the usual value range reported in literature for nanocrystalline TiO_2. The crystal size increases at 500°C (Figure 1.c), leading to well-defined diffraction patterns, which result from this size increasing.

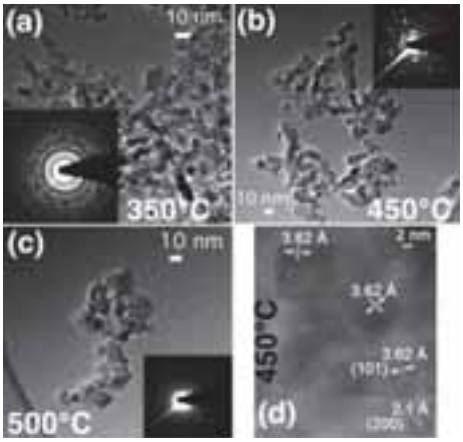

Figure 1: TEM micrographs and the corresponding diffraction patterns of nanocrystalline anatase TiO2 nanoparticles annealed at (a) 350 °C, (b) 450 °C, and (c) 500°C. (d) HR-TEM of TiO2

3.1.2 Organic additives

A TiO_2 paste was prepared with the addition of various organic additives used as binders: (i) Pluronic P123, (ii) PEG 12,000, or (iii) Span80/Tween20/acetic acid. These organics were chosen as plasticizers for facilitating the film formation. They were added to the anatase nanoparticles previously annealed at 350°C for 4 hours. As these organics must be removed after the film formation, we tested two types of curing, with a short thermal treatment (450°C, 30 min), or high intensity UV (300 W/in^2, 15 min). An observation by TEM (not shown) did not reveal any drastic change in the structure of titania particles, after either thermal or UV curing, irrespective of the type of additive.

Both surface area and porosity of the film are two important parameters in performance of DSSC, and porosity should be typically in the 50%-65% range (van de Lagemaat et al. 2001). Previous analyses showed that the small size of these nanoparticles create a significant textural porosity in the mesoporous range, with both specific surface area and porous volume changing with the thermal treatment (Hegazy and Prouzet 2012). We report in Figure 2, the N2 adsorption/desorption isotherms for the powder annealed at 350°C, and

the same powder prepared with the Span/Tween mixture plasticizing additive and cured either at 450°C, or under UV. Figure 3.a shows that all isotherms are rather similar (Type IV isotherms), with a steep adsorption between 0.6 and 0.9 of partial pressure. The specific surface area calculated via the multipoint BET model, gives values of 130, 160, and 200 $m^2.g^{-1}$ for the annealed, thermally cured, and UV cured samples, respectively. Their respective porous volume is 58% for the annealed powder, and 63% for both cured samples. The modeling of the pore size distribution (PSD), using the desorption isotherm, (Figure 2.b) allowed us to assess the possible influence of curing on the material porous structure. The initial PSD lies between 8 and 13 nm, and both materials after either thermal or UV curing, show only a slight broadening of PSD toward larger pores (8 – 18 nm range). We assign this PSD shift toward larger values, as a result of the organic additive that acts as a pore promoter and contributes to create some larger pores in addition to the initial PSD (the PSD is only broadened toward larger values, not fully shifted).

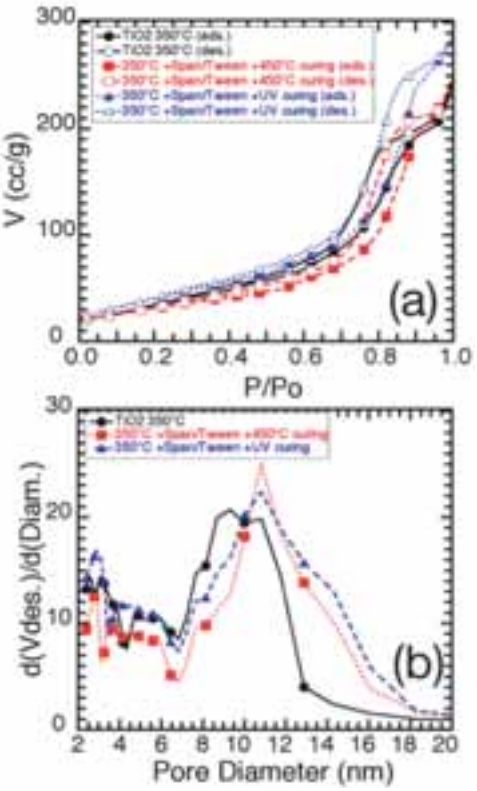

Figure 2: Nitrogen adsorption isotherms for the nanopowder after thermal annealing (350°C, 4h), and the same material after addition of the Span/Tween mixture additive, and either thermal (450°C, 30 min.) or UV (15 min) curing: (a) ads

3.2. Effect of dye absorption and photoelectronic properties onTiO_2 film

The cell performance is strongly affected by the efficiency of injected electrons from the dye to the conduction band of the TiO_2, which reflects the importance of the way the dye anchored to TiO_2 surface. As it has been demonstrated that both UV exposure and HCl treatment improve the photoanode properties, (Lee at al. 213; Hao et al. 2004). The thermally cured TiO_2 film was additionally activated under UV (10 min) and immersed into a 0.1 M hydrochloric aqueous solution for two hours, then rinsed with DI water until no acid trace could be found in washing water. The major effect of UV exposure is to reversibly create a high concentration of photoactive surface states, which were described as being continuously distributed below the conduction-band edge as shallow electron traps that would be beneficial for electron injection from the dye and transport by thermally activated detrapping (Lee at al.213; Hao et al. 2004; Tebby et al. 2009). The major effect of acid treatment is to increase the density of protonated sites, which favors multidentate dye adsorption. The actual influence of this HCl treatment is illustrated by comparing the UV-Vis spectra for both films prepared according to the procedure (thermally annealed and cured), and exposed to UV: adding an HCl treatment before dye adsorption, increases in the absorbance. A similar blue shift was observed for

all samples, which reveals a change in the electronic structure of the thin films surface, probably due to surface hydroxylation (Hao et al. 2004).

Figure 3 shows the J -V characteristics of the solar cell device made using thermally treated TiO_2/ plutonic P123 films at 450°C, the TiO_2 nanoparticles were preheated at 350°C. The photovoltaic parameters of the devices made using initially treated nanoparticles at 350°C and 450°C with and without HCl treatment. The short-circuit photocurrent density (Jsc) and the photoconversion efficiency (η) of the treated TiO_2 films are higher than those of the untreated counterparts, the active surface area was 5 cm^2 for all samples. After HCl treatment of the 350°C sample, the Jsc and η were increased by 28.4% and 4.5%, respectively. However, the open circuit voltage (Voc) was slightly changed and the fill factor (FF) was decreased. Whereas, for the sample prepared at 450°C, J_{sc} was increased by 36.3%, η by 37.2% and Voc by 8.6%. The poor FF is a result of a combination of the high series resistance (Rseries) and low shunt resistance (Rshunt). Figure 4 demonstrates that both devices made using our synthesized TiO_2 exhibit higher cell performance compared to the commercial ones. Although the sample prepared by surfactant and acetic acid displays higher efficiency than that made using pluronic, the later provides higher shunt resistance, Table 2.

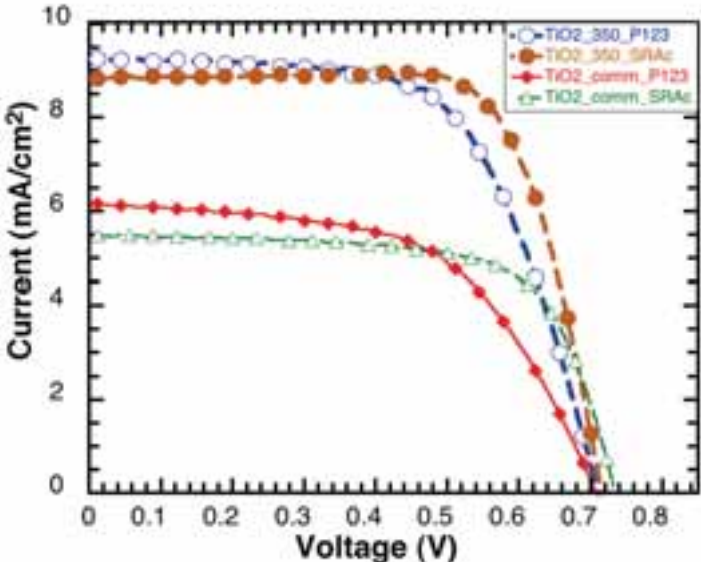

Figure 4: J-V curves of dye-sensitized TiO_2 films prepared on FTO/glass: with different organic additives to our nanopowder and the commercial one(active area=5 cm^2)

Table 1: Comparison between photovoltaic parameters of DSSCs prepared by the synthesized TiO_2 nanoparticles and the commercial TiO_2 counterparts.

Sample	V_{oc} (V)	J_{sc} (mA/cm^2)	*FF*	Efficiency %	R_s (Ω)	R_{sh} (Ω)
TiO_2_350°C_P123	0.713	9.43	62.6	4.21	16.6	1392
TiO_2_Degussa_P123	0.707	6.16	56.7	2.47	15.72	462
TiO_2_350°C_SRAc	0.72	8.41	77.1	4.67	2.21	324
TiO_2_Degussa_SRAc	0.734	5.47	68.9	2.77	4.12	606

Several DSSC devices were fabricated based on the TiO_2 films treated under different conditions. Unlike usual testing cells with an active surface area close to 1 cm^2, our cells were assembled with an active surface area of 5 cm^2, Fig.5 represents a picture of the tested cell. Therefore, the performances of the cells can hardly be compared to literature, and they were initially used as comparative within this study.

Figure 5 Picture of the full-assembled cell

The adsorption of Z907 Dye on the TiO_2 surface was characterized by ATR-FTIR spectroscopy. Figure 4 shows the ATR-FTIR absorption spectra of the Z907 dye adsorbed onto the TiO_2 surface. Many studies have shown that the dye anchors to the TiO_2 surface through different carboxylate anchoring modes, like physisorbed through hydrogen bonding, or chemisorbed via various types of chemical bonds (unidentate, bidentate, and bridging), with bridging and bidentate being the most stable ones (Lee et al. 2011; Leon et al. 2006; Wang et al. 2004).

Strong peaks were observed at 1,380 cm^{-1} and 1,613 cm^{-1} characteristics of the vsym (COO-) and vasym (COO-), respectively (Finnie et al.1998; Agrell et al. 2004). There is no indication of the presence of carboxylic bond at 1,716 cm-1. This indicates that the dye is anchored to the TiO_2 surface via bidentate or bridging not via unidentate mode. The saturated hydrocarbon chains are identified by the C-H stretch modes in the 2,800-3,000 cm^{-1} region with vibration modes of 2,852 cm^{-1} and 2,924 cm^{-1} for symmetric and asymmetric -CH_2-, respectively. The corresponding CH_3– peak is observed at 2,956 cm^{-1}. A broad absorption

peak is observed between 3,200-3,400 cm^{-1} (not displayed), corresponding to the –OH stretching modes of hydroxo and aquo ligands.

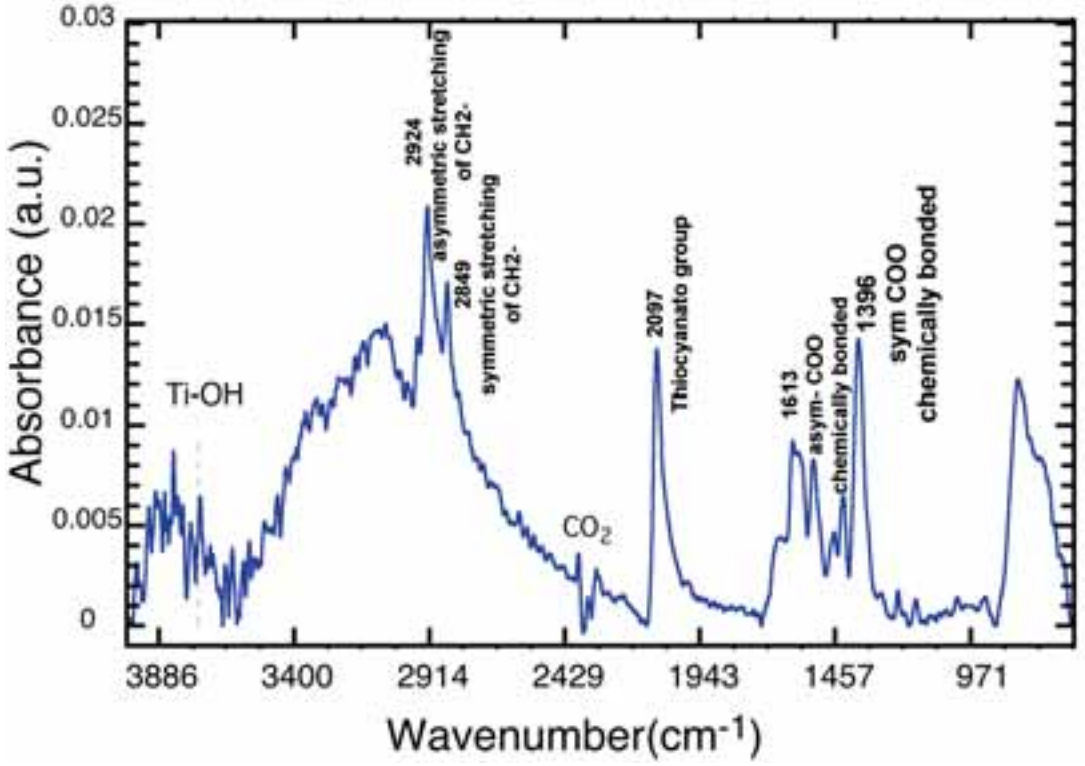

Figure5: FTIR spectrum of the TiO2- thin film after dye adsorption.

Another significant difference between our nanopowder and the commercial one is the strength of the dye adsorption. The samples prepared with Span/Tween show higher absorbance, which is consistent with the overall cell efficiency. All the reference cells made from the commercial TiO_2 exhibit lower absorbance, as a result of the dye being less adsorbed or easily removed before measurements. Our nanoparticles have the ability to keep 7 times more of dye after this process, than the commercial powder.

We performed an EIS analysis on different configurations to get more insights into the effect of resistances on the cell performance. We display the results obtained with TiO_2 films prepared with Span/Tween (Figure 5.a) or Pluronic P123 (Figure 5.b). A large semicircle can be observed in the Nyquist plot, which corresponds to the TiO2/dye/electrolyte triple interface. The interface between the high–frequency semicircle and the intermediate–frequency semicircle is difficult to distinguish due to the strong overlap of the charge transfer resistance on the TiO_2 surface and that on the Pt surface. A sub-circle in the low-frequency response is observed, which accounts for the contribution of the diffusion of the electro-active species in the liquid electrolyte (Longo et al. 2004). In the dark, the solar cells showed high impedance and the time constants are not well defined. For all devices testes (see Table 2), almost all the impedance parameters show a difference between illuminated and non-illuminated cells. The response at the intermediate interface under dark condition is much higher than the one under illumination, which corresponds to a high capacitance because of the expected accumulation of electrons and redox species at this interface (Nogeira et al.2004). From our results, it appears that the cells prepared with span/Tween exhibit a longer electron lifetime than those prepared with Pluronic(P123). The reference cells (commercial TiO_2 powder) showed an electron lifetime half times shorter electrons for recombination under illumination compared to the cells made with our

nanocrystalline TiO_2 material. Higher electron lifetime leads to significant electron transfer, and thus, an improved Jsc. Therefore, EIS analysis confirms the promising results obtained with cells assembled with our synthesized nanocrystalline material.

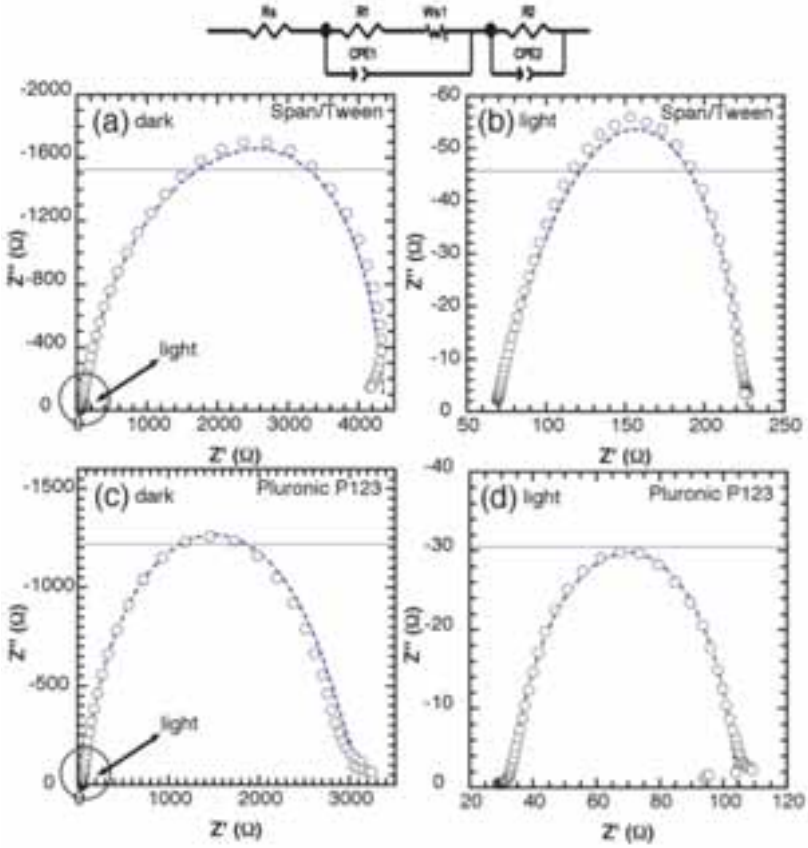

Figure 5: Nyquist representation of the impedance data obtained for Z907 dye–sensitized TiO2 solar cells prepared with preheated nanoparticles at 350oC mixed with (a,b) Span/Tween, (c,d) Pluronic P123, measured in the dark (a,c) or under light (b,d). 4. Summary

In summary, we have successfully synthesized small crystalline TiO_2 nanoparticles by a novel soft chemistry method and investigated their properties in dye–sensitized solar cells. We also demonstrated that different organic additives can be used to prepare the photoanode and obtain the well defined working range of the porosity. The effect of UV exposure on the structure and crystal size of as-synthesized TiO_2 nanoparticles was tested through the XRD and N_2 isotherm characterization, which indicates no change in the crystal size and a higher surface area, respectively. Furthermore, various treatment methods (UV alone, thermal treatment alone, and combination of both) were applied. Although, UV treatment is able to clean the TiO_2 surface from organic contaminates, it is less efficient to be used alone, and leads to lower performance of solar cells, compared to thermal treatment. Interestingly, when it is used after the thermal treatment, the cells seem to show better efficiency, which will have to be confirmed in the future with more tests. The HCl treatment increases the cell efficiency by almost one to three. The enhancement was attributed to the increase of the amount of the dye. An intensive investigation on the effect of HCl on the adsorbed dye was done by the FTIR analysis. More investigation on the dye by the FTIR, demonstrates that the dye anchored chemically to TiO_2 surface. The amount of adsorbed dye for our TiO_2 films was 6 times compared to the amount of the commercial ones. The internal resistance of the cells were checked with EIS analysis, which shows higher electron lifetime, smaller charge transfer resistance for counter electrode and high recombination resistance compared to the commercial cells.

Abstract

Solar cells utilize a small portion of solar spectrum depending on the technology while solar radiation being a full of UV-VIS-IR wavelengths does not leave absorbing and other layers unaffected. Only the photon energy that matches with absorber layer contributes to effective power generation of solar cell. Higher and lower energy wavelengths induce thermalization and absorption losses which in turn introduce several consequences including heating and degradation in the cell level. Therefore engineered absorbing layer such as nanowire based solar cell holds huge potential. Here in this work, we have investigated and simulated four deterministic characteristics, *viz*, absorption depth profile, electromagnetic field, Poynting vector and exciton generation rate distribution at different incidents. Flat silicon and silicon nanowire were considered as examples along with a comparative outlook. Such predictive studies facilitate the choice of technology and how to improve the cell efficiency using light trapping technique.

Key-words: Optical characteristics, Silicon nanowire, FDTD simulation, Optical confinement.

1. Introduction

Solar radiation per second (i.e. 1.74×10^5 TW) is more than sufficient to provide all the energy demands needed to facilitate entire world population in a year. Unfortunately it has been impractical because of technological challenges. Silicon (Si)-based solar panel is the most popular one in this regard and holds more than 90% of current photovoltaic (PV) market

doi:10.18086/swc.2017.20.06 Available at http://proceedings.ises.org

(Sachs 2011). Although Si is abundant and superior in stability and non-toxicity, the Shockley and Queisser efficiency limit (i.e. ~31%) for a single band gap Si-based solar cell has become an issue and a matter of challenge for current research community. A small portion of solar spectrum contribute to solar cells performances, whereas solar radiation being a full of other wavelengths does not leave the associate layers unaffected. The photon energy that matches with absorber layer contributes to effective power generation of solar cell. Higher and lower energy wavelengths induce thermalization and absorption losses respectively which in turn introduce several subsequent problems including heating and degradation in the cell level. These additional consequences add up extra cost whereas current technology is already facing various challenges to limit the cost below 1¢ per kWh. Therefore, it is important to increase the cell efficiency at low cost to bring this technology within afford and reach.

Si nanowires (Si-NWs) have been considered potential to face the efficiency constrain because of nanometric features led unique properties (Kelzenberg et al. 2010; Polman and Atwater 2012; Zhao at al. 2004; Krogstrup et al. 2013; Yu et al. 2014). Si-NWs have strong optical absorption compared to that of flat silicon along with many other electrical characteristics that lead to reduced production cost (Salhi et al. 2016). The efficiency can be further improved by optimizing and tuning incident solar spectrum that is useful in efficient solar cell system. A predictive analysis of inherent optical characteristics of such nanowire based system indeed facilitates to determine and improve other associate layers of the solar cell. Previously we have reported absorption profile, energy flow, EM field distribution and exciton generation rate at 740 nm in addition to spectral analysis of absorption depth profile for Si-NW system (Hossain 2016a, 2016b). Nevertheless, further correlated spectral analysis on absorption profile, energy flow, EM field distribution and exciton generation rate distributions is indispensable.

Two key challenges, low cost materials as well as higher efficiency, are immensely needed at this moment to accelerate mass-production and utilization of PV technology. PV solar cell based on nanometric Si-NW-based possess huge potential in this regard. Apart from optical characteristics, short collection length for charge carriers in Si-NWs boosts up efficiency and allows to use down grade absorbing materials. First ever PIN configured solar cells based on Si-NWs was presented by Tian group in 2007 (Tian et al., 2007). The Si-NWs were grown by vapor-liquid-vapor process. Since then, a variety of methods have been reported to obtain Si-NW such as high temperature evaporation of silicon powder in furnace (Cui et al., 2001,

2000; Wu et al., 2004), vapor-liquid-solid process (Wang et al., 1999; Westwater, et al 1997), laser ablation (Zhang et al., 1999), liquid solution solid process (Davidson et al., 2004), solid liquid solid process (Yan et al., 2000), metal catalyst assisted electroless etching (Peng et al., 2009, 2006a. 2006b, 2005, 2002), etc. There are huge and extensive studies on conventional flat panel, although 3rd generation solar cell especially nanostructured materials based photovoltaic solar cell is not well understood. Numerical studies always support to implement the proof-of-concept into prototype that ultimately ends up with a suitable product. The studies also open up new avenue and in-depth understanding of the technology. Therefore, an correlated and simulative study, such as absorption profile, electromagnetic (EM) field, Poynting vector, excitation generation rate distribution, etc. are inevitable.

Here in this work, we have investigated and simulated four deterministic characteristics, *viz*, spectral absorption depth profile, electromagnetic field, Poynting vector and exciton generation rate distribution. Two Si-based absorbing layers generally used in thin film solar cell, such as flat silicon and silicon nanowire, were considered as examples. A comparative study has been carried out to illustrate how an efficient light management can be obtained in silicon nanowire based solar cell.

2. Method and materials

c-Si slab and Si-NW on c-Si wafer were modeled in FDTD package of Lumerical Solution (ver 8.6) and a three-dimensional (3D) analysis was carried out to obtain and compare optical characteristics of such systems. The model geometry was selected in such a way so that the parameters can be as close as of those reported previously (Hossain et al. 2016). Absorption profile, Poynting vector, EM field distribution, and generation rate distributions at different wavelengths ranging from UV to NIR region were extracted. Unpolarized plane wave as illumination source was set as incident to the vertically modelled Si-NW. The characteristics of Si-NW system were compared with that of c-Si slab only. Intensities of absorption profile, Poynting vector, EM field and exciton generation rate distributions were obtained slice by slice at different incident wavelengths.

3. Results and discussion

Solar cell internal quantum efficiency is known to be directly related to the photon absorption profile of the absorbing layer. Such photon absorption can be confined and enhanced depending on the geometry of absorbing layer in solar cell. Absorption profile, EM field distribution, Poynting energy and excitation generation rate distribution are inter-related and

deterministic factor to efficient solar cell. We have extracted aforementioned characteristics at different wavelength ranging from UV to NIR region (i.e. at 300, 500, 700, 900, and 1100 nm). Figure1a–c and Fig. 2a-c show absorption profiles and electromagnetic field distribution

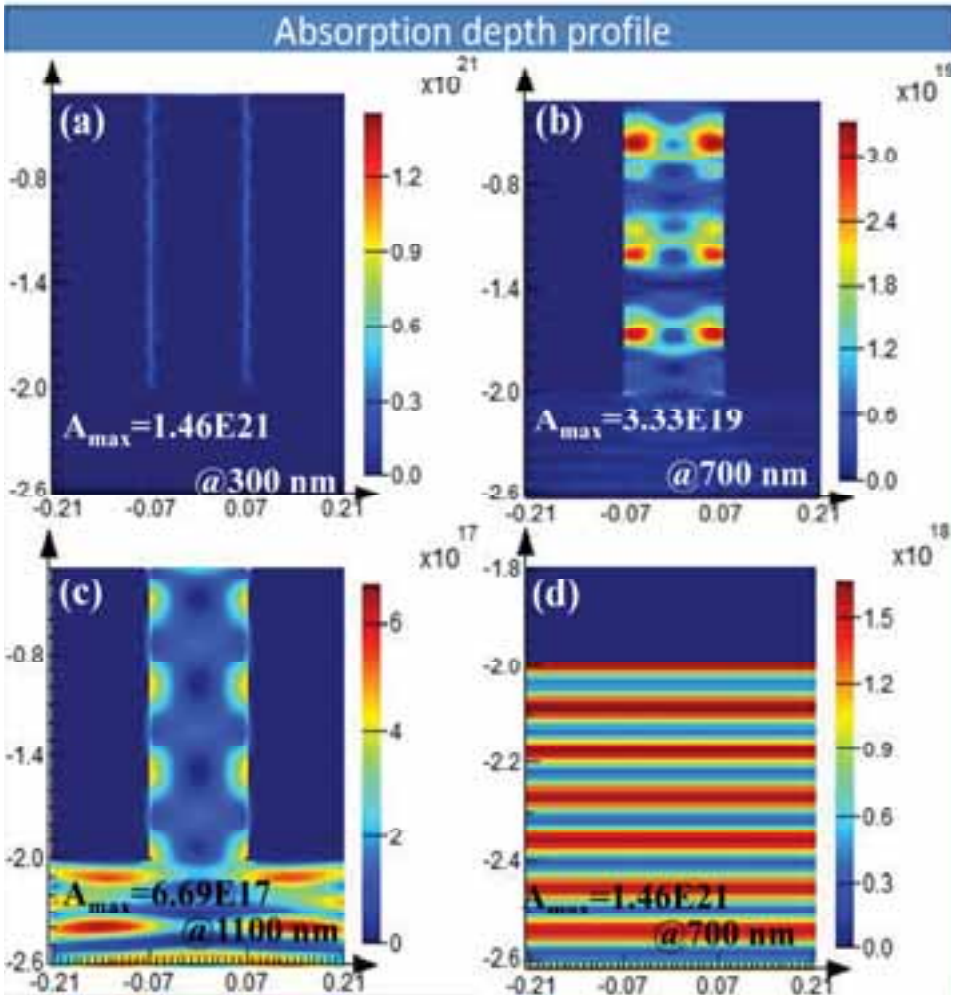

Fig. 1: (a)-(c) Spectral absorption depth profile of Si-NW model system at 300, 700 and 1100 nm wavelengths respectively, and (d) that of flat c-Si slab at 700 nm wavelength.

of nanowire model system at 300, 700, and 1100 nm wavelength respectively. Absorption profile and electromagnetic field distribution of c-Si slab only at 700 nm wavelength of solar spectrum was shown in Fig. 1.d and Fig. 2d respectively as references. For shorter wavelength with higher energy, such as at 300 nm, almost no absorption and EM field distribution was observed. On the other hand, for longer wavelengths, such as at 1100 nm, slight distribution was observed near the edge and started to reduce within the absorbing layer. At 700 nm wavelength of solar spectrum, the intensity distribution was confined within

the nanowire model system. For conventional flat panel Si-based solar cell, single band gap material (E_g= 1.8 eV or 700 nm) utilizes the solar spectrum at around 700 nm.

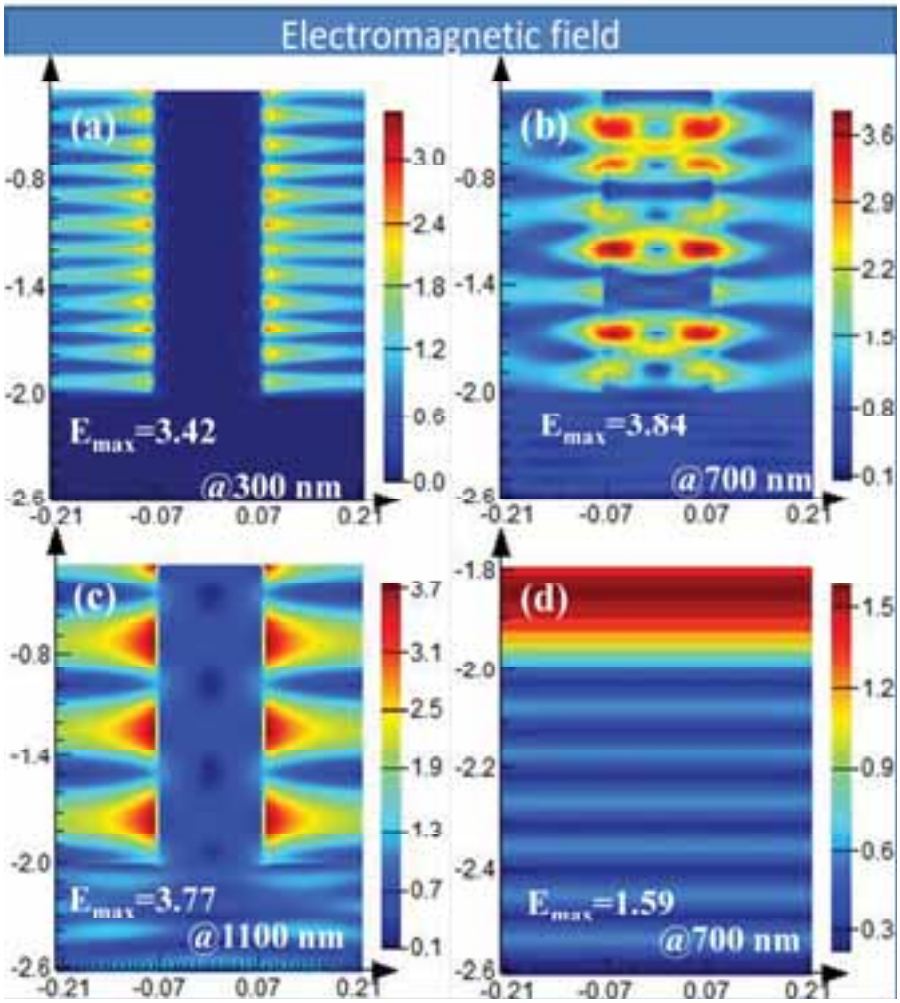

Fig. 2: (a)-(c) spectral EM field distribution for Si-NW model system at 300, 700 and 1100 nm wavelengths respectively and (d) that of flat c-Si slab at 700 nm wavelength.

In photovoltaics, excitation generation rate defines how many of excess excitons (i.e., excited electrons and holes) are available to collect. Number of useful excitons per incident photon is very crucial in designing efficient solar cell. Current (i.e. rate of charge flow) in solar cell depends on the concentration of such excitons. Therefore, generation rate is calculated by taking divergence of Poynting vector considering a zero recombination loss. Therefore, understanding of spectral distribution of Poynting vector and excitation generation rate within flat silicon as well as Si-NW system is very important. Energy flow distribution throughout a

single Si-NW from top to the bottom are shown in Fig. 3a–c at different wavelength such as 300, 700, and 1100 nm wavelength respectively. At shorter wavelength, such as at 300 nm, distributions were found intense near the edge and there was almost no distribution within the nanowire model system. For longer wavelengths with lower energy, such as at 1100 nm, there was slight confined distribution but that started to reduce within the absorbing layer. At 700 nm wavelength of solar spectrum, the intensity distribution was observed to be confine and well distributed. Confined energy flow distribution was observed within the nanowire model system. Figure 3d shows the Poynting vector profile obtained in flat c-Si slab at 700 nm wavelength as reference.

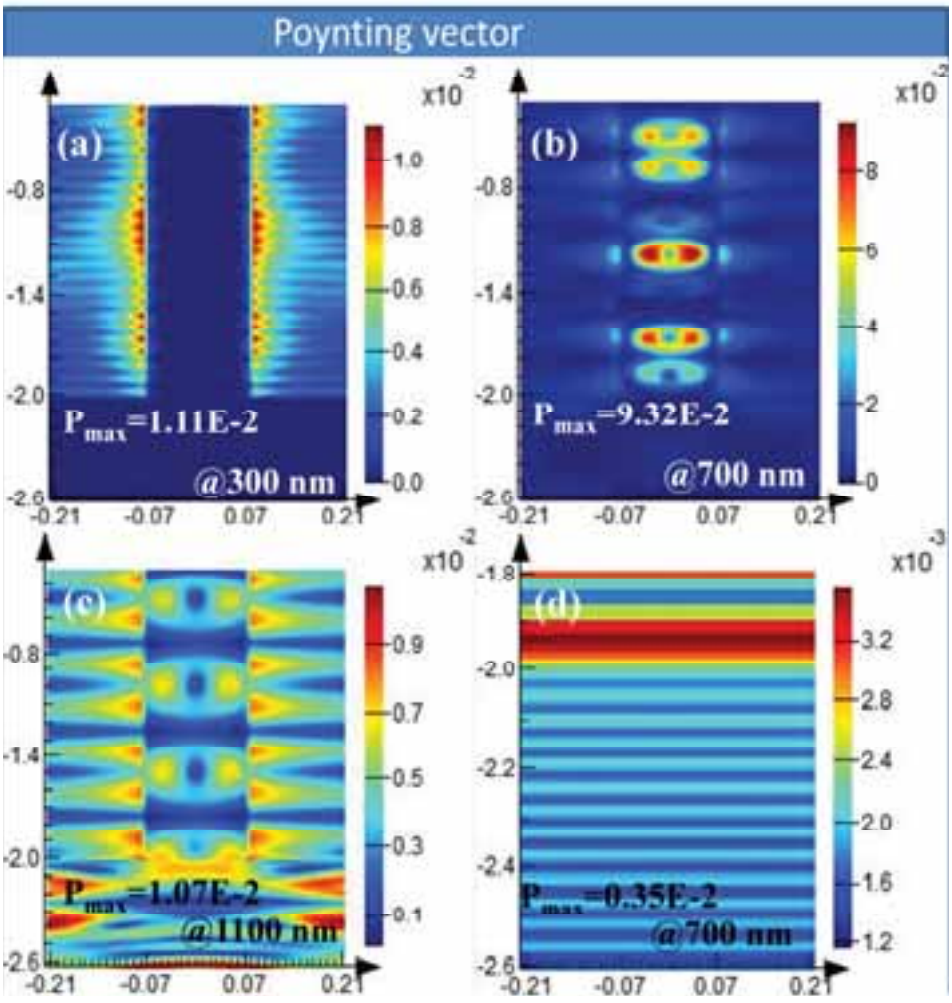

Fig. 3: (a)-(c) Spectral Poynting vector profile of Si-NW model system at 300, 700 and 1100 nm wavelengths respectively, and (d) that of flat c-Si slab at 700 nm wavelength.

Figure 4a-c show excitation generation rate distribution of nanowire model at 300, 700, and

1100 nm wavelength, respectively. At shorter wavelength with higher energy, no excitation generation rate distribution was observed. For longer wavelengths, such as at 1100 nm, slight distribution near the edge was observed. At 700 nm wavelength of solar spectrum, most of the exciton generation rate distribution was confined within the nanowire model system and the intensity distribution was well distributed. Excitation generation rate distribution of c-Si slab only at 700 nm wavelength of solar spectrum was shown in Fig. 4d as references.

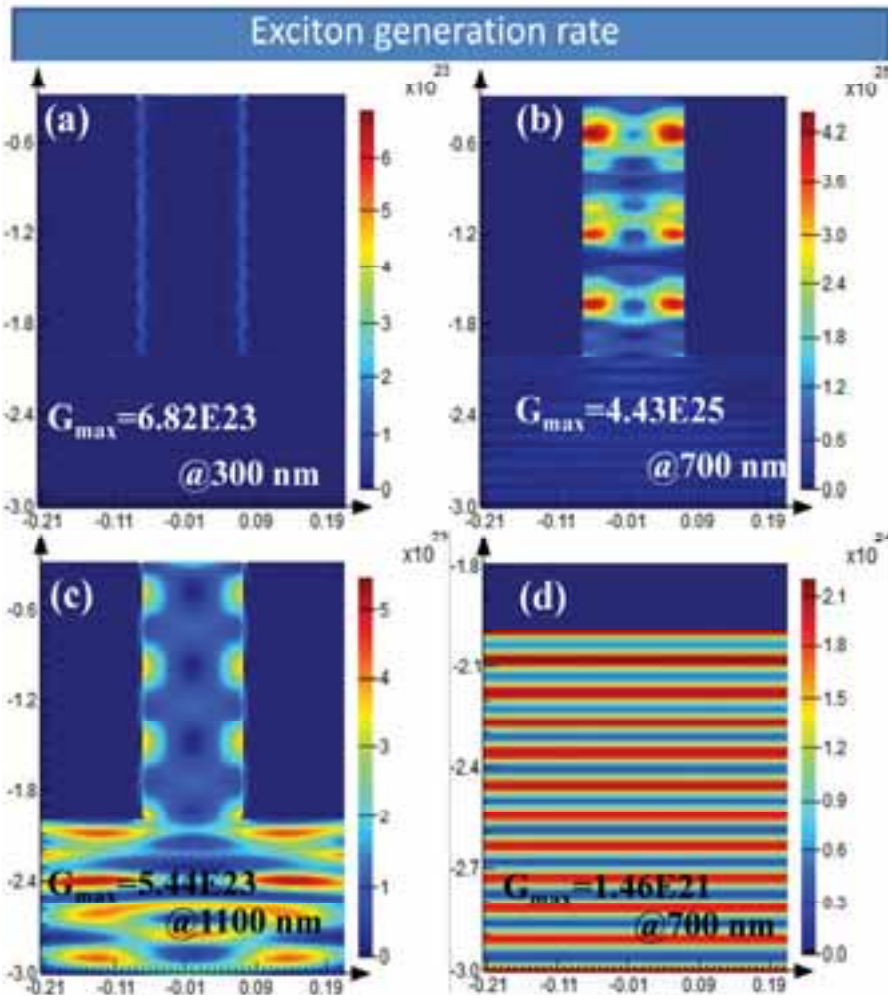

Fig. 4: (a)-(c) spectral exciton generation rate distribution for Si-NW model system at 300, 700 and 1100 nm wavelengths respectively and (d) that of flat c-Si slab at 700 nm wavelength.

4. Conclusion

Absorption depth profile, electromagnetic field, Poynting vector, and excitation generation rate distribution of two typical model systems, flat silicon and nanowire model systems, were observed at different wavelengths. At around 700 nm (band gap, E_g= 1.8 eV), intensity distributions were found confined and well distributed within the Si-NW model system with reference to those obtained at other wavelengths. Exciton generation rate was available and well distributed all the way down to the bottom of the wire. Lower wavelength with higher energy solar spectrum was not found to be efficient for Si-NW model system.

Performance and economic optimization of hybrid solar thermal and photovoltaic power plants with dynamic simulation

Hannah O'Hern[1], Todd Otanicar[1] and Matthew Orosz[1]

[1] The University of Tulsa, Tulsa (USA)

Abstract

Energy storage is a critical determinant of grid stability under scenarios with a high percentage of renewables in the generation portfolio. Concentrating solar thermal power traditionally offers high capacity thermal energy storage (TES) on timescales up to 24 hours, while photovoltaics operate with comparatively better economy but are limited to direct injection into the grid during the daytime in the absence of mature, high throughput battery storage technology. Obtaining the advantages of both systems through hybridization has been proposed in the ARPA-E FOCUS program, and this work investigates the performance and cost trade-offs of updating existing CSP infrastructure to include superimposed spectral filtering and concentrating photovoltaics in a linear optical configuration. A numerical energy balance model for a retrofit parabolic trough collector is deployed in an hourly simulation using plant characteristics and typical meteorological year (TMY) data for a location of interest. Design features including PV band pass filtering, operating temperature, and primary optics intercept are varied for an optimization of levelized cost of electricity. A case study for the US southwest illustrates the potential for performance enhancement relative to a CSP baseline via increased photovoltaic output (>30%), and favourable financial returns in comparison to greenfield PV plant development (with installed specific costs <1.5 USD/W), that preserves the advantages for grid operators of maintaining the dispatchability of TES.

Keywords: Solar thermal, concentrating photovoltaics, energy storage, dynamic simulation, hybrid system, CSP, CPV

1. Introduction

The hybridization of CSP and concentrated photovoltaics (CPV) technologies combines the energy storage capabilities of CSP with the economy of PV conversion. Retrofitting an existing parabolic trough collector CSP plant with a spectral splitting filter reflecting optimal wavelengths to a CPV receiver is expected to increase the annual power output of a traditionally configured CSP plant using linear Parabolic Trough Collectors (PTCs). This is due to the relatively higher in-band efficiency of PV cells compared to the output of a steam Rankine cycle after accounting for optical and thermal losses in the CSP array. The concept of interposed secondary optics has been considered previously as means to increase the concentration ratio onto the PV cell, however, in this study we take advantage of an existing as-built CSP array, with its energy storage benefits, and add secondary optics to redirect specific wavelengths of light to a CPV receiver. The key advantage of the hybrid CSP-CPV system is that the filter can be designed to reflect wavelengths optimal for conversion in the PV cell, while passing the poorly utilized wavelengths through to the CSP, thus allowing the PV cell to operate effectively while ensuring that light wavelengths that would otherwise go to waste are exploited (Orosz 2015). The hybrid CPV retrofit of a CSP plant would be an economical option to increase the annual power output, while still utilizing the energy storage capabilities of CSP.

The secondary optic consists of a dichroic filter attached in plane intermediate between the primary mirror and the focal line of the parabolic trough mirror, with the CSP heat collection element (HCE) above it and the CPV receiver below, as shown in Figure 1. The filter splits the spectrum such that ultraviolet and infrared wavelengths pass through the dichroic mirror to the HCE while wavelengths that are efficiently used by the CPV cell are reflected down to the CPV receiver. The diversion of part of the solar spectrum results in reduced CSP power output, however, the CPV power output increases the net output of the plant due to its higher in-band conversion efficiency.

doi:10.18086/swc.2017.20.07 Available at http://proceedings.ises.org

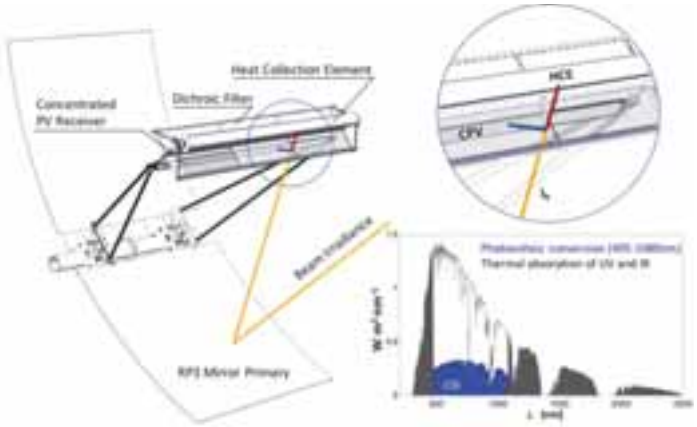

Figure 1: A CPV retrofit attaches to and operates with an existing standard parabolic trough collector (RP3 outer mirrors not shown). Inset shows a detail of the beam splitting secondary optics, the respective CSP and CPV targets, and the AM1.5 band of photovoltaic conversion (lower right) where the right band edge is set to the cSi band gap and the left band edge is tuned to maximize combined CSP and CPV output.

2. Annual Performance Model

Probabilistic yield estimation (monthly and annual energy output) based on design and location is an important input in the development cycle of solar energy projects and critically determines the financial merit of a proposed solar plant. There are many commercial software packages (PVSyst, Helioscope, etc.) in use for determining the annual yield of a solar PV power plant. The System Advisor Model (SAM) is a free software developed by NREL (National Renewable Energy Laboratory 2016) that is utilized for both performance and detailed financial modelling. While SAM and other specialized tools are capable of modelling PV, parabolic trough CSP and CPV plants, there is no commercially available platform that can simulate a hybrid of both CSP and CPV, and in particular with reference to spectral dependencies e.g. the secondary optics used in the retrofit which our team is developing with support from the U.S. Department of Energy (DOE) Advanced Research Projects Agency (ARPA-E) FOCUS program (ARPA-E n.d.). To address this observed gap in performance prediction tools, a dynamic simulation was created in Python which embeds a previously developed detailed steady-state model of the energy balance of a parabolic trough CSP plant with a coupled spectrum-splitting filter and CPV cell retrofit (Orosz et al. 2016).

2.1. Steady-State Energy Balance Model

A steady-state physics based energy balance model was developed in Python, based on the Forristall energy balance model (Forristall 2003). The heat transfer equations of the Forristall model are combined with the necessary equations to determine PV power generation, in order to determine the net generation of a retrofitted plant. Inputs into the model include collector and HCE geometry, heat transfer fluid (HTF) properties, inlet temperature, and flow rate, optical properties, and ambient weather conditions. In addition to CSP generation, with and without the retrofit and CPV generation, the model also determines HTF outlet temperature, necessary pumping power, and thermal and optical losses.
The HCE is comprised of a stainless steel tube with a selective coating inside a glass envelope, with an evacuated annulus. The model assumes all temperatures, heat fluxes, and thermodynamic properties are uniform around the circumference of the HCE, and that the only heat transfer in the axial direction along the length of the trough is via the HTF. The effective incoming energy is the solar beam irradiance reduced by optical losses incurred through the dichroic filter. The incoming irradiance is predominantly transmitted through the glass jacket, absorbed and conducted through stainless steel absorber, and finally transferred to the HTF by convection. Residual energy is lost to the environment via convection and radiation. The beam irradiance that is reflected by the dichroic filter is converted to electricity directly by the CPV reciever. These energy losses and gains are calculated along the length of the trough.

2.2 Model Reduction and Annual Simulation

A meaningful comparison between a CSP plant and hybrid retrofitted plant would need to be done on at least an annual scale to determine how the plants differ throughout a year. The computational effort associated with running the steady-state model at every hourly time step for a year to build up an annual generation profile would be extensive. In order to reduce this computational effort a model reduction strategy was implemented by means of a parametric sweep, varying dry bulb temperature and direct normal irradiance. The resulting dataset was subjected to a symbolic regression algorithm (Schmidt and Lipson 2009) to simultaneously search the parameter and form space for highly fitted equations representing the steady-state model's prediction for CSP and CPV yields of the retrofit.

Equation 1:

$$\eta_{CSP} = a_0 + a_1 * T_{amb} + \frac{a_2}{I_b}$$
$$R^2 = 0.99783307$$

Equation 2 (Curzon and Ahlborn 1975):

$$\eta_{carnot} = 1 - \sqrt{\frac{T_{amb} + 273}{663}}$$

Equation 3:

$$CSP\ (MW) = \frac{\eta_{CSP} * \eta_{carnot} * I_b * A}{1000000}$$

Equation 4:

$$CPV\ (MW) = \frac{A * ((b_0 * I_b) - b_1 - (b_2 * T_{amb} * I_b) - (b_3 * {I_b}^2))/32}{1000000}$$
$$R^2 = 0.99999724$$

TABLE 2: Parameters used for dynamic simulation calculations

Parameter	Value
A	Aperture Area (190,338 m^2)
T_{amb}	Ambient Dry Bulb Temperature
I_b	Beam Irradiance
$TES_{SOC\ IN}$	Thermal Energy Storage state of charge from previous time step

To initialize the annual simulation model, typical meteorological year (TMY) data (National Renewable Energy Laboratory 2003), consisting of 8760 hourly values for ambient conditions, is read into the model. The correlation equations, from the symbolic regression, that make up the annual simulation model are shown in equations 1-4, with coefficients in Table 1, and parameters in Table 2. The ambient dry bulb temperature and direct normal irradiance is applied to these equations at each hourly time step for a year. The model calculates the CSP yield before the retrofit, as well as the CSP and CPV yields with the retrofit. This simulation can be applied to any plant as long at the aperture area and TMY data is available. After the model calculates the yields of the plant, the CSP yields are compared to the nameplate capacity of the power block to ensure the power block is not being overloaded. If the CSP load is greater than the nameplate capacity, the model assumes that collectors will be defocused to avoid this overload and therefore the CSP yield is set equal to the nameplate capacity of the power block, as shown in Figure 2. The model also assumes that there will be no yield of any kind if the sun is not shining, e.g. direct normal irradiance is less than 200 W/m^2.

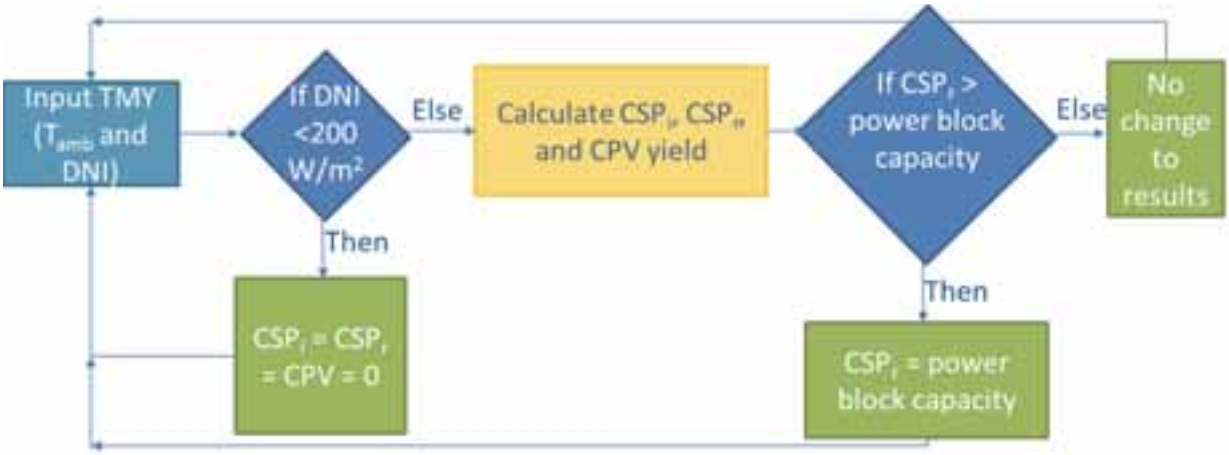

Figure 2: Annual performance model block diagram

3. Case Study

For this study the CPV retrofit of the Genesis solar trough plant in the Mojave Desert near Blythe, California (33.6650°N, 114.9948°W) is investigated. The Genesis CSP plant features linear parabolic trough collectors in a solar field with an aperture area of 1,928,320 m^2 and average annual power block output of 580,000 MWh (National Renewable Energy Laboratory 2014). This facility has a steam Rankine power block of 250 MW net capacity and no Thermal Energy Storage (TES)(U.S. Department of the Interior Bureau of Land Management 2016), consequently the CSP electricity power output in the model was capped at 250 MW. The model assumes that the entire solar field aperture area is retrofitted with the hybrid CPV system.

The Genesis plant's first full year of operation was 2014 and monthly data for the energy output in MWh is published online (National Renewable Energy Laboratory 2014). Actual meteorological data for Blythe, CA for 2014, 2015, and 2016 was obtained to initialize the dynamic simulation; the dry bulb temperatures and irradiances for every hour of those years are shown in Figure 3. The measured data provides direct normal irradiance, which does not account for the cosine losses of a single axis tracking plane. To increase the accuracy of the dynamic simulation, the direct normal irradiance is multiplied by the plane of array cosine loss factor for each hour, using a method adapted from (Duffie, Beckman, and Worek 1994).

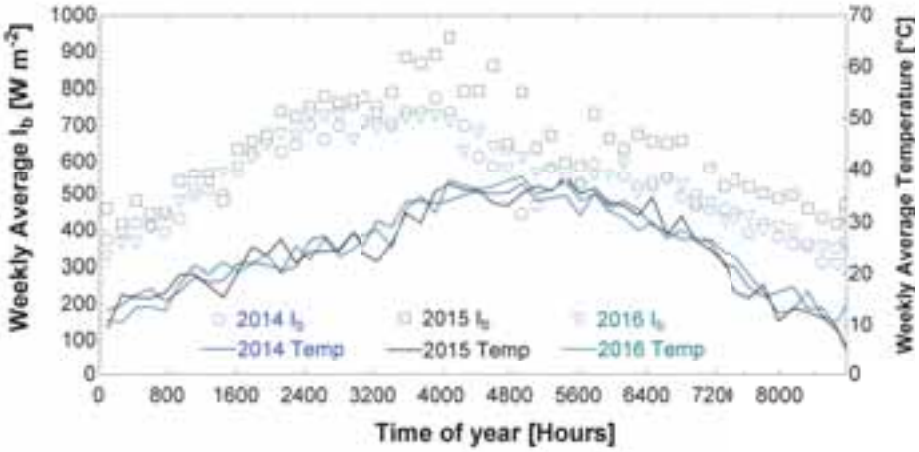

Figure 3: Beam Irradiance and Dry Bulb Temperature for 2014, 2015, and 2016 in Blythe, CA. The beam irradiance is a modification of the direct normal irradiance considering cosine losses of a single axis tracking plane.

4. Results

4.1. Model Validation

The optical and thermal validation and parametric tuning of the dynamic simulation is achieved through comparison of the predicted output of the CSP component (without the retrofit) to the published output data for the Genesis plant. The model calculates the output for every hour. These were summed into each month for comparison to the measured

data. Each of the modelled months was then compared to the measured data. A relationship is found to improve the closeness of fit between the results of physical modeling and the published output of the genesis plant:
Equation 5:

$$Model_2 = c_1 * I_b + c_2 * CSP * T_{amb} + \frac{c_3 * \tan\left({}^{c_4}/_{I_b}\right)}{{T_{amb}}^2} + \tan(c_5 * I_b + c_6 * CSP * T_{amb}) - c_7 * CSP - c_8 * T_{amb} * I_b - c_9 * \sin(c_{10} * I_b)$$

Table 3: Values of coefficients for tuned model simulation

Coefficient	Value
c_1	329.1380845
c_2	0.168203567
c_3	332684.8232
c_4	367.1260423
c_5	329.1380845
c_6	0.168203567
c_7	3.462152074
c_8	12.08652194
c_9	5303.369644
c_{10}	13796.71749

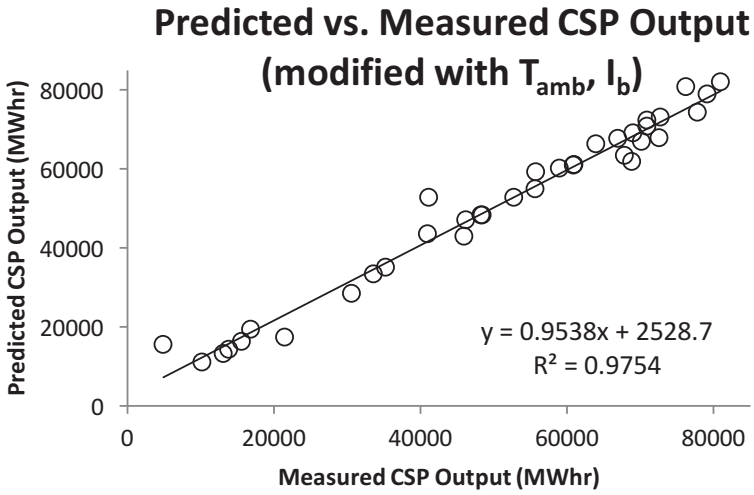

Figure 4: Predicted vs. measured CSP output modified by equation 5 with temperature and irradiance dependencies

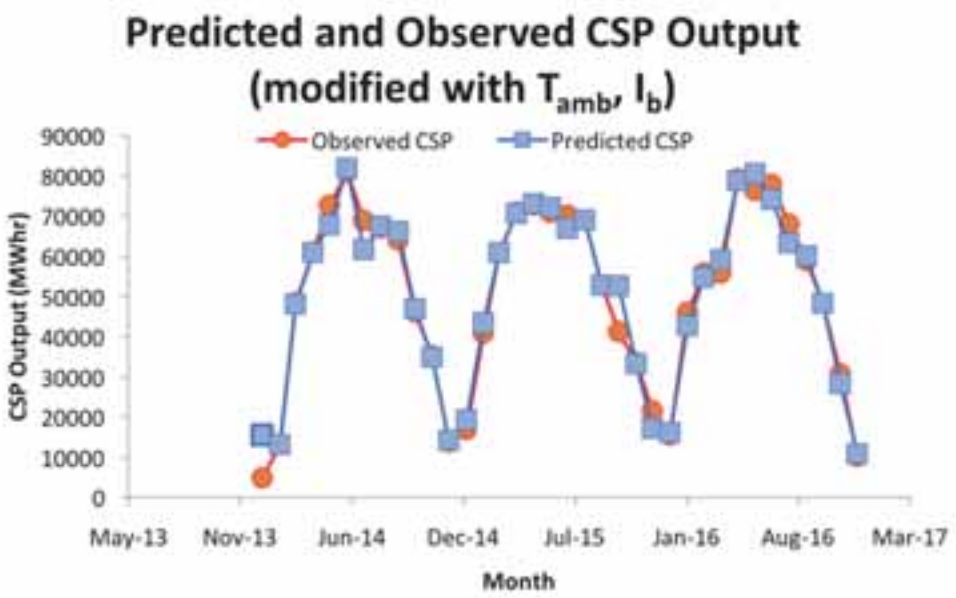

Figure 5: Modelled and Actual CSP Output (MWhr) for each month of the years of operation, modified equation 5.

As shown in **Figure 4**, using average temperature and daytime irradiance the predicted data matches closely with the measured data, with an R^2 value of 0.9754. Accuracy can be improved in sub-annual time periods by using the average data. The predicted CSP output matches the observed data well for each month, as shown in Figure 5.

4.2. Retrofit Yield Estimate

The overall yield of the plant with the retrofit, as well as the baseline measured CSP yield for the three years of operation is shown in Figure 6. The total yield of the plant is increased by 25%.

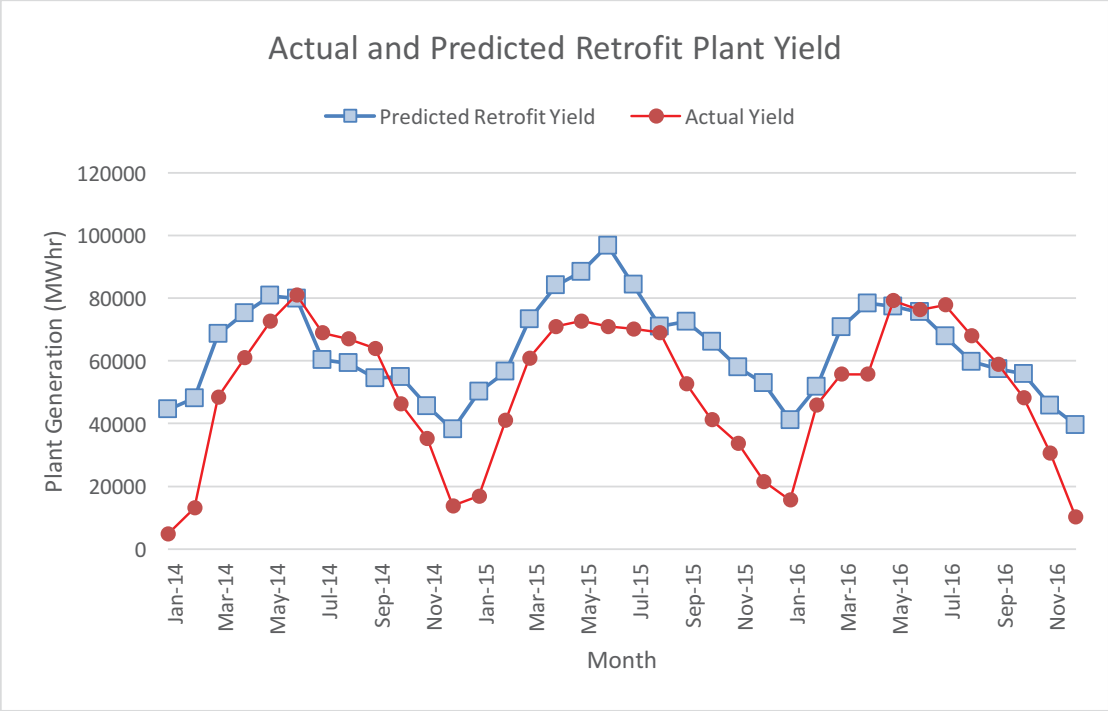

Figure 6: Actual and predicted retrofit(modelled) annual yield of Genesis plant.

5. Conclusions

The addition of a dichroic filter as a secondary optic in a Parabolic Trough Collector allows for the concentration of selected bands of the solar spectrum onto two physically and thermally decoupled receiver targets. This approach is proposed as a retrofit to existing CSP plants using the PTC format, whereby the second receiver is a solar panel. To characterize the performance of this hybrid retrofit, a dynamic simulation model is developed using correlation equations derived from a detailed steady state energy balance model, as a tool to facilitate the calculation of the change in yield of an existing CSP plant with the addition of a CPV retrofit. The overall yield of the plant with the retrofit, as well as the baseline measured CSP yield for the three years of operation is evaluated for a case study CSP plant (Genesis) located in California in the USA, and the results of this analysis indicate that the total yield of the plant is increased by 25%. The magnitude of the performance increase and the comparatively minor equipment investment supports further investigation of this technology as a retrofit to the currently operating fleet of PTC plants, and future work includes experimental validation of a prototype retrofit in a controlled environment in operating solar fields.

The Back Contact in CdTe/CdS Thin Film Solar Cells

Nicola Romeo, Alessio Bosio, Greta Rosa

University of Parma, Viale delle Scienze 7/A, 43124 - Parma

Summary

A barrier-free back contact in CdTe/CdS solar cells is fundamental for obtaining high-efficiency devices. Generally, the back contact is made by depositing a few nanometres of copper onto an etched CdTe surface, where a thin layer of tellurium is formed. In this way, a Cu_xTe film is obtained forming an ohmic contact with CdTe. However, if x exceeds 0.4 the contact is not stable and the solar cell degrades. Several attempts were made to make a barrier-free contact by using low-resistivity p-type materials such as: Sb_2Te_3, As_2Te_3, Bi_2Te_3, MoO_x and ZnTe but the results were not definitive. Still some copper seems to be needed. We used As_2Te_3, Bi_2Te_3 and ZnTe as buffers covered by ~10 nm of copper deposited at 520 K substrate temperature. This kind of contact works very well but only if the final contact is made of a thin layer of platinum covered by a thicker layer of molybdenum. Platinum exhibits a high work function (5.8 eV) and it is thus suitable to make an ohmic contact to the p-type high-conductivity buffer layers. Keywords: CdTe, Back Contact

1. Introduction

The CdTe/CdS solar cell has reached an efficiency of 22.1% [1] which, together with $CuInGaSe_2$ (CIGS), is the highest efficiency obtained for thin film solar cells. This efficiency is comparable with that of the best crystalline silcon solar cells. However, there is something which has not been completely clarified. That is, how to make an ohmic and stable contact to CdTe? Is it necessary to use copper? If yes, how to limit the copper diffusion into CdTe? It is known that, if copper reaches the junction, it can cause short-circuits or it can dope CdS, which becomes insulating. Several attempts have been made in order to avoid the use of copper in the back contact. For example, Lin et al. [2] and Drayton et al. [3] used MoO_3 thermally evaporated onto the CdTe surface as back contact. They find that this kind of contact works well on CdTe made both by closed-space sublimation (CSS) or R.F. sputtering. However, this contact works well if MoO_3 exhibits the right stoichiometry, which is not so simple to be obtained. Another promising material to be used as a Cu-free back contact is iron pyrite [4] but the obtained results are not definitive. In the past, we reported the preparation of a copper-free back-contact to CdTe by using a low resistivity p-type material such as Sb_2Te_3 [5] covered by molybdenum. Despite a high efficiency (~15%) was obtained, we found out that a roll-over is present in the J-V characteristics which is an indication that some barrier still exists at the back-contact. More recently, we used other buffers such as As_2Te_3 and Bi_2Te_3 covered by 5 – 10 nm of copper and we have demonstrated that an annealing at 520 K in air frees tellurium which combines with copper that, diffusing through the buffer, forms a thin layer of Cu_xTe on the CdTe surface [6-7]. If the Cu-diffusion is controlled in order that the x in the Cu_xTe is less than 0.4, then the contact is quite stable over time. It seems that a Cu_xTe (with $x \leq 0.4$) film is necessary to form a good contact with CdTe. In theory, the most suitable contact should be ZnTe since it is p-type, it does not exhibit any lattice mismatch with CdTe and its valence band is aligned to that of CdTe. However, ZnTe thin films generally exhibit high resistivity. We found out that, if ZnTe thin films are grown by radio frequency (R.F.) magnetron sputtering at 300 K substrate temperature and then annealed at 520 K for 20 minutes, their resistivity is lowered from 10^5 Ω cm to 2 Ω cm. In these conditions, ZnTe is suitable to be used as a back contact for CdTe. In any case, in order to make a good contact, a few nanometers of copper (~ 10 nm) on top of ZnTe are necessary in order to form, through Cu-diffusion, a Cu_xTe layer in the CdTe surface. Finally, the last contact on the buffer layer must be a metal which must form an ohmic contact with the buffer layer. We found out that, in order to avoid any roll-over and to have always a fill factor (F.F.) greater than 0.7, we had to use a few nanometers of platinum covered by molybdenum, that is, only platinum which exhibits a work function of 5.8 eV makes an ohmic contact with ZnTe. The same results are obtained if As_2Te_3 or Bi_2Te_3 are used as buffer layers.

2. Experimental

As shown in figure 1, CdTe/CdS solar cells are made up of 4 main layers. As a substrate, a 1 inch square soda lime glass is used. The front contact is prepared by depositing in sequence on the glass 500 nm of indium tin oxide (ITO) and 150 nm of pure ZnO at a substrate temperature of ~ 670 K. ITO is prepared by direct current (D.C.) pulsed magnetron sputtering in an atmosphere of Ar + 2% of O_2, while ZnO is prepared by R.F. magnetron sputtering from a target of pure Zn in an atmosphere of Ar + 10% of O_2. In both cases O_2 has to be minimized in order to avoid any excess of oxygen in the films. CdS is also prepared by R.F. magnetron

doi:10.18086/swc.2017.20.08 Available at http://proceedings.ises.org

sputtering in an atmosphere of Ar + 6% Trifluorometane (CHF_3). This gas contains F, which is freed in the sputtering discharge and, being electronegative, bombards the substrate during the growth of the CdS film. In this way, any excess of Cd or S are removed from CdS during its growth and the film results stoichiometric with a forbidden gap a little higher than that of the film grown without CHF_3 [8]. CdTe is prepared by CSS at a substrate temperature of 773 K. Typical thickness of CdS is 100 nm while CdTe thickness is 6 μm. Before making the back-contact CdTe is treated for 20 – 30 minutes at 690 K in an atmosphere containing 2 x 10^3 Pa of Freon R22, whose formula is $CHClF_3$, and 5 x 10^4 Pa of argon.

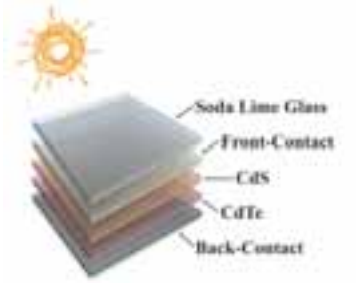

Fig. 1: Outline of CdTe/CdS solar cell.

For the back-contact we experimented four buffer layers namely: Sb_2Te_3, As_2Te_3, Bi_2Te_3 and ZnTe. Those buffer layers are generally covered by 10 nm of copper and the external layer is made by depositing in sequence 10 nm of platinum and 200 nm of molybdenum (as shown in figure 2).

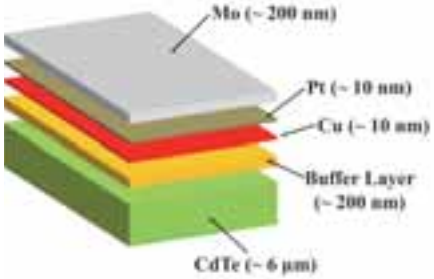

Fig. 2: Scheme of back-contact structure.

Sb_2Te_3, As_2Te_3, Bi_2Te_3 all exhibit a low resistivity on the order of 10^{-2} – 10^{-3} Ω cm but ZnTe exhibits a high resistivity. The lowest resistivity observed on ZnTe is about 10^5 Ω cm, when it is deposited by R.F. sputtering with the substrate kept at room temperature. But, it is enough a 20 minutes annealing made at 520 K in vacuum to lower the resistivity to 2 Ω cm. At higher annealing temperatures the resistivity tends to increase again. The results obtained with As_2Te_3, Bi_2Te_3 and ZnTe are very similar while the efficiency obtained with Sb_2Te_3 is a little smaller. Efficiency for these cells is on the order of 15 - 16% with a fill factor of 0.7 - 0.72. Figure 3 shows the J-V characteristics of the solar cell with a buffer layer of ZnTe and the external contact made with or without platinum. While the short-circuit current density (J_{SC}), open-circuit voltage (V_{OC}) and F.F. are almost the same, a roll-over appears in the J-V characteristic when platinum is not used. From these results it comes out that in order to get CdS/CdTe solar cells with high efficiency without any roll-over:

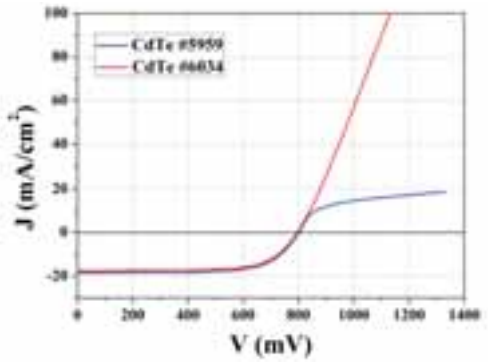

Fig. 3: Sample CdTe #5959: external contact is made without platinum. Sample CdTe #6034: external contact is made with platinum.

1 - Copper is necessary in order that a Cu_xTe layer is formed on top of CdTe. 2 - The diffusion of copper has to be controlled in order to form a Cu_xTe layer with $x \leq 0.4$. 3 - A buffer layer is needed in order to control the Cu-diffusion. 4 - A contact with a high work function, such as platinum (with a work function of 5.8 eV) is needed in order to make an ohmic contact to the buffer layer.

3. Stability tests

Accelerated lifetime tests have been done on solar cells with different buffer layers. Typically, the tests are made by keeping the devices in a box in which the temperature is controlled at 350 K. During the tests the solar cells are exposed to one sun light for about 1200 hours. Almost no efficiency degradation is observed on solar cells with ZnTe buffer layers. There is an initial increase in the efficiency which then stabilizes at values close to the initial value. For the other buffer layers the efficiency decrease from 5% to 10% after 1200 hours of light soaking at 350 K.

4. Conclusion

Here we described a way to make a non-rectifying back-contact to CdS/CdTe solar cells. We found out that the back-contact can contain copper whose diffusion must be controlled by a buffer layer. Finally, we would like to put in evidence that, in order to avoid any roll-over in the J-V characteristic, the contact on the buffer layer has to be made with a high work function metal such as platinum.

Advantages and Limitations of Thermography in Utility Scale Solar PV Plants

Rajat Sethi[1] and Pankaj Kumar[2]

Tata Power Solar Systems Ltd, Bangalore (India)

Abstract

Thermal Imaging has always been used in military applications along with night vision, when there is no sun. Now is the time we need thermal imaging technology to check the performance and find out abnormalities/underperforming areas in Solar PV power plant. While the advantages of thermal imaging are large in number, but it comes with a need of awareness of the concepts of heat transfer and fundamentals of measurement. A lot of research has been done, on how to do the thermal imaging of various type of surfaces, which have glazing or some type of coating over them. This paper tries to summarize the knowledge gained in the field of heat transfer along with the application areas where Infrared (IR) thermography can help us track down high temperature regions (hot spots) in a Utility Scale Solar PV Plant. This paper will also serve as a quick reference guide for the Solar industry engineers for a fast set up, measurement and understanding of Thermographic Instruments. For the analysis purpose, a 100MW Utility scale solar site and few rooftop solar projects in India were chosen to collect the data and for taking the measurements.

Keywords: Thermal Imaging, Performance of PV plant, Hot Spot, Heat Transfer, IR Thermography, Reference guide

1. Introduction

Numerous techniques are being used to measure the performance of components in a PV plant. Monitoring systems come into play, starting from the string level/array level data and it goes till current reaches the grid. Sensors are used to measure temperature of modules, ambient temperature, Irradiance, wind speed, wind direction and also in the electrical and electronic equipment to keep a check on the performance and operation. The solar industry has started using Infrared thermography for finding the underperformance in their modules and to narrow down the faults to specific cells (Hot Spots). It is also being used for checking the uniform oil flow in heat exchangers of transformers and check whether the oil is circulating as expected or there are regions of blockage by seeing the thermal image of the equipment. Similarly, this can be used to check spark or loose contacts at isolator or evacuations points or substation level of a solar power plant. So, a lot of early failures can be detected.

To check the performance of the components, one needs a good understanding of materials, their glazing behavior as well as knowledge of heat transfer subject. Every object can emit, reflect and transmit radiations in different band of the electromagnetic spectrum, depending on the properties of the material and the temperature of the object. Sun is emitting electromagnetic (EM) radiations in a broad range of Infrared (IR), Visible, UV and X-ray, etc. Every object above 0 K (Kelvin) emits and receives energy (Plank's Law). In IR thermography, we use the infrared emitting capacity of a body which most of the time is a strong function of temperature (Stefan-Boltzmann law). A thermal imager can capture the IR radiations emitted and can convert the IR data in high and low temperature regions using visible spectrum on our display screen.

2. Working of Thermal Imaging Technology:

2.1 Background

In the last 50 years, there have been three major developments in area of thermal imaging and these are: (1) Scanners or Scanning Systems, (2) Pyroelectric Videocon's (PEVs), and (3) Focal Plane Arrays (FPAs). FPA technology is more popular these days due to advancement in semiconductor industry and because of the accuracy possible with them. The function of the equipment is to detect the infrared radiations emitted by

doi:10.18086/swc.2017.20.09 Available at http://proceedings.ises.org

an object or equipment (known as Target). Corresponding to the Radiosity (sum of radiations, emitted, reflected and transmitted per unit surface area) of the object, there is induced voltage or change in resistance of semiconductor array. These signals are then read by the electronic circuits present in the equipment and a thermogram is created which is visible to us on the display screen of equipment (Fig. 1). Each pixel of thermogram inherits the point to point temperature measurement on the surface of the object. This is done by an array of semiconductor detectors, which are placed on a plane and are highly sensitive to temperature. More is the density of plane of the array; more will be the resolution of the thermal image and hence higher accuracy of measurement. Typical arrays used are 256x256, 320x240, etc. For the current analysis, we have used thermal equipment of Testo and Fluke companies, and used their respective software for the analysis.

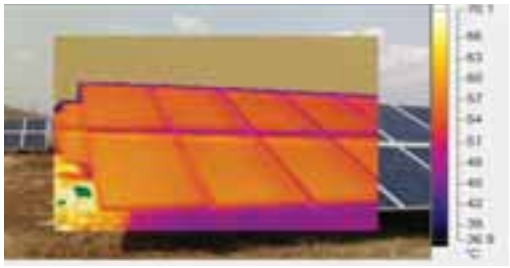

Fig.1: Thermal image distinguishing the high and low temperature regions with the help of the visible spectrum, white and yellow being the highest temperature region while black and blue indicating a lower temperature range. (Image taken at one of the megawatt scale solar plant in India)

2.2 Sun's Spectrum

Sun has always been the source of energy for earth. From photosynthesis to blowing wind, it is all because of the sun. In recent years, we have learnt the importance of using sun's energy directly instead of stored forms like fossil fuels, as we don't have to spend extra money for their extraction and purification. We just need technology, which can convert Sun energy directly to electricity. Solar PV technology is at the forefront of all renewable energy sources. As per International Energy Outlook 2016 by the IEA, around 30% of total electricity generation in 2040 will be from Renewable sources of energy (International Energy Outlook, 2016). In another Annual Energy Outlook report 2017 of the IEA, solar capacity addition is projected to be the primary replacement of retiring coal power plants between 2030 and 2040 (Annual Energy Outlook, 2017). Utilizing sun's energy will be the most economical and most sustainable option in coming years. The more we know about the sun and the ways to utilize its energy, the better it will be for us.

The photons coming from the sun, carrying this energy, have a wavelength varying from high energy X-rays and gamma rays to visible light to the infrared and radio. However, here on earth, we receive only a certain portion of the spectrum. Sun's spectrum (shown in Fig.2) is similar to that of a spectrum of black body at 5800K as mentioned by Duffie and Beckman (Duffie and Beckman, 2013). Out of these radiations, around 44% of radiation are in visible range, i.e. 400-700 nm or 0.4-0.7 μm and 49% in the infrared region.

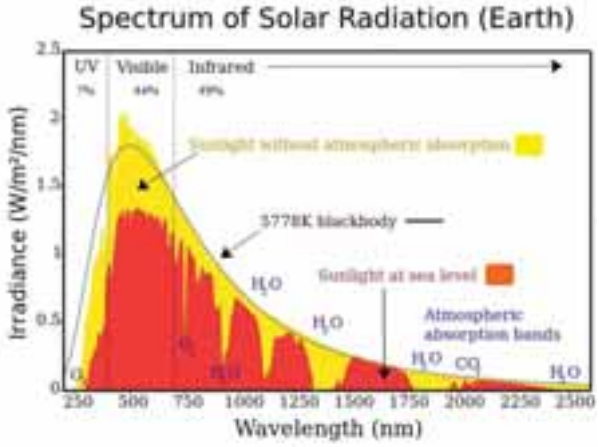

Figure 2: Sun's Electromagnetic Spectrum (Nick, wikipedia)

2.3 Infrared Radiations (IR)

Any Radiation falling on any object is never perfectly absorbed, transmitted or reflected. Always, two or all three of these phenomena happen at once. For a typical transparent glass, 92% of the radiation are transmitted, 6% are reflected at the glass surface and 2% are absorbed. In the solar PV modules, the glass used is extra clear glass with low iron oxide content, which helps in less absorption of light. The transmission curve of glass also shows us that the glass is somewhat transparent in the short waveband and opaque in the long waveband. All these phenomena are also true for IR falling/transmitting through the glass surface.

When we see a surface, we can see the radaitions being absorbed by it along with the radiations reflected or transmitted by it. Neither the reflected nor the transmitted radiations, provide any details about the temperature of the object. Only emitted radiation coming out of a body give us a sense of temperature. This radiation being emitted by a body is directly dependent on the emissivity of the surface.

In thermography, the biggest task for a professional is to separate the reflected and transmitted part of radiation from the emitted radiations. Glasses are typically transparent to short IR wavelengths and opaque to long IR wavelengths. Our atmosphere is transparent in two regions of wave i.e. visble, infared and radio wave bands, rest of thermal spectrum is absorbed by water vapors, carbon dioxide and other gases (Fig.3).

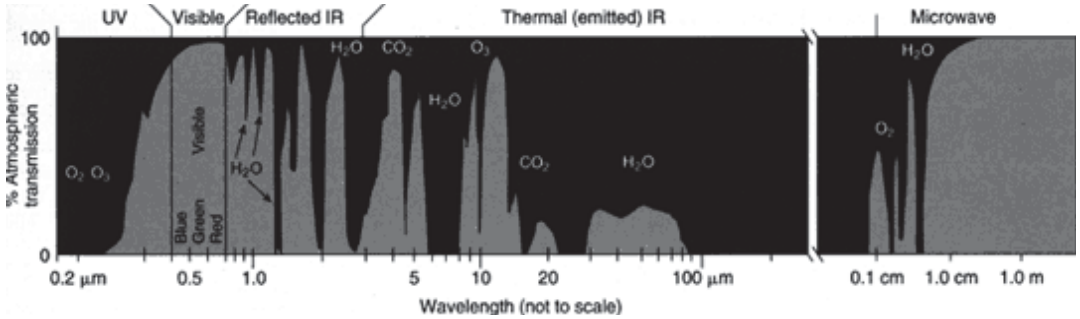

Fig.3: Absoption spectrum of earth's atmosphere. Chemical notation (CO2, O3) indicates the gas responsible for blocking sunlight at a particular wavelength. (Earth observatory, NASA)

2.4 Materials and Emissivity measurement

A black body is a perfect absorber and emitter of radiation. The emissivity of a surface represents the ratio of the radiation emitted by the surface at a given temperature to the radiation emitted by a blackbody at the same temperature. The emissivity of a surface is denoted by ε, and it varies between zero and one, $0< \varepsilon<1$. Emissivity is a measure of how closely a surface approximates a black body, for which $\varepsilon=1$ (Yunus A. Çengel, 2002).

For better measurements, we also need to know about the absorption property of a body. Absorptivity is a measure of how much fraction of the radiation falling on the object/medium is absorbed by it. Radiation falling on a surface/medium could have encountered three phenomena (a.) Absorption (b.) Reflection (c.) Transmission (explained in eq.1). The fraction of these will vary depending on property of the object/medium.

From the first law of thermodynamics we can say that,

Energy Incident = Energy Absorbed + Energy Reflected + Energy Transmitted

1 = (Energy Absorbed + Energy Reflected + Energy Transmitted) / (Energy Incident)

Or, $1 = \alpha + \rho + \tau$ (eq. 1)

Where, α is Absorptivity, ρ is Reflectivity and τ is Transmissivity of the material.

For finding the temperature of any object, there are equipment available. There are Infrared thermometers, which can give us point-to-point temperature readings and there are thermal imagers, which gives us the 2D image of the surface showing hot and cold regions with different colors/contrast. Many Instruments from various manufacturers like Fluke, Meco, Testo etc. have come into the market. But, measurements made by these instruments do not make sense till accurate values of material/media properties, external factors are given as input first.

For example: To find out any hotspot in a string or array we need to have knowledge of emissivity of silicon material (assuming multi crystalline silicon solar cells) and how the upper glazing is affecting the measurement. All the metals are good conductors of heat and electricity, so they don't emit a lot of radiation

in IR region and also they don't emit the radiation from the same place where radiation has fallen. Inside metals molecules vibrate quickly and energy gets conducted to all surrounding molecules, which results in lesser values of emittance. Metals also reflect a part of incoming energy/light falling on it. This kind of behavior is not shown by semiconductor materials. They absorb the radiation and emit it in the IR region. Most of the radiation is emitted from the same place where incident radiations fell. So, most of the time Semiconductors and insulators have higher emissive values. Table 1 lists the common materials encountered while doing thermal imaging along with their emmissivity values.

Tab 1: List of common materials and their emissivity.
(Fluke, Emissivity of materials), (Transmetra, Emissivity for various surfaces)

Sr. No.	Material	Emissivity	Sr. No.	Material	Emissivity
1	Aluminum Foil	0.04	26	Mild Steel	0.20 0.32
2	Aluminum Highly Polished	0.039-0.057	27	Paper	0.93
3	Aluminum Heavily Oxidized	0.2-0.31	28	Plastics	0.90-0.97
4	Asbestos board	0.96	29	PVC	0.91-0.93
5	Asphalt	0.93	30	Silica	0.79-0.85
6	Brick, red rough	0.93	31	Soil	0.79
7	Brick, fireclay	0.75	32	Steel Polished	0.07
8	Cast Iron, newly turned	0.44	33	Steel Galvenized old	0.88
9	Cast Iron, turned and heated	0.60 0.70	34	Steel Galvenized new	0.23
10	Cement	0.54	35	Tin unoxidized	0.04
11	Clay	0.91	36	Titanium polished	0.19
12	Coal	0.8	37	Tungsten polished	0.04
13	Concrete	0.85	38	Water 0.95 0.963	0.95 0.963
14	Cotton cloth	0.77	39	Wood Beech, planned	0.935
15	Copper electroplated	0.03	40	Wood Oak, planned	0.885
16	Copper heated and covered with thick oxide layer	0.78	41	Wood, Pine	0.95
17	Copper Polished	0.023-0.052	42	Wrought Iron	0.94
18	Copper Nickel Alloy, polished	0.059	43	Zink Tarnished	0.25
19	Glass smooth	0.92 0.94	44	Zink polished	0.045
20	Human Skin	0.985	45		
21	Ice smooth	0.966	46		
22	Ice rough	0.985	47		
23	Iron polished	0.14 0.38	48		
24	Iron, plate rusted red	0.61	49		
25	Mercury liquid	0.1	50		

Note: As we know, emissivity of a given material will vary with temperature and surface finish, the value in these tables should be used only as a guide for relative or differential temperature measurements. The exact emissivity of a material should be determined when high accuracy is required.

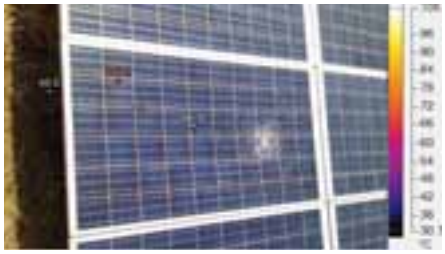

Fig. 4: Optical Image of a damaged module.

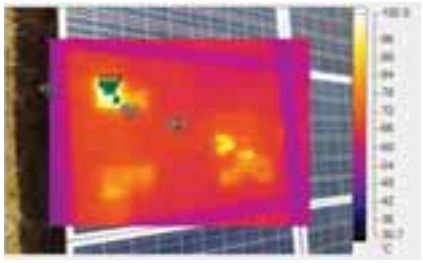

Fig. 5: IR Image for damaged module (fig.4) with hot spot and high temperature region.

In IR thermography, camera sensor takes the IR radiations emitted by a body as its input to calculate the temperature of the body. These instruments most often need the ambient temperature values for reference temperature and then calculate the temperature of materials/medium accordingly. For silicon, two values of emissivity are given in standards 0.8 and 0.9, depending on glazing. Assuming the value of emissivity as 0.8 and setting the measurement range at 35 to 75 degree centigrade in the equipment, we were able to get better results. For cross checking our measurement, we had used a thermocouple at the back of one of the solar modules.

3. Application of Thermography in Solar PV Plants

Thermal imagers will pin point us in the direction where fault/abnormality is present. By using electrical instruments like Multimeter, Clampmeter and Resistance measuring units, we can get into the root cause of an issue. Suppose there is an extra heating in one phase out of the three, thermal imager will direct us to that phase, now to find out the reason for heating, we need to check the amount of current flowing as well as the resistance in the circuit. A list of solar plant areas, where thermal imaging is used, is mentioned below:

3.1 Application area: To check underperforming solar strings and arrays:

Solar modules are the main component of energy conversion. The plant‘s efficiency depends primarily on this conversion process. We can also calculate overall solar plant efficiency as the product of all the efficiency in the process (as shown in eq. 2). For the efficiency calculation, we must know the losses in each step of conversion.

The losses in a solar plant are as follow:

1. Loss due to temperature (The rated power of modules is calculated at 25°C) = L1
2. Dirt or soiling on face of solar module (Often, Dirt loss=5-10% or 0.05) = L2
3. Manufacturer's tolerance (3-4% or 0.03, given by the manufacturer) = L3
4. Voltage drop through AC and DC cabling = L4
5. Inverter efficiency/loss = L5
6. Shading = L6
7. Tilt angle of the solar modules = L7
8. Orientation of solar modules = L8

Overall efficiency= (1-L1) x (1-L2) x (1-L3) x (1-L4) x (1-L5) x (1-L6) x (1-L7) x (1-L8) (eq. 2) (GSES,2013)

Using this only, we also calculate the Energy yield of the plant,

Energy Yield = Irradiation x Module rated power x Losses (as efficiencies)

Using a thermal imager, we can calculate the thermal loss of the module and if there is any hotspot areas on the panel.

In a solar panel, generally the cell temperature is 20-25°C higher than the ambient temperature because of continuous heat generation at cell level. So, in the countries, which lie in between the tropic of cancer and the tropic of capricon, this thermal loss can reach upto 20% (considering ambient temperature can go upto 50°C). The performance of these semiconductor solar cells is highest when the temperature is 0 degree C,

which is not usually the case. This is one of the reasons that a place with high radiation need not be generating the most amount of energy, compared to a place with low irradiance and low temperature.

So, thermal cameras can be used to check the healthiness of modules and for each degree higher temperature, we lose roughly 0.3-0.5% of power output of cells. The Supervisory control and data acquisition (SCADA) systems used currently will tell us the strings which are not giving full output and combined with thermal cameras we can easily distinguish the faulty or damaged module which are making the loss.

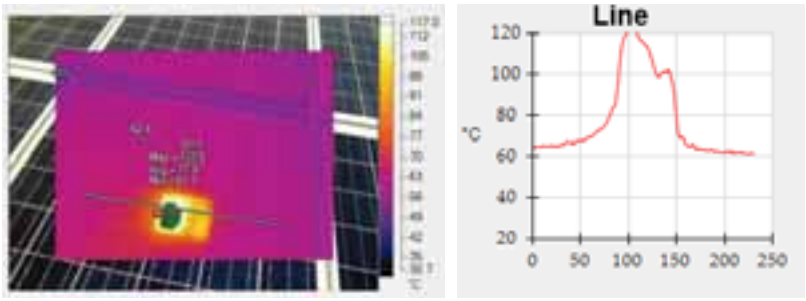

Fig 6: The image on left shows the hot spot on a module and the damaged cell with temperatre going upto 120°C (Shown in right side figure with line graph)

3.2 Application Area: String Monitoring Unit (SMU)/ String Combinor Box Monitoring (SCB)

These days SCADA systems are primarily used to check the string current in a large solar plant. Burning issues in SCB/SMU are also common. At places around the world, fire incidents have also occurred because of overheating issues at the terminal inside the SCB. On many occasions, it is found that connecting terminals/joints are getting heated, but the temperature is not high enough that they will glow brightly and it will become visible to the naked eye. The temperatures will go upto 200-250°C before the melting and burning of plastics/rubber happen on wire insulation. Most plastics used are fire retardant but not fire proof, so till date, early detection is the only key to avoid these accidents. Thermography being a non-contact type technique, we can easily distinguish the overheated points, which may be because of any of the reasons like, loose connection, dust in between the joints, some malfunctioning etc. The same is true for isolator panel boxes also on AC and DC sides.

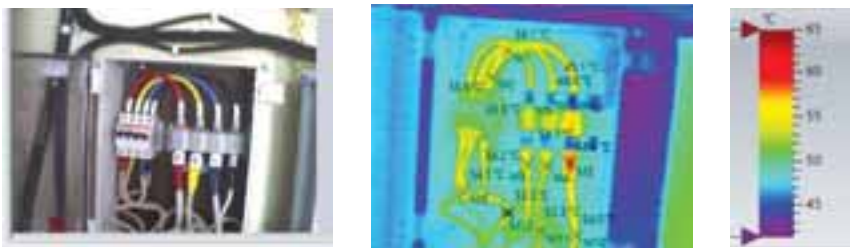

Fig 7: Normal and Thermal image of a typical Isolator Panel of a rooftop solar plant. In centre image we see that blue phase wire temperature is roughly 5°C higher than wires of remaining two phases.

Action plan for relative temperature difference between phase connections:

40°C or more : Failure can happen at any time and corrective measure should be taken immediately

20°C-40°C : Corrective measures to be taken at earliest to avoid failure in coming hours/days

20°C : Corrective measure required to prevent from failure in coming weeks

Below 20°C : Chance of failure; measure should be taken in next scheduled maintenance activity

3.3 Application Area 3: Power Conditioning Unit (PCU) / Inverter Level Inspection:

Inverters available in the market now (2016 onwards) have efficiencies of 95-98%. The remaining are the conversion losses which happen in electrical and electronic components of the inverter. High quantity of current coming from PV panels enters the inverter as Direct Current (DC) and we get 3-phase Alternating

Current (AC) at the output. In recent inverter models, it is hard to see insulated-gate bipolar transistor (IGBT) from outside, which is responsible for DC to AC conversion. This is adopted because of safety features and Ingression protection standards like IP 65, IP 66 etc. In some older Inverter models (prior to 2014-15), checking healthiness of IGBT's against overheating was possible with thermal cameras. We can also check the heat emitted by bus bars, circuit breakers and at other connection points and can tell whether there is something abnormal or not. In some cases, because of less space below Inverters and Junction boxes, wires are bent in 'U' shape, This causes a lot of resistance to current flow and hence heating of wires. We can inspect such areas with thermal cameras.

3.4 Application Area: Switchyard and Substation Area:

Switch yard is the area, where the same power, which is generated by a solar plant, is transmitted to the state electricity board substation or transmission company. Substation steps up or steps down the voltages coming from the generating station. In both substation and Switch yard areas, thermography has huge application because of the criticality of the equipments used. The components include circuit breakers of various types, isolators, isolated phase buses, T joints, straight joints, bolts on bus bars, various fuses, transformers, etc. Heating of bolts, moving contact parts, etc. in substation are often checked with thermal cameras. The fault or failure of any of the components can lead to significant breakdown and hence loss of power. To confirm the healthy functioning of these areas, in terms of smooth power evacuation without excessive heat being generated on isolators, at bus bar connection points, we use thermal cameras. Depending on the material used like bus bars are generally aluminium rods; we can set our instrument for the measurement. For high voltages, aluminium is the most preferred choice because of conductivity, strength and corrosion resistance.

This not only saves time but also gives us confidence about the smooth operation of the plant.

Fig 8: Visible and infrared image of isolator and bus bars.

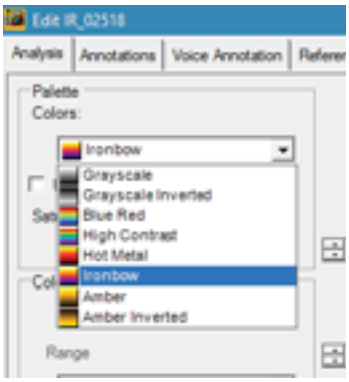

Fig 9: Palette options available in softwares to have better visual effect. (Screen: Fluke smart view software)

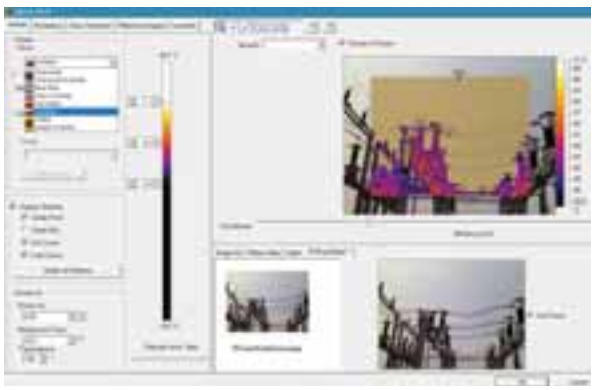

Fig 10: Fluke Smart view software window with image of a typical isolation yard.

Note: When using the software for analysis, we need to put correct emissivity one by one for materials under observation to see correct values of temperature. One should not conclude on basis of half-baked information. One can also choose different kind of palettes as per one's ease and visual advantage (Fig 9).

4. Advantages and Limitations of IR Thermography

4.1 Advantages of Thermography (Tequipments.net)

- It uses non-contact type of measuring technique, which makes it safe.
- It is fast, accurate and easy to use.
- It helps in detecting situations of electrical unbalance or overloads.
- It can be used for electrical, mechanical and other building envelope related work.
- It helps in fast identification of loose, corroded connections even if they are not visible to naked eye.
- It helps in developing the Inspection program for various equipment and machineries.
- It can be driver in making predictive and preventive maintenance schedules.
- It can be used to check, heating in electronic circuit board and narrowing down to faulty area.

4.2 Limitation of Thermography

- High reflecting metals: Using thermal imaging becomes tricky, when one takes measurement of isolation yard on a sunny day. Unlike coal thermal stations or other energy generating stations, in solar plants peak generation is in the hours, when the sun is shining bright. At this point of time, the metals also reflect a lot of visible light. The expert has to carefully choose an angle, where sun interferes least and try to get more radiations, which are emitted by the target equipment under consideration. This can be done by varying the emissivity value or using some correction factor.
- Trapping of IR radiation inside glass enclosures: Most of the thermal cameras available today can take the measurement in short and medium infrared region. Filters are available to take care of interference by glazing and other radiations.
- Weather dependence in solar plant also plays a role. Recommended time for taking measurement is peak sunshine hours. (between 11 am -2 pm in India)
- Significant change in readings, when angle of measurement change. The recommended practice is to take the measurement at an angle of 90 degree (normal) to the surface of object. If we take the image at acute angles, then, the measurement will be incorrect.
- When wind blows over a surface, a boundary layer is formed which effects the heat transfer. Recommended practice is to take the measurement in still air conditions and at steady state conditions.
- IR themography takes the instantaneous measurement and not the gradient. In some cases, when temperature is rising and falling with time, we cannot find the rate of change of temperature directly. In those areas, thermocouples are best suited to analyze the trend with time.
- For small rooftop solar plants, the cost of thermal equipment is high in comparison to the investment one has done. So, it is common practice to ask an O&M company, which has taken annual maintenance contract to do the themographic exercise once a year. This has more application in large scale utility solar plants, where electricity is directly going to national grid and one can not afford any failure in any components.

4.3 Other Application Areas:

- Used commonly by Energy Auditors to find the areas of heat loss and poor insulation in processing industry and manufacturing industry.
- Used to find oil/gas leakages from the vessels.
- Used by civil work departments and building professionals to check the structural integrity and sometimes the moisture inside the roof/wall etc.
- Military use this technology along with night vision cameras in aircraft and auto guided missile systems.
- Used oftenly, in industries where lot of motors and rolling machines are present. This technology helps in planning their maintenance schedules.

5. Conclusion

As solar energy sector has shown its dominance in last few years, with accelerated growth rates; in coming years, our life will be surrounded by equipment, machines and homes, running completely on solar energy. This paper has tried to summarize the learning from megawatt scale solar plants in India, along with the general understanding about IR thermal imaging technology. Most suitable person for thermal inspection activity will be an engineer with basic understanding of concepts of heat transfer like radiosity, boundary layer along with some knowledge of material science. The awareness of parameters like background temperature, ambient air temperature, relative humidity, information on effect of wind or convection heat transfer, emissivity properties, effect of sun, ideal distance of target, angle of incidence, will make the measurement highly accurate. This paper has tried to touch upon these above parameters with field examples and learnings from the SPV power plant. Few general thumb rules are also suggested, on the how to decide the criticality and frequency of maintenance activity, based on the temperature readings (sub-section 3.2). This paper will also serve as a reference guide, for using thermal imaging in different solar power plants and other areas of energy efficiency.

Correlation of Leakage Current Pathways and Potential Induced Degradation of CIGS Thin Film Solar Modules

Sebastian Voswinckel, Viktor Wesselak, Sven Münter, Lukas Gerstenberg
Institute for Renewable Energy Technologies/ University of Applied Sciences Nordhausen (Germany)

Abstract

The life time of over 20 years is a unique feature of PV modules. Because of weather exposition and the system design of PV power plants system induced degradation can occur. In case of CIGS PV modules it is called Potential Induced Degradation (PID). The rate of degradation depends on the transferred charge, which can be determined by measuring the leakage currents because of the potential between module connectors and ground. Thereby only the sum of the leakage current can be measured, but there are different leakage current pathways. The main pathways are through the cover glass and the back glass/ material. For a real lifetime prediction the correlation of climate chamber tests and outdoor conditions is necessary. A method for measuring the exclusive leakage current pathway through the cover or the back glass was developed. The encapsulation foil enables the possibility to deactivate the leakage current pathways which is more harmful in relation to PID of CIGS PV modules.

Keywords: CIGS, Potential Induced Degradation, leakage current, transferred charge

1. Introduction

Like all other module technologies, thin film solar modules (TFSM) are exposed to the environmental conditions during lifetime. Because of the repeated long term environmental stress (e.g. temperature changes, UV radiation, moisture ingress, mechanical stress etc.) the material properties may change and loss their functionality. Furthermore, the environmental stress can accelerate the movement of volatile components of materials or semiconductor layers. Especially reactive sodium ions are suspected to move into the semiconductor layers. This can be lead to reversible or irreversible degradation of thin film solar cells (Osterwald et al., 2003). However, because of the module wiring and the inverter concept a potential between module connectors and ground can occur (Schmidt, 2009). The result is a leakage current between these two connection points. In principle this effect can be observed for all module technologies. In this context, the specific effects, strategies for prevention and notations are different for each technology. In case of crystalline silicon the term used is Potential Induced Degradation (PID). In case of TFSM TCO corrosion occurs for superstrate modules and PID can be observed for CIGS modules (substrate modules). Note, the PID effect for CIGS modules differs from the PID effect for cSi modules. In both cases a sodium ion diffusion is suggested to reduce the efficiency. But for CIGS modules a diffusion into the CdS/CIGS interface is supposed (Fjällström et al., 2013) whereas for cSi modules the anti-reflection coating plays the main role (Naumann et al., 2012).

1.1 Module Technology

Thin film solar modules (TFSM) represent a young technology in comparison to crystalline silicon solar modules. There are two main production technologies for TFSM: Superstrate and substrate modules. As shown in Fig. 1, the layer deposition of superstrate modules starts with the front contact on the cover glass. CIGS thin film solar modules are produced in substrate technology. The layer deposition starts with the back contact on the back glass. The CIGS absorber will be deposited by co-evaporation, where the CIGS is formed during the deposition or by a deposition reaction, where a precursor will be deposited and the CIGS formation occurs during a second step (Scheer and Schock, 2011). On top of the CIGS layer a CdS buffer layer will avoid

doi:10.18086/swc.2017.20.10 Available at http://proceedings.ises.org

shunting paths followed by transparent intrinsic ZnO (i-ZnO) and an aluminum doped ZnO (ZnO:Al) layer as front contact. Because of the material consumption of the CIGS the absorber is p-type whereas CdS and the

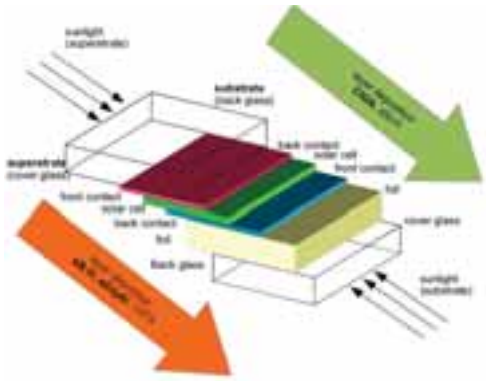

Fig. 1: Order of layer deposition for substrate and superstrate thin film solar modules.

ZnO layers are n-type.

Between the single deposition steps a structuring via mechanical tools or laser will separate the homogeneous layers into single cells. Because of the structuring between the single deposition steps a monolithical series connections as shown in Fig. 2 will occur. These created scribes are specified in order of the structuring step as scribe P1 to P3. The first scribe separates the back contact, P2 the CIGS/ CdS/ i-ZnO layer and P3 the separate the front contact and the CIGS layer again. Following by this a series connection of the solar cells is realized. However, scribe P1 leads to direct connection between CIGS and back glass. For the substrate soda lime glass with a high content of earth alkali ions is used. As indicated in Fig. 2, a fraction of selenium which is part of the absorber formation reacts with the molybdenum back contact to $MoSe_2$. This is the precondition for a low resistant contact on the back side of the cell.

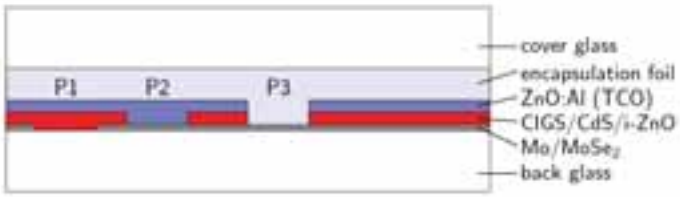

Fig. 2: Simplified illustration of layer order and solar cell connection.

1.2 Potential Induced Degradation of CIGS thin film solar modules

In PV power plants a series connection of PV modules is called module string. The aim of the series connection is to scale up the power of the PV system with ohmic losses as small as possible. This is realized by high system voltages. The system voltage V_{sys} can be measured between the first and the last module in a module string, as shown in Fig. 3. Typical system voltages in Europe achieve up to 1000 V DC, in some cases up to 1500 V DC.

In addition, a voltage between the positive and negative pole of the module string occur. The grounding situation of the module string and the type of inverter influence the amount and sign of this voltage (Schmidt, 2009). For ungrounded systems a voltage of -½ V_{sys} can be measured between the negative pole and ground. In case of the positive pole + ½ V_{sys} can be measured. In dependency of the type of inverter the amount of this voltage can be shifted to higher negative voltages and lower positive voltages or vice versa. Normally only in case of inverters with transformers an external grounding of the module string is possible. For the grounding of the negative pole a voltage of $+V_{sys}$ can be measured between the positive pole and ground, and no voltage between the negative pole occurs. For the grounding of the positive pole the opposite is the case. This voltage is

the reason for an accelerated migration of alkali ions and lead to PID. Furthermore, because of this voltage a current flow between module connector and ground can arise, the so called leakage current. The amount of the leakage current depends on the potential between the module connectors and ground. The leakage current is suspected to be an indicator of the progress of PID. However, the conductivity of the module is influenced by temperature and humidity. Following by this, the influence of environmental conditions in relation to PID has to be taken into account.

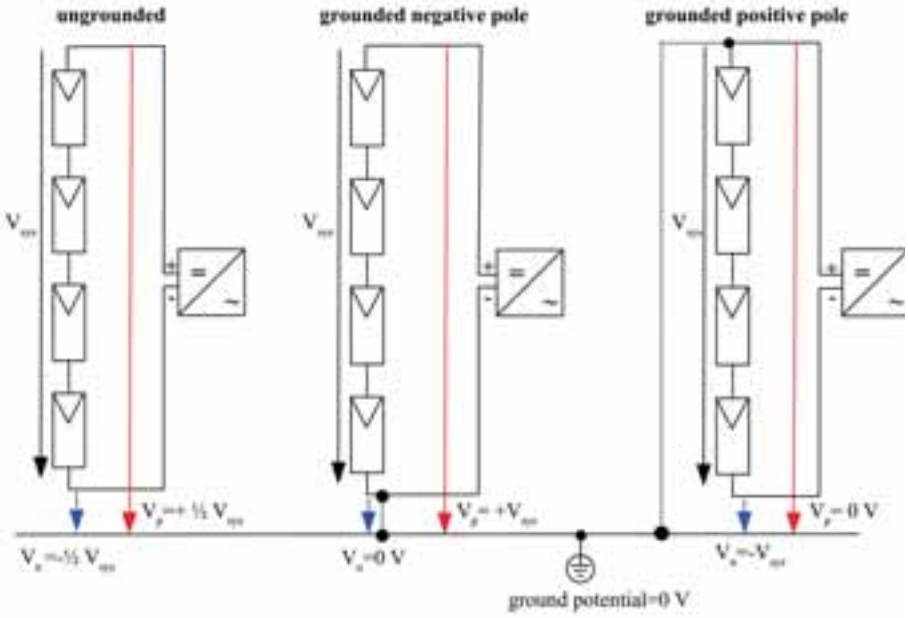

Fig. 3: Potential against ground for different grounding situations.

There are mainly four leakage current pathways in a module. The leakage current from the solar cell through the encapsulation foil and the cover glass is called I_1. The leakage current through the encapsulation foil, the edge sealing and the frame is called I_2. If the leakage current flows through the interface of the encapsulation foil and back glass and the edge sealing it is called I_3. Leakage current I_4 flows from the solar cell through the back glass. From Ohm's law it is known that the current takes the path of least resistance. This depends on the conductivity of the materials and the influence of humidity and temperature. So this lead to the question weather the current through the cover glass is most harmful or one of the others.

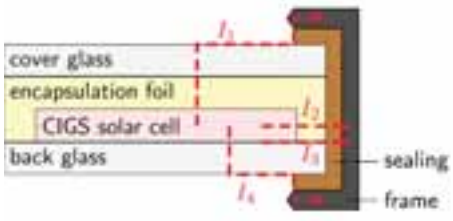

Fig. 4: Simplified illustration of the main leakage current pathways of a CIGS thin film solar module.

The aim of this study is to prove the origin of the leakage current for CIGS photovoltaic modules. The leakage current can take several different pathways. Fig. 1 shows the four main pathways for a CIGS thin film solar module. Especially the leakage current through the cover glass and through the back glass are from special interest. For a correlation of accelerated aging tests in climate chambers with outdoor exposure in the field the knowledge of active leakage current pathway is necessary. Thereby, the path activation depends on the surface

and the volume conductivity of the cover and back glass as well on the encapsulation foil. Especially the surface conductivity is influenced by the environmental conditions. Consequently, a method for modeling the active leakage current as a function of environmental conditions will be shown. Therefore, lab tests are performed to correlate the outdoor measured leakage current to indoor measurements.

2. Experimental

2.1 Outdoor Test Facility

On an outdoor test facility six CIGS TFSM with two different encapsulation foils are mounted on individually insulated racks. The semiconductor device of the modules is identical. These are framed glass glass modules. However, for each foil type one module is connected with an external applied voltage of -500 V and -1000 V between module connectors and ground. The remaining two modules are mounted as reference modules, without any applied external voltage. So degradation effects because of metastable defects can be detected and differentiated from the degradation which are investigated in this study. Every ten seconds the leakage current is measured through a shunt resistant. The schematic circuit diagram of the test setup is shown in Fig. 5. Thereby,

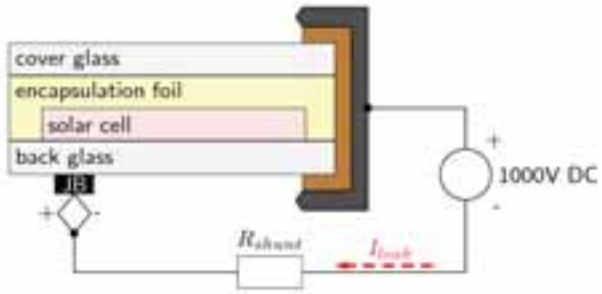

Fig. 5: Standard test setup for accelerated aging tests.

the problem that only the sum of all leakage currents can be measured occurs. But depending on the surface humidity the main leakage current pathway will change. Therefore, in addition climate chamber and water basin tests has to be done to assess the actual pathway. In order to simulate real operating conditions the external applied voltage is switched off during night and irradiations below 50 W/m^2. During the test, the modules are operated near their maximum power points. The climate conditions are measured directly adjacent to the test rack by a weather station. So at the end of the tests for each climate condition the leakage current and the pathway can be classified.

2.2 Water basin tests

For analyzing typical leakage current magnitudes depending on the leakage current pathway three different contacting methods are realized. To measure current I_1 only the cover glass is connected with an external voltage supply. In this case the current has to be overcome the resistant of the encapsulation foil and of the cover glass. However, this electrical contacting method corresponds with a wet surface of the cover glass in the field and a dry back glass surface. This can occur if it starts to rain.

In principle the same method is used to measure exclusively the current I_4 through the back glass. For this purpose only the back glass is connected. In the field this condition arise if there is dew on both sides of the module and sun is rising. The sun is drying the cover glass where the back glass is still wet. Consequently, in the third case both sides are connected to the voltage source.

All setups are realized in a water basin, as shown in Fig. 6. In the first case only the cover glass is wetted, in the second case only the back glass is wetted and for the sum of the currents the whole module is submerged in water. Furthermore, in the field a wide range of temperature for different moisture rates on the module can be

observed. So the water basin is heated during the tests. The result is a temperature dependent leakage current, which can be clearly attributed to one leakage current pathway.

Water basin tests are suitable to realize a homogeneous contact on the cover or back glass as well as for the hole module. In climatic chamber tests the contact is often realized by metal plate. A gap between plate and glass can occur. In the gap water vapor can condensate and lead to local reduction of conductivity (Voswinckel et. al., 2015). With a homogeneous water film the contact can be improved and local reductions of conductivity can be neglected. With an external heat source the water can be tempered. Following by this the leakage current behavior for different conditions which correspondent with real operating conditions and accelerated aging tests can be simulated and verified. For accelerated aging tests high temperatures are needed. This leads to evaporation of the water in the basin and to reduction of the water level, which can lead to a lack on electrical conduction. So it is obvious that this test setup is only appropriate for short testing times and the analysis of special operating points. For the analysis of the aging behavior accelerated aging tests in climate chambers are necessary. Note, the typical test duration of an accelerated aging test is between one and four weeks.

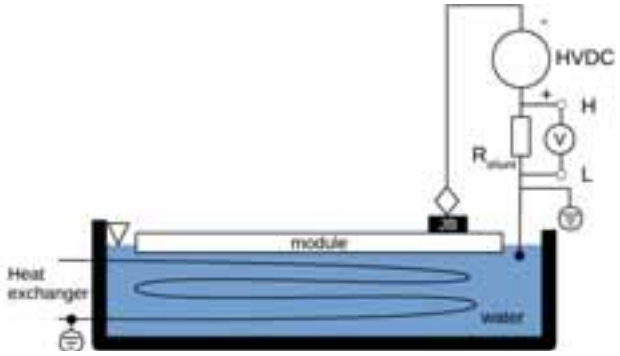

Fig. 6: Water basin test for a separate activation of one leakage current pathway.

2.3 climate chamber tests

According to the outdoor tests the climate chamber tests include two different potentials. In a first step two modules for each encapsulation foil are applied with an external voltage about -500 V. Thereby, one module is connected to module frame and the other is connected over the entire area of the cover glass. Differently from the outdoor tests, the modules are short circuited. This is done, because no irradiation is applied to the modules and no illuminated operation point can be chosen. The climate conditions during this tests are kept constant to 85°C and 85 percent relative humidity. Before and after 500 hour testing the I-V-curves are measured before and after a light soaking for four hours. The light soaking is used to stabilize the module performance before the test and to determine any regeneration effects after the tests. During the climate chamber tests the leakage currents between module connectors and frame respectively the cover glass contact are measured in a ten second interval. Furthermore, before and after the tests electroluminescence images are recorded. The influence of dark soaking in accordance to a possible regeneration or further degradation is measured in a monthly interval after the climate chamber tests. After the first experiment run the tests will be repeated with an external applied voltage of -1000 V.

For verifying the results of the water basin tests climate chamber tests with fluctuating climate conditions are performed. So, modules are connected to an external voltage supply for a bias damp heat test. However, several states of temperature in a range of -5°C and 90°C and relative humidity between 10 and 95 percent are realized. The modules are connected by metal plates on the cover glass and on the back glass. The result is a map of leakage currents for a wide range of temperature and humidity states as well as for different contacting methods.

3. Results

2.1 Degradation rate

Different climatic chamber tests are performed to analyze the degradation behavior regarding PID of CIGS TFSM. On the left side in Fig. 7 the power loss depending different contacting methods and different voltage levels is shown. One module group was contacted with metals blade on the cover glass (front) and the other group on the back glass (back). The encapsulation foil of this test run consist of PVB. The aging time was about 500 h with interruptions for measuring the I-V vurve of the modules. The results are shown for -500 V and -1000 V. It is clear visible that a higher voltage amount leads to a faster transferred charge and a faster degradation rate. However, there is a clear difference between the degradation rate of the front contacted and the back contacted modules. For the back contacted modules less transferred charge is needed to induce a power loss regarding to the front contact. The back contact corespondent with water on the backside of the module. This can occur in case of dew, if the dew on the front side is dried because of sunshine, or rain.

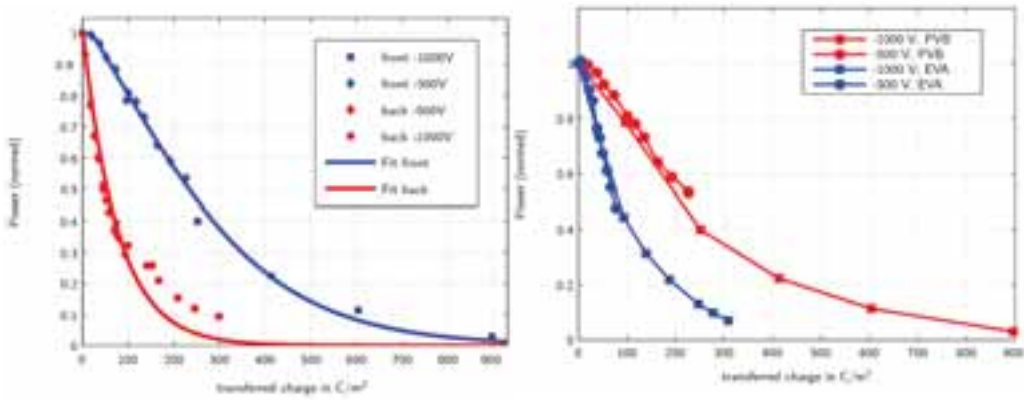

Fig. 7: Power loss as a function of transferred charge for different contact methods (left) and encapsulation foils (right).

The power loss depending on the transferred charge for different evaluated foil types is shown in Fig. 7 (right). Modules with a PVB and a EVA encapsulation foil are tested with an external voltage about -500 V and -1000 V. For the same test conditions and voltages there are clear differences regarding to power loss and transferred charge between these foil types. This indicates that there are differences in conductivity. The Foil EVA shows a faster degradation rate with higher power losses at lower transferred charges. The results show that there is a clear dependency if the leakage current flows through the back or the cover glass. The current through the back glass is more harmful than his counterpart through the cover glass. Furthermore, a clear dependency of the used encapsulation foil exists. The degradation rate can be reduced by a decrease of the conductivity of the encapsulation foil. This leads to less transferred charge and less power loss.

2.2 Leakage current pathway

Two module types with different encapsulation foils are tested. The first one is standard PVB and the second one is an EVA foil. The results of the water basin tests confirm the result of the climatic chamber tests.There is a clear difference depending on the encapsulation foil. The measured and modeled leakage current values are shown in Fig. 8. It is clear visible, that the leakage current I_1 through the cover glass for PVB is more dominant than I_4 through the back glass. In contrast, for EVA I_4 is more dominant. Nevertheless, the magnitude of I_4 for both modules is in the same range. In addition, the activation energy of the currents through the back glass is also the same for both foils, for the cover glass it is quite different. This fact is no surprise, because for both modules the same back glass is used. Whereas, in case of I_1 the material properties of the different encapsulation foils has been taken into account. Additionally, climate chamber tests are performed. Therefore, the modules are connected by a metal plate on the back glass. The results of the leakage currents measured in the water basin correspond with leakage currents in climate chamber well. However, there are some states in the climate chamber with dew on the module. In that case, the main current flow through the cover glass for PVB. In

contrast to that, for EVA the main current flow through the back glass at the same condition (water on the cover glass). A comparison with former bias damp heat tests show qualitatively comparable results. In a first approach, outdoor measured leakage currents can be correlate qualitative to these results.

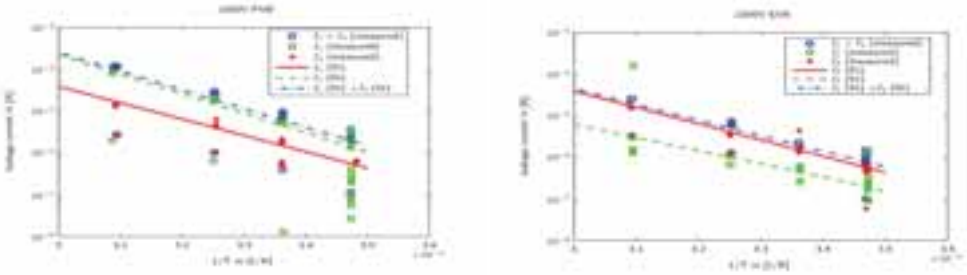

Fig. 8: Measured and modeled leakage currents through the cover glass (I_1) and the back glass (I_4) of a CIGS module with PVB (left) and EVA (right) encapsulation foil.

The Arrhenius plots in Fig. 8 can be used to extract the activation energy. The results are shown in Tab. 1. For the leakage current pathway I_4 through the back glass the same activation energy occur. The lack of differences between the two module types is because of the use of the same type of back glass. However, the estimated activation energy is typicall for soda lime glass. Regarding the leakage current pathway through the cover glass clear differences occur. The activation energy for the module with a EVA encapsulation foil is lower than for the module with PVB foil. For the latter the activation energy is also in the typicall range as for soda lime glass. This indicates, that in case of EVA the encapsulation foil limit the activation energy whereas in case of PVB the cover glass is the limiting factor.

Tab. 1: Activation energy for the leakage current pathways (Manz, 2015)

Leakage current pathway	$I_{1,\,EVA}$	$I_{1,\,PVB}$	I_4
Activation energy	0,63 eV	0,82 eV	0,78 eV

2.3 Outdoor relevance

Considering the Arrhenius equation, high temperatures lead to high degradation rates. Following by this, also

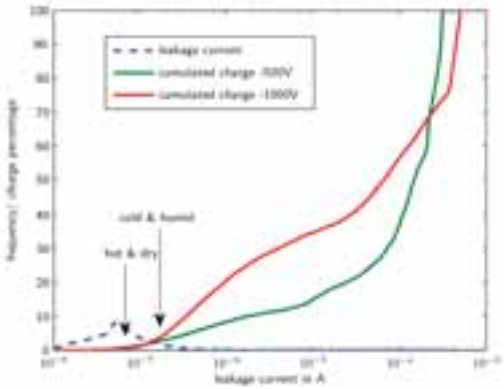

Fig. 9: .Leakage current frequency (dashed) and cumulated transferred charge (solid) in dependency of leakage current.

high leakage currents must occur. This relation is well proven by climatic chamber and water basin tests (Manz, 2015). It seems reasonable to suppose that especially the hot and humid climate regime has to considered to prevent PID of CIGS TFSM. This assumption could be true for tropic climatic regions. But for

moderate climates like in central Europe the opposite is the case. Fig. 9 shows the frequency of the leakage currents (dashed) and the cumulated transferred charge (solid) for the corresponding leakage current amount over one year in Nordhausen/ Germany. Most leakage currents occur for hot and dry conditions up to leakage currents amounts in the range of 10^{-7} A. But this lead only to a transferred charge less than one percent of the hole year. Also the cold and humid regime shows a high frequency of leakage currents. The cumulation of the transferred charge to the hot and dry regime leads to three percent of the hole transferred charge. Nearly 96 percent of the transferred charge occurs during dew and rain. This conditions are infrequent but the leakage current arise up to two or three magnitudes of orders in comparison to hot and dry and cold and humid states.

4. Summary

Accelerated aging tests regarding PID observe normaly only one leakage current path. Uncontrolled condensation can occur and can falsify the measurement. The results show that for realistic life time predictions the knowledge of the active leakage current pathway for the whole operating time is necessary. So in case of CIGS thin film solar modules more than simple climatic chamber tests are necessary to predict their lifetime.

Leakage current pathways for two different encapsulation foils of CIGS thin film solar modules are investigated. The results show that there is a difference of the dominating pathway if the glass surface is wet. For PVB a wet cover glass surface leads to a dominating current through this part of the modules. Whereas for EVA a wet cover glass surface do not lead to a dominating leakage current through it. As expected, for both encapsulation materials the leakage through the back glass shows a comparable magnitude. However, the results are compliant to climate chamber and outdoor measurements. As a result, these measurements can be used to identify the active leakage current pathway in the field. In combination with weather measurements this will enable a correlation of accelerated aging tests and outdoor measurements regarding the transferred charge. Last but not least, the encapsulation foil is generally suitable to influence the active leakage current pathway.

There is a clear difference regarding the amount and the consequences of the leakage currents through the cover and the back glass. The leakage current of the back glass can be over a magnitude lower than the current through the cover glass. But the power loss followed by the leakage current through the back glass needs much less transferred charge. There is a factor of up to 20 between the relevant charge which is needed to damage the module. To carry out the relevant active leakage current pathway a homogeneous contact of the glass plates is necessary (Voswinckel et al., 2015). For analyzing the amount of the leakage current a water basin is suitable. For climatic chamber tests at high temperatures metal plates are more suitable. However, this can lead to non connected areas.

Structural and Optical Characterization of Polymer based TiO_2 films for Photovoltaic Applications

Sebastian Waita* and Bernard Aduda

Condensed Matter Group, Department of Physics, University of Nairobi, P.O BOX 30197-00100, Nairobi, Kenya.

Abstract

The demand for energy worldwide is rising almost on a daily basis. There is need to research on new materials and ways to provide energy. In this preliminary study, we explore the properties of polymer based TiO_2 films for possible photovoltaic applications. TiO_2 films incorporating Polyvinylidene Fluoride-Co-Hexa fluoropropylene (PVDF-HFP) as the structure directing polymer and using Titanium Isopropoxide as the precursor were deposited by both dipping and spin coating techniques. The films were optimized with respect to solution concentration, and spin coater speeds as well as dip coating with drawl speed. X-Ray diffraction (XRD) structural, as well as transmittance studies were carried out. XRD spectra showed crystalline anatase films with crystal sizes of about 18-24 nm after annealing at about 430±50 ^oC for 30 minutes. The as deposited films were amorphous. For spin coated films, the films uniformity became better with spin speed. However, the optimum speed that ensures uniformity and lack of pin holes was found to be about 3000 RPM. The transmittance of the films decreased with the coater speed. As for the dip coated films the concentration of the solution and the withdrawal speed affect the film thickness and therefore the transmittance of the films. Thicker films were obtained from more concentrated solutions. Decrease in concentration of the solution tended to produce a minimum thickness at some withdrawal speed. It was found that higher withdrawal speeds led to lower transmittance due to thicker films.

Key words: TiO_2, Anatase, Polymer, Dip coating, spin coating, transmittance, thickness, structural, Optical, photovoltaic

1.0 Introduction

With almost no exception, the current generation has assumed a lifestyle of using gadgets that need to be powered. Current estimates for the power needs of the roughly 7 Billion people worldwide are as high as 13 Terrawatts (TW) and it is estimated that in less than half a century, the demand will peak to about 23 Terrawatts (TW) (Kalyanasundaram, 2010). There is, therefore concerted effort in search for alternative energy sources to supplement the current sources. Fossil fuels, nuclear power and renewable energy (solar, wind, hydro etc.) are the key options. Of the three options, renewable energy based on solar resource could be the most appealing and promising since it is free, abundant and free from pollution.

Since the break through work on the possibility of generating electricity by applying the photosynthesis principle, a lot of research has gone in to this area due to its potential to offer cheaper power compared to conventional solar cell (Brain O'Regan and Michael Gratzel, 1991). This type of solar cell device is referred to as the Dye Sensitized Solar Cell (DSSC). In brief, a DSSC is composed of a nanocrystalline

semiconducting film sand winched between two photo electrodes; a photo electrode and a counter electrode. The nanocrystalline semiconducting film has a monolayer of a dye to enhance the absorption of incident photons. On illumination, the absorption of the radiation excites an electron from the dye which is conducted through the back contact of the photo electrode and regenerated through the counter electrode which is usually coated with an electron regeneration catalyst like platinic acid. The electron generated by irradiation on the dye is finally recovered at the counter electrode. Therefore, there is no electron loss.

The DSSC technology however has to overcome a number of bottlenecks before it is competitive enough with the conventional solar cell technology-the p-n junction. Research is ongoing to overcome shortcomings like electron loss through the back contact (Petra and Peter 2003; Waita et al., 2007), improving on the dyes (Kohjiro H. and Nagatoshi K., 2009), increasing porosity of the semi conducting film, (Waita et al., 2006, 2007, Kiema et al., 2005), use of other counter electrodes (Kim et al., 2012) among other approaches.

A number of techniques have been used in depositing the semiconducting film: Sputtering (Waita et al., 2007; J. Rodri´guez et al., 2000; M. Go´mez , et al., 2000), Screen printing (S. Burnside et al., 2000), Spray pyrolysis (A.Conde-Gallardo et al., 2005,),hydrolysis of TiCL4 (Kristel Möldre, et al., 2015), and sol-gel dip coating (Jan Prochazka et al., 2013). In their work, Jan Prochazka et al., (2013) incorporated the use of a polymer (poly (Hexafluorobutyl Methacrylate)) as the structure directing agent and titanium ethoxide as the precursor using the dip coating techniques. The films were found to be dense and promoted thixotropic properties. We would like, in this work try a different polymer and determine the properties of the film so obtained. Furthermore, we use two deposition techniques and compare the film properties.

In this paper therefore, we report the structural and optical properties of TiO_2 films that use Titanium Isopropoxide as the precursor and incorporating Polyvinylidene Fluoride-Co-Hexa fluoropropylene (PVDF-HFP) as the structure directing polymer deposited by the dipping and spin coating techniques.

2.0 Experimental Techniques

2.1 Solution Preparation

Two solutions, herein referred to as solution 1 and 2 were separately prepared at room temperature and then mixed together under magnetic stirring. Solution 1 was made by mixing ≈2.2 ml of Hydrochloric Acid (HCl) (Aq) (Aldrich) (37%) and ≈2.55 g of Titanium Isopropoxide (Aq) (Aldrich) with magnetic stirring and stirred until the solution was homogeneous (≈ 30 minutes). This formed the precursor solution. Solution 2 was also made under stirring and composed of ≈ 0.55 g (11-12 pellets) of Polyvinylidene Fluoride-Co-Hexa fluoropropylene (PVDF-HFP) (Aldrich) in a mixture of Acetone and N-Methyl-2-Pyrrolidone (NMP) (Aldrich) in the ratio of 2:3, Acetone to NMP, total volume of mixture, 60 ml. Magnetic Stirring was done until all polymer was dissolved (≈ 90 minutes). Solution 1 was then mixed with solution 2 under constant stirring which continued until the solution became homogeneous (≈ 2 hrs). All solutions were prepared at room temperature and kept covered thereafter.

2.2 Substrate cleaning

Both plain glass and Fluorine Doped Tin Oxide (FT0) (15 Ω/m^2) (Hartford) substrates were used for film deposition after cleaning. The substrates were cleaned by ultra-sonicating (about 30 minutes) in deionized soapy water, then in pure deionized water for about 10 minutes. Thereafter, the substrates were ultrasonically cleaned in ethanol which had 2-3 drops Hydrochloric Acid (HCl) added for about 30 minutes followed by 30 minutes in Acetone and 30 minutes in Ethanol. Finally, the substrates were rinsed with deionized water and dried by blowing with nitrogen gas.

2.3 Film deposition for Structural studies

Two films (4(a) and 4 (b)) were deposited on FTO glass substrates and allowed to dry at room temperature. 4(a) was used as deposited while 4 (b) was heat treated in a programmable oven (Nabertherm) for ≈ 30 mins at ≈ 430 ±50 ^oC and allowed to cool down to room temperature.

2.3 Film deposition and heat treatment

Pre-cleaned Flourine Doped Tin Oxide (FTO) glass substrates where used as substrates and the films were coated by simple hand dipping. For each solution, two films were made: 4a and 4b. 4a deposited and allowed to dry at room temperature (as deposited) while 4b was heat treated in open air for ≈ 30 minutes at ≈ 430 ±50 ^oC after coating and allowed to cool down to room temperature.

2.4 Thickness optimization

The amounts of Acetone and NMP were varied in order to vary the film thickness. The solution with concentration 1 (conc 1) was, 12 ml of Acetone and 18 ml of NMP. Two more dilute solutions were made: concentration 2 and 3 (conc 2 and conc 3). These concentrations were made by reducing the amount of polymer in the solvent in conc 1 while maintaining all else constant. The film thickness was measured using a Dektak 3 surface profilometer (Sloan Technology).

2.5 Film deposition by spin coater

The spin coater used was a KW-4A Model (CHETMAT Technology) and was first calibrated to create a correlation between the knob setting and the digital display. Film deposition using the spin coater was done on pre cleaned glass substrates masked at one end using a scotch tape to create a step for thickness measurements. The substrates were kept fixed on the coater using a double sided tape. About 500 µl of the solution was then carefully spread on the substrate using a calibrated pipette. Depositions were done at various digital speeds.

2.6 Film deposition by Dip coating

Dip coating was done using an automated, computer controlled Dip coater Robot (R & K Germany). Two solutions were made and added together making a total volume of 60 ml and were used immediately after preparation (concentration 1, (conc 1) . Different coatings on plain glass substrates were deposited by varying the withdrawal speed of the substrate. After deposition, the films were kept at room temperature until they were dry before heat treatment at ≈ 450 ^oC for ≈ 30 minutes in a programmable furnace.

2.7 Structural studies

X-ray diffraction (XRD) of the deposited films was done using a computer controlled Siemens Diffractometer at a voltage of 45 KV and current 40 mA. The diffraction angle was varied from 20^o to 60^o.

SEBASTIAN WAITA

2.8 Optical measurements

Optical measurements were done using both a computer controlled single beam UV-VIS-NIR High Resolution Spectacular HR 2000 Light Source Spectrometer (Ocean Optics Inc.) which was equipped with Halogen and Deuterium lamps..

3.0 Results and Discussion

3.1 Structural characterization of the coated films

The XRD patterns for the films is displayed in fig 1 below. Film 4a was found to be amorphous while 4b was found to be crystalline with Anatase phase. The average crystal size estimated from Scherer's formula was ~ 18-24 nm. The crystal size is critical in photovoltaics for it affects both the electron mobility as well as light harvesting. Small crystal sizes (< 20 nm) reduce the space charge area leading to electron recombination due to lack of electron /electron interface energy barrier as well as low conduction (Zaban et al., 2000, Gratzel, 2000). On the hand, large crystals create large surface area for more dye anchoring increasing electron generation rate, faster electron transport as well as slower recombination rate (S. Nakade et al., 2003).

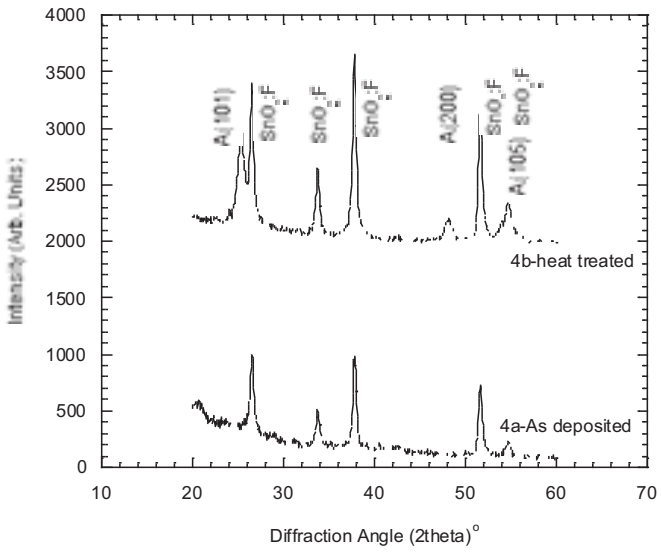

Fig 1. XRD patterns for the deposited films on FTO substrates

3.2 Spin coating

3.2.1 Spin Coater Calibration

The spin coater was calibrated and fig 2 below shows the variation of digital spin coater display with the position of the spin coater knob. As can be observed, there is a direct correlation between the two. This enabled us to determine the speed of the coater at various knob settings.

SEBASTIAN WAITA

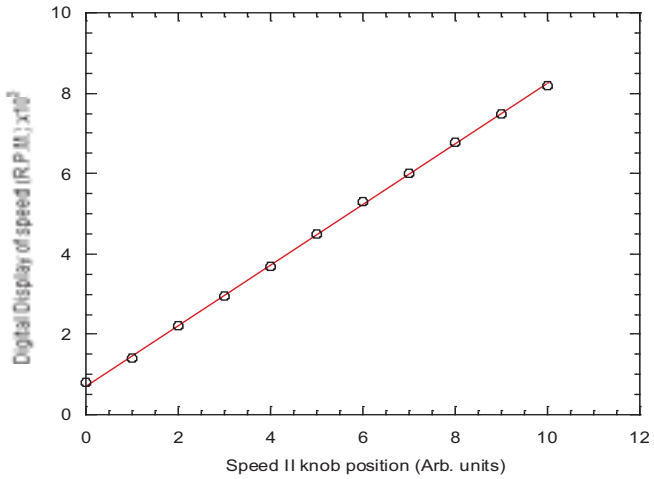

Fig 2. The spin coater calibration: Digital speed display versus the speed knob position

Fig 3 below shows the variation of film thickness with speed of the spin coater. The film thickness was measured using a Dektak 3 surface profilometer (Sloan Technology). Visual inspection was used to gauge how uniform the films were. The films deposited at 800 and 1400 R.P.M. 470 nm and 297 nm thick respectively (first two data points below)and did not appear very uniform. On the other hand, the films deposited at speeds of about 3000 R.P.M and above appeared uniform with the uniformity getting better with increase in speed but tended to lose continuity as the speed increased. The thickness of the films were measured for the various increasing spin speeds. Pinholes were visible in some of the films. The general trend observed is a decrease of the film thickness with the coater speed. Increased speeds increases also the centrifugal force accelerating the solution to the edges of the substrate. The solution spreads more and the film thickness therefore decreases.

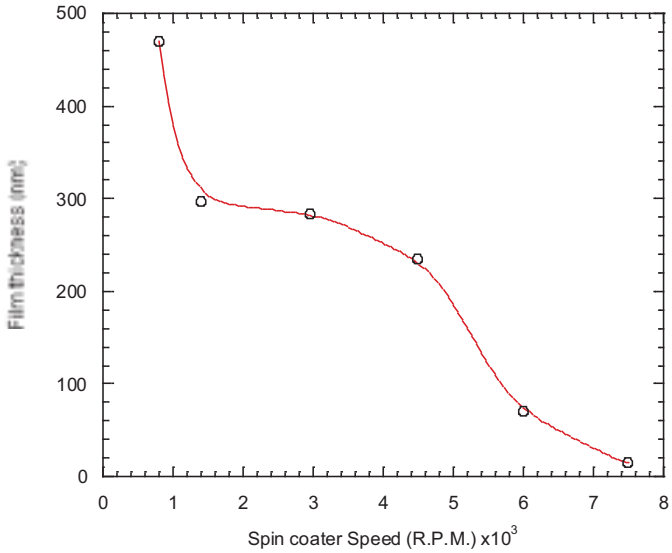

Fig. 3 . The Spin coater calibration: variation of film thickness with spin coater speed

SEBASTIAN WAITA

3.2.2 Optical measurements

The variation of transmittance and spin coater speed is displayed in figure 4 below. The transmittance of the films tend to increase with the spin coater speed. This observation is in agreement with the observation discussed above on speed variation with film thickness. This is because as the film thickness decreases due to higher speeds, the film will become more transparent. From our data, it appears that speeds of about 3000 and above would give us films with above 60 % transmittance for most of the wavelength and the film thickness can be carefully monitored so that it does not become too thin to create pin hole and no uniformity. Lower speeds produced films that seem to compromise the film's transmittance.It is also noted that at higher speeds, transmittance of the coated films and that of the plain glass tend to be close, a possible indication of pinholes in the coated films. However, we did not do further study to confirm this although it is needed.

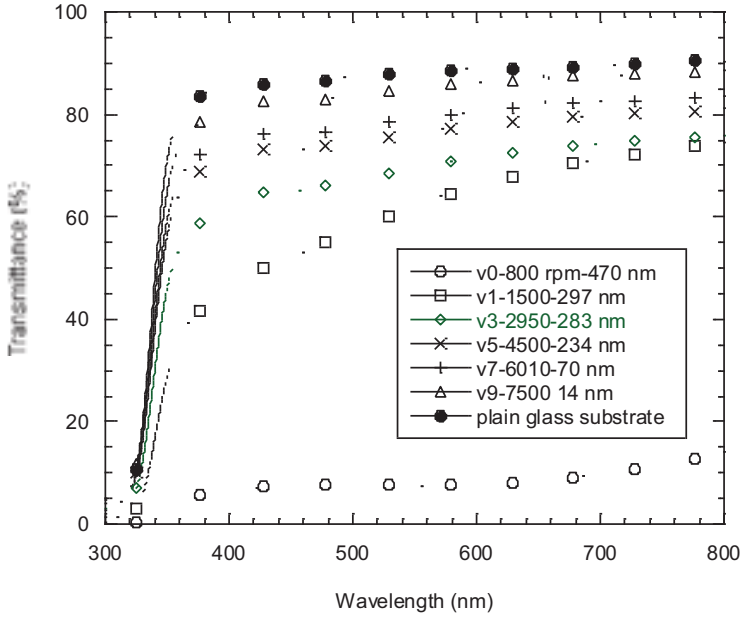

Fig 4. Transmittance of the films deposited at various spin coater speeds

3.3 DIP COATING

3.3.1 Film thickness variation with withdrawal speed

A plot of film thickness against withdrawal speed for the three concentrations is as displayed below in figure 5. The spectra for concentration 1 (conc 1) appears like a smooth tick/right (√) changing shape to more of a bowel as the solution concentration reduces. Thus, as the solution concentration reduces, the film thickness variation at low and high speeds becomes less significant. In other words, the withdrawal speed does not lead to large differences in the film thickness at low and high with drawal speeds. We explain the observation as follows: At low withdrawal speeds, evaporation as well as convection effects determine the film deposition rate. Due to the slow withdrawal speeds, these two effects create a low film deposition rate leading to thin films. As the withdrawal speed increases, gravity related viscous drag force dominates leading to increase in film thickness. This effect seems to become more prominent as the concentration of the solution increase. According to David Grosso (2011), the dip coating technique has three regimes: Capillary at low withdrawal speeds, draining at high withdrawal speeds and Intermediate which is an overlap of the two regimes and his observation of dip coating concurs with ours.

SEBASTIAN WAITA

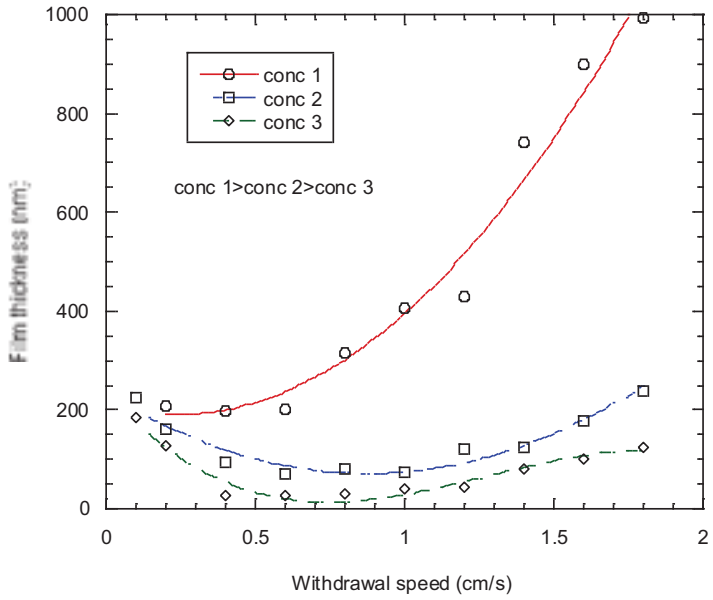

Fig 5. Film thickness variation with withdrawal speed for various concentrations of the solution

3.3.2 Transmittance of the films

The transmittance of the films deposited using the three different concentrations showed the same trend and behavior. The only difference was the level of transmittance which decreased as the concentration increased. Due to this, we present the transmittance spectra for the films deposited using concentration 1 only, as in figure 6 below. The observation below is that the higher the withdrawal speed, the lower the transmittance. This behavior has a direct correlation to film thickness because concentrated solutions produced thicker films. As a matter of fact, the transmittance of such films would be lower compared to less concentrated solutions. For films meant to have high transparency to radiation in the visible range, low withdrawal speeds are therefore recommended although that has to be balanced with the film thickness required.

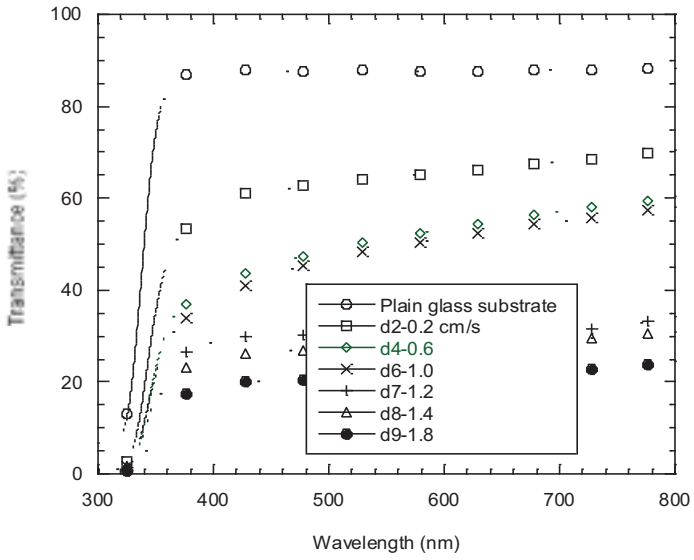

Fig 6. Transmittance versus wavelength for the films deposited at various withdrawal speeds. The films were made through solution of concentration 1 (conc 1).

3. 4 Conclusion

The structural and transmittance properties of TiO_2 incorporating Polyvinylidene Fluoride-Co-Hexa fluoropropylene (PVDF-HFP) as the structure directing polymer and using Titanium Isopropoxide as the precursor have been deposited by both dipping and spin coating techniques.

XRD structural studies revealed that as deposited films were amorphous but heat treated films at about 450±50 ^oC exhibited crystalline nature while revealing the Anatase phase of TiO_2 considered better for photovoltaic application than the other phases of TiO_2. The average crystal size estimated from Scherer's formula was ~ 18-24 nm.

Films deposited by spin coating showed better uniformity of thickness as the speed increased, although at very high spin speeds, the films showed some pin holes. The thickness also decreased with the spin coater speed. The optimum speed that ensures uniformity and lack of pin holes was found to be about 3000 RPM. Since the film thickness decreases with spin coater speed, it is expected that the transmittance of the films decreases with the coater speed. This was confirmed through our measurements.

As for the dip coated films, it was observed that the concentration of the solution as well as the withdrawal speed both affect the film thickness and therefore the transmittance of the films. More concentrated solutions had thicker films. The difference in thickness of the films at low and high speeds was also bigger as the solution concentration increased. Low concentrations had speeds where the film thickness was minimum.

The transmittance of the films deposited using the three different concentrations had the same trend. It was found that higher withdrawal speeds led to lower transmittance due to thicker films.

In order to complete our optimization of the films, we shall, in our next communication report on more optical parameters of the films as well as the performance of the solar cells fabricated using these films.

A Transfer Matrix Approach to Aid in The Design and Optimization of Hybrid Advanced Passive Structures for Enhancing Photovoltaic Efficiency

James Walshe[1], Sarah. J Mc Cormack[2], Hind Ahmed[2], John Doran[1]

[1] Dublin Institute of Technology, Dublin (Ireland)

[2] Trinity College Dublin, Dublin (Ireland)

Abstract

The addition of a luminescent down-shifting (LDS) layer directly onto a photovoltaic (PV) cell introduces additional loss mechanisms within the system. The combination of non-ideal photo-luminescent materials encapsulated within a limited range of viable host materials, with the increased reflection losses arising from the newly created interface represent losses which must be overcome for LDS to offer an enhancement to the underlying cells efficiency. Exploiting the interaction between the highly enhanced electric fields established close to a metal nanoparticles (MNP's) surface is one route aimed at mitigating the poor optical properties of the luminophore-host combinations available. Alternative approaches, aimed at addressing the other loss mechanisms within such a system have gone relatively unexplored. Exploiting the non-ideal nature of the photo-luminescent materials available, offers a possibility of recycling the photons which previously did not undergo photoluminescence while also addressing the reflection losses through the inclusion of selectively reflecting optical structures. The hybrid device designs, incorporating single- and double layer- antireflection coatings composed of commonly available materials offer enhancements in the underlying PV cells performance of 8% - 30% depending upon the design criteria established. The transfer matrix approach adopted allowed the impact of individual design considerations on the reflection suppression capabilities of the structure, as well as their impact on the underlying cells efficiency to be readily determined.

Keywords: Spectral losses, Photovoltaics, Photoluminescence, Plasmonics, Nanophotonic's, Optical modelling

1. Introduction

Using luminescent materials to capture high energy photons, previously poorly utilized by a cell, and re-emit the energy at a longer wavelength, where a cell is more efficient, led to the development of luminescent down-shifting (LDS) layers as a potential solution to increase the efficiencies achievable by PVs (Strümpel et al. 2007; Klampaftis et al. 2009; Thomas, Wedding, and Martin 2012; Ahmed et al. 2013; Ahmed, Doran, and McCormack 2016; Ahmed, McCormack, and Doran 2016; de la Mora et al. 2017). The enhancement offered by LDS is limited by the optical properties (low luminescent quantum yield, re-absorption losses, fluorescent quenching, etc.) of the luminescent and encapsulating materials (Klampaftis et al. 2009; Rothemund 2014; Ahmed, McCormack, and Doran 2016; Ahmed et al. 2013; de la Mora et al. 2017).

Further enhancements in the short wavelength response of PV technologies can be enabled by exploiting the plasmonic interaction between a specific combination of metal (e.g. Ag) nanoparticles (NPs) and luminescent species. The highly localized electromagnetic fields established on a nanostructures surface, tailored through the structures morphology and size, allow the optical properties of luminescent species within the near fields to be augmented. Enhancements in the optical properties of luminescent materials, previously deemed non-viable for their inclusion in an LDS device due to their poor optical characteristics, has showcased the merits of including nanostructures within the encapsulating material (Smitha et al. 2008; Shen et al. 2009; Power 2011; Chen et al. 2013; Ahmed, McCormack, and Doran 2017; Rothemund et al. 2011). The wide range of synthesis routes, structure morphologies, and material combinations possible allows the optimization of such plasmonic enhanced luminescent down shifting (PLDS) designs.

doi:10.18086/swc.2017.20.12 Available at http://proceedings.ises.org

The premise of using additional optical structures, which are selectively reflecting, would allow recycling the photons that did not previously interact with the luminescent species present within a PLDS layer. Increasing the probability of a photoluminescence event, mitigating some of the losses associated with the non-unity luminescent quantum yield of the luminophore, through the recycling of these photons. Exploiting the Stokes shift between absorption and emission peaks of a luminescent species pushes the boundaries of the enhancement attainable with a conventional PLDS approach. The optical structures consisting of a series of 'anti-reflection' type coatings would permit a high reflectivity of photons within a luminophores absorption range, a moderately low reflectivity across the remaining the response range being still present (Walshe et al. 2016).

The effect of the design of single- and double-layer reflecting structures, constructed using materials commonly used in the fabrication of antireflection coatings, on the performance of a mono-crystalline silicon (mc-Si) solar cell was theoretically evaluated. By adopting a transfer matrix approach, the effect of each design parameter was evaluated in terms of its impact on the underlying solar cells performance. The aim is to establish a set of initial design considerations that will allow for both the development of a prototype device and further refinement in the design of such devices. This can be achieved by employing the model developed i.e. using more complex structure designs, different luminescent species, different nanoparticle morphologies or a different underlying PV cell type.

2. Structure Enhanced Luminescent Down-Shifting (SE-LDS)

The addition of an LDS layer directly on top of a PV cell increases the number of loss mechanisms available within the system (Klampaftis et al. 2009; Rothemund 2014). The non-ideal optical properties of the luminescent materials available, coupled with losses introduced through the parasitic absorption and poor photo-stability of the encapsulating materials, will allow further design revisions (McKenna and Evans 2017; de la Mora et al. 2017; Mayr 2016; Klampaftis et al. 2009). The typically low refractive index (n = 1.5 – 2.2) of the host materials employed in LDS devices to date is introducing reflection losses from the LDS layers front surface (McKenna and Evans 2017). Structure-enhanced LDS (SE-LDS) devices (figure 1A) could be one such design option as it is allowing to recycle photons and, also, minimizing the surface reflection losses introduced through the addition of the LDS layer.

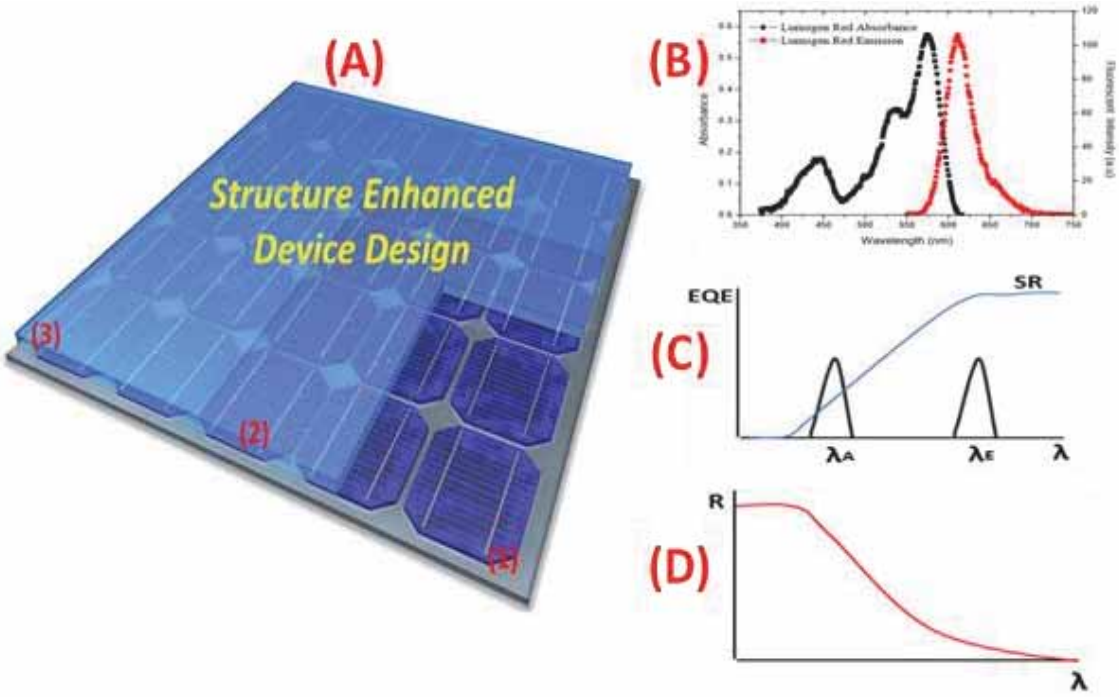

Figure 1: (A) Structure-enhanced (SE) device design concept consisting of three primary components (1) a photovoltaic cell, (2) a transparent matrix encapsulating either a luminescent material (B) or a combination of a luminescent material and metal nanoparticle and (3) a selectively reflecting coating with a reflection profile similar to that presented in (D). The selectivity of the reflecting structures can allows for recycling the photons lying within the encapsulated luminophore's absorption band (λ_A). This allows more photons to be shifted to higher wavelengths (λ_A) where the cells spectral response (SR) is greater (C)

The combination of a relatively small Stokes shift and the sub-unitary LQY are pushing for exploring more energy efficient architectures and novel design considerations. Through selectively designing the reflecting structures (similar to ARC's) a graded reflectivity profile (figure 1D) can be generated allowing for the recylcing of photons, which previously did not get a chance to undergo photoluminescence.

Utilising the formation of highly localized electromagnetic (EM) fields established within metal nanostructure vicinity further mitigates the loss mechanisms inherent within their electronic structure. Incorporating metal nanostructures within the transparent host media offers the capability of augmenting the luminophores optical properties through careful control of the nanostructures composition, morphology, physiochemical characteristics and size (Stalmashonak, Seifert, and Abdolvand 2013; Wiley et al. 2006; Ahmed, McCormack, and Doran 2017; Ahmed, Doran, and McCormack 2016; Zimbone et al. 2015; Power 2011; Smitha et al. 2008). Combining the PLDS approach with the structural enhanced element proposed here could allow for further enhancements in the cell performance.

3. Transfer Matrix Model

The propagation of light through a multi-layered structure, consisting of a series of thin dielectric media, with the variation between the refractive indices of subsequent layers varying significantly can be evaluated using a Transfer matrix model (TMM)(L, Matthew, and S 2007; Sánchez-Soto et al. 2012; Sahouane and Zerga 2014; Shabat and Ubeid 2014; Saylan et al. 2015; Shabat, El-Amassi, and Schaadt 2016; Sikder and Zaman 2016; Hamouche, Shabat, and Schaadt 2017). The TMM utilizes Maxwell's equations to connect the electric and magnetic field components across an existing boundary between two different isotropic dielectric media, allowing the interaction of the incident light with a single layer to be represented as a 2x2 transfer matrix (L, Matthew, and S 2007; Sánchez-Soto et al. 2012; Sahouane and Zerga 2014; Shabat and Ubeid 2014; Saylan et al. 2015; Shabat, El-Amassi, and Schaadt 2016; Sikder and Zaman 2016; Hamouche, Shabat, and Schaadt 2017). Extending this process to a multilayer structure is carried out through the determination of the matrix of each individual layer, with the overall systems matrix being the product of the individual layers matrices. The overall structures matrix is then converted back into transmission and reflection amplitude coefficients, allowing the resulting reflection, absorption and transmission spectra for complex multilayer structures to be readily determined.

4. Design Considerations

The wide range of ARC architectures, the different types of luminophore available and the tuneability of nanostructures granted by the numerous synthesis routes available allows for a large number of design considerations. To prove the viability of the SE-LDS concept only the simplest of structure designs were considered, consisting of single- and two-layer 'Bragg' structures. Here, the effect of the structures design and the numerous design parameters that are available were investigated using the transfer matrix approach. Two initial designs were selected for SE-LDS mc-Si devices (figure 2).

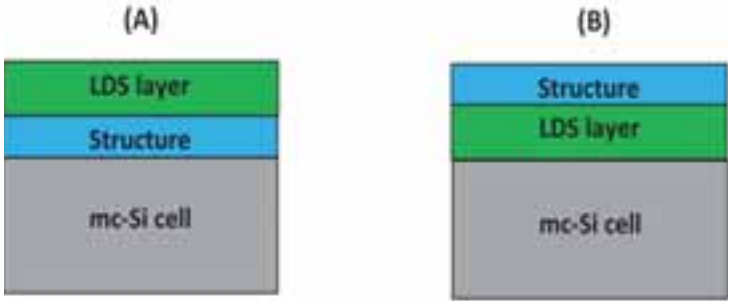

Figure 2: Initial designs for a structure-enhanced luminescent down-shifting (SE-LDS) mc-Si device with the selectively reflecting 'Bragg' structure situated (A) below the LDS layer and (B) above the LDS layer

Anti-reflection coatings (ARC's) can consist of a single layer or multilayer structure, with multilayer coatings offering the possibility of a greatly reduced broadband reflectance at one or more reflectance minima. Selectively reflecting structures were designed using both single and two layer ARC's to produce maximum reflection suppression at a series of wavelengths across the spectral range investigated (300nm – 1100nm), allowing the optimal materials and corresponding thicknesses to be determined for each structure investigated. Based upon the idealised refractive indices for both single and two layer ARC type structures, a range of suitable materials whose refractive indices lay both above and below the ideal values were considered. The materials utilized in the study outlined in table 1.

Table 1: List of the materials used to design structure enhanced elements (Green and Keevers 1995; Raut et al. 2011; 'SOPRA materials database' 2017; Polyanskiy 2017)

Single layer	Two layers
MgF_2	MgF_2-SiO
SiO	MgF_2-CeO_2
CeO_2	MgF_2-ZnS
ZnS	SiO_2-Si_3N_4
Ideal	MgF_2-Ta_2O_5
	MgF_2-TiO_2
	Ideal

To develop a deep understanding of the effect of the individual optical parameters (structure composition and design, dispersive media, optically thick layers, non-homogenous media etc.) of the system, the study was separated into components of increasing complexity. Adding each new element individually allowed monitoring the effect of the reflection suppression capabilities of an array of different structure enahcned (SE) designs and the impact of SE when are incorporated in the architecture of a silicon based device. Refining the optical properties of such structures can lead to viable structural and material configurations for the architectures of the SE-LDS (or PLDS) devices. As an initial approximation, all media are represented as being non-dispersive and homogeneous, with the optical properties of a layer being quantified by a single value of the refractive index and of the thickness.

5. Structure Enhanced (SE) Luminescent Down-Shifting (LDS) Devices

The single layer (SL) antireflection (AR) structures, comprising of the materials previously employed in two different design configurations, highlighted the ability of such simple structures to offer significant enhancements in the underlying cells performance (figure 3). Placing the AR structures below an LDS layer resulted in the greatest enhancement in device performance, with an 8% - 18% improvement in overall device achieved performance (figure 3A). The only instance in which a decrease in performance was observed was when the design included MgF_2. The MgF_2 refractive index is lower than the represented LDS layer, mitigating the π phase shift occurring when the $n1 < n2 < n3$ condition if fulfilled.

Through careful control of the AR structures composition and design, the enhancement factor can be maximised, with the maximum performance occurring for structures designed to suppress reflections at 600 nm - 650 nm. Reducing the thickness of the LDS had little effect on the enhancement offered by the addition of such structures to a LDS equipped device, leading to a 0.1% - 0.4% variation in the enhancement.

Considering the AR structure above an LDS layer resulted in a decrease in the overall device performance (figure 3B). As the light propagates from a media of lower refractive index to one with a higher index, it undergoes an 180^0 phase shift at the interface. This condition is only fulfilled for the structure design incorporating the material MgF_2 (figure 3B). Without the fulfilment of this condition the waves reflected from the two interfaces within such a system don't produce destructive interference but rather a collective of both constructive and destructive interference. The remaining materials employed possessed a refractive index larger than the polymer (PMMA) used to represent the LDS layer throughout the study. Decreasing the thickness of the LDS layer from 90 μm to 9 μm reduced the decrease in device performance for the majority of designs investigated (figure 3B) with values between 1% and 3%.

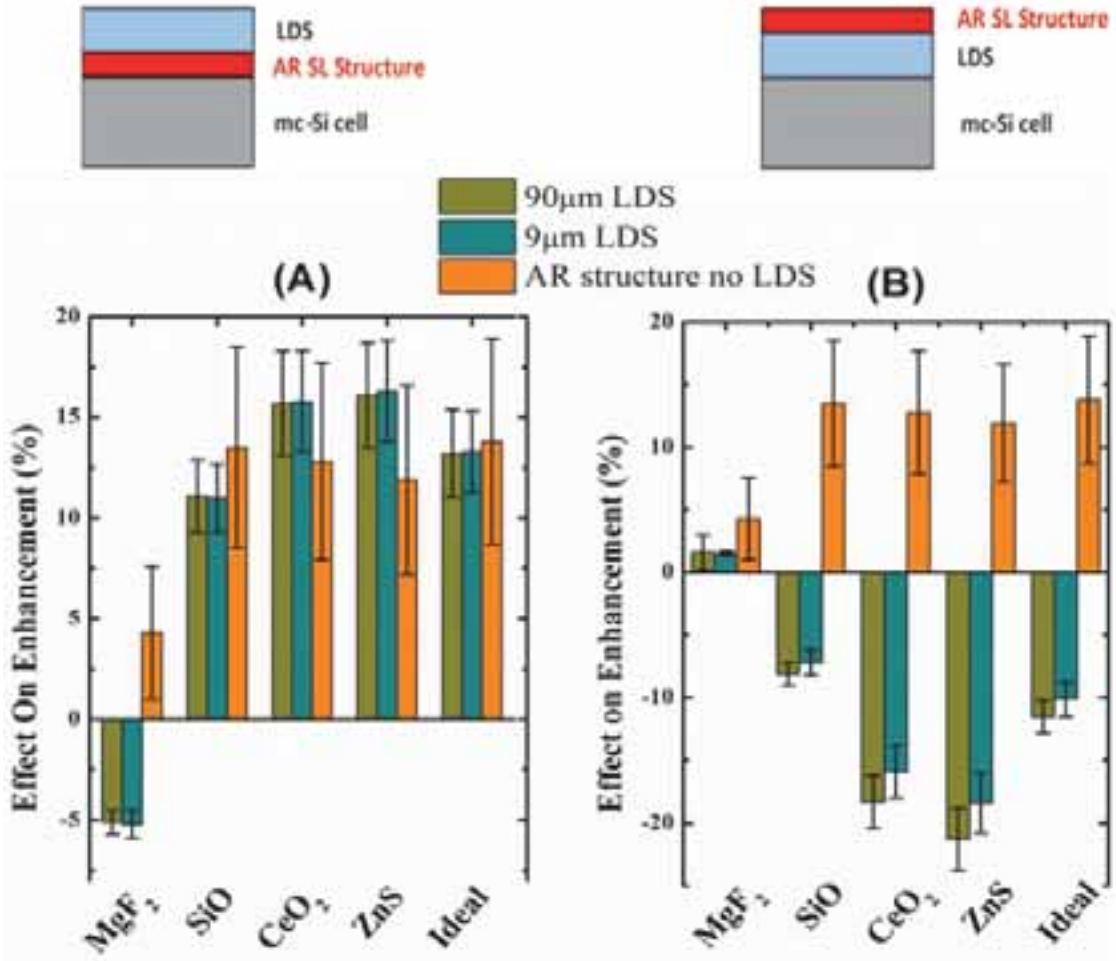

Figure 3: Average percentage (%) increase in the performance of mc-Si when fitted with two different structure enhanced LDS designs: (A)antireflection single-layer structure deposited directly below an LDS layer and (B) the antireflection single-layer structure deposited above. In all cases, the optical properties of the LDS layer were considered to be the optical properties of the polymer matrix material (PMMA), with two different layer thicknesses (90 μm and 9 μm). The variation in the levels of enhancement reported for each material is due to the variation in the wavelength at which the structures were designed to suppress reflection (λ0). Schematics of the design under consideration are included in the figure for each case.

Increasing to two the number of layers comprising the AR structure offered an even greater degree of enhancement in device performance (figure 4). The same trend for both initial outlined designs was reported. Placing the AR structure above the LDS layer results in a decrease in the mc-Si performance with values between 5% and 20% (figure 4). Initially, the SE devices designs that incorporated a selectively reflecting structure directly above the LDS layer (figure 3B and figure 4B) have shown no merit in enhancing the mc-Si cells performance and, consequently, they could be non-viable options.

Housing the AR structure between the LDS layer and mc-Si cell led to enhancements of 10% -24% in the cells energy conversion efficiency (figure 4A). Irrespective of the material combination employed in the device design, the cells performance was increased by 10% (figure 4). Fine-tuning of the design parameters facilitates enhancements on the order of 24%, a slight increase from the increase in performance being reported for single-layer structure designs (figure 3). Reducing the LDS layers thickness produces an increase in the enhancement offered by the structures in figure 24A with values between 2% - 4%.

Fabricating a SE device such that the AR component is located between the LDS layer and underlying PV cell shows the premise to deliver a significant enhancement to the PV cells conversion efficiency (figures 3A & 4A). In reality, the design process of the AR structures should contain a cost analysis element, whereby the

advancement in the performance enhancement will need to be weighed against the cost of increasing the structures complexity.

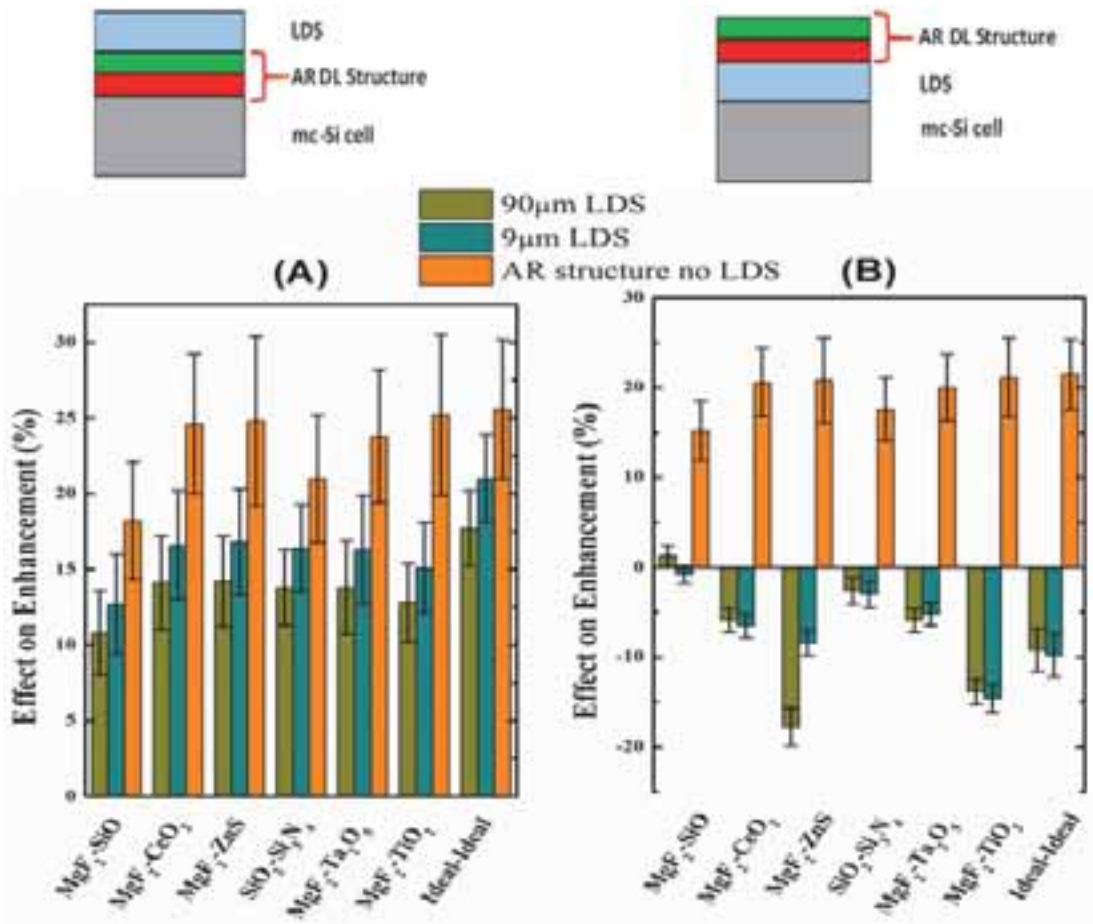

Figure 4: Average percentage (%) increase in the performance of mc-Si when fitted with two different structure-enhanced LDS designs: (A) antireflection bi-layer structure deposited directly below an LDS layer and (B) the antireflection bi-layer structure deposited above. The LDS layer in all cases have the optical properties of the commonly used polymer matrix material (PMMA) with two different layer thickness (90 μm and 9 μm). The variation in the levels of enhancement reported for each material is due to the variation in the wavelength at which the structures were designed to suppress reflection (λ_0). Schematics of the design under consideration are included in the figure for each case.

6. Conclusion

The premise of exploiting the incorporation of novel optical structures into the architecture of a mc-Si solar cell has been established using a TMM model. The structure designs considered highlighted their capacity to mitigate some of the loss mechanisms inherent in LDS and PLDS device designs. By careful selection of the design materials and the tolerance granted over their fabrication, the structures could offer potential device enhancements of 8% - 30% irrespective of photo-luminescent or metal nanostructure interactions. The transfer matrix approach adopted could potentially allow the design process to be automated and optimized for a given set of input criteria i.e. structure architecture, nanostructure and luminophore combination, as well as for the photovoltaic generation upon which the architecture is based. Refinements in the model investigated through experimental fabrication and characterization of such devices would help to establish a deeper understanding of the optical interactions within each component of the design.

Performance analysis of one-axis tracking photovoltaic system with flat planar reflectors

Ryoma Yoshimori*, **Masayuki Nakayama***, **Atsushi Akisawa***
*Tokyo University Agriculture and Technology, Tokyo (Japan)

Abstract

This study examined the performance of a photovoltaic system with flat planar reflectors and south-to-north direction sun tracking system. In order to enhance sunlight collection with simple mechanism, the flat planar reflectors are connected to the solar cells alternately, which can track the sun by expansion and contraction of the system. The objectives are to find out the optimum operation of the inclination angle of the solar cell and to design the ratio of the length of the flat planar reflector and the solar cell by ray-tracing simulations. According to the simulation results, the larger the reflector is the more sunlight is collected in winter. On the other hand, in summer the shorter reflector is effective. The system with short reflector collects more sunlight and less area for installation than conventional PV system. Simulations show that the system with reflectors, which is 1.5 times longer than solar cell is the best in consideration of both concentration performance and area for installation. Its annual sunlight collection is 41 % higher and area for installation is 19 % smaller than those of conventional PV system. The experiments were conducted outside in August and September. The solar radiation intesity on the solar cell of the system was higher than that of conventional PV system throughout the experiment period by 40 - 50 %. Power output of the system was larger than that of conventional PV system by at most 50 % on August 24th and 20 % on September 14th. Non-uniformity of the reflected sunlight affects the output of the system.

Keywords: Low concentrating PV system, Flat-planar mirrors, One-axis tracking, Ray-tracing simulation

1. Introduction

Renewable energies are expected to increase the installation to reduce the consumption of fossil fuels. Photovoltaic (PV) system is the most widely spread energy source using renewable energy all over the world. The main problem of the PV system is still more expensive than conventional electricity. This is caused by the cost of semi-conductors which is the most expensive part in the PV system, and low conversion efficiency. Conventional Si-based PV cells convert approximately 20 % of sunlight into electricity [1–3].

One of the effective measures to reduce the cost is concentrating photovoltaic (CPV) system, which enhance the sunlight on the PV cells. The CPV system reduces the use of PV cells for given power demand. Inexpensive optical devices such as lenses and mirrors are used for concentrator of the CPV system. Sunlight hits the earth surface in the forms of direct and diffuse radiations and their share in total received sunlight depends on the local climate, weather and sky conditions such as pollutants in the air and clouds. Sun tracking is required as concentrators only respond to direct radiation [4].

CPV systems are crassified with their concentrating ratio namely high and low concentration PV systems [5, 6].

High concentration PV (HCPV) system concentrates 500 suns or higher and it is usually constituted by multi-junction cells, which efficiency is reported over 40 % [7, 8]. Yuan-Hsiang Zou obtained effciency of 28.6 % with 800 suns concentrator and PV cell with the effciency of 35.5 % [10]. One of the disadvantages of this technology is the system needs highly accurate tracking system. The optical efficiency of HCPV system using Fresnel lenses, which concentrate approximately 150 suns, is about 20 % lower than its peak when the incident angle is 0.5 degree, reported by Dianhong Li [11]. The other disadvantage is that concentrators only respond to the direct sunlight. When the weather conditon changes from sunny to cloudy, the energy yield significantly decreases. HCPV system is suitable for the places like desert area, where almost all the days are sunny for whole year.

On the other hand, low concentration PV (LCPV) system concentrates up to 40 suns. The concentrating ratio is lower than HCPV system, however conventional silicon solar cells, which made for 1 sun, can be used for LCPV systems. The sollar cells are used under the concentration of 10 suns or below [5, 7, 12]. LCPV systems have less demand on tracking accuracy than HCPV systems. In the Giorgio Grasso's report [13], the prism-coupled compound parabola system is designed with 5 suns concentration. The optical efficiency

doi:10.18086/swc.2017.20.13 Available at http://proceedings.ises.org

does not decrease until incident angle is changed 15 degree in north and south direction. Consequently, LCPV system can be a low-cost solution to increase the density of the sunlight and to reduce the use of solar cells. For LCPV systems, compound parabolic reflectors, V-trough reflectors or flat planar reflectors are used [14–16]. In particular, the flat planar reflectors have the advantage of being inexpensive compared with both V-trough and parabolic reflectors [17].

The sun always changes its position in the sky. The location depends on the longtitude and the latitude, the date and the time. To harvest energy effectively PV modules and mirrors should be placed on the solar tracker. However this two-axis tracking system could be complicated in terms of structure and causes to be expensive. One-axis tracking systems, which moves north-south direction or west-east direction, can have more simple structure.

In this paper, a one-axis tracking LCPV system with flat planar reflectors is proposed. The flat planar reflectors are connected to solar cells alternately. This system enhances the sunlight to the solar cells by the reflectors and tracking when the system expands or contracts to control the inclination angles. Two main activities were conducted in this study. One is ray-tracing simulation described in section 3 which predicts the energy yield and evaluates the performance of the systems with different length of reflectors. It is one of the objectives to find out the optimum operation of the inclination angles of the solar cells and the flat planar reflectors. The other objective is the experiment investigation for confirming the performance under the real sunlight which is described in section 4. The optimum system model and the operation derived in section 3 was used in the experiments.

2. One-axis tracking LCPV system with flat planar reflectors

The one-axis tracking LCPV system with flat planar reflectors is represented by Fig.1 where solar cells are inclined at angle θ and the flat planar reflectors are declined at angle ϕ. The solar cells and the flat planar reflectors are connected each other in north and south direction. The inclination angle of the flat planar reflectors move in response to that of the solar cells. The equation of the relation of both angles is defined by Eq.(1). In this study, the inclination angle of the solar cells is controlled. This structure allows one driving source to controll multiple units. A unit means a combination of one solar cell and one flat planar reflector. There is a design parameter R which is the ratio of the length of the solar cell L_{PV} and the flat planar reflector L_m as defined by Eq.(2).

$$L_{PV} \cdot sin\theta = L_m \cdot sin\phi \tag{1}$$

$$R = L_m / L_{PV} \tag{2}$$

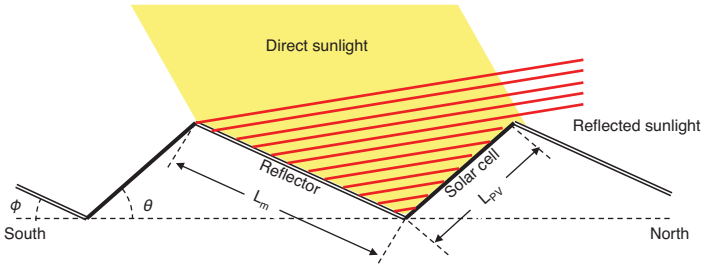

Fig. 1: Geometric scheme of the one-axis tracking LCPV system with flat planar reflectors

3. Ray-tracing simulaion for estimating sunlight intake

3. 1. Simulation conditions

Ray-tracing simulation was conducted as Fig.2 using *Solar Emulator* of *Tracepro* [18]. The sun positions were calculated automatically from the latitude and the longtitude of the system placed, date and time. To model the sunlight parallel light source is assumed. The power flux is set to 1067 W/m^2 considering atmospheric transmittance of whole year average. The weather in the simulation is all cloudlessness and direct radiation was considered while scattered radiation was neglected. The wavelength of sunlight spectrum was set to 550 nm since the software does not provide a continuous sunlight spectrum. The hourly data of solar

radiation from 6:00 to 18:00 in Tokyo were used in the simulations.

The solar cell was set to perfect absorber to evaluate the sunlight intake of the system that is the amount of the solar radiation collected on the solar cell. The reflection ratio of flat planar reflector was set to 0.95. The resolution of inclination angle was set to 10 degree from 10 degree to 80 degree and it was adjusted to optimum angle every one hour. The parameter R was selected from 1.0 to 3.5.

The concentration performances were calculated in the simulations. The monthly and annual concentration are expressed by the ratio of the proposed system to the conventional PV system of which PV system cells are fixed with the inclination angle of 35 degree. The seasonal, monthly annual concentration performances are reported in the following subsections. Moreover the areas of solar cells, mirrors and the land for the installation are also discussed to compare the performances.

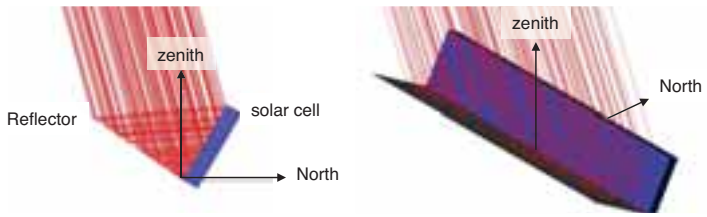

Fig. 2: Example of the ray-tracing simulation of the one-axis tracking LCPV system with the R = 1.5, θ = 60 degree on June 20th

3. 2. Seasonal concentration performance

The seasonal optimum inclination angle θ and concetration performances are represented in Fig.3. The representative dates of the seasons were selected as June 20th for summer, September 20th for fall and December 20th for winter. The optimum inclination angles and concentration performance of March 20th are similar to those of September 20th therefore they are left out on this paper.

In summer when the sun height is high, the systems with smaller R obtained high concentration performance ratios as Fig.4(a) shows. The system with R = 1.0 has the highest concentration performance. It is about 60 % higher than that of conventional system named as *std* in the graphs. The angles of the PV cells and the reflectors are relatively large. The more reflected sunlight hits the solar cells. On the other hand, The systems with large R such as R =3.0 and 3.5 give low concentration performance. The angles of the PV cells and the reflectors are small. Since most of reflected sunlight goes to the sky, the concentration performance of the systems with large R are low.

In middle season such as spring and fall show similar results. The results of fall are shown in Fig.3(b) and Fig.4(b). The concentration performance of each system is higher than the conventional system by 40 % to 60 %. All systems obtained reflected sunlight compared with the case of summer.

In winter when the sun height is low, the systems with larger R obtain high concentration performance as Fig.4(c) shows. The system with R = 3.5 has the highest concentration performance. It was twice as high as that of the conventional system. The larger area of the reflectors is advantageous to collect sunlight with low incident angle in winter. On the other hand, inclination angle of the PV cells with smaller R can not be large because there is a risk that the system makes the shade on the solar cells. Since the system with R = 1.0 makes shade on the solar cells, the concentration performance is lower than that of the conventional system.

Fig. 4: Concentration performance

3. 3. Monthly and annual concentration performance

Monthly concentration performances of the proposed system with various R are represented in Fig.5. Here the improvement ratio is defined so that the performance of the proposed system is normalized with that of the conventional system. When the ratio is higher than 1.0, the proposed system works better. The ratios were calculated using total collected sunlight when the hourly inclination angle of the solar cells was operated optimally. In summer season, the concentration performance ratios of the systems with smaller R are higher. The system with R = 1.0 is the highest in June by 60 % higher than the conventional system. The system with R = 1.5 shows good performance from April to September by 50 % or higher than the conventional system. In winter season, the systems with larger R work effectively. The system with R = 3.5 shows relatively high performance from November to January by about 70 % as high as the conventional system. In December, the concentration performance ratio of the system with R = 1.0 is lower than that of the conventional PV system. As already mentioned in the previous subsection, the system makes shade on the solar cells.

Annual concentration performance ratios of the proposed system are represented in Fig.6. The system with R = 2.5 shows the highest performance by 44 % higher than the conventional PV system. When R is above 1.5, the system has stably high performance than the conventional PV system by 40 to 44 %. The system with R = 1.0 decreases the improvement. The result implies that the system should be designed with R more than 1.5.

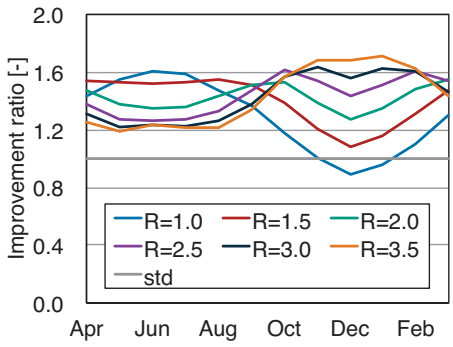

Fig. 5: Monthly concentration performance of the proposed system with various R normalized with the performance of the conventional PV system

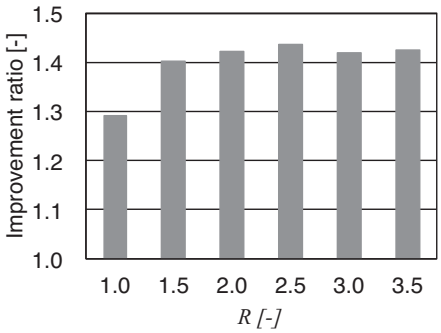

Fig. 6: Effect of R on the annual concentration performance of the proposed system compared with the conventional PV system

3. 4. Efficiency of land use of the installation

The comparison of land use for the systems is disscussed in this subsection. The size of the proposed system can be bigger than the conventional PV system because of additional reflectors. The conventional PV system is installed with a rule that is avoiding the PV array making shade on the other PV array behind [19]. It means avoiding shade when between 9 a.m. and 15 p.m. in Japan. For example, PV array with 1 m in length at 35 degree of inclination angle needs 2.2 m of distance including the gap between 2 arrays. On the other hand, the length of the land use for installation the proposed system is simply the sum of PV cell and the reflector, where the system is flat. For example, one unit of the system with R = 1.5 needs 2.5 m, where 1.0 m is for solar cell and 1.5 m for the reflector.

Here the efficiency of land use was defined as the land area needed to capture a given amount of solar irradiation for one year. The comaprison index was made so that the land area for the proposed system was divided by that of the conventional system. The conventional system uses 45 % of the land area for the solar cells. The system with R = 1.0 needs the smallest land area. It is 30 % smaller than that of the conventional PV system. The area of solar cells is 23 % as small as that of the conventional system. The system with R = 1.5 can make the land area smaller than conventional PV system by 20 %. Moreover the area of solar cells is smaller than that of conventional system by 30 % as shown in Fig.8. It is obvious that the wider the reflectors are the larger becomes the land area for the proposed systems. The systems with R over 1.5 use almost the same area of the solar cells while the area of the reflctors increases gradually.

In regard to the area of land, the systems with R = 1.0 and 1.5 have advantage. However, it should be noted that the performance of the system with R = 1.0 in winter is less than that of the conventional system due to the shade. From the viewpoints of monthly and annual performance, the system with R = 1.5 will be the best choice. As Fig.8 the area for system installation was 20 % smaller than the conventional PV system and cell area was 30 % smaller.

4. Experiments for evaluating system performance

4. 1. Experimental setup

Based on simulation analysis, the system with R = 1.5 was selected to be build for the actual measurement of the perfromance by experiments. Figure 9 shows the experimental setup of the system with R = 1.5 which connects 2 solar panels and 2 reflectors. These solar panels and the reflectors can change their inclination angles at the same time by linear guide. The solar panels consist of single crystalline silicon. The single panel has the nominal maximun output of 5.5 W. The length of the solar panel is 100 mm and the width is 500 mm. The length of the mirror is 150 mm and the width is 500 mm. Cell A in Fig.9 measures the output of the conventional PV system by setting the inclination angle of Cell A to 35 degree while Cell B measures the output of the system with R = 1.5 by operating optimum angles calculated by the simulations. The solar radiation intensity on the solar panels was measured by a pyranometer. The pyranometer changed its position depending on the measurement. When measuring the solar radiation intensity of the conventional PV system, the pyranometer is set in front of the Cell A. On the other hand, when measuring the system with R = 1.5, the pyranometer is set behind the rear reflector as shown Fig.9. The output of the solar panels are measured by an I-V checker (EKO INSTRUMENTS CO., LTD, MP-170).

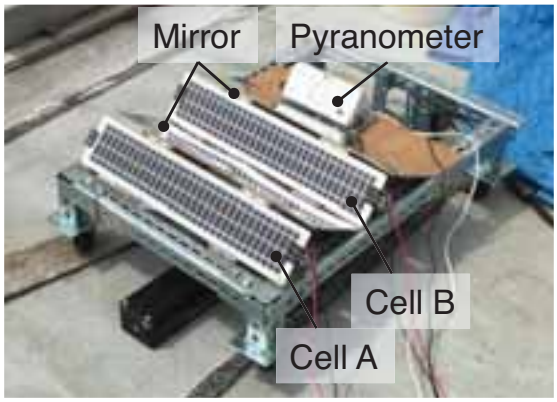

Fig. 9: The experimental setup of the system with R = 1.5

4. 2. Methods of experiment

Experiments were held with the following procedure. The weather conditions were sunny or partly cloudy.

Measurement of conventional PV system

1) Setting the inclination angle of Cell A to 35 degree and locating the pyranometer in front of the Cell A.

2) Measuring the solar radiation intensity by the pyranometer and the output by the I-V checker.

Measurement of the proposed system

3) Setting the inclination angle of Cell B to a specified degree and locating the pyranometer behind the rear reflector.

4) Measuring the radiation intensity by the pyranometer and the output by the I-V checker. The pyranometer detects the direct sunlight from the sun and reflected sunlight from the reflector.

This procedure was repeated every 20 minutes during the measurement period. Time lags occurred the measurements of Cell A and Cell B. The solar radiation intensity sometimes changes suddenly during the time lag.

The performances of partly cloudy day and sunny day were observed. The optimum angle of the system on these dates are shown in Table.1.

Table. 1: Operation of the inclination angles of the system with R =1.5

Weather	Time	9:00	10:00	11:00	12:00	13:00	14:00	15:00
Partly cloudy	Aug 24th	60 °	60 °	50 °	50 °	50 °	60 °	60 °
Sunny	Sep 14th	50 °	50 °	50 °	50 °	50 °	50 °	50 °

4. 3. Results of the experiments

The experiments were conducted outside in August and September. The results of August 24th, which was partly cloudy and September 14th, which was sunny, are reported in this paper.

Figure 10 (a) represents the solar radiation intensity on each of the solar panels on the 24th of August. The weather condition was partly cloudy therefore global solar radiation intensity was up and down with short steps. The solar radiation intensity on the solar cell of the system with R = 1.5 was higher than that of the conventional PV system almost every time, especially it was about 50 % higher around noon. As seen in Fig.10 (b), the output of the solar panels were in accordance with the solar radiation intensity from 11:00 until 13:00. In contrast the effect was not significant after 13:00.

Figure 11 represents the measurement results on the 14th of September which was sunny day. The solar radiation intensity on the solar panel of the system with R = 1.5 was about 50 % higher than that of the conventional PV system every time. However the output of the system with R = 1.5 was higher than that of conventional PV system only by 10 to 20 % around noon. It was found that the solar concentration did not enhance the power generation significantly.

In order to understand what caused the insufficient performance of the proposed system, it was observed how the mirror concentrated the irradiation on the solar panel. Fig.12 (a) to (e) show the reflected sunlight distribution on the solar panel of the system with R = 1.5. As can be seen in the graphs, there existed non-uniform distribution which changed time to time. Fig.12 (c) shows that the illuminated area was largest among the samples. The non-uniformity is considered to degrade the power generation as discussed by Hasan et al. [20]. The results suggest that the proposed system needs to employ suitable PV panels which can work even with non-uniform irradiation on it. The pyranometer measures the solar radiation intensity of the area the reflected sunlight hit.

5. Conclusion

The one-axis tracking LCPV system with flat planar reflectors was examined in this study. The performance was analysed by ray-tracing simulations and also investigated by experiments.

It was found from the simulations that the length of the reflector would affect the seasonal concentration performance of the proposed systems. The system with small reflectors shows high concentration performance in summer while the system with large reflectors gives high concentration performance in winter. The system with $R = 2.5$ showed the heighest annual concentraion performance, which is 44 % higher than that of the conventional PV system. The system with $R = 1.5$ gives similar performance of 41 % even though the area of the reflectors are three-fifth of the system with $R = 2.5$.

Regarding the area for system installation, the systems with $R = 1.0$, 1.5 or 2.0 need smaller area than the conventional PV system. Although the system with $R = 1.0$ shows the best result, its concentration performance is lower than the conventional PV system in winter. Consequently the system with $R = 1.5$ is considered the best design under the assumed operating conditions. The area of the installation and the solar panels of the system are 20 % and 30 % smaller than the conventional PV system respectively.

The system with $R = 1.5$ was built as an experiment setup. Experiments were conducted under the weather of partly cloudy and sunny in August and September. The solar radiation intesity on the solar panel of the system with $R = 1.5$ was successfully enhanced by the reflector up to 50 % at the maximum. In contrast, the

output power was not improved so much as the concentration. It was considered to be caused by the non-uniform distribution of the solar illumination on the solar panel. The results suggest that suitable PV panels are necessary to boost the output even with non-uniform illumination.

Nomenclature

L_m	The length of the flat planar reflrctor
L_{land}	The length of the land for installation of the conventional PV system
L_{PV}	The length of the solar cell
R	The ratio of the length of the solar cell and flat planar
W_{land}	The width of the land for installation of the conventional PV system
θ	The inclination angle of the solar cell
ϕ	The inclination angle of the flat planar reflector reflector

Abstract

Photovoltaic, PV, power generation is reaching unprecedented levels of penetration in many power grids around the world. Such trend is forcing utilities and transmission system operators to rethink the traditional ways to schedule the operation of their power generators. In this study we investigate the impact of day-ahead forecasts of PV power on the unit commitment scheduling of a regional power system. To do that we assumed a scenario of 33 GW of PV installed in the Kanto region in Japan, and that PV power can be curtailed. Using day-ahead forecasts of PV power, we generated daily unit commitment scheduling for one year, and compared them with those generated with a forecast without error. Annually, the amount of power curtailed based on the day-ahead forecasts differed in 1% of the amount required when a perfect forecast was used. Nevertheless, day-ahead forecast errors caused an increase 1.7% of the generators fuel costs (a significant value for cost). Day-ahead forecast errors also caused a need of curtailment in months when the relation between power demand and PV power generation by itself would not require it, such as June and July. Finally, the detection of PV curtailment based on day-ahead forecasts had a positive predictive value (precision) of 73%, but a true positive rate (hit rate) of 32%. Such results are mainly explained by the poor performance of the forecasts on spring and summer in Kanto, indicating a specific period when the forecast error should be improved.

Keywords: Photovoltaic Power, Day-ahead Forecasting, Power System Simulation, Curtailment of Power.

1. Introduction

Scenarios of high penetration of photovoltaic, PV, power generation on power grids are becoming reality in many places around the world. Such growth is causing transmission system operators (system operators hereinafter) to search for new ways to operate their systems so that PV, and renewable energy systems in general, can be smoothly integrated with conventional power generators. To support such integration process, measures such as construction of better transmission lines, storage solutions, demand response measures, etc., should also be taken to prepare power grids and power systems to high levels of renewable energy penetration. The implementation of such measures, however, require considerable investments, and long periods. Thus, in markets where the penetration of renewable energy is growing sharply short-term measures must be taken to support renewable while long-term measures are being implemented. One of such short-term measures is curtailment of renewable power generation.

In Japan, a rapid growth of PV systems associated with limited interconnection capacity between balancing areas caused the government to authorize, since April of 2016, utilities to curtail PV power without quantity or period limitation whenever they judge its generation will affect the stability of the power grid. However, to do that the utilities must inform PV systems owners one day ahead of the time that their PV system's power generation should be curtailed. This rule makes the use of day-ahead forecasts of PV power an essential condition in the operation of PV systems in Japan. Unfortunately, day-ahead forecasts of PV power are not always accurate. Thus, it is necessary to evaluate the impact that forecast errors will have on the effective curtailment of PV power, and on the overall operation of power systems. In technical literature many studies focus on the unit commitment side of the problem, including the development of stochastic of probabilistic unit commitment planning that can integrate uncertainty of renewable energy system's power forecasts (Lowery and O'Malley, 2012), (Wang et al, 2011), (Peng and Jirutitijaroen, 2009), (Ikeda et al, 2012). Nevertheless, studies that evaluate directly the impact of forecast errors of PV system's power generation on its curtailment and on unit commitment planning are still scarce.

doi:10.18086/swc.2017.21.01 Available at http://proceedings.ises.org

Our research group has been investigating the general effects of different kind of PV and wind power forecasts and the use uncertainty information regarding such forecasts in modeling the operation of power grids (Udagawa et al, 2016, 2017a, 2017b). In this study our objective is to clarify the direct relation between day-ahead forecast inaccuracies and errors on curtailment of PV power. Specifically, we investigate such relation in a scenario of high penetration of PV power and when its curtailment is regarded as a routine to deal with PV power fluctuations. To provide realistic results, 30-minute UC scheduling for the region of Kanto in Japan, considering also a scenario for the distribution of power generators installed in the area by 2030, was done for a period of one year. The UC scheduling used day-ahead forecasts of PV power and the expected power demand for each day of the period studied. The impact of the forecast error on curtailment of PV, was also evaluated using as reference a second UC scheduling done with PV forecasts without errors. Such scheduling represents an ideal or perfect one as it is based on zero errors forecasts. Comparing both UC scheduling we analyze how forecasts affect the annual amount of power curtailed, if it is properly detected one day ahead of time, the annual running costs of the power generators, and other characteristics of the regional power system in different time scales.

2. PV Power Forecasting and Uncertainty Estimation

To forecast regional PV power generation a method developed by Fonseca et al., 2015a was used. With this method first insolation in 6 points locations within the Kanto area were forecasted hourly one day ahead of time. Point insolation values were used to obtain the regional yield, which then was converted to regional PV power generation. This calculation procedure was repeated for each targeted hour within the period studied. A brief description of the data and methods used are described in the following paragraphs.

The forecasts of insolation were done for each hour using as input data numerical weather prediction data of the Japan Meteorological Agency. Namely, data from the grid-point value meso-scale model, GPV-MSM, developed by Saito et al., 2006, were used. From the data set related with this model, air temperature, relative humidity and cloudiness in 3 levels were retrieved and used as input data of the forecasts of insolation. In its most recent version the GPV-MSM provides data with a lead time of up to 39 hours ahead of time, with a spatial resolution of 5 km by 5 km in Japan and surroundings. For the day-ahead forecasts data released at 12 h, Japan Standard Time, of the day preceding each targeted day were used as input. The targeted hours to be forecasted were within 5 h and 20 h of each day. Thus, the insolation and PV power forecasts were done one day ahead of time with a lead time varying from 17 hours to 33 hours. Besides the GPV-MSM variables the theoretical horizontal plane extraterrestrial insolation of each hour targeted was also used as input data of the forecasts. Finally, regarding the data used in the PV forecasts, they correspond to the fiscal year of 2013, April to March, and the forecasts were interpolated to 30-minute values to perform the UC scheduling calculations.

To make the forecasts a machine learning technique known as support vector regression was used. The support vector regression technique converts the learning problem as an optimization procedure, and the relation between the input and output variables is modeled through a linear fit in a high-dimensional space. The original problem is mapped to a high-dimensional space with kernels. Thus a kernel function has to be chosen and set as part of the problem. In this study the Gaussian kernel was used. The specific support vector regression technique used was the ν-support vector regression, which was developed by Schölkopf et al., 1998, implemented in port of the LibSVM library (Chang et al., 2001) for the R language.

Before being used in the training stage, the support vector regression algorithm has to have its configuration parameters set. The configuration parameters in this case were set with an ensemble based approach also described in Fonseca el al., 2015a. Regarding the training data, each set of 16 hours characterizing one day-ahead forecasts was done with a support vector regression model trained with data of the 60 days preceding the targeted day of the forecasts. Thus a unique forecast model for each day forecasted was developed.

Once an insolation forecast for a given hour and day is done for each of the 6 point locations within Kanto area, the regional value was obtained with an upscaling procedure, regarding the regional yield as the average value of the 6 point forecasts as showed in Eq. 1. Once the regional insolation forecast is obtained for a given hour, its value is converted to regional PV power following the formulation suggested by JISC8907 standard to calculate PV power from insolation. In this formulation all non-linearities and losses involved in insolation to PV power power are represented by a performance ratio factor as showed in Eq. 2.

$$H_{rj} = \frac{1}{N} \sum_{n=1}^{N} H_{p(n)} \quad (1)$$

$$P_{rf} = P_{ins} \cdot \frac{H_{rf}}{G_s} \cdot K \quad (2)$$

In Eq. 1 H_{rf} is the regional insolation forecasts, in kW/m^2, calculated for a given hour based on the insolation forecast H_p of N points within the target region. This regional insolation forecast is used in Eq. 2 with the PV installed capacity P_{ins}, in kW, the insolation in standard conditions G_s, regarded as 1 kW/m^2, and a performance ratio K, set as 0.8, to calculate the PV power forecast.

To make the UC scheduling with the model described in section 3, besides the deterministic forecast of PV power generation at a given time, it is also necessary to have information about the uncertainty of such forecast. If such information is not available, uncertainty could be represented by a margin of variation from the forecasted value, such as 10% or 20% of it. In this study, for each forecast value of day-ahead regional PV power generation, the uncertainty of it was estimated via prediction intervals. The prediction intervals for the forecasts of PV were calculated using a method we proposed in Fonseca et al, 2015b. In this method, past forecasts are used to estimate the prediction intervals of a target forecast. Basically, this is done in 3 steps. First, past forecasts are selected from a database of forecasts for the region based on how similar their input data are to those of the target hour. Once a set of past forecast is formed, their error is calculated and it is assumed that its distribution follows a Laplacian distribution. Finally, through the maximum likelihood method the best Laplacian distribution that fits the data is selected. Prediction intervals for any forecast are then calculated using the selected distribution. Details about the calculation of prediction intervals for PV forecasts are in Fonseca et al., 2015b. Prediction intervals for the PV forecasts with confidence level of 90% were used in the UC scheduling.

3. Power System Scheduling Model

The operation of power systems in Japan is executed by different system operators depending on the region of the country. Each system operator must schedule the use of their power generators in different time frames so that power demand is always properly and timely supplied. At the day-ahead time frame, the use of power generators available to the operator is planned so that total operational costs required to supply demand of power are minimized under constraints that guarantee all security of supply requirements and the balance between supply and demand of power are met. After that, in intra-day and real-time operation the use of the generators follow dispatch strategies with the similar objectives.

At day-ahead level, one way of scheduling power generators of a region is known as unit commitment, UC, scheduling. In this study we used an UC scheduling model developed by Udagawa et al, 2016. This model minimizes the fuel, *CF*, and start-up, *CS*, costs of a set of *n* thermal power generators in a given area necessary to meet the expected power demand of the 24 hours of the next day in each *t*, 30-minute intervals (Eq. 3). In Eq. 3 *pSt* is a binary variable (0 or 1) indicating if generator *n* is going to be started or not at time *t*. The fuel costs are calculated based on the power output of each power generator considering partial load efficiency and series of constraints that ensure that power demand will be met and that secondary regulation control reserves of power will be available in real time operation of the power system.

Detailed description of the basic model and its constraints are available at Udagawa, 2016. The development of specific constraint conditions model PV curtailment was presented in Udagawa, 2017b. In this section only the main constraints are presented. The constraint in Eq. 4 ensure that power demand forecast $d_t^{(f)}$, in MW, is met by power provided by *n* thermal power generators $p_{n,t}$, by *m* hydro-pumped power generators ($g_{m,t}$ for generated power and $h_{m,t}$ for consumed power) and by PV power after curtailment, pv_t. The constraint in Eq. 5, guarantees that PV power after curtailment is always equal to or smaller than the amount forecasted, $pv_t^{(f)}$, (as it is a day-ahead scheduling). Constraints in Eq. 6 to Eq. 11, ensure that the thermal generators operate within their maximum and minimum operation loads at any time, mxT_n, mnT_n, allowing for reserves of secondary regulation control, for each power generator. For example, the constraint in Eq. 6 controls the upward spinning reserves, Eq. 7 the downward spinning reserves, and Eq. 8 controls the maximum amount allowed for upward secondary control regulation reserve. Finally, Eq. 9 guarantees that the operation of the power generator does not exceed its maximum capacity and E.q 10 and Eq. 11 control downward secondary control regulation reserves. These constraints also ensure that at any given time there will be always power reserve available to deal with the forecast error up to a margin given by the superior and inferior prediction intervals, pv_t^{fu} and pv_t^{fd} provided with the forecasts.

Minimize $\sum_{t=1}^{T}\sum_{n=1}^{N}(CF_{n,t} + CS_{n,t} \cdot pSt_{n,t})$ (3)

Subject to

$$\sum_{n=1}^{N} p_{n,t} + \sum_{m=1}^{M} (g_{m,t} - h_{m,t}) + pv_t \geq d_t^l, \forall t \quad (4)$$

$$pv_t \leq pv_t^f \forall t \quad (5)$$

$$\sum_{n=1}^{N} (p_{n,t} - p_{n,t-1}) \geq 0.05 d_{t,max}^l + \max(pv_t - (pv_t)^f, 0), \forall t \quad (6)$$

$$\sum_{n=1}^{N} (p_{n,t} - p_{n,t-1}) \geq 0.05 d_{t,max}^l, \forall t \quad (7)$$

$$pWk_{n,t} \cdot mxT_n \cdot (1 - blT_n) \leq p_{n,t}, \forall t, \forall n \quad (8)$$

$$p_{n,t} \leq pWk_{n,t} \cdot mxT_n, \forall t, \forall n \quad (9)$$

$$pWk_{n,t} \cdot (mnT_n + mxT_n) - p_{n,t} \leq p_{n,t}, \forall t, \forall n \quad (10)$$

$$p_{n,t} \leq \bar{p}_{n,t}, \forall t, \forall n \quad (11)$$

In Eq. 5, Eq. 6, Eq. 7, Eq. 8, Eq. 9, Eq. 10 and Eq. 11, $\dot{p}_{n,t\ t}$ is the maximum power output of a thermal generator *n* at time *t* discounting its secondary regulation control reserve margin. The symbol $\underline{p_{n,t}}$ is the minimal power output of a thermal generator *n* at time *t*, discounting its secondary regulation. In Eq. 6 $pWk_{n,t}$ is a binary decision variable indicating if thermal generator *n* is online or not at time *t*, and blT_n is the maximum amount of secondary regulation reserve that can be provided by a thermal generator, and it is expressed as a ratio of the generator's maximum power output. Constraints that allow for the determination of the optimum number of power generator needed to provide necessary secondary regulation reserve are also inserted in the optimization model. They are described in in Udagawa et al, 2016.

It was assumed in this model that up to 5% of the maximum operation loads of online thermal generators are regarded as reserve for secondary regulation control reserves. For pumped hydro power the maximum values were 16.5% when generating power and 10% when pumping up water to the reservoir. Moreover, only 11 pumped hydro-power plants were regarded as capable to provide LFC reserve in pumping mode as not all of them have this capability. Pumped hydro power efficiency values were set with values from 60% to 70% depending of the plant. These values are regarded as typical values for the area studied and are also based on Udagawa et al, 2016.

In the UC scheduling calculation, PV power generation is used also to determine the necessary power reserve to deal fluctuations of power in real-time operations. Curtailment of PV will be scheduled then, whenever it is not possible to allocate enough power reserve to deal with PV power fluctuations at a feasible cost. The required reserve of power as having the magnitude of the prediction intervals of the forecasts of PV with a confidence level of 90% plus the power demand fluctuation. Every time, for any given operation time, power reserve required to cover forecasted PV and associated prediction intervals reach physically unfeasible values or has cost beyond acceptable values, curtailment of PV is scheduled.

Depending on how curtailment is applied in practice, different interpretations of the effects of the forecast errors can be done. We assumed, that when curtailment request signal is sent one day ahead of the time to a PV system owner, it sets in the power conditioning system, PCS, of the PV system a maximum output value allowed at a given hour. This value is fixed and based on the capacity of the PCS. Thus, if a curtailment request is issued at a given hour, and less insolation than forecasted is realized (yielding less PV than the maximum allowed), no curtailment of PV is done.

4. Target Region and Simulated Scenario Description

The Kanto region in Japan was the target area of the study. It is where Tokyo is located. It is the region with the highest regional power demand in Japan. The regional power system comprising power generation, transmission, distribution is operated by TEPCO power utility, although the market is currently in the process of being liberalized. Besides Kanto area, TEPCO operates also in parts of the prefecture of Shizuoka and Yamanashi. In this study we considered the whole area operated by TEPCO as Kanto area, so that the real balancing area could be better simulated. Regarding power generators installed in Kanto region, a scenario for 2030 regarding their configuration and installed capacity based on the study of Ogimoto et al., 2012 was used. The assumed values for number of generators, their type and capacity are in Table 1.

Tab. 1: Characteristics of the power plants simulated for Kanto region power system.

Type of Generator	Number of Generators	Installed Capacity (GW)
Coal	15	9.6
LNG	57	22.1
Oil	20	10.8
Hydro Pump Storage	52	13.68
Nuclear and Hydro	Assumed as providers of base load	13.1

A scenario of high penetration of PV was also assumed. Such scenario is based on a study published by New Energy and Industrial Technology Development Organization, NEDO (2010), investigating the possibility of 100 GW of PV power penetration in Japan by 2030 (NEDO, 2014). Based on this value, we considered PV installed capacity as following the ratio between each region and the national annual power demand. Doing that, in a scenario of 100 GW for Japan and if PV is deployed proportionally to the area power demand, Kanto area should have 33.1 GW of PV power installed, which was the scenario simulated.

To simulate real operation conditions of the power system in Kanto, power demand and weather forecast data of the region were used. Power demand data for 1 year, from April 2013 to March 2014, for Kanto region, with a temporal resolution of 30 minutes were used. Accordingly, weather data of the same period was used to yield the insolation and PV power forecasts. Forecast of insolation for 6 points within Kanto area were done one-day ahead of time, from 5h to 20h of each target day. The insolation forecasts were done hourly due to the temporal resolution of the weather data used as input of the forecasts. Thus a simple interpolation procedure was applied using values of two consecutive hours to obtain 30 minute forecasts. This procedure was only applied after the regional forecast of PV power was calculated. The names and approximate location of the 6 places within Kanto for which insolation forecasts were done and, from which the regional yield was estimated, are in Table 2. In each location there is a weather measurement station of the Japan Meteorological Agency.

Tab. 2: Location of the 6 points within Kanto for which forecasts of insolation were done.

Location	Utsunomiya	Maebashi	Kofu	Tsukuba	Choshi	Tokyo
Latitude	36.54 N	36.40 N	35.66 N	36.05 N	35.73 N	35.68 N

5. Results

In Fig. 1 four annual values of the day-ahead forecast errors are presented. The root mean square error, $RMSE_n$, mean absolute error, MAE_n and mean bias, $Mbias_n$, were calculated hourly and normalized by the total rated PV power assumed to be installed in the region. To offer a extra measurement of the accuracy of the forecasts the mean absolute percent error $MAPE_n$ is also provided. In this case, it was calculated in daily fashion and normalized by average PV power generation (also daily). The values in Fig. 1 indicate that the accuracy of the regional day-ahead forecasts for Kanto had usual values found for this kind of forecast in Japan (Fonseca et al, 2014).

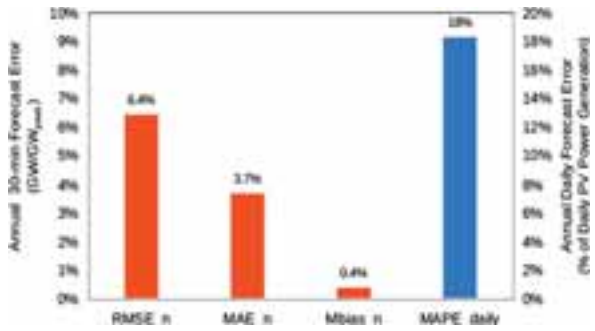

Figure 1: Regional PV Power Forecast Errors for Kanto.

One way to assess the impact of the day-ahead forecast errors showed in Fig. 1 on the UC scheduling of Kanto's power system is to compare the performance of a UC scheduling based on such forecasts with the performance of one based on a forecast without error (a perfect forecast). In Table 3, we present the annual amount of PV curtailed, fuel cost and curtailment period that both kinds of UC scheduling would yield. The results in Table 3 indicate that annually the total amount of PV curtailed, when each kind of forecasts was used, was near to 5% of total PV generated.

Tab. 3: Scheduling of PV curtailment and Running Cost of Kanto Power System in 1 Year based on a UC using day-ahead forecasts, and a UC using a perfect forecast (without forecast errors).

Forecast	PV curtailment scheduled (% of total PV power generated)	Generators' Fuel Cost (10^9 JPY)	Curtailment Period (% of total 30m intervals*)	PV Curtailment MAE_n (scheduled vs. total PV surplus) (% of average PV Power generated*)
Day-ahead	4.90	715.7	18.3	7.2
Perfect	4.96	703.7	13.0	--
Variation	-1.2%	+1.7%	+41%	--

*Within the period of PV forecasts (1 year from 5h to 20h).

Regarding the forecast error, its impact in the annual PV curtailed was relatively small; when day-ahead forecasts were used in the UC the annual PV scheduled to be curtailed was 1.2% lower than the amount that would be curtailed if perfect forecasts were used. On the other hand, looking at the curtailment period at Table 3, when day-ahead forecasts were used, curtailment was scheduled to happen for a longer period than it should reaching 18.3% of the time in the year studied (against 13% of the case when perfect forecasts were used). Thus, the forecast error caused scheduling of PV curtailment in hours when it was not necessary, and also insufficient scheduling of curtailment in the hours when it was necessary. The impact of the forecast error also caused an increase of 1.7% of the power systems fuel cost. Although this value seems small, as its unit is 10^9 JPY it has considerable impact in the operation cost of the system. Such increase of the operation cost is related with how the thermal and hydro pump power generators are used to satisfy the residual power demand in the day-ahead forecast based and perfect forecast based UC. It represents the impact of having to maintain reserve power to deal with the forecast error.

Finally, the cost of the forecast error can be expressed as the mean absolute error of PV power scheduled to be curtailed when compared with the total PV power surplus at each hour. Table 3 shows that, in average, 7.2% of the average annual PV power generated (in GW) was wrongly curtailed. In the cases that PV curtailment errors were negative, more PV than scheduled was curtailed, yielding higher economic and energy losses to owners of PV systems than expected. When the error was positive less PV than scheduled was curtailed (due to less PV generation than forecasted). Although, in this case some PV systems' owners will have less economic losses than expected, there will be losses due to issuing unnecessary PV curtailment requests.

In Fig. 2 the amounts of PV scheduled to be curtailed monthly with the the real forecast based UC and with the one based on a perfect forecast are presented. Because the day-ahead forecasts contain errors, when using them to curtail PV power, two other quantities will appear besides the scheduled PV curtailment. The first one is the actual curtailment of PV power, and it is a direct consequence of the way curtailment was applied (section 3). It represents the difference between actual PV power surplus and PV power scheduled to be used in the power grid, when curtailment was scheduled to happen. The second quantity is the required curtailment of PV. It represents the actual PV curtailment (black dotted line in Fig. 2) plus the PV surplus that must be curtailed but it was outside the hours in which PV curtailment was scheduled to happen. In the case of a perfect forecast both quantities disappear.

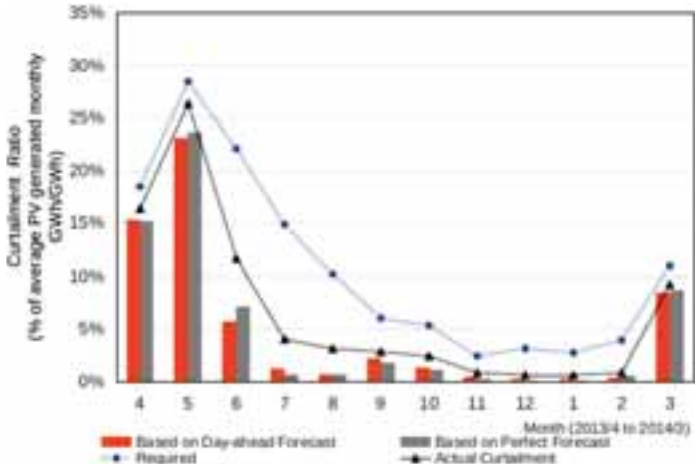

Figure 2: Monthly PV power curtailment ratio in Kanto using real day-ahead forecasts and perfect ones.

The results in Fig. 2 show that if there were no forecast errors, the months when PV would be strongly curtailed would be April and May, and at a lower level March and June. In spring in Kanto, insolation is almost as high as summer but power demand is lower than in winter and summer. In such conditions even using the conventional

power generators at their minimum loads would not be enough to prevent considerable curtailment of PV for the scenario studied. On summer, higher power demand reduces considerably the need for curtailment of PV. The result would be July and August with low PV curtailment as showed by day-ahead and perfect forecast based UC scheduling results in Fig. 2. Nevertheless, what happens is different due to the forecast error. The curtailment required item in Fig. 2 indicates that from June to August between 10% to 25% of the average PV generated in these months should be curtailed if day-ahead forecasts with errors were used. Moreover, in June the required curtailment was more than 2 times higher than the actual one. That result indicates that in June there were many hours in which there was surplus of PV power but there was no scheduling for its curtailment. These hours, in which curtailment happened, were not regarded as such one day ahead of the time.

A forecast error of the PV generation expected at a given hour can cause a difference between PV scheduled to be curtailed, the actual amount curtailed and the required amount to be curtailed. If such PV generation is underestimated, for example, the required curtailment of PV will be higher than the scheduled and the actually curtailed PV power. The result will be an unexpected surplus of PV that the power utility will have to deal with in a short period of time during the operation day. The results in Fig. 2, show that such unexpected surpluses of PV can occur even in months with high demand of power such as July and August.

To better understand the relation between the day-ahead PV power forecast error and the difference between actual PV curtailed and required curtailment in Fig. 2, in Fig. 3 we plotted the monthly PV forecast mean absolute errors and their respective mean biases.

Figure 3: Monthly day-ahead PV power .forecast mean absolute errors and mean biases of Kanto region.

The results in Fig. 3 show that June and July had the PV power forecasts with the highest mean absolute errors of the period studied. Furthermore, these two months also had not only negative biases but also the lowest ones of the period. These two characteristics indicate that in many hours in those months, the PV forecasts underestimated significantly the PV generated. As a consequence, the associated UC scheduling in this period did not curtail enough PV, yielding the behavior presented in Fig. 2.

Continuing the comparison between the curtailment of PV scheduled with day-ahead forecasts with the one curtailed with a perfect forecast, Fig. 4 shows the direct relation between both curtailment values throughout the period studied. A linear fitting is also plotted with the respective coefficient of determination. The value of coefficient of determination indicates that in general there was good agreement between both variables. It shows that 83% of the variance of the curtailment scheduled with a perfect forecast was explained by the curtailment scheduled with the day-ahead forecast. A particularly good relation between both variables is observed when curtailment of PV was higher than 10 GW. In this range, scheduled curtailment based on day-ahead forecasts of PV was usually similar to the one based on a perfect PV forecast. The lower the curtailment of PV based on day-ahead forecasts, the higher was the largest deviation from the curtailment value based on perfect

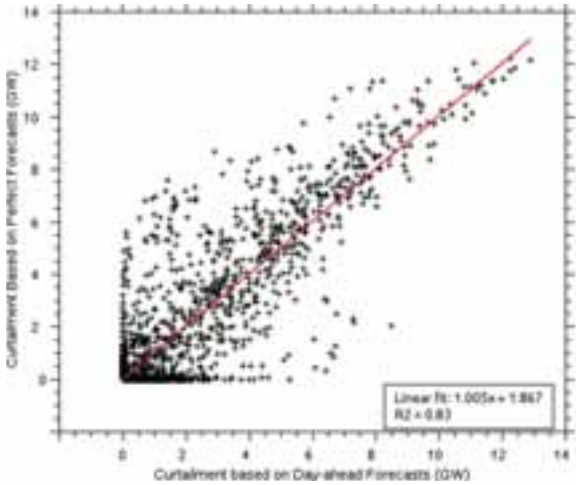

Figure 4: Curtailment of PV based on a perfect forecast versus curtailment of PV based on day-ahead forecasts for Kanto region.

forecasts. For example, when 2 GW of PV were scheduled to be curtailed with day-ahead forecasts, their errors caused a deviation of almost 6 GW from the value that would be curtailed if perfect forecasts were available. For this specific hour, the forecast of PV power generation greatly underestimated the amount actually of PV generated.

Besides the fuel cost of the power system and the error of the amount of PV curtailed, another effect of the day-ahead PV power forecast error on PV curtailment, regards the identification of the hours in a day when curtailment of PV should be applied. If PV curtailment is scheduled to happen at a given hour and due to the real amount generated, it is found that such curtailment was not necessary, this is an hour when curtailment was wrongly scheduled. The opposite, no curtailment scheduled but actually required, is also a scheduling error. To verify the effects of the forecast error from this point of view, Table 4 contains a contingency table of the hours (counted as two 30m time intervals) of the period studied with and without curtailment; the precision and hit rate achieved in the same table.

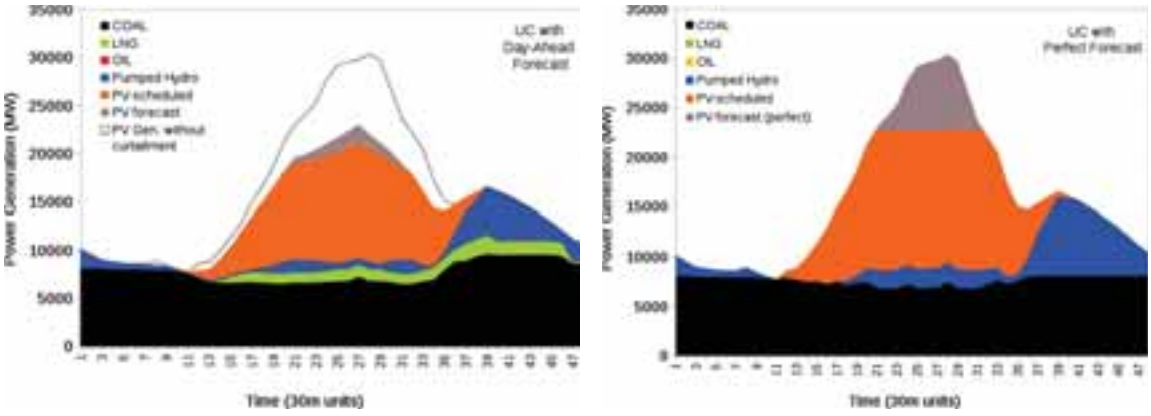
Table. 4: Hours with PV curtailment based on day-ahead forecasts of PV for Kanto region in 1 year.

		Required		Precision (AC/(AC+AB))
		Yes (A)	No (B)	
Based on day-ahead Forecasts	Yes (C)	1517	552	73.3%
	No (D)	3161	6085	
Hit rate (AC/(AC+AD))		32.4%		

The precision indicates how reliable was the PV curtailment scheduling based on day-ahead PV forecasts, when it indicates that in given hour curtailment will happen. According to this parameter, curtailment scheduling based on day-ahead forecasts had a good level of reliability; in 73% of the hours that curtailment was forecasted, it was actually required. The accuracy (ability to identify correctly the hour with and without PV curtailment) of the scheduling based on day-ahead forecasts was slightly lower than its precision, reaching 67.1%. Nonetheless, the corresponding hit rate was low, indicating that most of the hours of the period studied in which curtailment was required, it was not detected. The low detection of curtailment hours is associated with forecasting less PV power than the actual value. Additionally, in months with negative bias the difference between scheduled curtailment and required one was considerable. We infer from these results that, even though the bias of the day-ahead forecasts, in Fig. 1 and Fig. 3, were not particularly high, reducing even further the forecasts' bias may improve PV curtailment scheduling.

Comparing with a perfect forecast, the curtailment scheduling based on day-ahead forecasts actually yielded more hours of curtailment, Table 3. This result seem to contradict the results of low hit rate in Table 4. However, when should keep mind that the day-ahead error affected the occurrence of curtailment itself, by scheduling curtailment in the wrong hours and by not scheduling it in the right ones. This wrong scheduling generated a need for curtailment that would not exist if a perfect forecasts were used. Therefore, reducing the day-ahead error of the forecasts should cause a reduction of item AD and BC in Table 4, and a proportional increase on item BD.

Besides the error regarding the amount and hours of PV curtailed, the error and uncertainty of the day-ahead forecasts also have an important effect on the way different conventional power generators are scheduled to be used. To show this effect, in Fig. 5 we plotted the UC scheduling with day-ahead forecast and with a perfect forecast. The plots represent the respective UC scheduling in a day in which the forecast of PV power strongly underestimated the the actual PV generation.



(a) (b)

Figure 5: UC scheduling of a day (June 2nd) based on day-ahead (a) and on perfect (b) forecasts of PV power generation for Kanto.

The UC scheduling based on day-ahead forecasts, in Fig. 5(a), shows that almost all of the PV generation forecasted was scheduled to be used, with small amounts pumped hydro and LNG, which are used to provide secondary regulation frequency control and to compensate for the uncertainty associated with the forecasts. Coal provides the remaining amount of power to meet the demand. Still, looking at the PV power generated in Fig. 5(a) one see that PV power generation greatly exceeded the forecasted amount even with the part scheduled to be curtailed. For example, looking at the dotted line in Fig. 5(a) at 13h30 (point 27 in the plot), 21 GW of PV were scheduled to be used from a forecast of 23 GW.The amount generated after curtailment was 27 GW, resulting in extra 6 GW of unscheduled PV power that will be curtailed. The economic loss for PV systems' owners will be in this case considerably higher than expected. On the other hand from point 11 to 20 and from point 32 to 35 no PV was scheduled to be curtailed and thus the surpluses generated at those hours will have to be dealt with in the intra-day operation to avoid frequency and instability problems on the power grid. In these hours unscheduled PV power curtailment occurs, something that could be avoided reducing the error of the forecast used.

In the UC scheduling based on a perfect forecast, the power generators are used differently. First, due to the lack of uncertainty of the perfect forecast and high amounts of PV power, LNG generators do not need to be used at all and pumped hydro increase its contribution on the total power generated. Moreover, in this case, from 9h to 16h, the maximum amount of PV the grid can absorb is scheduled, near to 22.5 GW, and the remaining PV generation is curtailed. The total amount scheduled to be curtailed in this day with the perfect forecast use was near to 50 GWh against 14 GWh with the day-ahead forecast. Although more PV is scheduled to be curtailed with the perfect forecast, considerably more PV is also used compared with the curve in Fig. 5(a) and no surplus of PV will have to be dealt with in intra-day operations. Moreover, although only 14 GWh of PV were scheduled to curtailed with the day-ahead forecast, in reality the actual curtailment reached by using the respective UC scheduling 94.7 GWh, considerably higher than what would be curtailed with a perfect forecast.

6. Conclusions

The objective of this study was to investigate the use of day-ahead forecasts of PV power in the unit commitment scheduling of a regional power system, and its effects of the scheduling of PV power curtailment. A comparison with a UC scheduling based on perfect forecasts showed that monthly, the use of the day-ahead approximates well the amount of PV power that should be curtailed with a perfect forecast.

Nevertheless, the day-ahead forecast errors had some important effects on UC scheduling and PV power curtailment. Annually, it caused a more expensive scheduling of power generators, and curtailment for longer periods than necessary and in the wrong hours. Additionally, although the monthly PV scheduled to be curtailed based on both UC scheduling were similar, the day-ahead forecast error caused a surplus of PV power generation that has to be curtailed in situations when insolation and power demand conditions would not justify curtailment. June and July were examples of when such cases occurred. In those months there was a negative bias of the day-ahead forecasts, which explain in part the poor detection of the hours when PV curtailment should happen. Thus, one potential measure to reduce such poor detection of curtailment is to further reduce the day-ahead forecast bias, particularly in spring and summer and in the hours when PV should be curtailed.

From the results we conclude that when using day-ahead forecasts of PV in the UC scheduling problem, the forecast error will cause not only affect the fuel cost of the power generators, but it will also yield a considerable

amount the PV surplus that will have to be dispatched or curtailed in intra-day operations. Thus, further measures to improve day-ahead forecast accuracy and to integrate PV forecast error in the UC modeling should be investigated to reduce PV curtailment and to support higher penetration of PV power in the power grid in Japan.

Finally, It should be mentioned that improvements on forecasting techniques are not the only way to deal with the problem of curtailment. Unoptimizing the tilt of PV panels, improved interconnections, demand response, and other measures can be applied together to reduce the need for curtailment of PV in a scenario of high penetration. The compound effect of all these measures together is an interesting topic that also should be investigated in further studies.

Analysis of Daylight Availability in Italy trough different Luminous Efficacy Models

Francesco Spinelli, Domenico Iatauro, Paolo Signoretti, Luciano Terrinoni, Michele Zinzi

ENEA

(*Italian National Agency for New Technologies, Energy and Sustainable Economic Development)*
Via Anguillarese 301, 00123 Rome, Italy

Abstract

This paper presents the results of a study aimed at developing an Italian database of Typical Meteorological Year (TMY) for the global and diffuse outdoor illuminance, starting from solar irradiation measurements and luminous efficacy models. The main objective is to provide reliable climatic data to be used for the estimation of the daylight availability in buildings and predict the energy requirements for electric lighting with higher accuracy than the actual relevant standard. ENEA developed the national solar radiation atlas during the past years, implementing validated models to predict the global, direct and diffuse irradiation, starting from satellite remote sensing. For this study, the most relevant luminous efficacy models were applied to develop illuminance TMY starting from solar irradiation data. Illuminance availability curves were developed for three reference localities of the Italian territory (Milan, Rome, Palermo), highlighting how results can be used to derive the potential contribution of daylight for buildings energy applications. In order to verify the results obtained, a ground measurements compaign of the outdoor illuminance, was started to test the effectiveness of model. The first data processed, show low differences between estimated values and measured data, confirming the validity of selected model.

Keywords: Daylight availability; luminous efficacy; outdoor illuminance, TMY,

1. Introduction

The building sector is responsible for more than 40% of the energy end uses in Europe and plays a relevant role to reach the environmental and energy targets, in national and European policies [1,2,3]. It is also recognized that the energy performances of building should be addressed to the whole energy services, and not only the space heating as happened in the past decades [4]. Relevant studies carried out during the past years demonstrated the impact of the electric lighting on the energy uses in buildings. The figures are particularly relevant for the not residential buildings: 14% of the total consumption in EU, 26% in USA [5,6]. A study carried out recently in Spain set in 31% the share of the electricity uses on the total final demand in commercial buildings [7]. As a consequence, the energy savings in this energy service are found to be highly competitive in technical and economical perspective [8]. A relevant potential hence exist to improve the performance of existing and new building in terms of lighting energy uses.

It has to be noted that potential energy savings are often estimated in terms of higher efficiency of the electrical devices (lamps, luminaries, control sensors and systems) more than exploiting the daylighting potentialities by the implementation of advanced strategy and solutions. The reference document in EU for the assessment of lighting requirements in building is the EN standard Energy performance of Buildings. Energy requirements for lighting, which provides an operational method and two calculation methods, different in accuracy and complexity [9]. However, the reliability of the prediction methods needs to be carefully addressed, since the over/underestimation of the consumption respect to the practice is an obstacle to the technology spread, especially in the nearly zero energy building (nZEB) vision.

A critical issue is the assessment of the daylight contribution, which does not take into account the climatic conditions of the investigated locality. The Daylight Autonomy concept emerged in the past years as relevant metric to assess the daylighting contribution and, as a consequence, potential energy savings that can be achieved in buildings for the electric lighting service [10, 11]. Climate based approaches are getting interest for

doi:10.18086/swc.2017.21.02 Available at http://proceedings.ises.org

daylighting design methods, as described in [12]. The approach is also adopted in the implementation of an Italian alternative method is currently on going [13], whose main objective is merging the climate based daylighting with the calculation flux defined in [9].

The alternative method evidences the importance of robust and reliable climatic data, in this case global, direct and diffuse illuminance. This paper presents the first results of a review work aimed at developing an national atlas for outdoor illuminance data for building applications.

2. Objective and method

ENEA has defined an extensive database of hourly values of radiometric quantities: global horizontal irradiance (Igh), diffuse horizontal irradiance (Idh) and Direct Normal Irradiance (Idn) for any Italian site, have been derived by processing satellite data [14,15,16,17] provided by the EUMETSAT [18]. Advantages of satellite based data respect to ground measurements mainly depend of the fact that the latter are taken on a limited number of stations, while the former can be derived, if accurately geo-referenced, for any locality on the earth surface. Satellite images provide a measure of the reflection coefficient (albedo) of the planet surface at the switch instant. The algorithms developed by ENEA, based on the original idea of D. Cano et al. [19], compare the actual albedo with a reference one and convert the difference into a clearness index, used to derive the Igh. The application of additional empirical models of the atmosphere [20,21] allows to split Igh in its components: direct and diffuse. The results of the zoning of the solar radiation in Italy are published in the solar radiation atlas published by ENEA [14], which is going to be updated so to cover a 10 years observation period (2006-2015).

Core of this study is the use of radiometric quantities to derive correspondent photometric quantities, in order to build illuminance typical reference years to be used to assess the lighting performance of buildings. It has to be noted that radiometric and the photometric quantities are closely related, as the former measure the energy and the power of electromagnetic radiations, while latter translate the same energy or power in terms of visible light, linked to the physiological ability of the human eye. Since very few data, based either on ground or satellite measurements, are available to build illuminance reference years, empirical models were implemented. These models express the luminous efficacy of the solar radiation (ratio of the illuminance on the irradiance) as a function of variables that describe the sky conditions and the and the solar zenithal angle θz, clearness index KT, diffuse to global radiation ratio k, "clearness" and/or "brightness" indexes. Non general models, as those not implementing all the radiation components or those implemented for specific orientations, were not taken into account. In the this study some of most relevant models were taken into account and from in [22,23,24,25,26,27]. From now on selected models will be identified by the main author of the above listed references.

- Cucumo model, calibrated by irradiance and illuminance measurements at Arcavacata di Rende (CS), Italy [22].It is the simplest model of correlation, based on the direct proportionality between outdoor illuminance and irradiances.
- Muneer model, based in measurements taken in five UK localities, taken in the last decade of the previous century [23]. It is a
- relatively simple model that doesn't consider the current position of the sun and assumes the luminous efficacy expressed by polynomial equation linked to the only global transmission and the poliynomial coefficients derived by statistical regression.
- Perez model. Based on measurements taken in 10 USA and 3 European localities for periods ranging from few months up to 3 years. The model takes into account also the atmospheric precipitable water or, alternatively, the dew point temperature [24]. The irradiance not directly appear in the model expressions, but are combined with extra atmospheric irradiance, in specific indices: Perez's sky clearness index and Perez sky's brightness index. The model also takes into account the position of the sun through the zenithal angle. In the Perez simplified model, the hourly data of dew points are replaced with a daily mean value, constant for all the year. This simplification was introduced to test the impact of the parameter on the model accuracy, being often the dew point data of difficult availability

- Robledo models, based on historical series of data measured in 1994/95 in Madrid, Spain [25,26,27].

The Robledo and Soler models are as accurate as the Perez one, since they take into account the sun position and the sky's brightness and, at the same time, they only need few coefficients. Several models were developed as a function of different sky conditions: clear sky, partly cloudy and overcast sky. Furthermore simplified models are available to consider any weather conditions.

Outdoor illuminance time series database were thus built starting from an extensive solar irradiation time series database and luminous efficacy models. The time series were, next, used to develop a hourly based TMY (Typical Meteorological Year). The adopted criteria was to select, for each month of the year, a real complete month, among those available in the multi-year series, which best fitted the average of the multi-year datasets related to the specific month. This approach allows keeping the average values on the long term and catching the short term variability of the analyzed quantity, as it takes place in the reality. Reference months were selected using GHI as driving parameter, being the quantity directly derived from the satellite image.

TMYs were implemented for the following quantities: global horizontal (Egh), diffuse horizontal (Edh) and direct-normal illuminance (Edn), as done in the past for the solar irradiation. The TMY were developed for three reference localities:

- Milan, latitude 45°N, climatic conditions characteristics of the northern Italian regions.
- Rome, Latitude 41°N, climatic conditions characteristics of the central Italian regions.
- Palermo, 38°N, climatic conditions characteristics of the southern Italian regions.

This preliminary exercise has also the objective of model calibration and/or adjustment by comparison with ground measured data as next step. A total of 15 TMYs was developed, including 3 localities and 5 different luminous efficacy models, having introduced a sensitivity test on water content in model [22]. The TMYs, implemented with the different models, were compared to assess coherence among them and their suitability in providing reliable data to predict energy requirement for lighting in buildings.

The comparisons were made for all models, with reference to the three locations and two lighting quantities (global and diffuse illuminance). The diagrams analyses and the approach indices show minimal differences of each model compared to any other. It is worth noting that for each model a very good agreement was found for the global luminous efficacy, while higher discrepancies were found for the diffuse luminous efficacy. This topic, which needs deeper analyses, might be related to selective phenomena related to the spectral distribution of the solar radiation under variable sky conditions

3. Calculation

Once the TMYs were developed, calculations were carried out to check and compare the different luminous efficacy models. A preliminary check was carried out for the Perez model, with the objective of quantify the impact of the simplification introduced in the previous section. The TMYs of the three localities for the simplified Perez model were implemented taking into account a constant dew point temperature Td (10.3 °C for Rome, 9.4 °C for Milan, 11.4 °C for Palermo). Relevant statistical parameters were calculated to quantify this assumption, namely: the Bias (or Mean Bias Error, MBE), the Mean Bias Error Percent (MBE%) and Root Mean Squared Error Percent (RMSE%), defined as follow:

$$MBE\% = \frac{MBE}{Mean\ of\ observations} x100 \qquad RMSE\% = \frac{RMSE}{Mean\ of\ observations} x100$$

in this case the "*observations*" are the Perez standard model values, considered as benchmark.

Calculation were carried out for the three localities, as an example for Rome (Tab. 1). It resulted: MBE = -155 lx; MBE% = –0.4 % e RMSE% = 1.3 %. The test was carried out for Rome also using extreme dew point values (Tab. 2), -13 °C and +22 °C. Negligible differences were found, in relation to the accuracy required for the purpose of the study.

Tab. 1: Comparisons simplified (max, min and average dew point) and standard Perez model. City: Rome

Model	Illum.	MBE [lx]	MBE %	RMSE [lx]	RMSE %	Mean [lx]
Perez with Dew point average = 10.3 °C	Global	-155	-0.4	531	1.3	42410
	Diffuse	-52	-0.3	297	1.8	16645
	Direct	-33	-0.1	627	1.5	40889
Perez with Dew point min = –13.3 °C	Global	-928	-2.2	1444	3.4	42410
	Diffuse	-519	-3.1	770	4.6	16645
	Direct	938	1.0	1608	3.9	40889
Perez with Dew point max = 22 °C	Global	1062	2.5	1529	3.6	42410
	Diffuse	683	4.1	970	5.8	16645
	Direct	-724	-1.8	2051	5.0	40889

Tab. 2 : Comparisons of simplified (average Dew Point) Perez model for different cities

Model	Illum.	MBE [lx]	MBE %	RMSE [lx]	RMSE %	Mean [lx]
Milan Perez with Dew point average = 9.4 °C	Global	-223	-0.6	601	1.6	37657
	Diffuse	-136	-0.8	397	2.5	16151
	Direct	87	0.3	762	2.2	34525
Rome Perez with Dew point average = 10.3 °C	Global	-155	-0.4	531	1.3	42410
	Diffuse	-52	-0.3	297	1.8	16645
	Direct	-33	-0.1	627	1.5	40889
Palermo Perez with Dew point average = 11.4 °C	Global	-175	-0.4	618	1.4	45653
	Diffuse	-77	-0.4	373	2.1	17963
	Direct	19	0.0	745	1.8	41779

According to the above tables it can be inferred the slight impact of the hourly dew point data on the final form of the luminous efficacy model, thus the simplified model was selected for the final comparison. Each model was compared versus the other three ones in the next step. An example is provided in figure 1, where a graphical comparison between two models is promptly achieved by scatter plots.

According to the approach index calculated for all the comparisons, it was found that differences among models are small. The calculation exercise led to the final decision of applying the Robledo model to build the Italian TMY illuminance database. In table 3 the comparison of the TMYs built using Robledo versus the TMYs based on the other model is presents by means of relevant statistic indicators

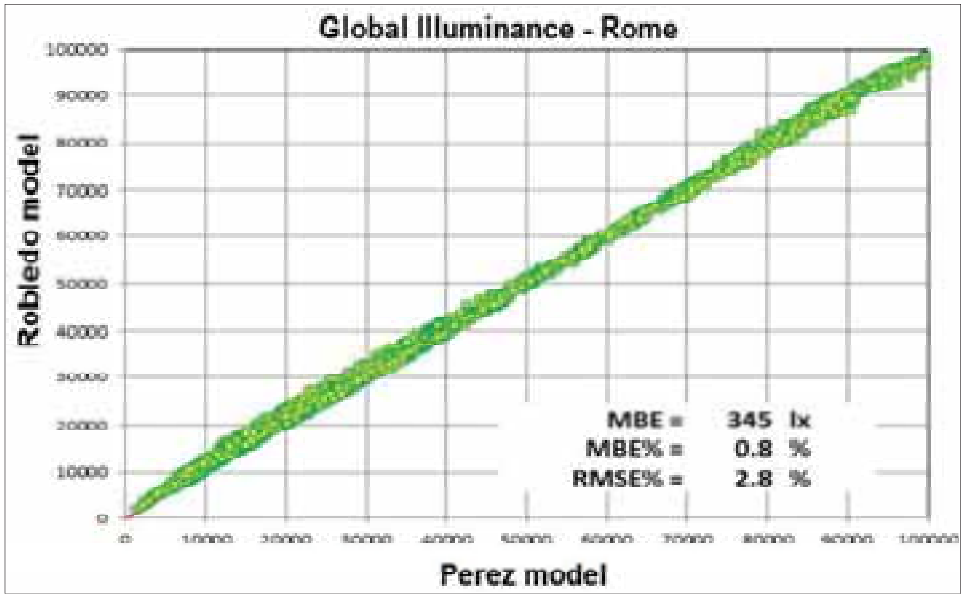

Fig. 1 Global illuminance values (Egh, in lx) of a typical year -town of Rome -comparison between two models

The Robledo model takes into account the sun position and the sky brightness, factors influencing the luminous efficacy, however the model is expressed in a compact form and do not takes into account the dew point temperature, figure of difficult availability. The Robledo model, here reported for clarity, is based upon the following equation set [25,26,27] :

$$\begin{cases} \eta_{dh} = \left(91.07 \cdot \Delta^{-0.254}\right) \ lm \ W^{-1} \\ \eta_{bn} = \left(134.27 \cdot \left(\cos \vartheta_z\right)^{0.269} \cdot \exp\left(-0.0045 \cdot \left(90° - \vartheta_z\right)\right) \cdot \left(1.045 - 0.427 \cdot \Delta\right)\right) \ lm \ W^{-1} \\ \eta_{gh} = \eta_{bn}\left(1-k\right) + \eta_{dh} k \end{cases} \quad \text{(eq. 1)}$$

Where:

Ƞ	luminous efficacy;
θz	zenith angle
Δ	sky brightness index:
dh	diffuse horizontal
bn	direct normal
gh	global horizontal

4. Results and Applications

The results following presented refer to the TMYs implementing the Robledo model. Figure 2 and 3 present the results of irradiance and illuminance availability for the global and diffuse quantities. The curves refer to the city of Rome, selected as exemplary locality for brevity, nevertheless similar results were found for Palermo and Milano. The radiometric and photometric quantities are expressed in relative figure (%) respect to the peak value to get rid of the different units and compare the profiles on the same graph.

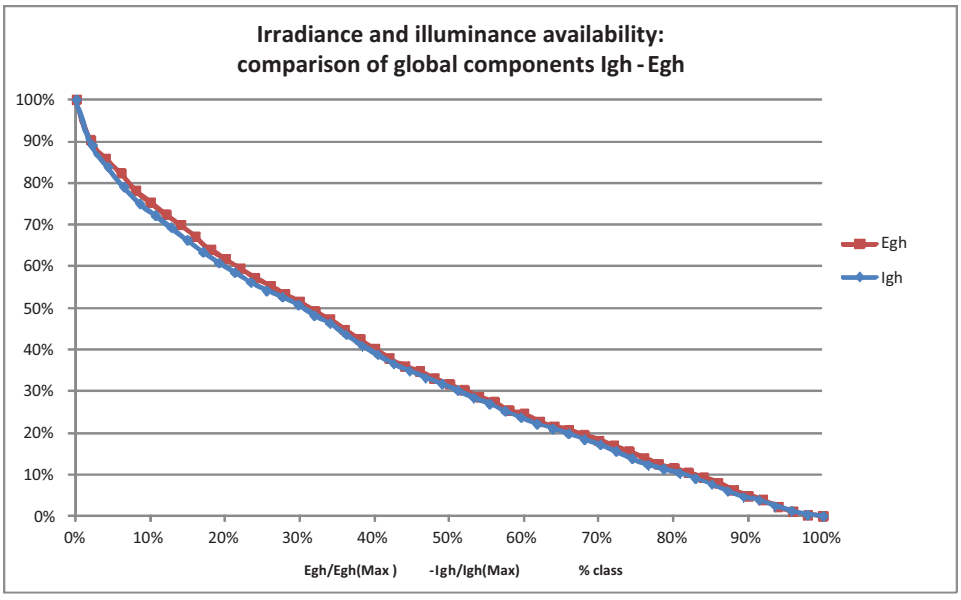

Fig. 2. Comparison of global irradiance Igh and global illuminance Egh

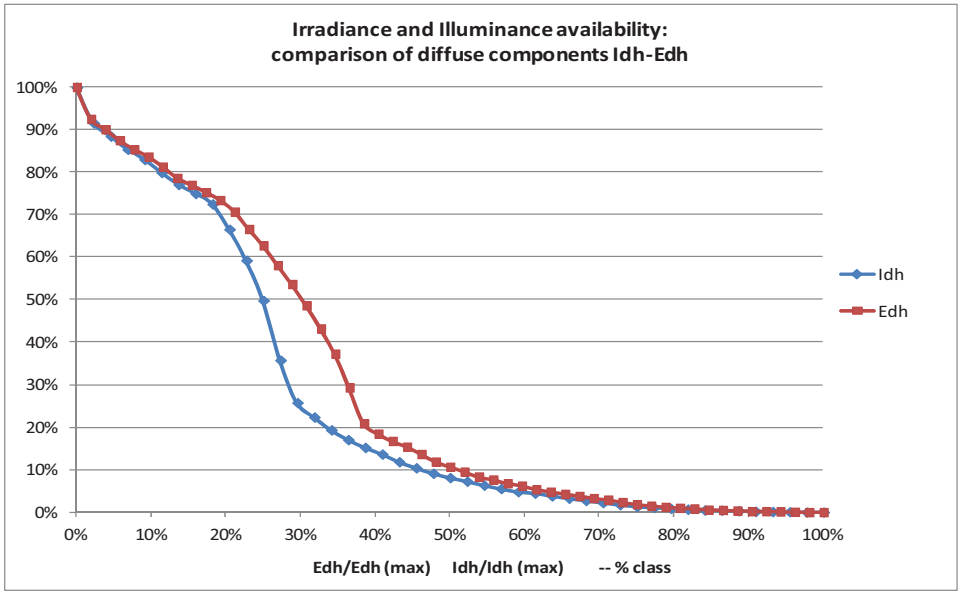

Fig. 3. Comparison of diffuse irradiance Idh and diffuse illuminance Edh

It is interesting to note that global quantities show similar trends, conversely corresponding diffuse components present a different behavior: trends are similar at high and very low relative values, but they show a significant deviation between 20% and 40% of such values.
This behavior evidences luminous efficacy variations, which needs further investigation. At the present stage, it can be noted that the luminous efficacy models takes into account the total solar irradiation, without considering changes in the spectral distribution arising from different sky conditions. Since daylighting metrics use the diffuse illuminance as driving climatic parameter, the latter is following used to present some results potentially relevant for building applications. Figure 3 presents an application of the implemented TMYs: the diffuse illuminance availability in the three reference localities considering the hours from dawn to dusk.

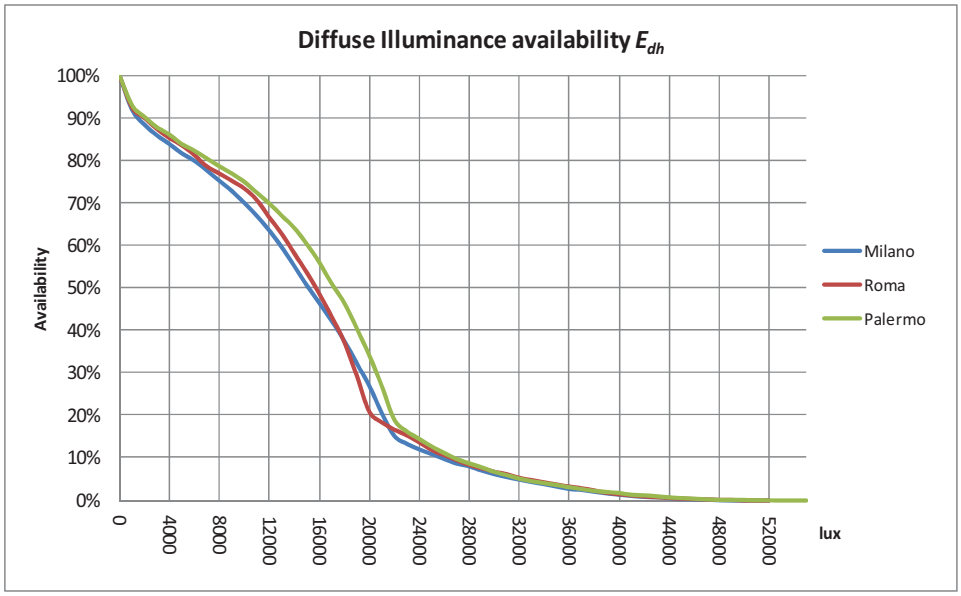

Fig. 4. Diffuse Illuminance availability MI-RM-PA -dawn to dusk-

As expected due its lower latitude, Palermo, have the greater outdoor illuminance availability. The latitude, on the other side, does not explain the result achieved for Rome and Milan. The two curves are very close, despite a latitude difference of about 4°, intersections at about 18000 and 21000 lux. This behaviour, which has a typical summer occurrence, is mainly due to the other higher water and aerosol content in the Milan region, which increases the diffuse components of the solar irradiation respect to the direct one.

Other operative results, derived by the illuminance TMYs, are presented in figures 4 and 5. The former presents the monthly mean diffuse illuminance for the three selected zones, these results are useful to analyze the seasonal variations of the daylight availability and address lighting solution for new and existing buildings, once operation times (8-18 in the example in figure) and indoor visual tasks are defined. Figure 5 presents possible manipulations of the TMYs to provide data tailored to the building needs. The two plots report the diffuse illuminance availability for the case of Rome for two different time usage: from dawn to dusk and for the 08:00-16:00 schedule, which is typical as an example for Italian schools. Holidays and festivities are excluded in the working hours count.

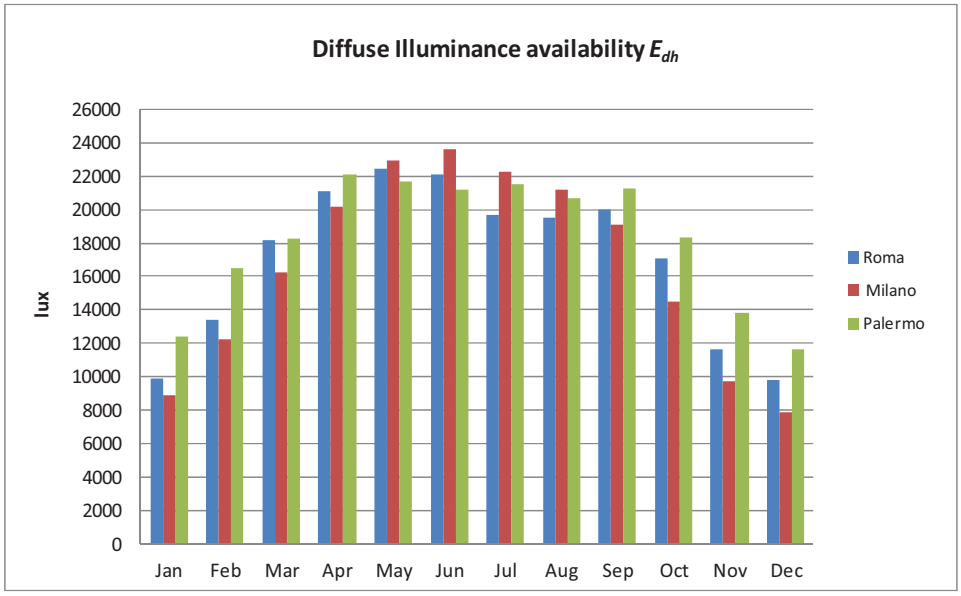

Fig. 5. Edh monthly average values MI-RM-PA operating time 8-18

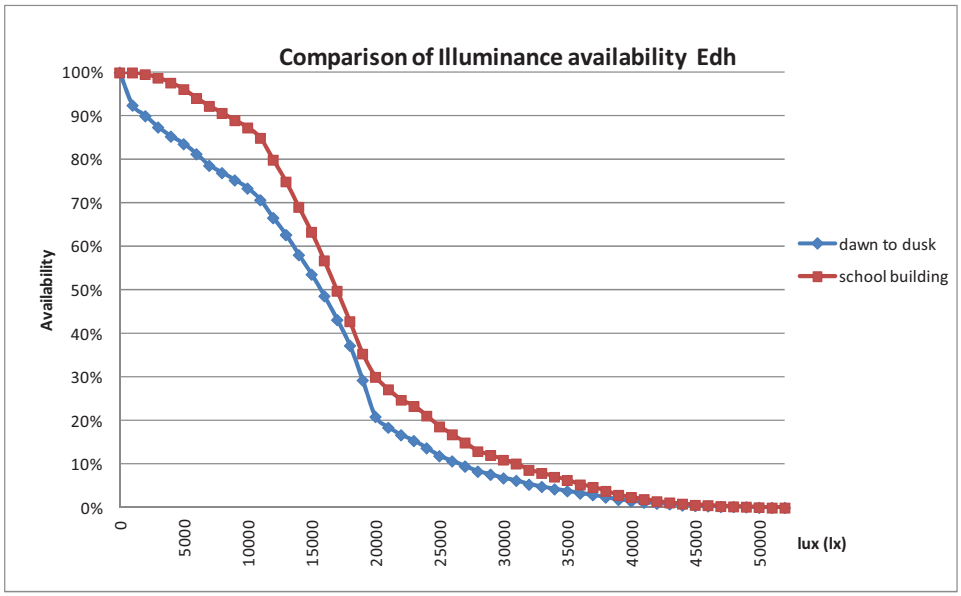

Fig. 5. Edh availability in Rome. Comparison: dawn to dusk and school building with operating time 8-16

5. Validation of model

In order to verify the results obtained, a ground measurements campaign was started in three different Italian sites, Milan, Rome and Lampedusa, to test the effectiveness of model, taking into account different latitudes of Italian territory (Tab 4). The scatter plots are reported figs. 6-7

Tab. 4: Measurements station sites

Site	Coordinates	Measurement [lx]	Sampling time [s]
Lampedusa island	35° 30.0' N 12° 36.5' E	Egh	10
Rome	42° 02.5' N 12° 18.4' E	Egh, Edh	10
Milan	45° 27.9' N 9° 11.3' E	Egh, Edh	10

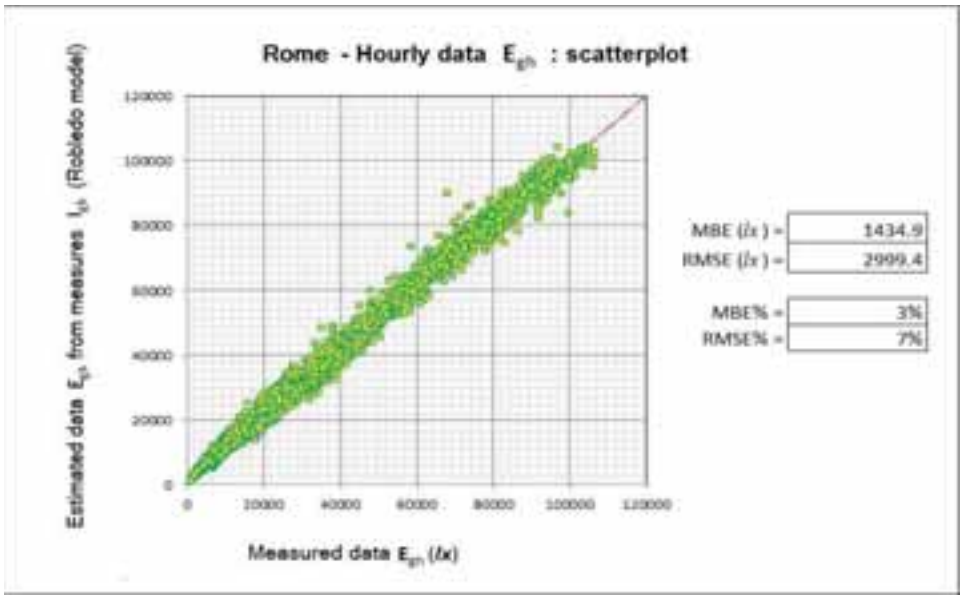

Fig. 6. Comparison: estimated (Robledo model) and measured data for Egh , Rome

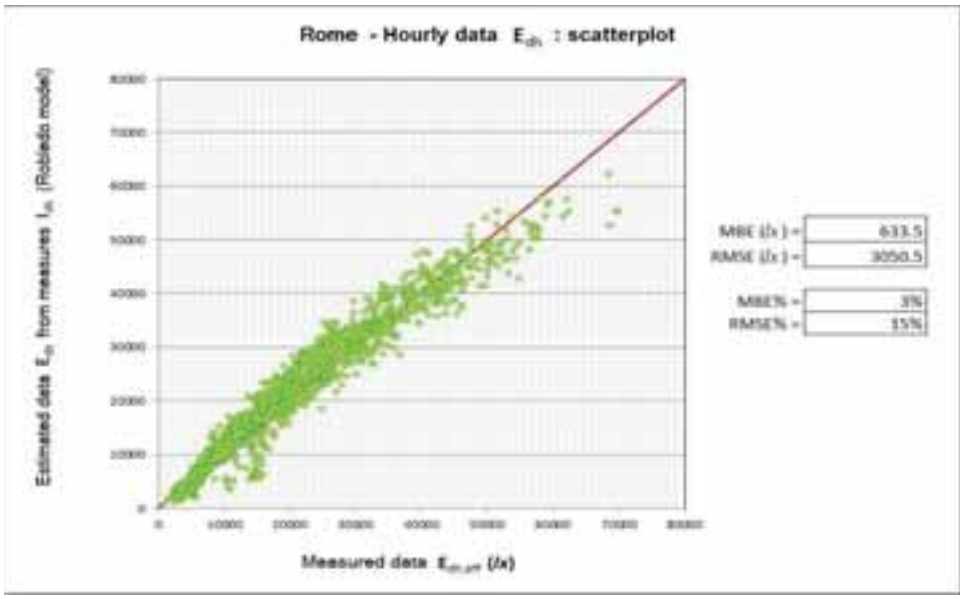

Fig. 7. Comparison: estimated (Robledo model) and measured data for Edh , Rome

The first data processed, for Rome (figs. 6-7), showed low differences between estimated values (R&S model) for Global (Egh) and Diffuse (Edh) illuminance and measured data. The findings have been confirmed by values of statistical indicators, MBE and RMSE, evaluated for both components. The measurements campaign is still ongoing and the further data, related to the other sites selected (Milan and Lampedusa) will allow to get an overall validation of model for Italian territory.

6. Conclusions

This paper presented preliminary studies for the preparation of a national atlas of illuminance data for building applications. Relevant models of luminous efficacy starting from solar radiation data were screened, in order to find the most suitable solution, in terms of accuracy and availability of the relevant input parameters.

Different illuminance hourly TMYs where hence built and comparisons were carried out in terms of daylight availability and autonomy. Discrepancies of the models in reproducing the diffuse component of the photometric quantities were highlighted. A reference model for the future national database was selected and compared with first land measurements data.

Preliminary results were presented to show how the data could be used for building applications. Further tests are ongoing to check, with ground measurements, the accuracy of the luminous efficacy models and eventually introduce refinements and adjustments. Final steps are: establish outdoor illuminance availability diagrams for main Italian towns for different operating times and plot Italian Daylight maps.

Abstract

With rapid deployment and penetration rates of residential photovoltaic (PV) systems in the distribution grid, there is growing need for accurate assessment of the real-time power generation for grid management and energy market operations. Many of these installed PV systems report their live power generation to online databases and can be used as references to estimate the power generation of neighbouring systems. Upscaling approaches have demonstrated their capability of using the data from these reference PV systems to estimate the power output of target PV systems that do not report their power generation data. However, there is an inherent issue with the representativeness of these reference PV systems power data, e.g. due to quality issues or system specific influences such as shading. Three methods were developed by the authors in earlier work: (1) a parametrisation of PV system metadata and quality control of the measured power, (2) a tuning routine that detects diurnal influences from shading and tunes the PV power in order to reach the expected generation without any shading. And (3) a method which eliminates high variances in k_{pv} based upscaling. An extensive cross-validation with 308 systems in Canberra, Australia in this paper shows significant improvements as a direct result of the application of these three methods. Furthermore, we present the preliminary findings for developments in: the parametrisation of shaded/multi-azimuth reference PV systems, as well as a method to reduce inertia in the shade detection and tuning. Overall, we successfully improve the management of reference PV system power data for use in upscaling.

Keywords – Upscaling, Parametrisation, Quality Control, Tuning, PV power

1. Introduction

In recent years, there has been worldwide growth in the total installed capacity of photovoltaic (PV) systems from 5.1 GWp to 300 GWp between 2005 and 2016 (REN21, 2016; Wedepohl, 2017). For operational control of the electricity grid and for economic trading in the electricity generation market, the precise knowledge of the current PV power generation is of increasingly high value (ENA, 2017).

A growing number of PV systems continuously report their power generation, enabling their data to be taken as a reference. These so called "reference PV systems" can be used to estimate the power of the remaining target PV systems through "upscaling" approaches. An extensive literature review covering upscaling approaches is provided by Bright et al. (2017). Upscaling approaches are impacted influences such as individual characteristics of the PV systems, their spatial distribution, the temporal and spatial aggregation level, interaction of individual and collective system behaviour and module orientation, as well as how variable small-scale weather conditions overlay each other in complex ways.

It is a direct consequence of these influences that not all reference PV systems reflect the power generation of neighboured systems. Earlier research present methods that improve upscaling approaches by increasing the representativeness of reference PV systems:

In Killinger et al. (2017b), a twofold routine is presented that parametrises metadata of reference PV systems (tilt β, azimuth γ and loss factor LF) and then quality controls their PV power output measurements. By eliminating measurement errors and other atypical data from the pool of reference PV systems, the representativeness can be increased. Killinger et al. (2017a) extends the concept of making refrernce PV systems appropriate for upscaling through the development of a tuning routine that can detect and balance diurnal patterns in PV power generation due to shading. The outcome of the tuning routine is an increase in representativeness of reference PV systems. This is because tuned reference PV systems better describe the current meteorological conditions and are a better source to estimate the power generation of other neighboured systems. Such is the success of reference PV system tuning, commercial solar forecasting company Solcast (2017); Engerer et al. (2017) are adopting the approach to drastically improve their forecasts. The preliminary use case for the tuning is demonstrated in Bright et al. (2017).

doi:10.18086/swc.2017.21.03 Available at http://proceedings.ises.org

Lingfors et al. (2017b) evaluated the tuning approach's capability at correctly detecting shading events and compared it with a LiDAR based approach (Lingfors et al., 2017a). The comparison highlighted important features in the tuning that had room for improvement, thus these improvements are the feature of this paper.

This paper has two main objectives. Firstly, the latest advancements in upscaling shall be evaluated in an extensive cross-validation with 308 systems in Canberra, Australia. These methods are briefly presented in section 2. In section 3, important data sources and models are announced. The evaluation is finally realised and discussed in section 4. Secondly, preliminary methods to further improve upscaling are developed and tested in section 5. The paper ends with a short conclusion in section 6.

2. Methodology

The methodological steps are presented in this section. An overview is illustrated in the flow chart of Fig. 1.

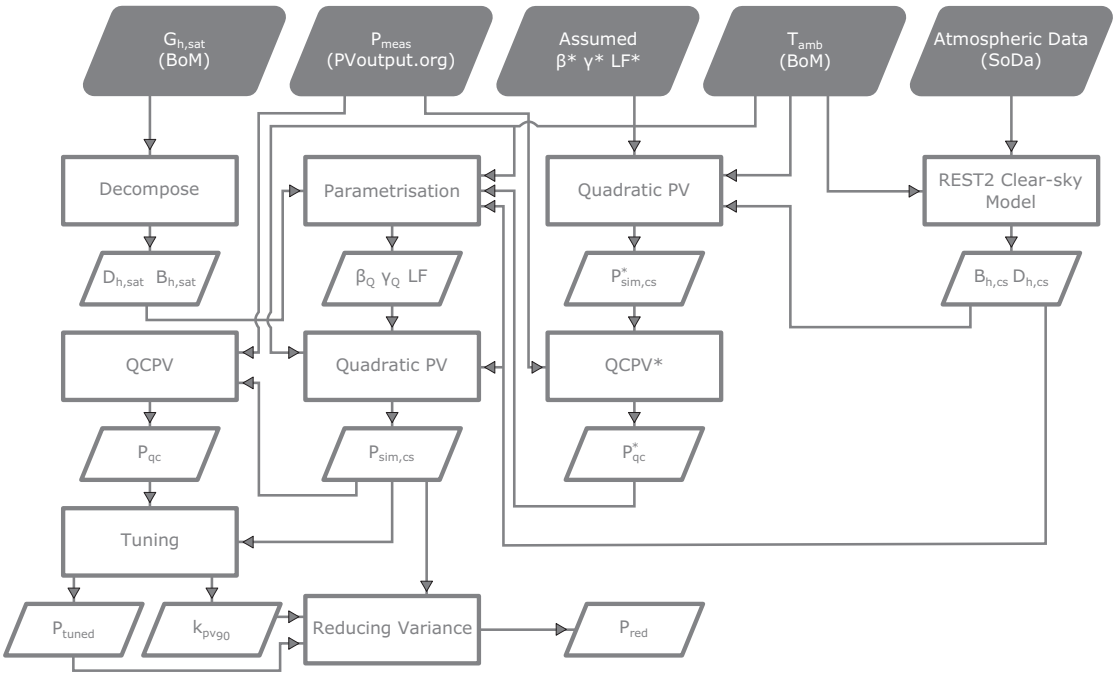

Fig. 1: Flow chart of the proposed methodology. Input data are in grey skewed boxes with data source provider in brackets. Model process steps are in rectangles and intermediate/final outputs are in white parallelograms.

2.1. Parametrisation and QCPV routine

An approach to parametrise the reference PV system metadata (tilt β, azimuth γ and loss factor LF) and to quality control the PV power measurements (QCPV routine) is presented by Killinger et al. (2017b). Both the parametrisation and QCPV routine were improved in Killinger et al. (2017a) and briefly summarised by Bright et al. (2017) and Lingfors et al. (2017b) Hence, only the basic principles of the methodology are detailed within this section.

1. To eliminate critical measurement errors from the parametrisation of the metadata, a modified version of the QCPV routine is applied to the measured power, P_{meas}, to find P^*_{qc} (Killinger et al., 2017a). All intermediate steps of the modified QCPV routine are marked with a * in Fig. 1. A central element in the routine to detect atypical behaviour is the simulation of the clear-sky power $P^*_{sim,cs}$. For the modified version of the quality control of PV power measurements (QCPV*), we assume the same metadata for all systems; north-facing azimuth (Canberra lies on the southern hemisphere), a tilt of 30°, and LF of 1. Two tests, the "maximum k_{pv}" and "cloud enhancements" criteria (section 5.1.3. and 5.2.1. in Killinger et al. (2017b), respectively) are excluded from the modified version QCPV*, as more detailed metadata would be required.

2. In the second step, the parametrisation of metadata is realised. The Non-linear Least-Square (NLS) solver takes satellite-derived beam ($B_{h,sat}$) and diffuse ($D_{h,sat}$) irradiance subcomponents (decomposed with

the Reindl decomposition model as inputs (Reindl et al., 1990a)), along with the ambient temperature (T_{amb}). These inputs are used to simulate PV power depending on the tilt, azimuth and LF. The three latter parameters are varied within the NLS solver until the squared error between the simulated power and the quality controlled measured power is minimal. Within the simulation chain, a quadratic PV power model (Killinger et al., 2017b) and transposition model (Reindl et al., 1990b) are applied. In a second step of the parametrisation, the derived LF is precisely adjusted based on detected clear-sky periods (see Killinger et al. (2017b) and Killinger et al. (2017a)).

3. Based on the parametrised metadata (tilt β_Q, azimuth γ_Q and loss factor LF), the PV power measurements are finally quality controlled. All tests are applied in this second run of the QCPV routine and atypical power values are set to NaN (not a number).

2.2. Tuning

The method for identification and correction of systematic influences that affect PV power output (particularly shading) at various time-steps throughout the day is known as the tuning routine, and is presented in detail by Killinger et al. (2017a). With the completion of parametrisation and QCPV routine, the quality controlled power output P_{qc} and the clear-sky power output at a reference PV system $P_{sim,cs}$ are used to calculate the clear-sky index for photovoltaics k_{pv} (Engerer and Mills, 2014):

$$k_{pv} = \frac{P_{qc}}{P_{sim,cs}}. \qquad \text{(Eq. 1)}$$

In theory, k_{pv} achieves a value of 1 when subjected to clear-sky conditions and higher values only when subjected to cloud enhancement events (Engerer, 2015; Killinger et al., 2017b). Low values of k_{pv} occur due to either increased thickness of cloud cover or reduced system performance. Conversely, in a case where a PV system never achieves clear-sky conditions in the form of $k_{pv} = 1$ for repeated particular time-steps in the course of the day, these periods can be considered to be influenced by systematic reduction, which is most predominantly caused by shading. For the reliable detection of shading, the k_{pv} values are analysed for a running window of time over 30 days. The 90$^{\text{th}}$ percentile ($k_{pv_{90}}$) is derived for each 10-min time-step of the day through an approach described by Lonij et al. (2012). The selection of the 90$^{\text{th}}$ percentile instead of other percentiles was a result of our analysis indicating it delivered a robust limit for representing clear-sky operations; in theory, k_{pv} values within the 90$^{\text{th}}$ are most likely to be clear-sky time periods. With the derivation of $k_{pv_{90}}$ and after the application of logical constraints, the tuning factor X can be calculated and allows for the tuning requirement of a system to be calculated for each time-step according to:

$$P_{tuned} = \frac{P_{qc}}{X}, \qquad \text{(Eq. 2)}$$

where P_{tuned} is the tuned power in $\mathrm{W/W_p}$ for a given system.

In essence, P_{tuned} represents the power profile of a reference PV system with all the systematic influences removed. By using P_{tuned} as opposed to P_{meas} or P_{qc} in the upscaling approach, power measurements recorded under shading of the reference PV system are corrected by balancing systematic influences (or tuned) before being used to estimate an unshaded neighbour.

2.3. Reducing k_{pv} related variance

Variances in k_{pv} are mainly due to cloud cover changes, systematic influences (e.g. shading), or inaccurate simulation of $P_{sim,cs}$. The latter two reasons are reference PV system specific and the influence of their probability and magnitude grows with increasing zenith angles θ_z. These reasons are increasingly important to consider when performing upscaling approaches as filtering system specific systematic influences in order to improve the representativeness of the reference PV systems. Systematic influences (such as shading) are already balanced with the tuning approach, and small inaccuracies in the simulation of $P_{sim,cs}$ can hardly be avoided. For example, if $P_{sim,cs}$ is slightly underestimated for small power measurements occurring during high zenith angles θ_z (0.005 $\mathrm{W/W_p}$ instead of 0.01 $\mathrm{W/W_p}$), the resultant k_{pv} factor would be twice as high; the same is applicable to overestimations in $P_{sim,cs}$. Should the same inaccuracy occur at midday (0.5 $\mathrm{W/W_p}$ instead of 0.505 $\mathrm{W/W_p}$), the effect on the k_{pv} value would be relatively insignificant. Consequently, the impact of such inaccuracies is limited by removing power measurements P_{tuned} from reference PV systems where time-steps exhibit high k_{pv}-related variances. This filter is realised by analysing the standard deviation of $k_{pv_{90}}$ in parallel to k_{pv}, detailed by Killinger et al. (2017a). With the removal of particularly large variances in the morning or evening by setting atypical values NaN, PV power with reduced variances (P_{red}) is derived from P_{tuned}.

3. Data

The data sources and models used within this paper are mostly identical with the ones described in Killinger et al. (2017a) and are mentioned in Fig. 1. Power output data is significantly extended in this paper covering 308 PV installations in Canberra, Australia, where previously only 78 were considered. The power measurements P_{meas} are extracted from http://pvoutput.org and subsequently normalised by their reported installed capacity. The collected power output data comprises a total period spanning from 7th September 2016 till 31st July 2017 with missing data from 25th March 2017 till 22nd April 2017. In contrary to Killinger et al. (2017a), multi-azimuth systems are considered within this work. Ambient temperature T_{amb} values are obtained from the Canberra airport (Australian Bureau of Meteorology station 070351) and missing data replaced by values from the numeric weather model MERRA, derived from http://www.soda-pro.com.

Climatological atmospheric parameters of ozone, water vapour, aerosol optical depth and Linke turbidity for the clear-sky irradiance modelling are retrieved from the SoDa database as described in Engerer and Mills (2015); Killinger et al. (2017b). These parameters are used to derive the beam ($B_{h,cs}$) and diffuse ($D_{h,cs}$) horizontal clear-sky irradiance via the REST2 model by Gueymard (2008). The derivation of the satellite based irradiance is described in detail in Engerer et al. (2017).

As the satellite based irradiance has a temporal resolution of 10-mins, all datasets used within this paper (e.g. the PV power measurements, ambient temperature, etc.) are aggregated to a resolution of 10 minutes in order to correspond.

4. Results and discussion

This section will firstly define the procedure of the cross-validations, and subsequently present and discuss the results.

4.1. Definition of the cross-validations

In this section, four different cross-validations (CV) labelled $k = 1, 2, 3, 4$ are realised. Within these cross-validations, the estimated power output of target PV systems P_{est,CV_k} is simulated using k_{pv}-based upscaling techniques (see Engerer and Mills (2014), Killinger et al. (2017a) and Bright et al. (2017)). k_{pv} based upscaling estimates the k_{pv} value at a target PV system's location using a geospatial interpolation approach called Inverse Distance Weighting (IDW, defined in Shepard (1968) and using the recommended factor of 2) and weights the influence of a reference PV system as a function of its distance to a target PV system; the closer a reference PV system is to the target, the more influence it has. With the interpolated k_{pv} value at a target PV system's location alongside its simulated clear-sky power $P_{sim,cs}$, the power output can now be estimated following the principle of Eq. 1.

Detailed assumptions of the cross-validations are provided in Tab. 1. CV1 is the baseline scenario without any data processing that uses metadata directly from http://pvoutput.org. Should metadata be missing, a north-facing azimuth and a tilt of 30° are assumed (P_{meas}). For all other validations (CV2-CV4), the parametrised metadata of both the reference and target PV systems as well as quality controlled power data from the methodology described in section 2.1 are used. In CV2, only the QCPV methodology from section 2.1 is applied (P_{qc}). In CV3, the additional inclusion of the tuning routine from section 2.2 is applied (P_{tuned}). Lastly, CV4 extends the tuning routine through application of the variance reduction routine (P_{red}) from section 2.3.

Estimates from each cross-validation are compared to the quality controlled version of the measured power P_{qc} in order to have a common dataset that is (mostly) free of measurement errors; using P_{meas} holds no value as there exists unquestionably erroneous data prevalent throughout the dataset. The simulated power estimates and number of NaN values are different in CV1-4 due to increased strictness of filtering with each methodology. If simulated or measured data registers a NaN, it is excluded from the evaluation.

Tab. 1: Definition for different cross-validations (CV).

	CV1	CV2	CV3	CV4
QCPV Routine		✓	✓	✓
Tuning			✓	✓
Reducing Variance				✓
Module Orientation	pvoutput.org	Simulated	Simulated	Simulated
Loss Factor LF	0.9	Simulated	Simulated	Simulated
P_{tar}	P_{qc}	P_{qc}	P_{qc}	P_{qc}

The cross-validations are conducted for an increasing number of reference PV systems I (2, 5, 10, 20, 30, 40, 50) and a fixed number of $J = 250$ target PV systems are simulated. The purpose is to explore the impact that number of available reference PV systems has on the accuracy of power estimate. For each value of I, simulations are repeated 100 times in order to obtain a representative distribution of error metrics and test reproducibility. With each test, the reference and target PV systems are randomly re-assigned each time while maintaining I and J allowing for a rich number of combinations per CV. The comparisons explore the performance of all the power estimates P_{est,CV_k} from each cross-validation $k = 1, 2, 3, 4$ against the actual power output from the target PV systems P_{tar}. Estimated and quality controlled measured target PV system power values are aggregated at each time-step t and normalised by J. P_{est,CV_k} and P_{tar} are, therefore, time series of aggregated power output for all J target PV systems.

An example test (1 of 100) to derive results is described:

1. $J = 250$ target PV systems randomly selected
2. I number of reference PV systems randomly selected from the remaining 58 systems
3. Aggregated P_{est,CV_k} calculated for each cross-validation $k = 1, 2, 3, 4$
4. Aggregated P_{tar} calculated
5. Compare power aggregate time series using different error metrics

Steps 1 to 5 are repeated 100 times before changing the value of I.

In the following evaluations, all results are restricted to time-steps fulfilling the zenith angle $\theta_z < 85°$ for the same reasons as mentioned in section 4.1. in Killinger et al. (2017a). Furthermore, all k_{pv} values used within the CV evaluations that are greater than 2 are excluded from the examinations as they represent an unrealistic magnitude.

4.2. Evaluation of the cross-validations

Results of the cross-validations are shown in Fig. 2. Each boxplot contains a distribution of results from the 100 different simulations, each with a unique combination of reference and target PV systems. The boxplots of the relative root mean square error ($rRMSE$, top plot in Fig. 2) indicate how each additional method presented in this paper further improves the estimated power outputs from the reference PV systems. The largest improvements are reached between CV1 and CV2 with the inclusion of QCPV. Although $rRMSE$ values further improve with CV3 and CV4, a decreasing marginal utility is visible.

Results in the $rRMSE$ also improve for an increasing number of reference PV systems with CV2-4. A similar improvement for an increasing number of reference PV systems can be seen for the baseline scenario CV1. An exception from this tendency occurs for a small number of reference PV systems in CV1 with $I = 2$ refrence PV systems, which is lower in $rRMSE$ than for $I = 5$; it is expected that this is a statistical coincidence which would disappear for a higher number of samples. Please also note that the ranges of the boxplots and outliers decrease for a greater number of reference PV systems; a balancing impact occurs with more reference PV systems and reduces uncertainty in the power estimation.

The uncertainty in the power simulation is not only reduced by an increasing number of reference PV systems, but also for the methods presented in this paper. This can be seen through analysis of the boxplots of the relative mean bias error ($rMBE$, middle plot in Fig. 2). The smallest ranges of $rMBE$ occur for CV3 and CV4 with a tendency towards overestimations. This can be explained with the tuning routine that increases the power magnitude of reference PV systems, however at present, this increase is applied to target PV systems that may also be shaded, resulting in an overestimation. These overestimations are not constant as shading only occurs for some systems at unique time-steps. In order to reduce such an estimation, future versions of the tuning must consider shading, perhaps by statistical diurnal consideration of typical shading events that can be probabilistically applied. This bias is rather dynamic and is different for each time-step of the day, making correction difficult.

Through the careful selection of time periods in the QCPV routine, as well as the constraints in the tuning and reduction of the variance, the number of NaN values in the time series of the reference PV systems increases. In the lower plot of Fig. 2 the time-steps excluded for the cross-validations are visualised. A time-step is excluded if either P_{est_k} or P_{tar} are NaN. While CV1 shows a rather consistent share of less than 25%, CV2-4 are greater for a small number of reference PV systems. The share slightly increases in CV4 due to the additional filters. At time-steps when a reference PV system registers a NaN value, it is obviously no longer able to estimate the power of other systems. Hence, for a very small number of reference PV systems, there can be individual time-steps in which it might be necessary to renounce the use of one of the methods or better use alternative data to estimate the power of the target PV systems. For all other time-steps, it is strongly recommended to use all the methods presented in this paper.

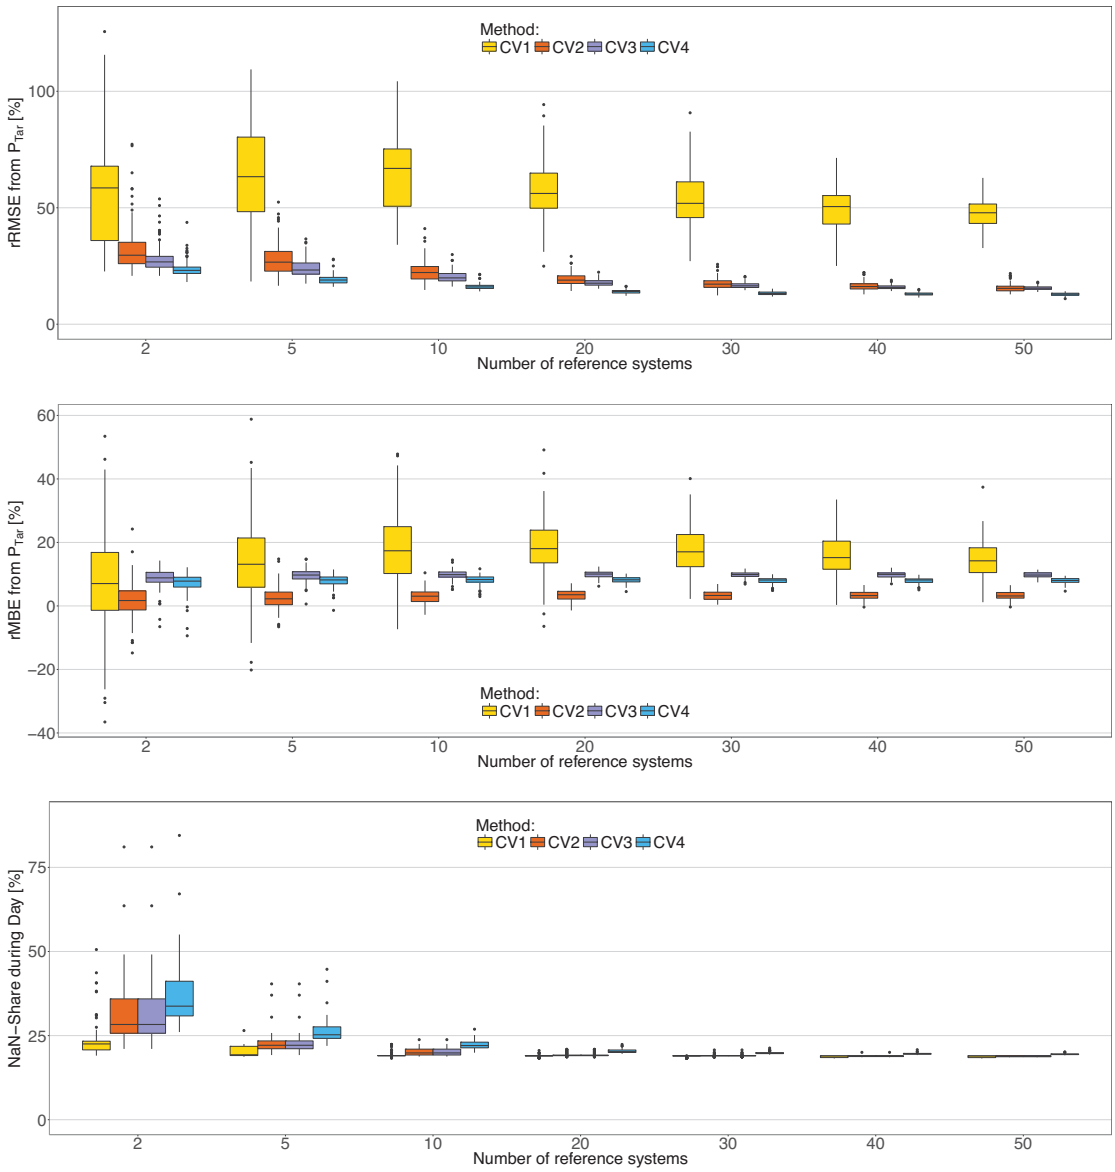

Fig. 2: Box plots indicating the four quartiles of error distributions. The lower, middle and upper lines of each box indicates the 25%, 50%/median, and 75% quartiles, respectively. Whiskers indicate the minimum and maximum values of the distribution. Outliers are represented as points and are defined as existing 1.5 times outside the inter-quartile range of the 25% and 75% quartiles. Each box plot represents the resulting error metric on the y-axis derived when comparing the estimate power value of a cross-validation $k = 1, 2, 3, 4$ (P_{est,CV_k}) against the target power value (P_{tar}). The error is plotted against the number of reference PV systems I. The colours represent the different cross-validations CV1-4. The top, middle and bottom plots indicate the relative root mean square error (rRMSE), the relative mean bias error (rMBE), and the fractional NaN-share, respectively.

5. Preliminary advancements

The analysis in the previous section showed that the strongest relative improvements are possible for a small number of available reference PV systems. Particularly for a small number of reference PV systems, it is important to better understand their individual behaviours. Hence, three different and preliminary methods are presented and evaluated within this section:

- The parametrisation of shaded systems in section 5.1
- The consideration of multi-azimuth systems in the parametrisation stage in section 5.2
- The reduction of the inertia in the tuning routine in section 5.3

The development of these methods are based on findings by Killinger et al. (2017a), Lingfors et al. (2017b), Bright et al. (2017) and from within this paper.

5.1. Parametrisation of shaded systems

Diurnal shading events can strongly influence the daily power profile of a PV system. Especially in case of strong shading in the morning or evening, it can be difficult for an observer to distinguish between shading events or a normal behaviour caused by an (extreme) azimuth angle of a system facing east or west. The parametrisation approach described in section 2.1 is facing exactly this challenge. Four PV systems are discussed in Lingfors et al. (2017b), which show significant errors in the parametrisation of the azimuth angles and strong influences of shading in the morning (see Lingfors et al. (2017b) ID 135, 157) or evening (ID 44, 67). The problem lies in the procedure of the NLS solver, which tries to find a combination of tilt (β_Q), azimuth (γ_Q) and loss factor (LF) leading to the smallest least square error. Even though this procedure hast a high rate of success for unshaded systems, there is a certain risk for erroneous parametrisation for shaded systems. As a consequence, all subsequent steps such as the QCPV and tuning routine are negatively influenced. Motivated by this challenge, an alternative procedure was developed and is presented next. The hypothesis behind this approach is that, should a system be shaded in the morning, the afternoon hours are more suitable to derive the correct module orientation, and vice versa. Hence, the approach uses different time periods throughout the days to run the parametrisation routine.

1. 00:00 - 23:55 ($\widehat{=}$ old procedure described in section 2.1)
2. 10:00 - 23:55 (if shaded in the early morning hours)
3. 12:00 - 23:55 (if shaded in the morning hours)
4. 00:00 - 13:00 (if shaded in the afternoon hours)
5. 00:00 - 15:00 (if shaded in the late afternoon hours)
6. 08:00 - 17:00 (if shaded in the early morning and late afternoon hours)
7. 10:00 - 14:00 (if shaded in the morning and afternoon hours)

The PV power is simulated with the derived parametrisation for each of the seven time periods. Then, the Mean Absolute Percentage Error (MAPE) is calculated between the simulated power and the quality controlled version of the measured power P^*_{qc}. The parametrisation leading to the smallest MAPE is then chosen.

Tab. 2: Tilt and azimuth of the studied PV systems identified by the old and new parametrisation approach. As a reference, reported tilt from SolarHub (SH, a reputable local solar installer in Canberra) and azimuths derived by inspecting aerial images (AI). The table includes in the last two columns the angle θ_n between the normal vector of the PV module (as derived from SH/AI) and the normal vector of the old and new parametrisation approach, respectively. The building ID corresponds to the study by Lingfors et al. (2017b).

ID	Tilt			Azimuth			θ_n	
	SH [°]	old [°]	new [°]	AI [°]	old [°]	new [°]	old [°]	new [°]
44	25	23	17	-57	-95	-83	18.9	12.1
67	20	28	17	55	10	70	18.6	5.5
135	22	22	9	5	46	1	16.9	12.5
157	18	30	15	-70	-18	-63	23.4	3.9

Tilt and azimuth of the studied PV systems identified by the old and new parametrisation approach are provided in Fig. 5. The tilt reported by SolarHub (SH) and the azimuth from an aerial inspection (AI) are given as references. It can be seen that the azimuth angles strongly improved with the new approach. This is also confirmed by smaller angles between the normal vector of the parametrised module orientation and the orientation from SH/AI. Presented in the table is θ_n, which is the angle between the normal vector of the reference PV system (calculated from from SH/AI metadata) and the parametrised-derived normal vector; an angle of $0°$ is an exact estimation. The use of θ_n is a better representation of the differences of orientation discrepancies than considering the azimuth and tilt separately. The new developments to the parametrisation routine show significant improvement for the four reference PV systems analysed with a 36%, 70%, 26% and 83% reduction in absolute deviation away from the normal for PV system IDs 44, 67, 135 and 157, respectively.

In Fig. 5 the simulated clear-sky curve with the old ($P_{cs,old}$) and new ($P_{cs,new}$) parametrisation method is visualised together with the measured power P_{meas} for an exemplary day. Both systems are facing strong shading events in the morning. As a consequence, the azimuth is overestimated by the old parametrisation, whereas the new method leads to a much more realistic clear-sky curve.

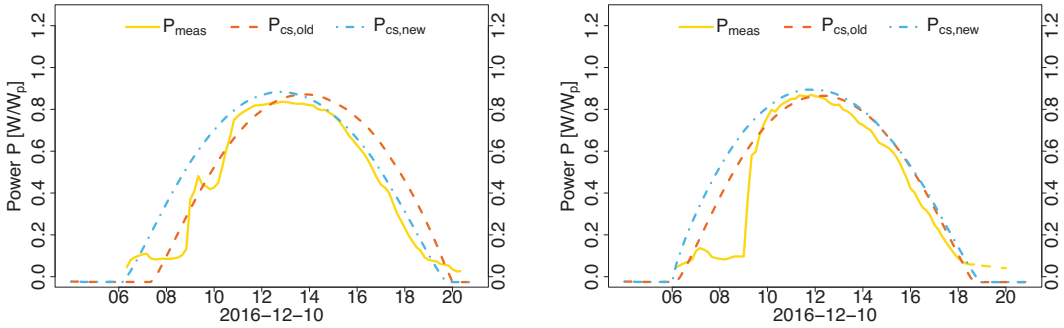

Fig. 3: PV systems (ID 135, left and ID 157, right) being influenced by strong shading events in the morning. Visualized is the measured power P_{meas} (yellow), the simulated clear-sky curve with the old parametrisation method from section 2.1 $P_{cs,old}$ (red) and the new approach from this section $P_{cs,new}$ (blue).

Even though the presented advancement of the parametrisation shows strong improvements for the four studied systems, first tests show problems for unshaded systems, leading sometimes to worsened results than the old parametrisation. Hence, the current challenge is to develop a method that helps to better decide which derived parametrisation option to use. Different error metrics were applied besides the MAPE, but no convincing strategy was found yet and is reserved to be the focus of future work.

5.2. Considering multi-azimuth systems

An additional challenge for the parametrisation approach are PV systems with modules facing different azimuth angles. Such multi-azimuth systems were not considered in Killinger et al. (2017b) and Killinger et al. (2017a) but included in this paper. The parametrisation approach was not adjusted in order to deal with PV power profile of such multi-azimuth systems. The NLS solver in this paper (see Eq. (1) in Killinger et al. (2017b)) estimates the parameters (tilt β_Q, azimuth γ_Q and loss factor LF) by minimising the least squares between the quality controlled version of the measured power P^*_{qc} and the simulated power based on the satellite derived irradiance $P_{sim,sat}$:

$$P^*_{qc} \sim P_{sim,sat}(\beta_Q, \gamma_Q, LF). \qquad \text{(Eq. 3)}$$

In order to deal with multi-azimuth systems, an alternative formulation was developed that allows the parametrisation of two different tilt and azimuth angles:

$$P^*_{qc} \sim \alpha \cdot P_{sim,sat,1}(\beta_{Q1}, \gamma_{Q1}, LF) + (1-\alpha) \cdot P_{sim,sat,2}(\beta_{Q2}, \gamma_{Q2}, LF) \qquad \text{(Eq. 4)}$$

The influence of the different module orientations is controlled by a factor α, being limited to a range between 0 and 1. In order to reduce the complexity, only one common loss factor LF is parametrised. To exclude other (disturbing) influences, this concept was tested based on simulated PV profiles. The findings from a multi and single azimuth system are presented next.

1. A multi-azimuth system (Tilt angles: $50°$ and $30°$; azimuth angles: $-45°$ and $90°$, $LF = 1$ and an $\alpha = 0.25$) was simulated with the transposition model from Reindl et al. (1990b) and the quadratic PV model from Killinger et al. (2017b). Then the NLS solver tried to derive the module orientation with Eq. 3 and alternatively with Eq. 4 based on the same irradiance and temperature data as input. The single azimuth approach lead to a tilt angle of $16°$, an azimuth of $68°$ and a $LF = 1$. Considering Fig. 4, the old parametrisation power estimate (P_{sing}, blue) seems to be a fair compromise for the multi-azimuth system and approximates the simulated PV profile (P_{sim}, yellow) well except for the early morning. The multi-azimuth approach from Eq. 4 (P_{multi}, red) is much more appropriate to approximate the simulated profile, as the morning pattern is excellently captured. The derived parametrisation was almost correct with tilt angles of $50°$ and $31°$; azimuth angles of $-47°$ and $90°$, $LF = 1$ and an $\alpha = 0.25$.

2. A single azimuth system (Tilt angle: 30°; azimuth angle: 0°, $LF = 1$) was simulated with the same models as above. This time the single azimuth approach from Eq. 3 finds the correct parametrisation and is able to perfectly approximate the simulated PV profile (P_{sim}, yellow), as is shown in the right plot of Fig. 4. However, the multi-azimuth approach from Eq. 4 shows small deviations in the late evening. The derived parametrisation in this scenario provides tilt angles of 35° and 17°; azimuth angles of −5° and 33°, $LF = 1$ and an $\alpha = 0.76$. The multi-azimuth approach obviously tried to find a combination of two module orientations describing the profile in the best way in order to satisfy Eq. 4.

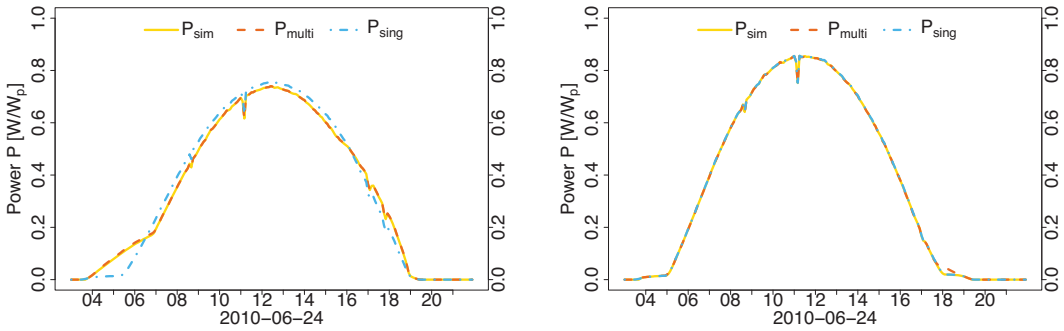

Fig. 4: Exemplary parametrisation for two different PV systems. In the left plot a multi-azimuth system (Tilt angles: 50° and 30°; azimuth angles: −45° and 90°, $LF = 1$ and an $\alpha = 0.25$) was simulated. In the right plot a single azimuth system (Tilt angle: 30°; azimuth angle: 0°, $LF = 1$) was simulated. The plots show the simulated profile (P_{sim}, yellow), the profile approximated by the multi-azimuth solver (P_{multi}, red) from Eq. 4 and the profile approximated by the single azimuth solver (P_{sing}, blue) from Eq. 3.

The above evaluations show that both the single and the multi-azimuth approach have their value and differences between the approaches are smaller than expected. Hence, future work is needed to quantify potential improvements of a multi-azimuth systems by analysing the presence and probability of such systems in reality. Similar to the approach in the last section, another challenge is when to use which approach without knowing if the parametrised system has a single or multi-azimuth angle. A selection based on error metrics between the actual (here: P_{sim}) and approximated (here: P_{sing} or P_{multi}) profiles were tested for some systems, but differences were insignificant. Further research is therefore needed to develop other selection criteria.

5.3. Reducing the inertia in the tuning routine

The discussion in Killinger et al. (2017a) revealed an inertia in the tuning approach that is mainly caused by the determination of $k_{pv_{90}}$ with a rolling window of time over 30 days (see section 2.2). As a consequence, time periods with shading cannot be completely compensated by the tuning approach as can be seen in the left plot in Fig. 5. Different approaches were developed and tested to overcome the inertia. One promising method considered $k_{pv_{90}}$ depending on the sun position as opposed to the time. However, the inertia still persisted. This is because the analysis had to be realised over a longer time period in order to differ between cycling shading influences and meteorological influences. Hence, the following advancement was developed and works in addition to the previous tuning routine.

1. For each time-step t within the time series of a PV system, the mean $k_{pv_{90}}$ values for the 30 minutes before and after the considered time-step are calculated. If one (or both) mean values are < 0.8, shading occurs during the 30 minute time period and criteria 1 is fulfilled. The idea behind this criteria is that, if shading occurs before or after a time-step t, the probability is increased that the current time-step is also affected. To further check if this is the case, two other criteria were developed.

2. Criteria 2 checks if the k_{pv} value of a system at time-step t is < 0.8. If this is the case, criteria 2 is fulfilled and an indication provided, that the system is influenced by shading.

3. In criteria 3, the mean k_{pv} value over all reference PV systems is calculated for time-step t and compared to the k_{pv} value of the analysed system at the same time-step. In case the k_{pv} value of the analysed system is no less than 0.2 smaller than the mean value, criteria 3 is fulfilled.

If criteria 1, 2 and 3 are all fulfilled, the $k_{pv_{90}}$ value is lowered for the analysed time-step t and the system is assigned the smallest mean $k_{pv_{90}}$ value from the 30 minutes before and after. The procedure with its three

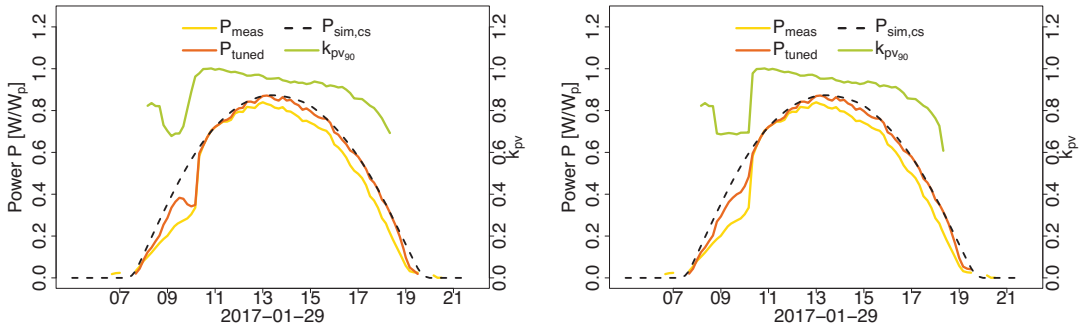

Fig. 5: Outputs for PV site 32 with the tuning method being described in section 2.2 in the left and an alternative approach being presented in section 5.3 in the right plot. The different series represent measured power output (yellow), tuned power output (orange), unsoiled clear-sky power output (black dashed line) and the running 90$^{\text{th}}$ percentile k_{pv} value $k_{pv_{90}}$ (green).

criteria is very cautious and tries to avoid an erroneous tuning. Results are promising as can be seen in the left plot in Fig. 5. The tuning method loses its inertia and is much more capable to balance the influence of shading. In future work this approach will be applied to more systems and carefully examined if the criteria are well suited.

Whilst the main objective of the three criteria was to find quantitative evidence that a time-step is subjected to shading, criteria 3 has an additional positive aspect. The across system analysis helps to consider the power generation of neighboured systems. If the power generation of these systems is reduced, e.g. due to the influence of an overcast sky, the calculated deviation to the analysed system is rather small and criteria 3 not satisfied. In cases where the analysed system is also under overcast skies, the procedure is advantageous because shading would be strongly reduced for an overcast sky. Hence, the consideration of across system analysis is an interesting feature for future developments of the tuning approach. However, there are also indisputable risks that some systems would be adjusted incorrectly by such an across system tuning routine and further developments would be necessary to handle them.

6. Conclusions

This paper aimed to address the latest suggestions and developments to the handling of reported power data from reference PV systems in the context of upscaling approaches. A central element of these upscaling approaches is the clear-sky index of photovoltaics k_{pv}, defined as the ratio between the current power generation of a system and its generation under clear-sky conditions. The key developments are (1) a parametrisation method to derive the module orientation (tilt and azimuth) as well as a loss factor for each system. This method is completed by a quality control routine to detect erroneous and atypical time-steps in PV power measurements. (2) a tuning routine that detects diurnal influences from shading and tunes the PV power in order to reach the expected generation without any shading. And (3) a method which eliminates high variances in k_{pv} based upscaling.

The application of these three advancements was evaluated based on power measurements of 308 PV systems in the region of Canberra, Australia, with data spanning almost one year of data. 250 of these systems are chosen as target PV systems, whereas a changing number systems are used as reference PV systems (2–50). Throughout many simulations, significant improvements were found as a direct result of the application of these three methods. Further improvements are possible when the number of reference PV systems is small, demonstrating the need to further consider individual characteristics of the reference PV systems. This reasoning provided the motivation for the development of three methods firstly presented in preliminary format within paper. These methods focus on (1) the parametrisation of shaded systems, (2) the consideration of multi-azimuth systems in the parametrisation, and (3) the reduction of the inertia in the tuning routine. These methods show preliminary merit in their application, however, have substantial potential for further improvements before they are of operational quality.

7. Conflict of interest

The authors declare no conflicts of interest.

Abstract

As bioclimatic design is becoming increasingly important in contemporary buildings, various analytical tools must be developed and introduced to the designers in order to guide them through the design process. Therefore, the BcChart v2.0 software was developed. It executes bioclimatic potential analysis of a location based on the theory of Olgyay's bioclimatic chart. The main advantage of the introduced tool, in contrast to other bioclimatic analysis tools, is that it directly considers the influence of solar radiation, which is factored through substitutive daily comfortable dry-bulb air temperature. The paper presents the theoretical background of the tool. Additionally, the capabilities and functionality of the software are demonstrated through bioclimatic analysis of two different locations with contrasting climates (i.e. Ljubljana, Slovenia and Abu Dhabi, UAE). The conclusions highlight the importance of considering solar radiation when performing bioclimatic analysis of a location in order to thoughtfully design bioclimatic buildings.

Keywords: bioclimatic analysis, climate analysis, bioclimatic potential, bioclimatic chart, solar radiation, sustainable building

1. Introduction

Bioclimatic building design is one of the key approaches to the design of buildings of the future. A building can be declared bioclimatic when it efficiently uses climatic resources of its location (Krainer, 2008). An aforementioned adapted building simultaneously provides comfortable indoor environment and efficiently uses energy sources, primarily with the help of building envelope elements. Although the use of bioclimatic design in architecture and construction industry was introduced decades ago by Victor Olgyay (1963), it was in some way overlooked by the designers and researchers. However, in recent years, research in the field of bioclimatic design is on the rise, as living comfort, energy use and climate change have been brought into the spotlight. Thus, several studies have been made encouraging the bioclimatic approach to building design. The most recent research by Pajek and Košir (2017), by Khambadkone and Jain (2017), or the one by Manzano-Agugliaro et al. (2015) highlighted the importance of bioclimatic analysis of a specific location in order to define the most efficient bioclimatic design strategies to be integrated into buildings.

Several tools can be used to bioclimatically asses a location. In this respect, the most elementary bioclimatic chart was developed by Olgyay (1963) or in a different form by Givoni (1969). Furthermore, new tools for bioclimatic analysis have been made by several other authors (Rohles et al., 1975; Arens et al., 1980; Al-Azri et al., 2013; Martínez and Freixanet, 2014; University of California, 2017). Martínez and Freixanet (2014) presented a comprehensive bioclimatic analysis tool, named BAT. It enables plotting of bioclimatic charts and several other graphs on the basis of climate data imputed by the user. Nonetheless, too many items of information given by BAT can disorient the user, thus lowering the user-friendliness of this tool. Furthermore, the main deficiency of the BAT tool is that the impact of solar radiation is not directly incorporated into the main bioclimatic analysis but is rather presented in a separate section. Another example of a broadly used bioclimatic analysis tool is also Climate Consultant software designed at the University of California, USA (University of California, 2017). The results of climate analysis performed by the Climate Consultant tool give its users an insight into climate specifics of a certain location. The tool also guides the user towards appropriate building design through a set of design strategies necessary to achieve human comfort with either passive or active solutions. However, similar as the BAT tool, Climate Consultant does not directly consider solar radiation in the determination of comfort conditions.

doi:10.18086/swc.2017.21.04 Available at http://proceedings.ises.org

To summarise, there exist several tools that can be used for a bioclimatic analysis in order to define possible passive building design measures. However, the above referenced tools do not sufficiently consolidate the influence of solar radiation into the calculations and consequential bioclimatic potential of a given location. This is of special interest in the case of locations with temperate and cold climatic characteristics. Although solar radiation is mostly presented as one of the decisive factors influencing bioclimatic potential, its influence is never directly incorporated into bioclimatic potential calculations. It is rather used comparatively as a separate quantity detached from the external air temperature and relative humidity. Such comparison between the two is relevant, but it is also likely prone to human errors. Bioclimatic location analysis is one of the most important initial steps when designing buildings. Thus, a tool used for the analysis must be on one hand very precise and user-friendly on the other. Nonetheless, it is crucial that bioclimatic analysis tool is freely available to the interested audience, as this will widen the number of designers applying bioclimatic solutions to their projects. All mentioned above is taken into account with BcChart v2.0 – a bioclimatic potential analysis tool, developed by the authors and presented in this paper.

2. Description of applied methodology

2.1 BcChart software and bioclimatic charts

The BcChart v2.0 software was developed at the University of Ljubljana, Slovenia, and has been validated and evaluated through the educational process at the Faculty of Civil and Geodetic Engineering. It can be used for the calculations of bioclimatic potential based on the theory of Olgyay's bioclimatic chart (Olgyay, 1963). Bioclimatic charts are initiated with human comfort, which is calculated for an average person. The basic input climate parameters are average minimum and maximum daily air temperature (T) and relative humidity (RH). However, in addition to the basic bioclimatic chart input data, the mean and maximum daily solar irradiation is also factored in, resulting in modifications of Olgyay's bioclimatic chart plots. Nonetheless, it has to be noted that the modifications of bioclimatic charts are made only when additional influence of solar irradiation does not cause overheating. In other words, it is presumed that whenever the solar irradiation could cause overheating, effective shading will be used (i.e. when ambient temperatures on the bioclimatic chart are above shading line). Thus, the substitutive daily comfortable dry-bulb air temperature for month i, $T_{sub,i}$ is introduced (Equation 1). The derivation of the calculations made with BcChart v2.0 is Equation 1, based on the equation for human body thermal equilibrium, presented by Olgyay (1963). Equation 2 is introduced to describe the influence of actually received solar irradiation.

$$T_{sub,i} = \frac{T_s-(M_m-E+R_i)\times(Clo/c+V.Clo/c)}{S\times S_c} \qquad \text{(eq. 1)}$$

$$R_i = G_i \times S_e \times \alpha \qquad \text{(eq. 2)}$$

Where R_i is radiation in W for month i, G_i is the mean daily global solar irradiance in W/m^2 for month i, S_e is the effective radiation area for a given subject in a given position and it is assumed as 0.5 m^2, and α = 0.4 is the absorptivity of the radiated surface of a clothed man. T_s is comfortable skin temperature, presumed as 33.9°C, M_m is the observed rate of metabolism 126 W, E is the rate of cooling due to perspiration actually evaporated 38 W, $Clo/c + V.Clo/c$ is clothing insulation and air effect on clothing coefficient (= 0.28) as defined by Olgyay (1963) and adapted to be expressed in m^{2}K/W. S is the mean body surface area of clothed man, assumed as 2.14 m^2 and S_c is the fraction of surface areas exposed to radiation and convection (= 0.9). Furthermore, the dry-bulb air temperature at which the passive solar heating (PSH) is still possible ($T_{PSH,i}$) was calculated using maximal daily global horizontal solar irradiance for each month ($G_{max,i}$). The plotted parts on bioclimatic chart, which are below this temperature, represent the part of each month, when passive solar heating cannot be used as an efficient passive strategy, because there is not enough solar energy available at a given location. Therefore, instead of the mean daily global solar irradiance (G_i) in Equations 1 and 2, the maximal values of solar radiation were used ($G_{max,i}$). T_{sub} and T_{PSH} were used only when modified bioclimatic charts were plotted, i.e. the solar radiation was directly incorporated into calculations. The main output of the BcChart v2.0 software is bioclimatic potential of the analysed location. It represents the time, expressed in % and presented either on yearly or monthly level, when the plotted combinations of temperature, relative humidity and solar irradiance fall either in or out of the comfort zone.

Tab. 1. Bioclimatic potential segments as calculated by BcChart.

Label	Colour	Bioclimatic potential	Suggested bioclimatic strategy
Q		mechanical cooling and/or dehumidification needed	
A		potential for passive solutions for hot arid climates	
V		natural ventilation needed	
M		natural ventilation and/or high thermal mass needed	
C_{sh}		comfort achieved with shading	
C_{sn}		comfort achieved with solar irradiation	
R		potential for passive solar heating	
H		no potential for passive solar heating	
S_h		shading needed ($S_h = Q + A + M + V + C_{sh}$)	

The described segments in Table 1 were calculated for every distinct month according to the length of the line plotted by using combinations of monthly average input climate data (Equation 3–14).

$$Q = \sum \frac{x_{q_j}}{l_j} \times \frac{100}{12} \quad \text{(eq. 3)}$$

$$A = \sum \frac{x_{a_j}}{l_j} \times \frac{100}{12} \quad \text{(eq. 4)}$$

$$V = \sum \frac{x_{v_j}}{l_j} \times \frac{100}{12} \quad \text{(eq. 5)}$$

$$M = \sum \frac{x_{m_j}}{l_j} \times \frac{100}{12} \quad \text{(eq. 6)}$$

$$C_{sh} = \sum \frac{x_{c_j}}{l_j} \times \frac{100}{12} \quad \text{(eq. 7)}$$

$$C_{sn} = \sum \frac{x'_{c_j}}{l'_j} \times \frac{100}{12} - C_{sh} \quad \text{(eq. 8)}$$

$$R = \sum \frac{x_{r_j}}{l_j} \times \frac{100}{12} \quad \text{(eq. 9)}$$

$$R' = \sum \frac{x'_{r_j}}{l'_j} \times \frac{100}{12} \quad \text{(eq. 10)}$$

$$H = \sum \frac{x_{h_j}}{l_j} \times \frac{100}{12} \quad \text{(eq. 11)}$$

$$H' = \sum \frac{x'_{h_j}}{l'_j} \times \frac{100}{12} \quad \text{(eq. 12)}$$

$$l_j = \sum x_{ij} \quad \text{(eq. 13)}$$

$$l'_j = \sum x'_{ij} \quad \text{(eq. 14)}$$

Where j = 1–12 or January–December and $i = q, a, m, v, c, c', r, r', h$ or h'. l_j is the total period of the month (i.e. the sum of x_{qj}, x_{aj}, x_{mj}, x_{vj}, x_{cj}, x_{rj} and x_{hj}). l'_j is the total period of the month considering solar irradiance, which is

different from l_j because of the consideration of solar radiation, thus the lengths of x_{ci}, x_{ri} and x_{hi} change. x_{ci} is the period of month (i.e. the length of the plotted line) inside the comfort zone when shading is needed, x'_{ci} is the period of month inside the comfort zone utilizing solar irradiance, x_{vi} is the period of month when ventilation in combination with shading is needed, etc. Definition of each calculated segment and the corresponding suggested bioclimatic strategy are explained in Table 1.

In the cases where the plotted lines fall inside the comfort zone, the achieving of comfort is defined as achieved by shading (C_{sh}) or by the use of solar energy (C_{sn}) (Table 1). Further on, the segments presented in Table 1 may also be combined into three main categories: shading needed ($S_h = Q + A + M + V + C_{sh}$), sun needed ($S_n = C_{sn} + R + H$) and comfort zone ($C_z = C_{sh} + C_{sn}$).

2.2 Limitations

The use of the bioclimatic chart used in the BcChart software is directly applicable only to inhabitants wearing customary indoor clothing, engaged in sedentary or light muscular work, at elevations not in excess of 300 m above sea level. The impact of sun radiation is calculated on the basis of Olgyay (1963), assuming the effective area of human body of 0.5 m^2. Internal heat gains cannot be considered when calculating bioclimatic potential, which can be determined as a limitation of the methodology. Another limitation of the BcChart software is that the borders of comfort zone, which is roughly between 21 and 27°C, cannot be manually modified in order to adapt it to different human comfort conditions.

3. BcChart v2.0 – user interface and functionality

The interface of the BcChart v2.0 software was created in MS Excel environment. It consists of 4 consecutive spreadsheets (see Fig. 1 and Fig. 2) guiding the user from input data to the result interpretation:

- Input data (climatological data and basic information about for the analysed location).
- Bioclimatic chart (plot of basic bioclimatic chart w/o the influence of solar radiation and modified bioclimatic chart w/ solar radiation).
- Bioclimatic potential analysis (interpretation of analysed data through yearly and monthly bioclimatic potential of the location).
- About (theoretical background explanation, copyright and terms of use and author contacts).

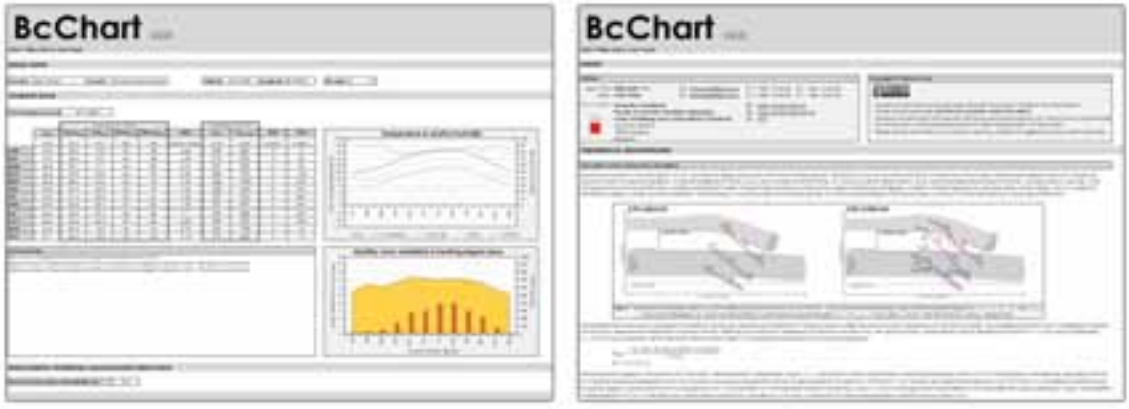

Fig. 1: BcChart v2.0 user interface screen shots: left – Input data (monthly average climatological data), right – About (explanation of calculation background).

In the first spreadsheet named Input data (Fig. 1, left), the user must input the location information data and key climate data used for the calculation of bioclimatic potential. The mandatory data are: average daily maximum ($Tmax_{avg}$) and minimum ($Tmin_{avg}$) dry bulb temperature (°C), average daily maximum ($RHmax_{avg}$) and minimum ($RHmin_{avg}$) relative humidity (%), average (G_{rad}) and maximum ($G_{rad,max}$) global daily irradiance (W/m^2) on the horizontal plane. In addition to the mandatory data necessary for the bioclimatic potential calculation, supplementary climatic characteristics can be entered as well. These are the following: average daily (T_{avg}) dry bulb temperature (°C), average sum of global irradiation ($IRAD$) on the horizontal plane (kWh/m^2) and heating

(*HDD*) and cooling (*CDD*) degree-days (Kday). However, these additional climate data do not influence the bioclimatic potential calculation and are only used in order to enable better interpretation of the bioclimatic analysis. Supplementary data are presented together with the mandatory data through diagrams (Fig. 1, left).

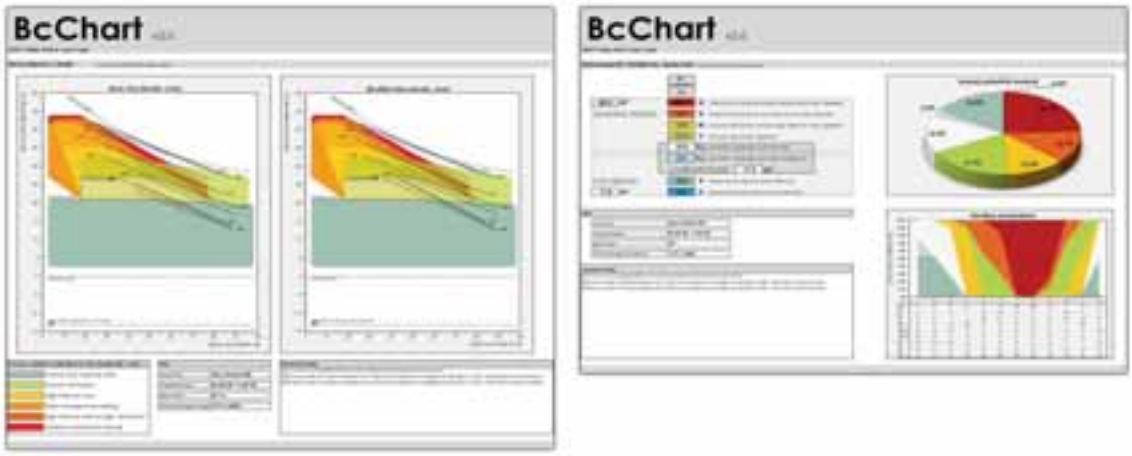

Fig. 2: BcChart v2.0 user interface screen shots: left – Bioclimatic chart (basic and modified bioclimatic chats), right – Bioclimatic potential analysis (yearly cumulative and monthly values of bioclimatic potential).

In the second spreadsheet (i.e. Bioclimatic chart) the basic and modified bioclimatic charts are plotted (Fig. 2, left). In the third spreadsheet (i.e. Bioclimatic potential analysis) the results of the bioclimatic interpretation are given (Fig. 2, right), while the fourth spreadsheet (i.e. About) gives information about the authors, copyright and basic information about used calculation methodology (Fig. 1, right). The results of the bioclimatic analysis can be interpreted directly through the evaluation of bioclimatic chart (Fig. 2, left) and the corresponding passive strategies marked on them, or by the results of yearly and monthly bioclimatic potential calculation (Fig. 2, right), which assist the user in the interpretation of the charts. It must be stressed that the calculated bioclimatic potential with its corresponding evaluation of the most important bioclimatic strategies for the analysed location is only a generic recommendation. Therefore, is up to the user of the software to appropriately apply the proposed solutions to a specific project.

4. Example of performed analysis and discussion

Functionality of the BcChart v2.0 software is presented through the evaluation and determination of bioclimatic potential at two selected characteristic locations. These were chosen in order to demonstrate how the bioclimatic potential analysis is performed with the BcChart v2.0 software. The chosen locations were the following:

- **Ljubljana, Slovenia, Europe** (46.22° N, 14.48°E); Köppen-Geiger climate classification: Cfb (temperate, without dry season, warm summer). In Ljubljana, the minimum average daily dry bulb temperature of –4.9°C occurs in January and the maximum of 26.4°C in July. The lowest average daily minimum *RH* of 43% occurs in July, while the maximum of 98% occurs in October. The lowest average daily global horizontal solar radiation of 17 Wh/m^2 occurs in December and the highest of 687 Wh/m^2 in July.
- **Abu Dhabi, UAE, Middle East** (24.43° N, 54.65°E); Köppen-Geiger climate classification: BWh (arid, desert, hot). In Abu Dhabi, the minimum average daily dry bulb temperature of 13.0°C occurs in January and the maximum of 42.0°C in August. The lowest average daily minimum *RH* of 22% occurs in May, while the maximum of 90% occurs in November. The lowest average daily global horizontal solar radiation of 140 Wh/m^2 occurs in December and the highest of 1020 Wh/m^2 in May.

Firstly, the results of the basic bioclimatic chart analysis (i.e. without considering the influence of solar radiation) are compared with those obtained by Climate Consultant software v6.0 (University of California, 2017) in the section 4.1. Secondly, the results without and with the influence of solar radiation (i.e. basic vs modified bioclimatic chart) are presented in section 4.2. Comparison of the basic and modified bioclimatic potential results will demonstrate the importance and impact of solar radiation on the prevalence of the determined bioclimatic design strategies.

4.1 BcChart vs Climate Consultant

In order to be able to compare the results obtained from both analyses (i.e. BcChart v2.0 and Climate Consultant v6.0), the boundary conditions were equalled as much as possible. Accordingly, the same input climatological data were used, namely the EPW weather data files for Ljubljana and Abu Dhabi (EnergyPlus, 2017). The calculation and the plot of psychrometric chart within Climate Consultant was made according to the ASHRAE Handbook of Fundamentals Comfort Model (up through 2005). Boundaries of comfort zone in the Climate Consultant were set in order to reflect those used by BcChart, i.e. comfort low temperature at 50% *RH* was set to 21°C and comfort high at 50% *RH* was set to 27°C. Minimal dry-bulb temperature when need for shading begins was set to 21°C.

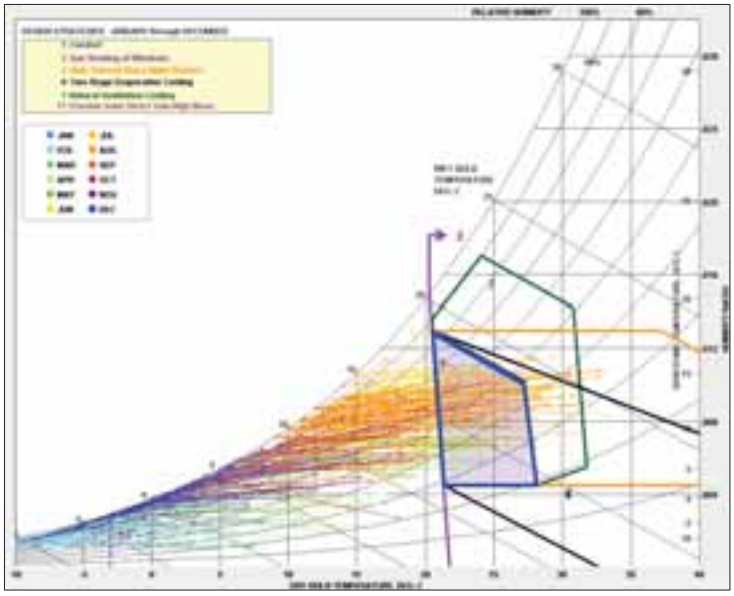

Fig. 3: Bioclimatic analysis for the location of Ljubljana created using Climate Consultant v6.0. Climate data are plotted as daily minimums and maximums in respect to the selected design strategies.

It has to be noted that the results obtained with Climate Consultant are calculated on the basis of hourly climate data, whereas the results obtained with BcChart are calculated using monthly daily averages. Recommended or effective passive measures, displayed on each of the two charts (bioclimatic chart in BcChart and psychrometric chart in Climate Consultant) are comparable but not equivalent. Therefore, a complete equivalency cannot be expected between the results of both tools. Correspondingly, in comparison to BcChart a broader set of passive and active measures is presented and proposed within Climate Consultant. Nevertheless, the results can be to some degree interpreted in such a way to enable the assessment of results between the two applications. For example, value *R* (for the explanation see Table 1) in BcChart can be compared to design strategy number 11 (i.e. passive solar direct gain, high mass) in Climate Consultant. Similarly, value C_z in BcChart is comparable to design strategy number 1 (i.e. comfort), value *V* to design strategy number 7 (i.e. natural ventilation), value *M* to design strategy number 4 (i.e. high thermal mass night flushed) and value *A* in BcChart to Climate Consultant design strategy number 6 (i.e. two-stage evaporative cooling). Other values found in BcChart (*H*, *Q*, C_{sn}, C_{sh}) cannot be directly paired with corresponding strategies proposed by Climate Consultant. All the described passive strategies can be observed and graphically compared in Figures 3 and 4, where the results for Ljubljana calculated with Climate Consultant and BcChart, respectively, are presented.

Because of the different methodology used in each of the selected software and the corresponding results, which cannot be directly compared, the results obtained by BcChart were compared by the Climate Consultant results only through the following three parameters: S_n – sun needed, C_z – comfort zone, S_h – shading needed. These results are presented in Table 2. Value S_n obtained by BcChart can be compared to design strategy number 11 (i.e. passive solar direct gain high mass) in Climate Consultant. Similarly, value S_h can be compared to a sum of design strategies number 1, 13, 14 and 15 in Climate Consultant (i.e. comfort, humidification only, dehumidification only and cooling, add dehumidification if needed). C_z is comparable to design strategy number 1 (i.e. comfort). In order to graphically compare the results, the psychrometric chart from Climate Consultant (Fig. 3) and bioclimatic chart

from BcChart (Fig. 4) were plotted for the city of Ljubljana. It can be noted from the results presented in Table 2 that the total sum of all three analysed parameters (S_n, C_z and S_h) is larger than 100%; the reason is that when comfort is achieved, also shading is needed (i.e. the lower boundary of comfort zone overlaps with the shading line – see Fig. 2 and 3). Although the described suggested passive strategies obtained by each of the considered tools are not completely equivalent, a correlation between the results is evident (Tab. 2, Fig. 3 and 4).

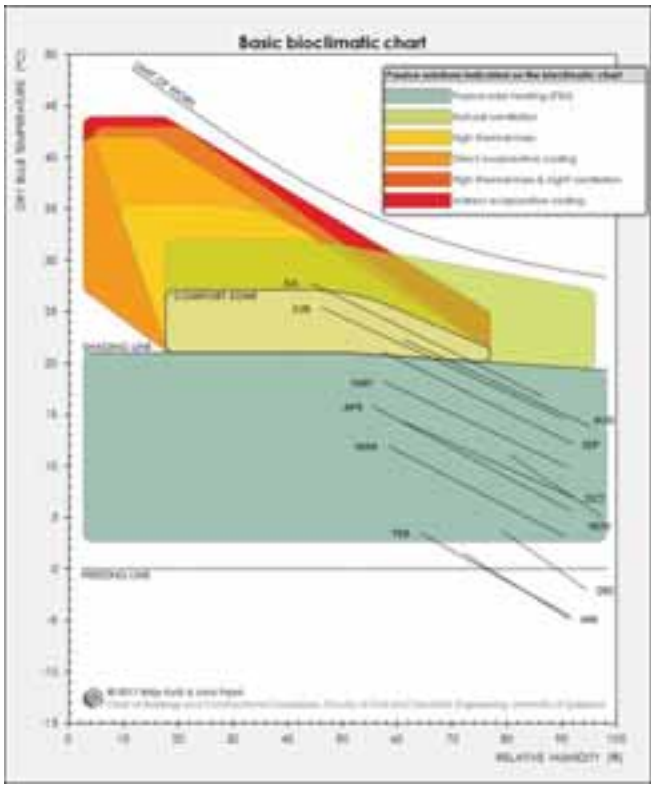

Fig. 4: Basic bioclimatic analysis for the location of Ljubljana created using BcChart v2.0. Climate data is plotted as monthly daily average minimum and maximum in respect to the selected passive solutions.

Observing Table 2 it can be concluded that the values of S_n, C_z and S_h, obtained by either BcChart or Climate Consultant are closer together in the case of Ljubljana. The latter was expected since the methodology, which runs in the background of the BcChart software, is more appropriate for the analysis of locations with temperate climate, rather than for locations with hot-arid, hot-humid or polar climate. The differences between the results obtained by BcChart and Climate Consultant in the case of the two selected locations range from 1.3 percentage points (pp) in the case of S_h and 3.9 pp for value C_z, both in Ljubljana (Tab. 2). The observed differences are most probably the consequence of differently processed climate data – Climate Consultant uses hourly, while BcChart uses monthly climate data. Additionally, dissimilarities in the results could also stem from different boundaries of passive (bioclimatic) strategies in both tools (i.e. the "areas of specific passive strategies" in the charts are not equivalent). Nonetheless, the obtained results in both applications can be considered as equivalent. Especially, if a substantial difference in the inputted climatic data is taken into account.

Tab. 2. The selected comparable parameters obtained by bioclimatic analysis using BcChart and Climate Consultant and their absolute differences.

	Abu Dhabi			**Ljubljana**		
	S_n	C_z	S_h	S_n	C_z	S_h
BcChart	17.8%	15.0%	82.2%	87.9%	11.5%	12.1%
Climate Consultant	21.2%	11.3%	78.8%	89.2%	7.6%	10.8%
|Δ|	3.4 pp	3.7 pp	3.4 pp	1.3 pp	3.9 pp	1.3 pp

4.2 Consideration of solar radiation and its effect on BcChart results

In order to assess the influence of the considered solar radiation influence on the BcChart tool results, this section studies monthly breakdown of bioclimatic potential with basic (i.e. original method – no direct consideration of solar radiation) and modified analysis (i.e. actually received solar radiation is included into the calculation) for both locations (i.e. Ljubljana and Abu Dhabi). Figures 5 and 6 represent basic and modified bioclimatic potential for Ljubljana and Abu Dhabi, respectively.

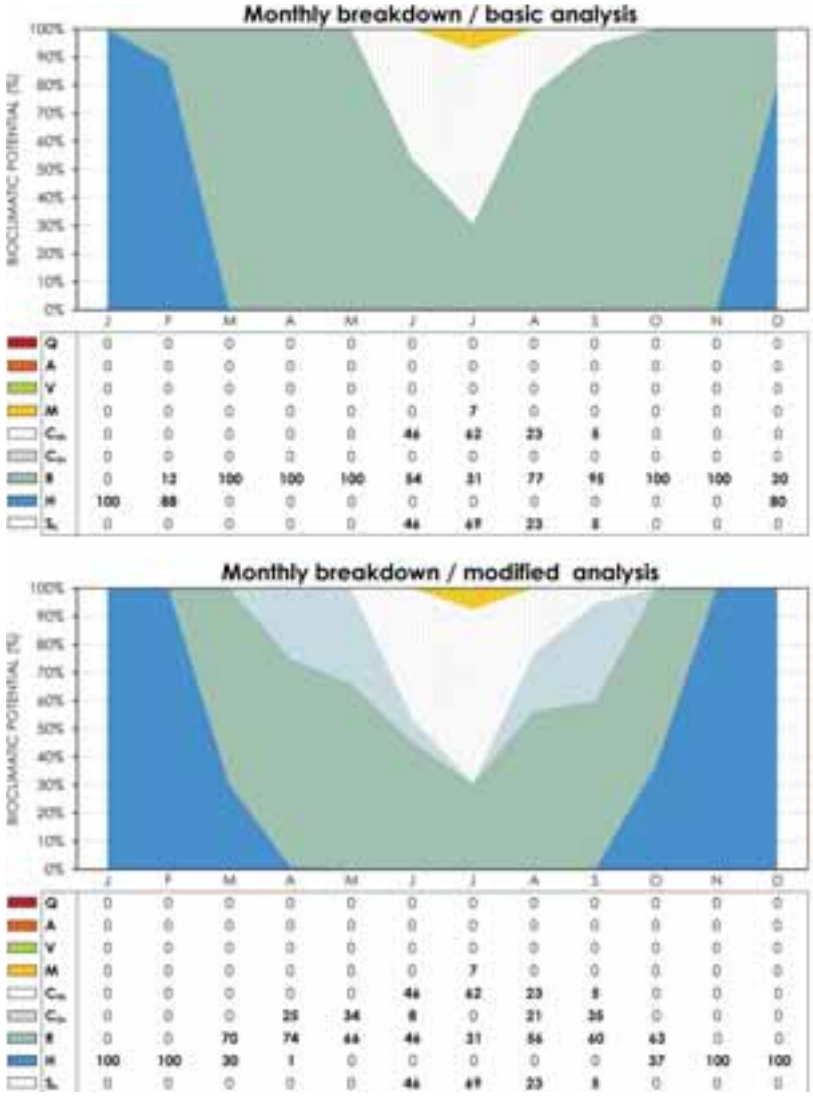

Fig. 5: Monthly breakdown of bioclimatic potential for Ljubljana using basic (top) or modified (bottom) method.

Observing Fig. 5 it can be seen that in Ljubljana, a location with temperate climate, solar radiation has a substantial effect on values C_{sn}, R and H. For example, in February value R changes from 12 to 0% and value H from 88 to 100%, while in April value R drops from 100 to 74%, value H increases from 0 to 1% and value C_{sn} increases to 25% as a consequence of solar energy utilization. The described phenomenon is expected, because values C_{sn} and R represent passive (bioclimatic) strategies, which utilize solar energy (Tab. 1), while value H is reciprocally connected with them. As expected, the modified analysis gives the same results as basic for hot (i.e. summer) months, where shading is needed and the excessive solar radiation is unwanted most of the time (i.e. shading is necessary). If bioclimatic potential in Ljubljana is observed on yearly level, the differences, which occur due to the solar energy consideration, are noteworthy. On yearly level value R decreases from 65.9 to 39.1% and value H increases from 22 to 38.6%, while the overall comfort zone increases by 10.2 pp from 11.5% (basic analysis) to 21.7% (modified analysis) due to the appearance of value C_{sn}. The latter means that in approximately 10% of the year, thermal comfort in Ljubljana can be achieved by utilizing solar energy.

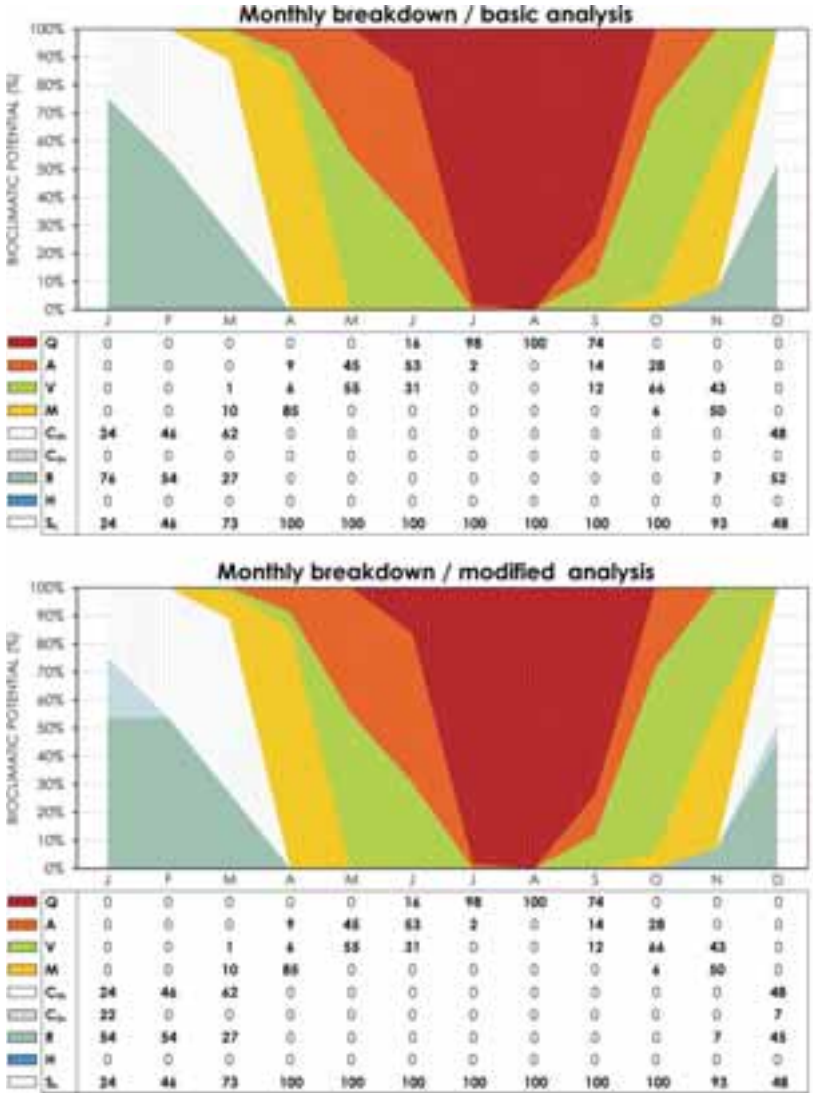

Fig. 6: Monthly breakdown of bioclimatic potential for Abu Dhabi using basic (top) or modified (bottom) method.

Observation of bioclimatic analysis for the location of Abu Dhabi with hot-arid climate in Fig. 6 gives completely different conclusions than in the case of Ljubljana. In Abu Dhabi the consideration of solar radiation has only minor effect on values C_{sn}, R and H. For example, the differences between basic and modified analysis appear only in January and December (Fig. 6), where value R changes from 76 to 54% and 52 to 45%, respectively. Consequentially, value C_{sn} appears only during these two months and amounts to 22 and 7% for January and December, respectively. The influence of solar radiation on bioclimatic potential calculation with BcChart in Abu Dhabi is of minor importance because, as mentioned before, solar radiation affects only values C_{sn}, R and H, which are in Abu Dhabi represented to a lesser extent. If these three values are compared on yearly level, value R decreases by 2.5 pp with a correspondingly equivalent increase of C_{sn}. Value H remains at 0%, as there is always enough solar energy and/or the ambient temperatures are high enough to heat up the living environment to comfortable temperatures.

4.3 Discussion

It is crucial to remember that the presented approach of solar energy inclusion into the bioclimatic analysis is extremely important, because such approach gives more precise results of locations' bioclimatic potential. Thus, the appropriate and most efficient bioclimatic strategies can be more accurately identified. However, the approach used by BcChart is far more useful in temperate, Mediterranean and cold climatic zones and less for the polar and hot-dry and hot-humid climatic zones, which was demonstrated in previous section. The main reason for this is that the relative importance of bioclimatic strategy for solar radiation harvesting is the greatest in the stated

climates. Another key note is that this theory used by BcChart applies only, when the actually received solar radiation is considered with a concurrent attention given to shading of transparent part of building envelope.

Further improvements of the BcChart tool are possible. It would be interesting to include in bioclimatic potential calculation the influence of actual wind speed at the analysed location, the same as it was done for solar radiation. However, it is questionable if such improvement would be reasonable, because air movement in buildings is a far more complex issue than solar energy utilization. In particular, air movement is harder to control and predict, due to various influential parameters, such as degree of urbanization, building aerodynamics, stack effect, etc. Additionally, with too many variables the tool would lose its simplicity and the results their universality. For such complex evaluations more sophisticated whole building simulation tools would be far better alternatives. Nonetheless, when quick and basic evaluations of applicable bioclimatic strategies in a specific location are needed, the BcChart tool represents the right choice in the early phases of building design.

5. Conclusions

As has been noted, the main advantage of the bioclimatic analysis using the BcChart v2.0 software is that it is simple and quick. The originality of the presented approach to bioclimatic potential analysis is expressed through the consideration of the actually received solar radiation with the introduction of T_{sub}. For instance, the performed analyses showed that solar radiation essentially influences the results of bioclimatic potential analysis, especially in temperate and cold climates, which was also highlighted by Pajek and Košir (2017). The analysis of the two selected locations determined the importance and usefulness of the approach incorporated in the BcChart v2.0. The indicated is certainly relevant when using climate data for the determination of relative importance of different bioclimatic design strategies.

2 Instituto de Física/Facultad de Ingeniería, UDELAR, Montevideo (Uruguay)

Summary

Three simple clear-sky models using easily available mean average atmospheric data are evaluated against hourly ground data for five sites in Uruguay. The ESRA model, based on a mean daily cycle Linke Turbidity calculated from independent GHI ground data, is the best model. It predicts hourly clear-sky irradiancie with typical uncertainties under 5 % and bias under 1 % of the average GHI for all sites considered. This is low enough for it to be useful in automatic quality check procedures for ground data and also as a basis for all-sky irradiance estimation based on satellite information.

Key-words: clear-sky irradiance, GHI, Linke Turbidity

1. Introduction

An accurate determination of clear-sky Global Horizontal Irradiation (GHI) is important both as a basis for satellite-based GHI estimation (Cano et al. 1986, Pérez et al. 2002, Rigollier et al. 2004, Pérez et al. 2015) and for automatized data quality assessment. Detailed clear-sky models, such as REST2 (Gueymard, 2008), require accurate data on the state of the atmosphere to achieve their full potential. This information has a local character and is not available at most locations worldwide. Broadband clear-sky models that can perform well using easily available average information, obtained either from ground data or from satellite-based estimates, are considered and evaluated here.

Comparisons between clear-sky models have been performed for several locations worldwide (Gueymard 2012, Reno et al., 2012, Inechien 2006). However, since both the quality of the available data and the climatic tendencies are location-dependent, the problem of choosing the best clear-sky model must be locally addressed. The review by (Gueymard 2012) provides a useful listing of eighteen clear-sky models with their inputs explicitly listed. They range form zero to eight inputs in the case of REST2, one the most sophisticated models. Acceptable models for clear-sky GHI have deviations under 6 % of the mean irradiation, the exact figure depending also on the quality of the data and the input parameters. In this work, we present a first inter-comparison between three simple hourly clear-sky models with a few daily-averaged inputs tested against quality-controlled hourly ground data from several sites in the territory of Uruguay, South America.

2. Models, methodology and data

2.1 Clear-sky models

Three models whose input parameters can be determined either from ground-based global horizontal irradiance (GHI) measurements or from reliable satellite-based estimates are considered: (i) the clear sky model used in the European Solar Radiation Atlas, ESRA (Rigollier et al., 2000), (ii) the model proposed in (Ineichen and Perez 2002) based on Kasten's pirheliometric formula (Kasten 1996) and (iii) the simplified version of the SOLIS model proposed in (Inechien, 2008). The first two rely on a single dimensionless parameter, the Linke Turbidity (TL) for air mass 2 and the third requires mean water vapor density (w) and mean Aerosol Optical Depth at 700 nm (aod700). In this work, we refer to these models as ESRA, KIP and
